| V | <150 | <3667 |

(c) The Socio-Economic Scale (rural) developed by Pareek attempts to measure socio-economic status of a rural family. It is based on the nine items as follows. The combined score for the nine items is graded to indicate socio-economic class categories.

(i) Caste (ii) Occupation of head of family
(iii) Education (iv) Levels of social participation
(v) Land holding (vi) Farm power (prestige animals)
(vIi) Housing (viii) Material possessions
(ix) Family type

**Juvenile delinquency**

There was a time when even small children were severely punished if they committed some crime. But as psychologists proceeded to draw the attention of the civilized world to the causes of juvenile delinquency, the tradition of punishing children lost favour, to be replaced by efforts of improving and rehabilitating them. To make the deviant once again a healthy and responsible person of society, efforts are made through reformatory schools, probation and other measures. Juvenile delinquency involves wrong doing by a child or a young person who is under an age specified by laws of the place concerned. In this manner, juvenile delinquent is one who forcibly possesses the property of another, or causes it damage, indulges in antisocial activities, creates danger to another's life or hinders the activities of others.

Causes of juvenile delinquency

(a) Social causes e.g. death of parents, separation of parents, step mothers, and disturbed home conditions, attitude of parents.
(b) Biological causes such as hereditary defects, feeblemindedness, physical defects and glandular imbalance.
(c) Psychological causes : Intellectual weakness, mental disease, emotional instability.
(d) Economic causes and other causes : Poverty, absence of recreation facilities, defective recreation, bad company, living in crime dominated areas, urbanization and industrialization.

Thus, a child becomes a criminal through the interaction of many causes, social and individual, familial, psychological and economic. In order to rehabilitate the juvenile delinquent as a healthy member of society, it is necessary to understand all these causes and remove them through improving family life, proper schooling, reducing harmful peer influences, social welfare services

Col RajVir Bhalwar & Mr SSL Parashar

# Medico-Social Case : History Taking

It is abundantly clear by now that every disease has a tremendous social component. It is the various components of sociology, as described in previous chapter, which decide whether a given human being will be exposed to the disease process or not; if exposed, whether disease process will perpetuate or not; and finally, what will be the outcome of the disease process. It is therefore extremely important that every Doctor should work up the psycho-social and behavioural components of a patient and not simply the clinical findings / laboratory investigative results, to effectively treat the patient and to prevent recurrence of the disease. For example, going simply by the clinical picture, we may treat a child with dehydration, with i.v. fluids and supportive therapy, and discharge her after a few days as "cured". However, if we did not work up the details of environmental sanitation and water supply at the child's house, the knowledge attitudes and health related practices of the mother, the family size, and so on, for certain the child will keep coming to us. Thus, for having a totalistic or holistic overview of our patient and to really treat the disease effectively, "from the root causes", we must take a proper medico-social history, work out the various sociological parameters and treat, not only the clinical disease, but also the social causes.

Medico-social history taking is, therefore, also an essential requirement at the undergraduate and postgraduate level of medical curriculum, with a view to prepare the general and specialist Doctors to function effectively as Community physicians. In the present chapter, we shall be dealing with the details of medico-social history taking and how to draw conclusions from such history.

### Approach to the patient

Introduce yourself with a friendly greeting, giving your name and status. Explain the purpose of your visit, ask for and remember the patient's name and request permission to interview and examine the patient. Some patients rapidly tire of being questioned or examined, and others may be depressed because they are ill or apprehensive. If there are difficulties in establishing a rapport, try to determine the reason; if in doubt, consult the medico-social worker or nursing staff. Show tolerance, particularly with the elderly and the challenged. Seek first to understand and not judge the patient so that you don't react to patients with criticism, anger or dismissal. Some additional tips for effective medico-social case taking are :

(a) Maintain good eye contact.
(b) Listen attentively.
(c) Facilitate verbally and non-verbally.
(d) Touch patients appropriately.
(e) Discuss patients' personal concerns.
(f) Give the patient your undivided attention
(g) Keep your note-taking to a minimum when the patient is talking
(h) Use language which the patient can understand
(j) Let patients tell their own story in their own way
(k) Use open questions initially and specific (closed) questions later
(l) Clarify the meaning of any lay terms which patients use. (A patient may use the term hypertension to refer to excess mental stress).
(m) Remember that the history includes events up to the day of interview
(n) Summarize (reflect back) the story for the patient to check
(o) Utilize all available sources of information

### The fundamental principles underlying medico-social case work-up

The basic principle which must be kept in mind while undertaking a medico-social work-up is that while the patient is the core issue, his disease is actually a result of complex psycho social interactions between the patient, his / her family members, the environment at the workplace (including school), the immediate community members comprising of friends and close associates, the community at large within which the patient lives, and the larger society which consists of the governmental and non-governmental systems. A systematic assessment of all these factors is therefore necessary to be able to reach the root of the problem and to effectively plan a holistic therapy, taking care of not only the biological cause of the disease but also the wider social reasons that lead to the causation and perpetuation of the disease. The factors to be considered at various levels are :

(a) Factors Within the Individual

The following variables should be recorded in detail :

(i) Age
(ii) Education
(iii) Occupation
(iv) Level of protection against common infectious diseases, by way of immunization or previous infection
(v) Lifestyle : details of habitual physical exercise, diet, tobacco, alcohol and substance abuse, sexual promiscuity
(vi) Knowledge, Attitudes & Practices (KAP) as regards common diseases and their prevention
(vii) Psycho-Emotive state : whether cheerful and optimistic or anxious / depressed or concerned.

(viii) Separation from family members / near & dear ones.

(ix) Attitudes towards

- Personal protection, as use of helmets, use of mosquito-nets, etc.
- Personal hygiene, as regular bathing, hand washing, oral care, etc.
- Attitudes towards Health Care System, whether positive and trusts the health care system or unhappy / skeptical.
- Attitudes as regards the disease from which the patient is suffering, and his / her concerns as regards it's perceived future course / management / rehabilitation

(b) Factors in the family

These will include three broad categories of factors, viz. , social factors, environmental factors and psycho-emotive factors.

**(i) Social Factors Within the Family**

- Type : Whether joint, three generation or nuclear
- Organization & Composition : Total number of members, head of the family, and description of family members by name, age, sex, and position relative to the head.
- Religion / caste
- Education : general level of education; attitudes towards formal education; proportion of members who are professionally qualified / having degree / educated / illiterate
- Occupational patterns in the family
- Income : Total family income; income of the index case; Per capita per month income
- Socio Economic Status according to acceptable scales as Kuppuswamy or Prasad scale.
- Knowledge, Attitudes & Practices in the family, in general towards healthy lifestyle, personal protection and prevention of common diseases.
- Health Care services for the family. These should be assessed in terms of availability, accessibility, affordability, quality and utilization
- Social aberrations if any in the family, as promiscuity, alcoholism, delinquency

**(ii) Environmental Factors in the Family. These will include :**

- Housing: General description, type of construction, area & space, ventilation, overcrowding, lighting, other comforts.
- Water Supply : Source, hygienicity, adequacy, storage
- Disposal of night soil, solid wastes, animal wastes, waste water.
- Food hygiene : methods of cooking, storage of raw and cooked food, food hygienic practices.
- Nutrition : Assessment of intake of overall calories and major macro / micronutrients; deficiency diseases; relative distribution of food among various members; percentage of monthly income spent on food.
- Exposure to and protection from insect vectors of diseases.

**(iii) Psycho-Emotive Factors in the Family : these include**

- Level of interactions / bondages between family members and between the index case and other family members
- Family Support Systems : In terms of financial support, physical support (as readiness to physically assist the patient in activities of daily living) and emotional support.
- Readiness of family members to provide "support"
- Understanding, by the family members, of the disease and it's determinant psycho-social problems that the patient is facing

(c) Factors in the workplace (note that for children, school is to be considered as workplace)

(i) General description

(ii) Attitude & Support (Emotional, Physical, Financial) on part of

- Employers / Superiors / Teachers
- Colleagues / Classmates
- Subordinates / ancillary staff in school

(iii) Availability of facilities, in school / workplace, to cater to special needs of the patient

(d) Factors in the Immediate Community

(Immediate community consists of the Village / Mohalla in which the patient is living. In case of Armed Forces personnel staying in barracks, it also means the military sub-unit as platoon / section in which they routinely live, sleep and eat).

(i) General description (income levels and standards of living in general, major occupations, general types of housing, educational levels, social aberrations as alcoholism, delinquency, etc.)

(ii) Community Organization, strength of community feeling, cohesiveness between the families in the community.

(iii) Interactions, of various community members, with the Index Case and his / her family members.

(iv) General attitude of community towards disease prevention & health care

(v) Availability of Physical, Financial & Emotional Support Systems within the community.

(vi) Health care facilities available

(vii) Availability of School / Special School catering to the special needs of the index case.

(viii) Availability of NGOs / Voluntary Bodies and description of their capabilities.

(ix) Availability of organised public health & social services as central water supply and it's

purification, disposal of wastes, transportation and communications.

(x) Internal political will and external influence on the political will

(xi) Identification of peers & influential leaders and their capabilities.

(e) Factors in the Community at Large

This includes the larger social environment as the District / State where the patient is living. In case of armed forces personnel, this would include the overall structure, organization and policies of the armed forces.

(i) General Attitude

- Towards Health maintenance, Disease Prevention & Rehabilitation
- Towards the disease in question

(ii) Availability of treatment facilities

(iii) Availability of Rehabilitation facilities

(iv) Statutory and Administrative provisions to protect / facilitate the index case.

(v) Availability of VHAs / NGOs

(f) Summarize The Medico-Social Findings

(i) What are the "**Key Psycho-Social Issues**" in the index case, his / her family, workplace, immediate community and the community at large.

(ii) What is the "**Social Pathology**", i. e. , the major "weaknesses" ; for example, in a medico-social case of an adolescent polio affected girl child, the major weaknesses could be summed up as "Alcoholism in the family" with "Poor purchasing power" with " Adverse attitudes towards the girl child"

(iii) What is the "**Social Diagnosis**" i.e. , those adverse psycho-social effects that the social pathology (major weaknesses) would lead to; for example, in the hypothetical example of the case of polio affected girl child, "Gross Physical handicap with Poor Rehabilitation facilities with Broken family and adversely predisposed community" may be identified as the social diagnosis, which will result from the identified social pathology, & will therefore need to be "treated", the way we treat a disease diagnosed by us.

(iv) What are the "**major strengths**" in our case. This will be worked out by analyzing the support systems – Physical, Social, Vocational, Emotional, Financial, which are available within the family, workplace, and community systems, as also the strengths within the index case (as determination, residual abilities, etc.).

**(g) Write down the Plan of Management & Social therapy**

(i) Write down in a line each, the following, for the case being worked up :

- The social pathology
- The social diagnosis

(ii) Write down your summarized analysis of the Strengths, Weaknesses, Opportunities and Threats (SWOT) in this case.

(iii) Write down what all

- Should be done, ideally, in this case
- Can be done in this case ("DO-ABILITY" analysis), after considering the SWOT.

(iv) Write down the overall aim and key objectives for the medical management part as well as the psycho-social management for the case.

(v) Now, write down a detailed plan for each of the following aspects, indicating "who will do what, how, and in what time-frame"

- Medical management
- Prevention of Other Diseases and for leading a healthy life
- Disability Limitation
- Physical rehabilitation, e. g. , physical help for activities of living, for going till the health care centre, etc.
- Vocational rehabilitation – training, education, earning a livelihood, reservation in job and education, etc.
- Emotional Rehabilitation
- Social Security

# Reproductive and Child Health (RCH)

## Introduction

It is the legitimate right of the citizens to be able to experience sound reproductive and child health and therefore, the RCH programme seeks to provide relevant services for assuring Reproductive & Child Health to all citizens. It is now well established that parents keep the family size small if they are assured about the health and longevity of the children and there is no better assurance of good health and longevity of the children than health care for the mothers.

## History and Background

Government of India in 8th plan period integrated all related programmes such as UIP, ORT & various other programmes under MCH into Child Survival and Safe Motherhood (CSSM) programme on 20 Aug 1992. In 1994, International Conference on Population and Development held in Cairo recommended that participant countries should implement unified programmes for RCH. Accordingly Govt of India, during 9th Plan period unified CSSM with two other programmes i.e. one related to sexually transmitted diseases and other related to reproductive tract infections and launched a unified, integrated programme of RCH on 10th October, 1997. Reproductive and Child Health (RCH) Program is the flagship program of the Department of Family Welfare, Government of India. It is the amalgamation of Maternal and Child Health (MCH), Child Survival and Safe Motherhood and Family Planning. The program is primarily offered through the Primary Health Infrastructure. It is re-oriented and refocused version of the family welfare programme, with the involvement of health of men. In 1998, ICMR set up a task force in Male reproductive health, so that equal emphasis could be given to Male Reproductive Health. RCH Phase II has been launched on 1st April 2005 with an objective to bring about a change in mainly three critical health indicators i.e. reducing total fertility rate, infant mortality rate and maternal mortality rate.

## Definition of RCH

Reproductive Health is defined by WHO as a state of complete physical, mental and social well being and not merely the absence of disease or infirmity in all matters relating to the reproductive system, its functions and processes.

## RCH Approach

RCH approach has been defined as “a state in which people have the ability to reproduce and regulate their fertility, women are able to go through pregnancy and child birth safely, the outcome of pregnancies is successful in terms of maternal and infant survival and well being and couples are able to have sexual relations free of fear of pregnancy and of contracting diseases" (1)

## Concept of RCH Programme

The concept of RCH is to provide to the beneficiaries need based, client centered, demand driven, high quality and integrated RCH services. This is a paradigm shift from the earlier approach under the National Family Welfare Programme, as shown below :

| Family Welfare Programme | RCH |
|---|---|
| Top down approach | Bottom up approach |
| Target centered | Target free |
| Centralized planning | Need based decentralized and participatory planning |
| Promoted specific method | Various methods offered |
| Method centered | Consumer or client centered |
| Quantity centered | Quality centered |
| Single objective | Concern for quality of life |
| Focus on targets | Focus on unmet needs |
| Gender insensitive | Gender sensitive (men) |
| Accountability to bureaucracy and | Accountability to clients workers |

## Objectives of RCH

(a) Reduction of Maternal Morbidity and Mortality (MMR)

(b) Reduction of Infant Morbidity and Mortality (IMR)

(c) Reduction of Under 5 Morbidity and Mortality (U5MR)

(d) Promotion of adolescent health

(e) Control of reproductive tract infections and sexually transmitted infections.

## Components of RCH Programme

(a) Family planning

(b) Maternal & child health

(c) Safe abortion service.

(d) Effective control of sexually transmitted diseases and reproductive tract infections.

(e) Prevention and management of infertility.

(f) Prevention, detection cum treatment of reproductive tract malignancies (WHO, 1990-91).

## Components of Male Reproductive Health

(a) Health care of male infants, children and adolescents.

(b) Adolescent education and the development of healthy and fulfilling male sexuality.

(c) Prevention and Control of RTIs, STDs & AIDS.

(d) Greater and more effective male participation in family planning and contraception

(e) Ensuring gender equity through free reproductive choice.

(f) Prevention & management of male infertility and other reproductive disorders.

(g) Reproductive health care of the elderly male.

**Highlights Of RCH Programme**

(a) Integration of all interventions of fertility regulation, maternal and child health with reproductive health of both men & women.

(b) The services are client-centered demand driven and based on the needs of the community.

(c) Decentralized planning involving community.

(d) Services are of high quality and based on "target free" approach.

(e) Upgradation of the level of facilities such as First Referral Units (FRUs) at sub divisional level to provide emergency obstetric & newborn care.

(f) Upgradation of RCH facilities in PHCs.

(g) Improvement of the access of the community to commonly required services such as MTP facilities at PHCs, counseling & IUD insertion at sub centres.

(h) Improving the out reach of services to the vulnerable groups of population such as urban slums, tribal population and adolescents.

(i) Involvement of NGOs in improving outreach and acceptance of programme.

(j) Upgrading the skills of practitioners of Indian systems of Medicine (ISM) by training.

(k) Support of research & development in ISM to improve the range of RCH services.

(l) To provide greater role to the Panchayati Raj System (District to village level) in planning, implementation and assessment of client satisfaction.

**Financial Assistance For Direction & Administration at State Level and District level officers**

With effect from 01 Apr 1998, states with more than 1 crore population are entitled to receive from the Govt of India, financial assistance upto 8% of the grants given by Dept of Family Welfare for FW programme in the states, whereas for states, with less than 1 crore population the financial assistance will be 12%. The funds given by Central Govt assistance will not be spent on purchase/maintenance of vehicles & construction activities. RCH implementation & flow of funds will be either through State Finance Dept or through SCOVA. (State Committee on Voluntary Action)

**Organisation of RCH services**

(a) State level

(i) Addl/Joint/Deputy Director for Maternal Health.

(ii) Addl/Joint/Deputy Director for Child Health

(iii) Addl/Joint/Deputy Director with qualifications in population science/statistics for monitoring, evaluation & statistical analysis.

(iv) Addl/Joint/Deputy Director for Finance

(v) Addl/Joint/Deputy Director for population control

(vi) Addl/Joint/Deputy Director for Admin/pers.

(vii) Engineer/Asst Engineer for State Cold Chain.

(viii) State media officer.

In smaller states posts at S. Nos 1 &2 can be combined & similarly posts at S. No 4 & 6 and 3 & 5 can be combined.

(b) District Level

| | |
|---|---|
| Dist Health & family Welfare Officer | 1 |
| RCH Officer | 1 |
| Population control officer | 1 |
| Training officer | 1 |
| Refrigeration Mechanic | 1 |

## Programme Interventions

Differential approach: RCH status of the districts is reflected on the basis of crude birth rate and female literacy rate. Based on these indicators, the districts have been categorised into three categories A, B & C. The RCH programme proposes to strengthen and streamline the basic facilities in weaker districts and provide more sophisticated facilities for the relatively advanced districts. These services are proposed to be provided in a phased manner for 3 years since inception of the programme. These interventions are as follows :

**RCH Interventions in all Districts (1)**

(a) Safe motherhood and child survival interventions under CSSM programme.

(b) Facilities for operationalisation of Target free approach.

(c) Institutional development.

(d) Integrated training package.

(e) Modified Management Information system (MIS).

(f) Information, Education & Communication (IEC) activities & counseling on health, sexuality & gender.

(g) RCH package for urban & tribal areas.

(h) District subprojects under local capacity enhancement.

(j) RTI/STI clinics at district hospitals.

(k) Facilities for MTPs at PHCs by providing equipment & contractual doctors.

(l) Enhanced community participation through Panchayats, women's groups and NGOs.

(m) Provision for lab technicians for lab diagnosis of RTI/STI & EsOC.

(n) Adolescence health & reproductive hygiene.

**RCH Intervention in Selected States/Districts**

(a) Screening and treatment of RTI/STI.

(b) EOC (emergency) at selected FRUs by providing drugs.

(c) Essential obstetric care by providing drugs and PHN/Staff Nurse at PHCs.

(d) Addl ANMs at subcentres in selected districts for ensuring MCH care.

(e) Improved delivery services and emergency care by providing Equipment, Kits, IUD insertions and

ANM kits at sub centres.

(f) Rental to contracted PHNs/ANMs, not provided Government Accommodation

(g) Facility of referral transport for pregnant women during emergency to the nearest referral centre

**Immunization**

UIP will continue to provide vaccines for Polio, Tetanus, DPT, DT, Measles & TB. The achievements so far all are 80-90% coverage. The objective in 9th Plan is to achieve 100% coverage for all vaccine preventable disease. After achieving about 95% coverage, special campaigns like PPI may be taken up later in the 9th plan for achieving near Zero incidence for Tetanus among pregnant women and newborns & for measles.

Inputs for Immunization & related CSSM Programme:

(a) Cold chain equipment for all PHCs in the country

(b) Supply of vaccines

(c) Repair of cold chain items which are already about 10 years old - Rs 500 / PHC / year

(d) Provisions of Dai kits

(e) Provisions of needles and syringes

(f) Procurement & supply of Disposable Delivery kits.

**Drug & Equipment kits**

Drug & equipment kits earlier supplied to CHCs/FRUs, PHCs & Sub Centres under CSSM programme will continue to be supplied under the RCH programme. In addition, drugs kit for essential obstetrics will be supplied to PHCs in category 'C' districts.

**Essential Obstetric Care (EsOC)**

Essential obstetric care includes those items of obstetric care, which any pregnant woman requires if there is no complication during pregnancy or delivery (3).

These items are

(a) Registration of pregnancy in the first 12-16 wks of pregnancy.

(b) At least 3 prenatal check ups by ANM or in dispensary.

(c) Assistance during delivery.

(d) At least 3 postnatal check ups.

Inputs for EsOC

(a) Training of ANMs & provision of equipment and drugs to them

(b) Supply of equipment kit to PHCs in category B & category C districts.

(c) Supply of Es OC drug kit to category B & C districts

(d) PHCs in category C Dists will engage PHNs / Staff Nurse on contract basis during the RCH project (Pay + DA+ Rs 400 HRA).

(e) In category C districts in remote sub centres an additional ANM will be provided on contract basis.

(f) 25% of ANMs working in sub centres will be provided loan for Mopeds to increase their mobility.

Emergency Obstetric Care (Em OC)

Em OC is an intervention for preventing maternal morbidity and mortality. Early detection and management of complications such as anaemia, haemorrhage, obstructed labour and sepsis can substantially reduce maternal mortality & morbidity. This requires competent supervision and check ups by ANM during antenatal & post natal period. ANM should refer all cases having complications during pregnancy or at the time of delivery to PHCs / FRUs (3).

Inputs

A total of 1748 FRUs have been identified & equipped under CSSM programme. Some of the FRUs are lacking in manpower or infrastructure. Under RCH programme, a provision has been kept for strengthening these FRUs through

(a) Supply of drugs kits worth 1.65 lakh to 3 FRUs in Category C & 2 FRUs in Cat B districts annually.

(b) Provision for appointment of contractual staff ie. PHN/Staff Nurses, ANM & Lab Assts. (Each Dist can engage only 2 Lab Tech.)

(c) Provision of Laparoscope at district and sub divisional hospitals/FRUs.

(d) Provision for providing EmOC requiring surgery, blood transfusion and anaesthesia at the FRU level.

(e) Provision for consultant anaesthetist for EmOC (Rs 500/- per case)

(f) Funding training for Diploma in Anaethesia.

**24 Hour Delivery Services at PHCs/CHCs**

Under RCH, arrangements have been made that a doctor on call duty, a nurse and cleaning staff are available beyond normal working hours to encourage people to seek deliveries in PHCs/CHCs. For this doctor could be paid Rs 200/- per delivery & other staff could be hired on contractual basis.

**Referral Transport to Indigent Families through Panchayats**

In category C districts of eight weakly performing states, communication infrastructure is weak and economic status of families in remote villages is poor. Because of this, even if there is a complication identified during pregnancy or delivery, the women have the delivery conducted in the village and frequently through untrained Dais. This is one of the causes of high maternal mortality and morbidity.

Inputs

25% subcentres of Category 'C' districts of 8 weakly performing states (UP, Bihar, MP, Rajasthan, Orissa, Assam, Nagaland & Haryana), a lump sum financial assistance is made available to Panchayats through District Family Welfare Officers.

**Blood Supply to FRUs/PHCs**

Dept of family welfare will be taking up pilot projects with the assistance of European Commission under the RCH programme for setting up of regular and reliable supply of

blood to PHCs/CHCs by linking them with the nearest blood bank.

### Essential New Born Care

Under CSSM programme, essential new born care equipment has been supplied to all Dist Hospitals, CHCs incl all FRUs & PHCs. The strategies for the essential new born care are as follows :

(a) Training of medical and paramedical staff in essential Newborn care.

(b) Provision of basic facilities for care of LBW babies in FRUs and District Hospital.

(c) Creating awareness among health care providers pregnant women and mother of newborn child about essential New born care,

(d) Use of low cost, effective and locally available equipment for newborn care.

(e) Improve maternal care and promote birth spacing

### MTP

MTP by untrained or experienced persons is responsible for high maternal mortality and morbidity. Therefore, increasing and improving facilities for MTP is an important component of the RCH programme at PHC level.

Inputs

(a) Need based training in MTP by NIHFW.

(b) Supply of MTP equipment to District Hospitals, CHCs & PHCs where trained staff is available.

(c) Assistance for engaging doctors trained in MTP to the PHCs once a week on fixed days for performing MTP (Pay Rs 500/- day). These doctors will also provide ANC and PNC to patients during their visit.

(d) Supply of MTP equipment to Private clinics if they have OT & trained doctors.

### RTI/STI Clinics

The incidence of RTI/STI is 20-30% in most parts of the country. Under RCH programme, all district hospitals and 3 FRUs in Category A district, two in category B district & one is Category C districts will be assisted for setting up RTI/STI clinics by imparting training through NIHFW and supply of drug kits(2).

### Indian System of Medicine

About 50% of population depends on the Indian systems of Medicine for health care.

About 5 lakh practitioners of Ayurveda & Unani systems are spread out in different pasts of the country especially rural areas.

Inputs

(a) **Training of ISM Practitioners** : Short term training of 2-4 weeks to ISM practitioners through ISM Medical Colleges, in areas relevant to RCH.

(b) **Improving awareness and availability of ISM remedies** : NGOs will be assisted for raising nurseries of medicinal plants and educate local population about the uses of locally available medicinal plants for preventive health & for curative purposes.

(c) **Research in ISM** : Research projects through ISM research institutions will be supported financially in areas of relevance to RCH.

(d) **Vanaspati Van** : Plantations of medicinal plants in the form of the vanaspati Van over wastelands or denuded forestland of 3000-5000 hectares of contiguous area is proposed.

### Additional Programme for the Urban Slums

About 9 crore people are living in urban slums. Slum population of Mumbai & Delhi is more than 30% of total population. An appropriate and effective Family Welfare set up for the Urban slums is being planned to cater for prevention and treatment of diarrhoea, malnutrition and vaccine preventable diseases apart from improving the RCH status (4).

### Special Programmes for Tribal Areas

The tribal areas have poor communication, low educational level & economic status. Hence the RCH status of tribal population is low. A committee of experts under Dept of Family Welfare is working out appropriate package of programmes for the tribal Areas.

### Special Programmes for Adolescents

The special package of programmes for adolescents includes.

(a) One more booster dose of TT at the age of 16 & immunisation of females against Rubella.

(b) Sex education to promote responsible and healthy reproductive & sexual behaviour.

(c) Prevention of STD/HIV and AIDS.

(d) Adult Literacy especially among women.

(e) Vocational training.

(f) Pre marital counseling

(g) Gender equality

(h) Family life education. It is defined as " an educational process designed to assist young people in their physical, social, emotional and moral development as they prepare for adulthood, marriage, parenthood, ageing as well as their social relationship in their socio cultural context of the family and society". (UNESCO).

### Research and Development

(a) Dept of Family Welfare will continue financing R&D through ICMR (at Bombay & at Hyderbad / National Institute of Nutrition (NIN)).

(b) Dept will provide support to basic research and operations research in areas relevant for RCH.

(c) Holding of conferences and seminars for researchers. The dept will extend financial assistance to well established NGOs and research institutes to the extent of upto Rs 1.5 lakh for seminars / workshops and upto 3 lakhs for national conference & 5 lakh for International conference.

## Training

This involves :

(a) Training for awareness generation & skill upgradation.

(b) Training of Panchayati Raj functionaries & other related depts. NIHFW will be the nodal agency for co-ordinating all training programmes of the Dept of Family Welfare. 15 collaborating institutions on regional basis will assist in implementation of RCH Training.

**Information, Education and Communication (IEC)**

Dept of Family Welfare is implementing a large IEC programme by making extensive use of Doordarshan, AIR, DAVP, and Directorate of field publicity Song & Drama division and film divisions under Ministry of Information and Broadcasting. In addition, 80,000 Mahila Swasthya Sanghs (MSS), opinion leaders & Nehru Yuvak Kendras are being involved. Use of print media is also being made to give a boost to the image of the programme particularly among youth.

**State Level**

Apart from the activities of Central Govt, State Govts are provided funds at the rate of Rs 25 lakh to large states, Rs 15 lakh to medium states & Rs 10 lakh to smaller states for IEC activities

**District Level**

At district level IEC programme is proposed to be linked up with National Literacy Mission which works through Zila Saksharta Samities as both these programmes are mutually supportive. For this, Rs 3-5 Lakh annually are provided to Zila Saksharta Samities.

## Management Information System (MIS) under RCH programme

An efficient MIS should provide regular & reliable information about the implementation of various activities of RCH programme & their impact in improving the health status of women & children.

"Target free approach" manual has been renamed as "Community Needs Assessment" manual & distributed to all districts for distribution among all health facilities and workers.

Under the RCH Programme, the following mechanisms have been proposed for getting information on selected RCH indicators on annual basis with district level estimates of the indicators.

**(a) Routine Reporting**

The reporting system on revised reporting format will be as follows :

(i) Health worker to report to PHC by 7th of every month.

(ii) PHCs worker to report to District HQ by 10th of every month.

(iii) Districts worker to report to state HQ by 20th of every month.

Community Needs Assessed by Health Worker
↓
Sub Centre Action Plan prepared by involving LHV/MO
↓
PHC Action Plan (Under supervision of next supervisory officer)
↓
District Action Plan - To be formulated annually

**(b) District Surveys**

It has been proposed to conduct district level surveys in half of the districts of the country every year by sample surveys. These surveys will provide information on selected indicators just in a few months time after the field work is completed.

**(c) Concurrent Surveys**

Under this scheme, evaluation of the availability and utilisation of RCH services will be done in at least one district per month in larger states, one sub division in the middle sized state and one block in the smaller state. These surveys will also be undertaken in selected population of these districts to ascertain quality of services and community satisfaction. The above surveys will help in effectively monitoring RCH programme & wherever gaps are found, Centre/State districts can take timely corrective action. The surveys will also help in accountability vis-à-vis the district health and family set up.

## RCH Phase II

The second phase of RCH program i.e. RCH – II has been commenced from 1st April, 2005 & will last till 2010. The main objective of the program is to bring about a change in mainly three critical health indicators i.e. reducing total fertility rate, infant mortality rate and maternal mortality rate.

**Highlights of RCH - II Program**

(a) Adoptions of Sector vide approach which effectively extends the program reach beyond RCH to the entire Family Welfare sector.

(b) Building State ownership by involving states and UT's from the outset in development of the program. Decentralization through development of District and State level need based plans. Flexible programming with a view to moving away from prescriptive scheme based micro planning and instead allowing States to develop need based work plans with freedom to decide upon program inputs.

(c) Capacity building at the District, State and the Central level to ensure improved program implementation. In particular, the emphasis being on strengthening financial management systems and monitoring and evaluation capabilities at different levels.

(d) Adoption of the logical frame works as a program management tour to support and outcome driven approach.

(e) Performance based funding to ensure adherence to program objectives, reward good performance and support weak performers through enhance

technical performance.

(f) Pool financing by the development partners to simplify and rationalized the process of assessing external assistance.

(g) Convergence, both inter sectoral as well as intra sectoral to optimize utilization of resource as well as infra structural facilities.

**Vision**

To bring about outcomes as envisioned in the

(a) Millennium Development Goals

(b) The National Population Policy 2000 (NPP 2000)Goals

(c) The Tenth Plan Goals

(d) The National Health Policy 2002

(e) Vision 2020 India

**Interventions**

Maternal Health

(a) 260 Primary Health Centres are proposed to be taken up for improving access to Essential Obstetric and New Born Care services round the clock. All CHC, & 50% PHCs to be made functional for 24 hrs delivery services,& 2000 FRU are proposed

(b) Improving quality of antenatal, neonatal and postnatal care by providing increased number of antenatal checkups, fixed day antenatal clinics, linking visits of neonates with postnatal care, empowering the ANMs in performing obstetric first aid and newborn care.

(c) Improvement of the referral networking systems by establishing emergency help line.

(d) Regular conduct of blood donation camps for the continued availability of blood in the blood banks.

(e) Universalizing the concept of birth companionship during the process of labour in all health facilities conducting deliveries.

(f) Operationalisation of maternal death audit to address the issues that have led to maternal deaths

Infant and Child Health

(a) Reduction of new-born deaths, infant deaths and child deaths by providing continuous health care and strengthening of new-born care infrastructure facilities.

(b) Organizing counselling sessions for the mothers.

(c) Implementing integrated management of neonatal and childhood illness as a pilot initiative in selected districts

(d) Operationalising infant death/stillbirth verbal autopsy.

(e) Addressing the issue of female infanticide and foeticide.

Adolescent Health

(a) Focusing adolescents as receivers and providers of knowledge and function as link volunteers in the community.

(b) Utilising the services of trained adolescents for propagating Indian System of Medicines.

(c) Broadcasting and Telecasting of programme by AIR/TV focusing adolescent, gender & health related subjects.

RCH – I & II, Differences

| RCH I | RCH II |
|---|---|
| Multiple fragmented projects | Common framework for entire Family Welfare sector |
| Centrally driven schemes - one size fits all | State plans based on district plans appraised by Centre |
| No incentive for better performance | Performance based funding |
| Inputs based monitoring services | Results focused on saving lives, stabilising population & improving |
| Limited engagement with private sector | Framework for public private partnership |

Table - 1 : Targets of Major Policies / Projects Relevant to MCH

| Indicator | Tenth Plan Goals (2002 – 2007) | RCH II Goals (2005 – 2010) | National Population Policy 2000 (by 2010) | Millennium Development Goal (by 2015) |
|---|---|---|---|---|
| Population Growth | 16.2% (2001-2011) | 16.2% (2001-2011) | - | - |
| Infant Mortality rate | 45 / 1000 | 35 / 1000 | 30 / 1000 | - |
| Under 5 Morality rate | - | - | - | Reduce by 2/3rds from 1990 levels |
| Maternal Mortality Ratio | 200 / 100,000 | 150 / 100,000 | 100 / 100,000 | Reduce by 3/4rds from 1990 levels |
| Total Fertility Ratio | 2.3 | 2.2 | 2.1 | - |
| Couple Protection Ratio | 65% | 65% | Meet 100% needs | - |

(d) Formation of co-ordination committee at the district level and monitoring committee at the State level for overseeing the AIR/TV programme.

Family Welfare

(a) While sustaining the ongoing family welfare interventions in all districts, 19 districts with higher order births will be targeted for intensified interventions.

(b) Social marketing programme for condom and other health commodities, promotion of IUD insertions, familiarizing the concept of one-stop Family Welfare Centre.

(c) Increasing access to safe abortion services by popularising manual vacuum aspiration (MVA) technique.

(d) Establishment of one-stop family welfare services at Comprehensive Emergency Obstetric and New Born Care (CEMONC) Centres.

(e) Popularizing No Scalpel Vasectomy.

Reproductive tract infections/ sexually transmitted infections/ cancer control.

(a) Establishment of Reproductive Tract Infection / Sexually Transmitted Infection, early Cancer detection clinics.

(b) Strengthening RCH outreach services.

(c) RTI/STD clinic in selected 70 primary health centers

**Other salient features of RCH II**

Infrastructure strengthening for service delivery:

(a) Construction of HSC buildings where HSCs are currently functioning in rented premises

(b) Rebuilding HSCs which are unfit for occupation.

(c) Taking up of repairs/renovation and provision of water supply/electrical works to PHCs/HSCs.

(d) Need-based supply of equipment/ furniture to the HSCs and PHCs as per the standard list including gas connections.

(e) Provision of Cell phones to HSCs where large number of deliveries take place.

(f) Provision of telephones to PHCs

**Training**

(a) Skill upgradation training with focus on improving / upgrading the skills of health care providers.

(b) Integrated skill training for peripheral health functionaries such as ANMs, SHNs, medical officers and health inspectors.

(c) Improving managerial and communication skills of health staff.

Behavioural change communication (BCC)

(a) Social mobilisation activity against female infanticide and foeticide by preventive counselling.

(b) Formation of HSC, Block, and District level committees for saving female babies.

(c) Conducting of travelling street theatre to promote social mobilization and to improve health care among the target population

(d) Telecasting of TV serials, Radio broadcasts, wall paintings, hoardings and glow signs for popularizing health and reproductive health messages in important places.

Health management information systems

(a) IT-enabled HMIS for planning and monitoring health services at the State/District /Block levels are introduced.

(b) Teaching Institutions are strengthened for providing optimum obstetric, family welfare, neonatal child health services.

(c) Urban Health Posts are established to provide an integrated and sustainable system for primary health care service delivery catering to the requirements of urban slum population and other vulnerable groups

**RCH II - Challenges**

Lead time for institutional strengthening

(a) Institutional mobilisation phase – strengthen management functions

(b) Institutional strengthening phase – financing linked with performance

(c) Institutional consolidation phase – Increased emphasis on performance

(d) Reduce inequities by increased focus on Empowered Action Group(EAG) states, urban and tribal areas

**Conclusion**

RCH programme has been evolved by integrating various related programmes such as Family Planning, ORT, RTI, STD and CSSM with a view to implement the unified programmes for reproductive child health. The RCH programme has a participatory approach of all communities including ISM practitioners, Dais, opinion leaders, NGOs apart from intersectoral co-ordination of Govt agencies at all levels. The programme lays great emphasis on training, IEC and Research & Development activities related to RCH. Procurement procedures & audit arrangements have been streamlined to ensure uniformity in accounting. The modern system of management information and evaluation system will ensure accountability especially at District Level. RCH programme is a comprehensive programme aimed at improving the Maternal and Child health all over the country.

# Maternal Care

## Care during pregnancy - antenatal care

### Early registration

The first visit or registration of a pregnant woman for ANC should take place as soon as the pregnancy is suspected. Ideally, the first visit should take place in the first trimester, before or at the 12th week of pregnancy.

### Record-keeping

Complete the antenatal card for every woman registered / examined by you. Instruct her to bring the card with her for all subsequent check-ups/visits. Record this information in the PHC / CHC antenatal register.

## Antenatal check-up

### Number and timing of visits

Ensure that every pregnant woman makes at least 4 visits for ANC, including the first visit/registration and any home visits by the ANM/lady health visitor (LHV). The first visit is recommended as soon as the pregnancy is suspected; the second visit should be scheduled between the 4-6 months (around 26 weeks). The third one should be planned in the 8th month (around 32 weeks) and the fourth one in the 9th month (36-40 weeks).

### History-taking

During the antenatal visits, take a detailed history of the woman:

(a) To diagnose the pregnancy (first visit only, if required)

(b) To identify any complications during previous pregnancies which may have a bearing on the present one

(c) To identify any medical or obstetric condition(s) that may complicate the present pregnancy (first and subsequent visits).

The LMP is used to calculate the gestational age at the time of check-up and the EDD. If the period of the menstrual cycle is more than 30 days, add the additional number of days in the cycle (beyond 28 days) to the EDD as calculated below.

EDD = LMP + 9 months + 7 days (+ additional days, if any)

Ask for age of woman, order of pregnancy and birth interval and any symptoms.

Previous pregnancies

It is essential to ask a woman about her previous obstetric history, this is important as some complications may recur during the present pregnancy.

History of any systemic illness

Rule out any personal history of systemic illnesses.

Family history of systemic illness

Ask for a family history of hypertension, diabetes and tuberculosis, thalassaemia, delivery of twins and/or the delivery of an infant with congenital malformation.

History of drug intake or allergies

Ask for history of drug intake during pregnancy, allergy to any drug, or drug taken for infertility.

History of intake of habit-forming or harmful substances

Ask the woman if she takes tobacco or alcohol. If yes, she needs to be counseled to discontinue.

### Physical examination

This activity will be nearly the same during all the visits. Initial readings may be taken as a baseline and compared with the later readings.

General examination

Specifically examine and record weight, blood pressure, pallor, respiratory rate, generalized oedema and also carry out breast examination.

Vaginal examination

(a) Vaginal examination is required, especially during the first visit, to confirm the pregnancy and to measure the gestational age.

(b) A per speculum (P/S) examination may be done especially if the woman complains of discharge P/V.

Abdominal examination

Examine the abdomen to monitor the progress of the pregnancy and foetal growth, and to check the foetal lie and presentation.

Assessment of the pelvis

Examination of the pelvis is required to assess if it is adequate for delivering the baby vaginally and is done during the last ANC visit (at about 36 weeks of gestation) to rule out any cephalopelvic disproportion (CPD).

### Laboratory investigations

The following laboratory investigations are recommended at the primary health care provider level to be carried out as a part of ANC.

(a) Haemoglobin estimation

(b) Blood grouping

(c) Testing the urine for the presence of sugar

(d) Testing the urine for bacteriuria

## Interventions

### Common symptoms and their management

See details in Table - 1

Iron-folic acid supplementation

All pregnant women need to be given one tablet of IFA (100 mg elemental iron and 0.5 mg folic acid) every day for at least 100 days. This is the prophylactic dose of IFA. If a woman is anaemic (Hb <11 g/dl or she has pallor), give her two tablets of IFA per day for three months.

This means a woman with anaemia in pregnancy needs to take at least 200 tablets of IFA. This is the therapeutic dose of IFA.

Table - 1 : Common symptoms during pregnancy and their management

| Symptoms | Signs / investigations | Most probable diagnosis | Action(s) to be taken |
|---|---|---|---|
| Excessive vomiting, especially after the first trimester; inability to retain anything | The woman may be dehydrated | Hyperemesis gravidarum | Admit her for a few days at the PHC and manage as given under the management of Hyperemesis gravidarum. |
| Palpitations, easy fatiguability, breathlessness at rest | ✐Conjunctival and / or palmar pallor present<br>✐Hb level <7 g/dl | Severe anaemia | ✐Start the woman on a double dose of IFA tablets.<br>✐Give her albendazole(second trimester onwards only).<br>✐Monitor the Hb level after one month. |
| Puffiness of the face, generalized body oedema | ✐BP >140/90 mmHg<br>✐Proteinuria absent<br>✐BP >140/90 mmHg<br>✐Proteinuria present | ✐Hypertensive disorder of pregnancy<br>✐Pre-eclampsia | ✐If the BP is <160/110 mm Hg, advise home management with rest and regular follow up.<br>✐If the BP is >160/110 mmHg, start on Nifedipine.<br>✐Start the woman on antihypertensive medication.<br>✐Refer to an FRU for further management.<br>✐Advise her on the danger signs of imminent eclampsia and eclampsia and refer to an FRU. |
| Heartburn and nausea | Reflux | Hypertensive disorder of pregnancy | ✐Advise the woman to avoid spicy and rich foods.<br>✐Ask her to take cold milk during attacks.<br>✐If severe, antacids may be prescribed. |
| ✐Increased frequency of urination up to 10-12 weeks of pregnancy<br>✐Increased frequency of urination after 12<br>✐weeks, or persistent<br>✐symptoms, or burning<br>✐on urination | Tenderness may be present at the sides of the abdomen and back.<br>The body temperature may be raised | ✐May be physiological due to pressure of the gravid uterus on the urinary bladder<br>✐Urinary tract infection | ✐Reassure her that it will be relieved on its own<br>✐Manage as given under the management of "UTI" |
| Constipation | | Physiological | ✐Advise the woman to take more fluids, leafy vegetables and a fibre rich diet.<br>✐If not relieved, prescribe Isabgol, 2 tablespoonful to be taken at bedtime, with water or with milk.<br>✐Do NOT prescribe strong laxatives as they may initiate uterine contractions. |
| ✐Bleeding P/V, before 20 weeks of gestation ·<br>✐Bleeding P/V, after 20 weeks of gestation | ✐Check the pulse and BP to assess for shock<br>✐Ask for history of violence<br>✐Check the pulse and BP to assess for shock | ✐Threatened abortion / spontaneous abortion / hydatidiform mole / ectopic pregnancy<br>✐Spontaneous abortion due to violence<br>✐Antepartum haemorrhage | ✐Carry out an MVA to evacuate the retained products of conception. · Ask the ANM to put the woman in touch with local support groups.<br>✐Do NOT carry out a vaginal examination<br>✐Refer to an FRU. |
| Fever | ✐The body temperature is raised<br>✐Blood peripheral smear is positive for malarial parasite | ✐ Site of infection somewhere, including possible sepsis<br>✐ Malaria | ✐Try to ascertain the cause of fever. Start the woman on antibiotics.<br>✐Manage according to the NAMP guidelines for malaria in pregnancy. Treat the malarial fever. |
| Decreased or absent foetal movements<br>(NOTE: Foetal movements are felt only after about 4 months of<br>gestation) | ✐FHS heard, and within the normal range of 120-160 beats/minute<br>✐FHS heard, but the rate is <120 beats / minute, or >160 beats / minute<br>✐FHS not heard | ✐Baby is normal<br>✐Foetal distress<br>✐Intrauterine foetal death | ✐Reassure the woman.<br>✐Re-check the FHS after 15 minutes.<br>✐If the FHS is still out of the normal range, manage as given under the management of "foetal distress."<br>✐Inform the woman and her family that the baby might not be well.<br>✐· If labour pains are present, conduct the delivery in the usual manner.<br>✐· If there are no labour pains, refer to an FRU for induction of labour to terminate the pregnancy. |
| Vaginal discharge, with or without abdominal pain | | ✐RTI / STI | ✐Start treatment as per the GoI Guidelines for<br>✐RTI/STI.<br>✐If there are no labour pains, refer to an FRU for induction of labour to terminate the pregnancy. |
| Leaking of watery fluids P/V | Wet pads/cloths | ✐Premature or prelabour | ✐Manage as given under the management of<br>✐"PROM". |

A woman with severe anaemia (Hb <7 g/dl, or those who have breathlessness and tachycardia due to anaemia) should be started on the therapeutic dose of IFA and also be investigated to detect the cause of anaemia. She may require injectable iron preparations.

Injection tetanus toxoid (Inj. TT) administration

Inj. TT is to be given as 0.5 ml per dose, deep intramuscular (IM) in the upper arm, administration of two doses of Inj. TT to an unimmunised pregnant woman. The first dose of TT should be given just after the first trimester, the second dose is to be given one month after the first dose, but preferably at least one month before the EDD.

Malaria prophylaxis

Guidelines of the National Anti-Malaria Programme (NAMP) should be followed.

Counselling

Counsel the mother for birth preparedness and complication readiness. The woman and her family/caretakers should be informed about potential danger signs during pregnancy, delivery and the postpartum period. She must be told that if she has any of the following she should immediately visit an FRU or the PHC, WITHOUT WAITING, be it day or night.

Danger signs : Visit an FRU (First referral unit) / MH

(a) Any bleeding P/V during pregnancy & heavy (>500 ml) vaginal bleeding during or following delivery
(b) Severe headache with blurred vision
(c) Convulsions or loss of consciousness
(d) Labour lasting for more than 12 hours
(e) Failure of delivery of the placenta within 30 minutes of delivery
(f) Preterm labour (onset of labour before 34 weeks of gestation)
(g) Cases with leaking P/V (PROM)
(h) Continuous severe abdominal pain
(j) All cases of medical illnesses associated with pregnancy, such as diabetes mellitus, heart disease, asthma, etc. at the onset of labour pains.

Danger signs: Visit a 24-hour PHC / MI room with MO

(a) High fever with or without abdominal pain, and the woman is too weak to get out of bed (indicating infection/sepsis)
(b) Fast or difficult breathing (dyspnoea)
(c) Decreased or absent foetal movements
(d) Excessive vomiting, wherein the woman is unable to take anything orally, leading to a decreased urinary output

Diet and rest

The woman should be advised to eat more than her normal diet throughout her pregnancy as she needs about 300 extra kcal per day compared to her usual diet.

(a) If a woman has PIH, she should be encouraged to eat a normal diet with no restrictions on fluid, calorie and/or salt intake; such restrictions do not prevent PIH from converting into pre-eclampsia, and may be harmful to the foetus.
(b) The woman should be advised to refrain from taking alcohol or smoking during pregnancy.
(c) The woman should be advised NOT to take any medication unless prescribed by a qualified health practitioner.
(d) The woman should be advised to sleep for 8 hours at night and rest for another 2 hours during the day. She should be advised to refrain from doing heavy work.
(e) All pregnant women should be told to avoid the supine position and should sleep in left lateral position.

Sex during pregnancy

(a) It is safe to have sex throughout the pregnancy, as long as the pregnancy is "normal".
(b) Sex should be avoided during pregnancy if there is a risk of abortion (h/o previous recurrent spontaneous abortions), or a risk of a preterm delivery (h/o previous preterm labour).

**Infant and young child feeding**

Pregnancy is the ideal time to counsel the mother regarding the benefits of breastfeeding.

Initiation of breastfeeding

(a) Counsel the mother that breastfeeding should ideally be initiated within half an hour of a normal delivery or within two hours of a caesarean section.
(b) Colostrum not to be thrown away.
(c) Exclusive breast feeding for 6 months.
(d) Demand feeding : This refers to the practice of breast feeding the child whenever he/she "demands" it.
(e) Rooming in: This refers to the practice of keeping the mother and baby in the same room and should be encouraged.

Complementary feeding at 6 months

The mother should be told that after 6 months of age, the baby needs supplementary food, IN ADDITION TO BREAST MILK. Advise the mother to begin with semi-solid soft food devoid of spices, supplemented with a small amount of ghee/butter/oil. The frequency of feeds and the quantity of each feed should be increased gradually.

**Contraception**

The woman should be advised regarding birth spacing (or limiting, as the case may be) Chapter on contraception may be referred.

**Compulsory institutional deliveries**

Every pregnant woman should be advised and encouraged to go in for an institutional delivery.

There are medical/obstetric conditions during a

pregnancy when the chances of a complication occurring are increased. Such conditions/complications where institutional delivery is must are:

24-hour PHC

(a) Mild pre-eclampsia
(b) PPH in the previous pregnancy
(c) More than 5 previous births
(d) Previous assisted delivery
(e) Maternal age less than 16 years
(f) H/o third-degree tear in the previous pregnancy
(g) FRU
(h) Severe anaemia
(j) Severe pre-eclampsia/eclampsia
(k) APH
(l) Transverse foetal lie or any other malpresentation
(m) Caesarean section in the previous pregnancy
(n) Multiple pregnancies
(o) Premature or prelabour rupture of membranes (PROM)
(p) Medical illnesses such as diabetes mellitus, heart disease, asthma, etc. during pregnancy.

## Care during labour and delivery - intrapartum care

### Diagnosis of labour

The onset of labour can be confirmed by the following:

(a) Cervical effacement-progressive shortening and thinning of the cervix during labour
(b) Cervical dilatation

### Stages of labour

(a) The first stage of labour starts with the onset of labour pains to full dilatation of the cervix. This stage takes about 12 hours in primigravidas and half that time for subsequent deliveries.
(b) The second stage starts from full dilatation of the cervix to the delivery of the baby. This stage takes about 2 hours for primigravidas and only about half an hour for subsequent deliveries.
(c) The third stage starts after the delivery of the baby and ends with the delivery of the placenta. This stage takes about 15 minutes to half an hour, irrespective of whether the woman is a primigravida or multigravida.
(d) Frequent monitoring for one hour immediately after delivery is critical to detect PPH. This period is sometimes referred to as the fourth stage of labour.

### Assessment of the progress of labour

The progress of labour is assessed by:

(a) Assessing the changes in cervical effacement and dilatation (by conducting a P/V examination)
(b) Assessing the progress in foetal descent (by conducting an abdominal and/or a P/V examination).

Abdominal examination to assess the descent of the presenting part

If the head is above the symphysis pubis it is fully palpable and mobile. If the head is entirely below the symphysis pubis it is not palpable abdominally.

Vaginal examination to assess the stage and progress of labour

Carry out the vaginal examination under strict aseptic conditions, and determine the following:

(a) Cervical effacement
(b) Cervical dilatation in cm
(c) The presenting part.
(d) The position or the station of the presenting part.
(e) Feel for the membranes. Are they intact?
(f) If the membranes have ruptured, check whether the colour of the amniotic fluid is clear or meconium-stained.
(g) Feel for the umbilical cord. If it is felt, it is a case of prolapsed cord. If the cord pulsations are felt, refer the woman to an FRU immediately.

### Supportive care to the woman during labour

(a) Explain all the procedures; keep the woman informed about the progress of labour.
(b) Praise the woman, encourage her and reassure her that things are going well.
(c) Encourage the woman to bathe or wash herself and her genitals at the onset of labour.
(d) Always wash your hands with soap and water before examining the woman
(e) Ensure cleanliness of the birthing area.
(f) Enema should be given only when needed.
(g) Encourage the woman to empty her bladder frequently. Remind her every 2 hours or so.
(h) Non-pharmacological methods of relieving pain during labour include:
    (i) Calm and gentle voice of the birth attendant
    (ii) Offering the woman encouragement, reassurance and praise
    (iii) Relaxation techniques performed by the woman such as deep breathing exercises and massage
    (iv) Placing a cool cloth on the woman's forehead
    (v) Assisting the woman in voiding urine and in changing her position.
(j) Women who are not at risk of requiring general anaesthesia can have light, easily digested, low-fat food during labour, if they wish.

### Normal delivery

Management of the first stage of labour

Not in active labour

The cervix is dilated 0-3 cm and contractions are weak, less than 2 in 10 minutes.

(a) Monitor the following every hour:
  (i) Frequency (once in how many minutes), intensity (how strong), and duration of contractions.
  (ii) FHR
  (iii) The presence of any sign that denotes an emergency (such as difficulty in breathing, shock, vaginal bleeding, convulsions or unconsciousness)

(b) Monitor the following every 4 hours
  (i) Cervical dilatation (in cm), temperature, pulse, BP

(c) Record the time of rupture of the membranes and the colour of the amniotic fluid.

(d) Never leave the woman alone.

(e) If after 8 hours, the contractions are stronger and more frequent, but there is no progress in cervical dilatation with or without rupture of the membranes, this is a case of non-progress of labour. Refer the woman immediately to an FRU.

(f) On the other hand, if after 8 hours, there is no increase in the intensity/frequency/duration of contractions, and the membranes have not ruptured and there is no progress in cervical dilatation, ask the woman to relax. Advise her to send for you again when the pain/discomfort increases, and/or there is vaginal bleeding, and/or the membranes rupture.

(g) If the membranes were already ruptured on admission, but even after 8 hours there is no increase in the frequency/intensity of contractions, refer the woman to an FRU (prolonged latent phase) for induction of labour.

In active labour

The cervix is dilated 3 cm or more:

(a) Monitor the following every 30 minutes:
  (i) Frequency, intensity and duration of the contractions
  (ii) FHR
  (iii) Presence of any emergency sign

(b) Monitor the following every 4 hours:
  (i) Cervical dilatation (in cm)
  (ii) Temperature, pulse, BP

(c) Again, do not leave the woman alone.

(d) Start maintaining a partograph once the woman is in active labour.

**Simplified partograph**

The partograph is a graphic recording of the progress of labour and salient features of the mother and foetus. It involves recording of FHR every half-an-hour, cervical dilatation (in cm) when the woman first reports in labour and then every four hours, maternal pulse and systolic and the diastolic BP every half-an-hour, food items and liquids consumed by the woman during that period.

Management of the second stage of labour

(a) If the cervix is fully dilated or the perineum is thin and bulging with the anus gaping and the head of the baby visible at the vaginal introitus, it is the second stage of labour.

(b) Monitor every 5 minutes: Frequency, duration and intensity of contractions, FHR, Perineal thinning and bulging, Visible descent of the foetal head during contractions, Presence of any signs indicating an emergency.

(c) The woman should be allowed to push down. Bearing down efforts are required after the cervix is fully dilated, and even more so when the head is distending the perineum.

(d) Asking the woman to hold her breath and bear down in the second stage of labour should NOT be done.

(e) Giving the woman oxytocics to shorten the second stage of labour is NOT advisable.

(f) Avoid ironing the perineum (or using the "Sweep and stretch" technique) to hasten delivery.

(g) Episiotomy: There is no evidence that routine episiotomy decreases perineal damage, future vaginal prolapse or urinary incontinence. Remember, whenever an episiotomy is required, a right paramedian episiotomy is preferred.

Indications for conducting an episiotomy
  (i) Complicated vaginal delivery (refer to a higher health facility in case of a malpresentation)
  (ii) H/o third or fourth - degree perineal tears
  (ii) Foetal distress
  (iii) Instrumental/assisted delivery

(h) Ensure a controlled delivery of the head by taking the following precautions:
  (i) Encourage the woman to push only during pains (a contraction).
  (ii) Keep one hand gently on the head as it advances with the contractions.
  (iii) Support the perineum with the other hand during delivery and cover the anus with a pad held in position by the side of the hand.
  (iv) Leave the perineum visible (between the thumb and the index finger).
  (v) Ask the mother to breathe steadily and to not push during delivery of the head.
  (vi) Encourage rapid breathing with the mouth open.
  (vii) Do NOT apply fundal pressure to hasten delivery of the head.

(j) Feel gently around the baby's neck for the presence of the umbilical cord around the neck. If the cord is present around the neck:
  (i) And if it is loose, deliver the baby through the

loop of the cord, or slip the cord over the baby's head.

(ii) If the cord is tight, clamp it and cut the cord, and then unwind it from around the neck.

(iii) Wait for spontaneous rotation and delivery of the shoulders. This usually happens within 1-2 minutes.

(iv) Perineal tears can be prevented by delivering one shoulder at a time. If there is difficulty in delivering the shoulder, suspect shoulder dystocia. Ask the woman to take a position with extreme flexion at the knees and hips with the knees wide apart. The shoulder may be released from behind the symphysis pubis and may deliver. If not, then refer the woman immediately to an FRU.

(k) In case of shoulder dystocia:

(i) Apply gentle pressure downwards to deliver the anterior shoulder.

(ii) Then lift the baby up, towards the mother's abdomen, to deliver the lower (posterior) shoulder.

(iii) The rest of the baby's body smoothly follows out.

(iv) Place the baby on the mother's abdomen or in the baby tray.

(l) Note the time of delivery.

(m) Cutting the cord:

(i) Tie and cut the cord after 2-3 minutes of delivery, during which time the cord will normally stop pulsating.

(ii) Put ties tightly around the cord at 2 cm and 5 cm from the baby's abdomen.

(iii) Cut between the ties with a sterile blade.

(iv) Look for oozing of blood from the stump. If these is oozing, place a second tie between the baby's skin and the first tie.

(n) Give immediate newborn care.

(o) Rule out the presence of another baby by palpating the abdomen and trying to feel for foetal parts.

(p) It is recommended that the umbilical cord stump be left dry, and only routine daily care be given with clean safe water. Do not apply any substance to the stump.

(q) Care of the newborn: The newborn needs to be taken care of. The elements of essential newborn care are given below.

#### Elements of essential newborn care

(a) Maintain the body temperature and prevent hypothermia

(b) Maintain the airway and breathing

(c) Breastfeed the newborn

(d) Take care of the cord

(e) Take care of the eyes

(f) Leave the baby on the mother's chest for skin-to-skin contact.

(g) Cover the baby to prevent loss of body heat. If the room is cool, use additional blankets to cover the mother and the baby.

(h) Encourage the mother to initiate breastfeeding.

#### Active management of the third stage of labour

The active management of the third stage of labour consists of the following three activities.

Uterotonic drug

Giving a uterotonic drug has been shown to be effective in preventing PPH.

Although Inj. Oxytocin (in a dose of 10 U IM) is the drug of choice for preventing PPH, due to administrative difficulties, Misoprostol can now be used for the same purpose. Three tablets of 200 mcg each of Misoprostol (a total dose of 600 mcg) should be given immediately after delivery of the baby. It should be given either sublingually or orally.

Before giving Misoprostol, ensure that there is no additional baby(ies). This can be done by palpating the abdomen and ruling out the presence of foetal parts.

Controlled cord traction (CCT)

This is a technique to assist the expulsion of the placenta and helps to reduce the chances of a retained placenta and subsequent PPH. Do NOT exert excessive traction on the cord while performing CCT.

Uterine massage

This technique helps in contraction of the uterus and thus prevents PPH. Immediately after delivery of the baby; massage the uterus by placing your hand on the woman's abdomen until it is well contracted. Repeat the massage every 15 minutes for the first 2 hours. Ensure that the uterus does not become relaxed (soft) after the massage is stopped. If the placenta is not delivered within 30 minutes of giving Misoprostol, and the woman is not bleeding, try and remove the placenta again by CCT. Empty the bladder, and encourage the woman to breastfeed. If the placenta cannot be delivered after another 20 minutes, and the woman is not bleeding, empty the bladder, initiate breastfeeding and repeat CCT. The placenta may separate. If it does not separate and the woman is still not bleeding, refer her to an FRU.

## Post Partum Care

#### Immediate postpartum care

(a) After delivery of the placenta, check that the uterus is well contracted, i.e. it is hard and round, and there is no heavy bleeding. Repeat the checking every 5 minutes. If the uterus is not well contracted, massage the uterus and expel the clots.

(b) Examine the perineum, lower vagina and vulva for tears. If present, manage the tears by suturing.

(c) Estimate and record the amount of blood lost throughout the third stage and immediately afterwards. If the loss is around 250 ml, but the bleeding has stopped, observe the woman for the next 24 hours.

(d) Monitor the following every 10 minutes for the first 30 minutes, then every 15 minutes for the next 30 minutes, and then every 30 minutes for the next three hours: BP, pulse, temperature, vaginal bleeding, uterus to make sure that it is well contracted.

(e) Clean the woman and the area beneath her. Put a sanitary pad or a folded cloth under her buttocks to collect blood. This will also help in estimating the amount of blood lost, by counting the number of pads/cloths soaked. Help her change her clothes, if necessary.

(f) Dispose of the placenta in the correct, safe and culturally appropriate manner. Use gloves while handling the placenta. Put the placenta into a leak-proof bag. Incinerate the placenta or bury it at least 10 m away from a water source, in a 2 m deep pit.

(g) Keep the mother and the baby together; do not separate them. Encourage early breastfeeding.

(h) Encourage the woman to eat and drink, and rest.

(j) Encourage the woman to pass urine. If the woman has difficulty in passing urine, or the bladder is full (as evidenced by a swelling over the lower abdomen) and she is uncomfortable, help her pass urine by gently pouring water over her vulva.

(k) Weigh the baby.

(l) Ask the birth companion to stay with the mother. Do not leave the mother and the newborn alone. Ask the companion to watch the woman and call for help if any of the following occurs:
   (i) The bleeding increases.
   (ii) The woman feels dizzy.
   (iii) The woman has severe headache.
   (iv) The woman has visual disturbance.
   (v) The woman has epigastric distress.
   (vi) The woman complains of breathlessness.
   (vii) The woman complains of increased abdominal or perineal pain.

(m) Enter the following information in the labour register:
   (i) Date & time of delivery
   (ii) Name of the woman
   (iii) Age of the woman
   (iv) Parity
   (v) ANC received (or not): mention the number of ANC visits
   (vi) Mode of delivery (normal or assisted)
   (vii) Birth weight of the baby
   (viii) Apgar score of the baby at 1 minute and 5 minutes after delivery.

(n) Do not discharge the woman before 24 hours after delivery. This is a crucial period for the occurrence and management of PPH. The woman must be kept under observation during this time.

**Counselling**

Counsel the woman regarding the aspects discussed below:

Postpartum care and hygiene

Advise and explain to the woman

(a) To always have someone near her for the first 24 hours after delivery to respond to any change in her condition.

(b) Not to insert anything into the vagina.

(c) To wash the perineum daily and after passing stools. Wash in an anteroposterior direction from the vulva to the anus.

(d) To change the perineal pads every 4-6 hours, or more frequently, if there is heavy lochia.

(e) To wash cloth pads, if used, with plenty of soap and water and dry them in the sun.

(f) To bathe daily.

(g) To have enough rest and sleep. For the first 6 weeks postpartum, advise the woman to not do anything except look after herself and her baby.

(h) To avoid sexual intercourse for the first six weeks or until the perineal wound heals, whichever is later.

(j) To wash her hands before handling the baby.

Nutrition

Advise the woman to eat a greater amount and variety of healthy foods. Give her examples of the types of food and how much to eat.

Contraception

Advise the woman regarding birth spacing or limiting as the case may be.

Breastfeeding

As discussed above.

Registration of birth

Emphasize to the woman that she must get the birth of the baby registered with the local Panchayat, or any other appropriate registering authority.

Postpartum visit

(a) Inform the woman about the next routine postpartum visit.

(b) As the woman is kept under observation for the first 24 hours after delivery, the first postpartum visit is taken care of during her stay at the PHC/health facility.

(c) The second postpartum visit should be planned within 7-10 days after delivery. Either ask the ANM of that area to pay a visit to the woman and her baby, or ask the woman to return to the PHC for a postpartum check-up.

(d) If the woman misses her postpartum visits, inform her regarding the danger signs and when to return.

(e) Danger signs

(f) For the following symptoms and signs in the mother, advise the woman and her family to go to an FRU immediately, day or night, WITHOUT WAITING.

(i) Excessive vaginal bleeding, i.e. soaking more than 2 or 3 pads in 20-30 minutes after delivery, or bleeding increases rather than decreases after the delivery

(ii) Convulsions

(iii) Fast or difficult breathing

(iv) Fever and weakness; inability to get out of bed

(v) Severe abdominal pain

(g) Advise the woman that she should visit the PHC as soon as possible, in case she suffers from any of the following symptoms:

(i) Fever

(ii) Abdominal pain

(iii) The woman feels ill

(iv) Swollen, red or tender breasts, or sore nipples

(v) Dribbling of urine or painful micturition

(vi) Pain in the perineum, or pus draining from the perineal area

(vii) Foul-smelling lochia.

Research has shown that more than 50% of maternal deaths take place during the postpartum period. Conventionally, the first 42 days (6 weeks) after delivery are taken as the postpartum period. Of this, it is the first 48 hours, followed by the first one week, which are the most crucial periods for the health and survival of both the mother and her newborn, as most of the fatal and near-fatal maternal and neonatal complications arise during this period.

**Postnatal check-ups**

The number and timing of PNC visits

(a) The first 48 hours following delivery are the most important. Take a history and do a quick examination, as described later to find out possible complications that could have arisen.

(b) The next most critical period is the first week following delivery. Ask the mother to pay another visit on day 3rd and day 7th, or ask the ANM in charge of that area to pay a home visit during this period.

The first postpartum visit

As explained earlier, the first postpartum visit should take place within the first 24 hours after delivery.

**History-taking**

The following questions should be asked:

(a) Where did the delivery take place?

(b) Who conducted the delivery?

**Maternal symptoms**

(a) H/o heavy bleeding P/V

(b) H/o convulsions or loss of consciousness

(c) H/o abdominal pain

(d) H/o fever

**Examination**

(a) Check the pulse, BP, temperature, pallor.

(b) Examine the abdomen to see if the uterus is well contracted.

(c) Examine the vulva and the perineum for the presence of any foul-smelling lochia, tear, swelling or pus discharge and also the pad for bleeding and any purulent discharge.

**Neonatal symptoms**

Check for signs of possible diseases and take appropriate action as given in Table - 2, Table - 3 & Table - 4.

The schedule of subsequent visits is based on birth weight. The recommended schedule for home visits is outlined below:

**Advise the Mother and the Family on Home Care**

(a) To breastfeed the infant frequently

(b) To ensure that the infant is kept warm at all times by placing the baby in skin to-skin contact with the mother

(c) Advise the mother not to apply anything on the cord and keep the cord and umbilicus dry.

(d) Also teach the mother to return immediately, if the young infant has any of these signs:

(e) Breastfeeding or drinking poorly

(i) Becomes sicker

(ii) Develops a fever or feels cold to touch

| | |
|---|---|
| All babies | 3, 7 days |
| Low birth weight babies (weight less than 2.5 kg) | 3, 7, 14, 21 and 28 days |

(iii) Fast breathing

(iv) Difficult breathing

(v) Blood in stool

**The second and third postpartum visits**

This is similar to the history yaking and examination conducted during the first visit

**Counselling**

Diet and rest

(a) Inform the woman that during lactation she needs approximately 550 kcal extra in a day during the

Table - 2 : Possible serious infections in neonate

| **Signs** | **If any one sign is present, Refer the child** |
|---|---|

first 6 months, and then 400 kcal extra during the next 6 months, compared to her pre-pregnancy diet.

(b) The woman needs sufficient rest during the postpartum period to be able to regain her strength.

Resumption of sex

The couple should be advised to abstain from having sex during the first 6 weeks following delivery.

Contraception

This issue must be emphasized again

Infant and young child feeding

The issues that need to be discussed and the woman counselled about have been detailed above.

Infant care

You must talk to the mother about:

(a) Child development and milestones
(b) Maintaining the hygiene of the baby
(c) Feeding the baby
(d) When and where to seek help in case of illness. Explain the danger signs
(e) How to interact with the child, etc.

## Essential newborn care

### Preparing for birth

Make sure that the following materials / conditions are available for the newborn:

(a) Two clean and warm towels for thermal protection of the baby; one for drying and wrapping the baby initially, the other for covering the newborn to prevent heat loss
(b) A draught-free delivery room with a temperature of at least 25 °C
(c) Soap, water, clean gloves, cotton, gauze and a clean labour table for delivery to ensure the six "cleans" (i.e. clean hands, clean surface, clean cord cut, clean cord tie, clean cord stump and clean perineum) during delivery
(d) A clean delivery kit for cord care
(e) Self-inflating bags (two, of a size appropriate for a newborn) and masks (sizes zero and one) for resuscitation
(f) A suction device (mucus extractor)
(g) A radiant heater
(h) A blanket
(j) A clock/watch to note the time of delivery.

### Routine care at birth

Over 90% of newborns do not require any active resuscitation at birth. Efforts are directed to maintain asepsis, prevent infection and hypothermia, and to keep the airway patent.

### Asepsis

Deliver the newborn under aseptic conditions.

Clamping of the cord

Clamp the umbilical cord 2-3 minutes after the neonate is delivered completely.

Care of the cord

(a) Inspect the cord for bleeding 2 hours after ligation.
(b) Do NOT apply anything on the stump; keep the cord clean and dry.
(c) Inspect for discharge or infection till healing occurs.

### Maintaining the body temperature

Newborns may be hypothermic at birth. Heat loss at birth can be prevented by the following simple interventions:

(a) Receive the baby in a dry, warm, clean towel. Dry the baby well. While drying, make sure that the head is in a neutral position. Discard the wet towel immediately and wrap/cover the baby (except for the face and upper chest) in a fresh, clean dry towel.
(b) Place the baby near a source of warmth.
(c) Bathing the newborn soon after birth is not recommended. The mother or the birth attendant can clean the baby by wiping with a soft moist cloth. If cultural tradition demands bathing, this should not be carried out before 6 hours after birth, and preferably on the second or third day of life as long as the baby is healthy and its temperature normal and that too with lukewarm water.

### Airway and breathing

If the baby is crying and the breathing is normal, resuscitation is not needed. Provide normal care and clear the upper airway by wiping the nose and mouth of the baby, and removing the ecretions present therein. If the baby is not crying, assess the breathing; if the chest is rising symmetrically and the RR is >30 breaths/minute, no immediate action is needed.

### Care of the skin

Clean the blood, mucus and meconium on the newborn's body.

### Care of the eyes

The eyes should be cleaned at birth and once every day using sterile cotton swabs soaked in sterile water or normal saline.

### Feeding

Initiate breastfeeding within one hour of a normal delivery.

### Apgar score

The Apgar score indicates the newborn's well-being. It should be calculated at 1 minute and at 5 minutes after birth. Table - 5 gives the criteria for calculating the Apgar score. An Apgar score of >7 is considered satisfactory.

Table -5 : Criteria for calculating the Apgar score

**Essential postnatal care**

(a) Nurse in thermal comfort (the baby should be warm to the touch at the abdomen and pink in the soles of the feet.
(b) Check the umbilicus, skin and eyes.
(c) Ensure good suckling at the breast.
(d) Screen for danger signs.
(e) Advise the family, especially the mother, on immunization.

Danger signs in a newborn

| Parameters | 0 | 1 | 2 |
|---|---|---|---|
| **Respiratory effort** | Absent | Gasping | Good cry |
| **Heart rate** | Zero | <100/minute | >100/minute |
| **Colour (cyanosis)** | Central cyanosis | Peripheral cyanosis | Pink |
| **Muscle tone** | Flaccid | Partial flexion of the extremities | Complete flexion |
| **Reflex (response to nasal catheter)** | None | Grimace | Sneeze |

The signs mentioned below are particularly important signs to watch to Return Immediately:

(a) Breastfeeding or drinking poorly
(b) Becomes sicker
(c) Develops a fever or feels cold to touch
(d) Fast breathing
(e) Difficult breathing
(f) Blood in stool

Basic newborn resuscitation

Effective basic resuscitation will revive more than 75% of newborns with birth asphyxia.

Birth asphyxia

It is estimated that 4%-6% of babies fail to establish breathing at birth. Birth asphyxia is the second most common cause of neonatal mortality next to septicaemia.

Defining birth asphyxia

Traditionally, birth asphyxia is defined on the basis of the Apgar score. An Apgar score of <7 at 1 minute is considered as birth asphyxia. Such a baby needs immediate resuscitation.

Initial assessment

The five questions to ask are:

(a) Is the amniotic fluid clear of meconium?
(b) Is the baby breathing or crying normally?
(c) Is the muscle tone good?
(d) Is the colour of the baby pink?
(e) Was the baby born at term?

If the answer to any of these questions is "NO" immediately begin the initial steps of resuscitation.

Managing birth asphyxia

If meconium is present in the amniotic fluid, apply suction to ensure that it is removed from the mouth, posterior pharynx and nose before delivery of the shoulders.

Suction apparatus: These could be either De Lee mucus traps, foot or electrically operated suction machines. While using electrical suction machines, care must be taken that the pressure does not exceed 100 mm Hg.

Tactile stimulation

If necessary, appropriate forms of tactile stimulation (gently rubbing the baby's back, flicking the soles of the feet) may be provided.

Heart rate

If the heart rate is less than 100 beats/minute, it indicates the need for assisted ventilation.

Open the airway - position and suction

Put the baby on its back. Position the head so that the neck is slightly extended. Clear the airway by suctioning first the mouth and then the nose. A mucus trap or a foot-operated suction machine may be used for the same.

Assisted ventilation

Assisted ventilation is indicated in any apnoeic baby who is not responding to tactile stimulation, or any baby who, though breathing, has a heart rate of <100 beats/minute. Ventilation may be provided either with a bag and mask or a bag and an endotracheal tube.

Risk identification in the newborn

An important task of the attending MO in the labour room is the identification of newborns at high risk for morbidity and mortality. These newborns would need special care, either at the PHC where the delivery took place (if the facilities and trained personnel exist) or at the FRU where these babies should be referred to.

**Guidelines to detect newborns at risk are given below**

(a) Birth asphyxia: Newborns who are asphyxiated at birth, especially those who do not establish spontaneous respiration by 5 minutes of birth.
(b) Danger Signs: Newborn with following signs:
  (i) Convulsions
  (ii) Fast breathing (60 breaths per minute or more)
  (iii) Severe chest indrawing
  (iv) Nasal flaring
  (v) Grunting
  (vi) Bulging fontanelle
  (vii) 10 or more skin pustules or a big boil

(viii) If axillary temperature 37.5°C or above (or feels hot to touch) or temperature less than 35.5°C (or feels cold to touch)

(ix) Lethargic or unconscious

(x) Less than normal movements

(xi) Severe Jaundice

(xii) Blood in the stools

(xiii) Not able to feed

(xiv) No attachment at all

(xv) Not sucking at all

(c) Major Malformations

# Integrated Management of Neonatal and Childhood Illnesses

The commonest causes of death in children below 5 years of age are acute respiratory illnesses (mostly pneumonia), diarrhea, measles, malaria, malnutrition and often a combination of these illnesses. In order to combat these illnesses, isolated preventive and treatment interventions such as antibiotics for pneumonia, oral rehydration therapy, prompt malarial treatment, vaccination etc have been employed over the years. It has been however recognized that childhood health programmes need to go beyond single diseases and should promote overall health and well being of a child. Moreover many sick children present with overlapping signs and symptoms of illnesses, and a single diagnosis may not be feasible or appropriate, especially in a primary care level with scarce resources. Accumulated evidence has also suggested that an integrated approach is needed in managing sick children to improve outcomes. Therefore, WHO in collaboration with UNICEF and many other agencies developed a strategy known as Integrated Management of Neonatal and Childhood Illnesses ( IMNCI) as a means of reducing morbidity and mortality in children below the age of 5 years. Apart from reducing deaths and frequency or severity of illnesses, this strategy addresses nutrition, growth, immunization and other important aspects prevention of disease and promotion of health.

The aim of managing children as per the Integrated Management of Neonatal and Childhood Illness (IMNCI) protocol is to use a syndromic approach to the common and serious problems affecting children. It is not based on arriving at a specific diagnosis and treatment but focuses on identifying a cluster of signs and symptoms most likely associated with serious, often life threatening diseases. Treatment can thereby be started at the earliest without the use of any laboratory tests or sophisticated investigations, and before referring the child to a higher centre. It involves triage to quickly decide and treat mild to moderate disease effectively while referring seriously ill children early and in a more stable condition.

A combination of symptoms and signs leads to an infant or child's 'classification', which indicates the severity of the condition, rather than a diagnosis. The specific action thereby can be either urgent referral to a higher level of care (colour coded pink), giving specific treatment in the primary health care facility (colour coded yellow) or safe home management (colour coded green). Pre-referral treatment, counseling of caretaker and follow up are unique components of the IMNCI programme.

Depending on the age of the child, various clinical signs and symptoms differ in their degree of reliability, diagnostic value and importance. The IMNCI guidelines therefore recommend case management procedures based on two age categories:

(a) Young infants age up to 2 months
(b) Children 2 months up to 5 years

## Outpatient management of the sick young infant Age up to 2 months

Neonates and infants below 2 months of age are considered as a special group in the IMNCI case management protocol for several reasons. They become sick rapidly and can die quickly due to serious bacterial infections. Certain general signs in these infants such as low body temperature, fever or less body movements may be the only manifestation of illness. On the other hand, a finding such as mild chest indrawing is normal in them due to a soft chest wall. Therefore the assessment and classification process is different from that in an older infant or child.

A young infant age up to 2 months brought to the primary health care facility is assessed as follows

(a) Assessment for possible serious bacterial infection or local infection
(b) Assessment for jaundice
(c) Assessment for low body temperature
(d) Assessment for diarrhea
(e) Assessment feeding problem or malnutrition and breast feeding
(f) Checking the immunization status and assessing other problems

### Assessment for possible serious bacterial infection

Any sick young infant who is brought to a health care provider should be first assessed for possible serious bacterial infection based on the following criteria:

(a) History of convulsions
(b) Presence of fast breathing (60 breaths per minute or more)
(c) Severe chest in-drawing
(d) Nasal flaring
(e) Grunting
(f) Bulging fontanel
(g) Skin pustules (10 or more)
(h) Large boil on the skin
(j) Abnormal axillary temperature ( more than 37.5$^{o}$C or less than 35.5$^{o}$C)
(k) Lethargy or unconsciousness
(l) Less than normal movements

If any one of these of these criteria is present the infant is classified as having possible serious bacterial infection. an infant is to be referred to hospital urgently for admission. The pre-referral treatment is important. It consists of administering first dose of antibiotics (intramuscular ampicillin 100 mg/Kg and gentamicin 5mg/Kg); giving expressed breast milk (or appropriate animal milk orally or by nasogastric tube) to prevent hypoglycemia and providing warmth by skin to skin contact (kangaroo care).

Assessment for local infection

The infant has local bacterial infectionif there is redness of umbilicus, pus discharge from ear or less than 10 skin pustules. all such cases an oral antibiotic is given (co-trimoxazole 6 mg/kg/day of trimethoprim or amoxycillin 30 mg/kg/day) for 5 days. The mother is taught to apply gentian violet and dry the ear by wicking. The infant is followed up after 2 days.

**Assessment and management of jaundice**

Jaundice should be looked for in any sick young infant. Jaundice in a neonate appearing at aless thanhours or after 14 days or associated with yellow discoloration of palms and soles is classified as severe jaundice. an infant

requires urgent referral to hospital after giving pre-referral treatment which includes oral expressed breast milk, skin to skin contact and advising mother to keep the infant warm en route to hospital. If the infant has jaundice but there are no signs of severity, mother is reassured and the infant is reviewed after 2 days. It is important to advice the mother to return immediately if the infant develops any signs of serious bacterial infection or jaundice on palms and soles.

**Assessment & management of low body temperature**

Axillary temperature should be recorded in every sick young infant and if it is 35.5 - 36.4°C, the infant has low body temperature. Such an infant should be warmed with skin to skin contact for one hour and reassessed. If there is no improvement, he is referred to hospital, while feeding expressed breast milk to prevent hypoglycemia.

**Assessment and management of diarrhea**

A young infant is said to have diarrhea if the stools have changed from the usual pattern and are increased in number and watery (more water then fecal matter). The normally frequent or loose stools of a breast fed baby are not considered as diarrhea.

Duration of diarrhea and history of blood in the stool are important questions in the history. Assessment for presence and severity of dehydration is done by looking at the infant's general condition, presence of sunken eyes and the response to skin pinch.

If the young infant has two of the following three signs, the classification is severe dehydration:

(a) Lethargic or unconscious
(b) Sunken eyes
(c) Skin pinch goes back very slowly.

If such an infant has low weight or any other severe classification, he is referred urgently to hospital. The pre-referral treatment comprises first dose of IM antibiotics (ampicillin and gentamicin), giving frequent sips of ORS on the way, continuing breast feeding and keeping the infant warm. If the infant does not have low weight or another severe classification, fluids are administered for severe dehydration as per **plan C** (Table - 1) and he is then referred to hospital after rehydration.

If the young infant has two of the following three signs,

(a) Restless, irritable
(b) Sunken eyes
(c) Skin pinch goes back slowly, he is classified to have some dehydration.

If the infant has low weight or another severe classification, first dose of IM antibiotics (ampicillin and gentamicin) are given and urgent referral to hospital is done, with mother giving frequent sips of ORS on the way, continuing breast feeding and keeping the infant warm. I f the infant does not have low weight or another severe classification, fluids are administered for some dehydration as per **plan B** (Table - 2). The mother is counseled to return for follow up in 2 days or return immediately if danger signs develop.

If there are not enough signs to classify as some or severe dehydration, the infant has no dehydration and is given fluids to treat diarrhea at home as per **plan A** (Table - 3). The follow up is done in 5 days and mother is also advised when to return immediately.

Severe persistent diarrhea is diarrhea lasting 14 days or more and the infant with this classification is referred to hospital. If there is blood in the stool, the young infant has severe dysentery and is similarly referred to hospital.

**Assessment and management of feeding problems and malnutrition**

Every sick young infant should be assessed for adequate feeding and weight. Mother should be enquired about any feeding difficulty, frequency of breast feeding, any other food or drink being given to the infant and frequency of such feeds. The present weight and birth weight should be noted and using the reference charts (Fig - 1), the infant is classified as very low weight for age, low weight for age or not low weight for age.

Feeding should be assessed immediately if the infant feeds less than 8 times in 24 hours, receives other foods or drinks, or is low weight for age and has no indications to refer urgently to hospital. The infant should be put to the breast and observed for attachment and effective suckling. Blocked nose, oral thrush and breast or nipple problems (flat or inverted nipples, sore nipples, engorged breasts or breast abscess) should be looked for.

If the young infant is not able to feed, has no attachment at all, is not sucking at all or is very low weight for age, he has a life threatening problem and needs urgent admission to hospital after administering pre-referral treatment.

If there are other feeding problems or the infant is low weight for age, counseling of the mother is done about correct position during breast feeding, increasing frequency of feeds, treatment of breast and nipple problems and treatment of thrush. The infant is followed up after 2 days for feeding problem and after 14 days for low weight for age.

**Checking the young infant's immunization status**

It is important to check whether OPV, BCG, DPT-1 and Hep B-1 vaccines have been administered in every sick young infant. An infant who is not sick enough to be referred to hospital should be given the necessary immunization before being sent home.

**Assessment of other problems**

The infant should be assessed for all other problems mentioned by the mother or observed during examination. If a potentially serious problem is found and there are no available means to manage the infant, he should be referred to hospital.

Case recording form for management of a sick young infant is as shown below.

## CASE RECORDING FORM FOR MANAGEMENT OF THE SICK YOUNG INFANT AGE UP TO 2 MONTHS

Name:_____ Age:____ Weight: ____kg Temperature:_____ °C Date:

ASK: What are the infant's problems? _____Initial visit? _____ Follow up Visit?_____

**ASSESS** (Circle all signs present) **CLASSIFY**

**CHECK FOR POSSIBLE BACTERIAL INFECTION / JAUNDICE**

- Has the infant had convulsions?
- Count the breaths in one minute. breaths per minute
- Repeat if elevated _____ Fast breathing?
- Look for severe chest indrawing.
- . Look for nasal flaring.
- Look and listen for grunting.
- Look and feel for bulging fontanelle.
- Look for pus draining from the ear.
- Look at the umbilicus. Is it red or draining pus?
- Look for skin pustules. Are there 10 or more pustules or a big boil?
- Measure axillary temperature (if not possible, feel for fever or low body temperature):
  - 37.5°C or more (or feels hot)?
  - Less than 35.5°C ?
  - Less than 36.5°C but above 35.4°C (or feels cold to touch)?
- See if young infant is lethargic or unconscious
- Look at young infant's movements. Less than normal?
- Look for jaundice. Are the palms and soles yellow?

**DOES THE YOUNG INFANT HAVE DIARRHEA?** Yes ___ No _

- For how long? ____ Days?
- Is there blood in the stool?
- Look at the young infant's general condition. Is the infant:
  - Lethargic or unconscious?
  - Restless and irritable?
- Look for sunken eyes.
- Pinch the skin of the abdomen. Does it go back:
  - Very slowly (longer than 2 seconds)?
  - Slowly

**THEN CHECK FOR FEEDING PROBLEM & MALNUTRITION**

- Is there any difficulty feeding? Yes __ No ___ . • Determine weight for age. Very low ___ Low ___ Not Low ___
- Is the infant breastfed? Yes _____ No ___
  If Yes, how many times in 24 hours? ____ times
- Does the infant usually receive any other foods or drinks? Yes ___ No ___
  If Yes, how often?
- What do you use to feed the infant?

**If the infant has any difficulty feeding, is feeding less than 8 times in 24 hours, is taking any other food or drinks, or is low weight for age AND has no indications to refer urgently to hospital:**

**ASSESS BREASTFEEDING:**

• Has the infant breastfed in the previous hour?

If infant has not fed in the previous hour, ask the mother to put her infant to the breast. Observe the breastfeed for 4 minutes.

• Is the infant able to attach? To check attachment, look for:
- Chin touching breast Yes ___ No ___
- Mouth wide open Yes _____ No ___
- Lower lip turned outward Yes ____ No ___
- More areola above than below the mouth Yes ___ No ___

*no attachment at all* *not well attached* *good attachment*

• Is the infant suckling effectively (that is, slow deep sucks, sometimes pausing)?

*not suckling at all* *not suckling effectively* *suckling effectively*

• Look for ulcers or white patches in the mouth (thrush).

• Does the mother have pain while breastfeeding? If yes, then look for:
- Flat or inverted nipples, or sore nipples
- Engorged breasts or breast abscess

**CHECK THE YOUNG INFANT'S IMMUNIZATION STATUS** Circle immunizations needed today.

Return for next immunization on:

Counsel the mother about her own health

## Outpatient management of the sick child - Age 2 months up to 5 years

A sick child aged 2 months to 5 years presenting to the primary health care facility is most likely to have pneumonia, diarrhea, fever or an ear infection. The child may in addition have malnutrition and anemia and should be evaluated in a comprehensive manner irrespective of the complaints as follows:

(a) Asking the mother about the child's problem.
(b) Checking for general danger signs.
(c) Asking the mother about the four main symptoms:
  (i) Cough or difficult breathing
  (ii) Diarrhea
  (iii) Fever
  (iv) Ear problem.
(d) If one of the above main symptoms is present:
  (i) Assessing the child further for signs related to the main symptom
  (ii) Classifying the illness according to the signs which are present or absent.
(e) Checking for signs of malnutrition and anemia and classifying the child's nutritional status.
(f) Checking the child's immunization status and deciding if the child needs any immunization immediately.
(g) Assessing for any other problems.

### Checking for general danger signs

A sick child brought to the primary health care facility may have signs that clearly indicate a specific problem. For example, a child may present with chest indrawing and cyanosis, which indicate severe pneumonia. However, some children may present with serious, non-specific signs called "general danger signs" that do not point to a particular diagnosis. For example, a child who is lethargic or unconscious may have meningitis, severe pneumonia, cerebral malaria or another severe disease. Great care should be taken to ensure that these general danger signs are not overlooked because they suggest that a child is severely ill and needs urgent attention.

The following general danger signs should be routinely checked in all children:

- Convulsions
- Repeated vomiting
- Inability to drink or breastfeed
- Lethargy or unconsciousness

If a child has one or more of these signs, he must be considered seriously ill and will almost always need referral. In order to start treatment for severe illnesses without delay, the child should be quickly assessed for the most important causes of serious illness and death - acute respiratory infection (ARI), diarrhea, and fever (especially associated with malaria and measles). A rapid assessment of nutritional status is also essential.

### Checking main symptoms

After checking for general danger signs, the health care provider must check for the following main symptoms:

(a) Cough or difficult breathing
(b) Diarrhea
(c) Fever
(d) Ear problems.

#### Cough or difficult breathing

Three key clinical signs are used to assess a sick child with cough or difficult breathing:

(a) Respiratory rate: A child's age cut-off rate for fast breathing that suggests pneumonia is:
  (i) 2 months up to 12 months: 50 breaths per minute or more
  (ii) 12 months up to 5 years : 40 breaths per minute or more
(b) Lower chest wall indrawing
(c) Stridor

Based on a combination of the above clinical signs, children presenting with cough or difficult breathing should be classified into three categories:

(a) Severe pneumonia or very severe disease
(b) Pneumonia
(c) No pneumonia (i.e. cough or cold).

Presence of any general danger sign or chest indrawing or stridor in a calm child classifies the child as **severe pneumonia /very severe disease**. This child should be urgently referred to hospital, after administering the first dose of injectable antibiotic (IM Chloramphenicol 40mg/kg/dose) or if not possible, oral amoxicillin 15mg/kg/dose.

If only fast breathing is present, the child is classified as having **pneumonia** and given oral antibiotics - cotrimoxazole (trimethoprim 8 mg/kg/day) for 5 days. Additional symptomatic treatment to soothe the throat and a safe cough remedy for children older than 6 months may be given. The mother is counseled to return for follow up after 2 days. However if danger signs develop or the child becomes sicker, the mother should be asked to return immediately.

If there are no signs of pneumonia, the classification is **no pneumonia: cough or cold**. Such a child is given symptomatic treatment, but followed up after 5 days if not improving, or immediately if danger signs develop or the child becomes sicker.

#### Diarrhea

A child presenting with diarrhea should first be assessed for general danger signs and the child's caretaker should also be asked if the child has cough or difficult breathing. A child with diarrhea may have three potentially lethal conditions:

(a) Acute watery diarrhea (including cholera)
(b) Dysentery (bloody diarrhea)
(c) Persistent diarrhea (diarrhea that lasts 14 days or more).

All children with diarrhea should be checked to determine the duration of diarrhea, if blood is present in the stool and if dehydration is present.

A number of clinical signs are used to determine the level of dehydration:

(a) Child's general condition ( lethargic, unconscious or restless /irritable).

(b) Sunken eyes.

(c) Child's reaction when offered to drink: Nable to drink /drinking poorly/ eagerly, thirsty

(d) Elasticity of skin : when released, the skin pinch goes back either slowly (longer than 2 seconds), or (skin stays up even for a brief instant), or immediately

Based on a combination of the above clinical signs, children presenting with diarrhea are classified into the three categories of **severe dehydration, some dehydration** and **no dehydration** and appropriate treatment should be given.

Presence of at least two of the following signs

(a) Lethargic or unconscious

(b) Sunken eyes

(c) Not able to drink or drinking poorly

(d) Skin pinch goes back very slowly

Classifies the child as having **severe dehydration**. Child should be managed in the primary health care facility with fluids as per **plan C** (Table - 1). However if the child has any other severe classification, he should be urgently referred to hospital. Oral doxycycline (5 mg/kg/day) should be administered if cholera is prevalent in the area.

If two of the following signs are present :

(a) Restless/ irritable

(b) Sunken eyes

(c) Drinks eagerly, thirsty

(d) Skin pinch goes back slowly.

The classification is **some dehydration**. The child should be treated as per **plan B** (Table - 2). Such a child is followed up after 5 days if not improving. Mother is however counseled to return immediatelyif child has any of the following signs: not able to drink or breast feed, becomes sicker, develops fever or passes blood in stool.

The child is classified as **no dehydration** if there are not enough signs to classify into some or severe dehydration. Treatment is given at home with fluids and feeds as per **plan A** (Table3). The mother is advised to return after 5 days or immediatelyif above danger signs develop.

Table - 1 : Plan C : Treat severe dehydration quickly

**If you can give IV fluid immediately**

- If the child can drink, give ORS by mouth while drip is set up.
- Give 100 ml/kg Ringers lactate solution or Normal saline as follows

| Age | First give 30 ml/kg in : | Then give 70 ml/kg in: |
|---|---|---|
| Infants( up to 12 months) | 1 hour ( repeat once if radial pulse is still very weak or not detectable) | 5 hours |
| Children (12 months – 5 years) | | 30 minutes( repeat |

- Reassess child every 1-2 hours. If hydration status is not improving, give the IV fluid more rapidly.
- Also give ORS (about 5 ml/kg/hour) as soon as the child can drink, usually after 3-4 hours(infants) or 1-2 hours( children)
- Reassess an infant after 6 hours and a child after 3 hours. Classify dehydration. Then choose the appropriate plan(A,B, or C) to continue

**If you cannot give IV fluids immediately and IV treatment is available nearby (within 30 min)**

- Refer urgently to hospital for IV treatment
- If the child can drink, provide the mother with ORS solution and show her how to give frequent sips during the trip \

**If IV treatment is not available immediately and you are trained to use nasogastric tube for rehydration**

- Start rehydration by tube (or mouth) with ORS solution: 20 ml/kg/hour for 6 hours (total of 120 ml/kg)
- Reassess the child every 1-2 hours
  - If there is repeated vomiting or increasing abdominal distension, give the fluid more slowly
  - If the hydration status is not improving after 3 hours, send the child for IV therapy
- After 6 hours, reassess the child. Classify dehydration. Then choose the appropriate plan (A, B, C) to continue treatment.

**If IV treatment is not available immediately ( within 30 min), you are not trained to use nasogastric tube and the child cannot drink**

Table - 2 : Plan B - Treat some dehydration with ORS

**Give recommended amount of ORS over a 4 hour period**

Determine the amount of ORS to give during next 4 hours as follows:

| Age | Up to 4 months | 4 months to 12 months | 12 months up to 2years | 2 years up top 5 years |
|---|---|---|---|---|
| Weight | < 6kg | 6<10 kg | 10 - <12 kg | 12-19 kg |
| In ml | 200-400 | 400-700 | 700-900 | 900-1400 |

- The approximate amount of ORS required (in ml) can also be calculated by multiplying the child's weight (in kg) times 75
- If a child wants more ORS than shown, give more.
- For infants who are not breast fed, also give 100-200 ml clean water during this period

**Show the mother how to give ORS:**

- Give frequent small sips from a cup
- If the child vomits, wait for 10 minutes. Then continue, but more slowly
- Continue breast feeding whenever the child wants

**After 4 hours**

- Reassess the child and classify for dehydration
- Select the appropriate plan and continue treatment
- Begin feeding the child in the clinic

**If the mother must leave before completing the treatment**

- Show her how to prepare ORS solution at home
- Show her how much ORS to give to finish 4 hour treatment at home
- Give her enough ORS packets to complete rehydration. Also give her two packets as recommended in plan A.

**Explain the 3 rules of home treatment:**

- Give extra fluids
- Continue feeding
- Return if child worsens, does not pass urine or refuses to drink

Table - 3 : Plan A - Treat diarrhea at home

Counsel the mother on the three rules of home treatment: Give extra fluids, continue feeding, return if child worsens

**Give extra fluids ( as much as the child will take)**

**Tell the mother :**

- If exclusively breast fed, breast feed frequently and for longer at each feed. If passing frequent watery stools: For less than 6 months age, give ORS and clean water in addition to breast milk. If 6 months or older, give one or more of the home fluids in addition to breast milk.
- If the child is not exclusively breast fed: give one or more of the following home fluids: ORS solution, yoghurt drink, milk, lemon drink, rice or pulse based drink, vegetable soup, green coconut water or plain clean water.

**It is especially important to give ORS at home when :**

- The child has been treated with plan B or Plan C during the visit
- The child cannot return to a clinic if the diarrhea gets worse

**Teach the mother how to mix and give ORS. Give the mother 2 packets of ORS to use at home.**

**Show the mother how much fluid to give in addition to the usual fluid intake:**

- Up to 2 years: 50 to 100 ml after each loose stool
- 2 years or more: 100 to 200 ml after each loose stool

**Tell the mother to :**

- Give frequent small sips from a cup
- If the child vomits, wait for 10 minutes. Then continue, but more slowly.
- Continue giving extra fluids until the diarrhea stops

**Dysentery**

A child is classified as having dysentery if the mother or caretaker reports blood in the child's stool. This should be treated with oral cotrimoxazole (8mg/kg/day of trimethoprim in 2 divided doses)for 5 days. The child is followed up after 2 days.

**Persistent diarrhea**

All children with diarrhea for 14 days or more are labeled to have persistent diarrhea. They should be classified based on the presence or absence of any dehydration. If dehydration is present, the child is classified as severe persistent diarrhea and urgently referred to hospital. If dehydration is not present, the mother or caretaker should be given feeding advice, and the child is given a single dose of vitamin A and oral zinc sulphate 20 mg daily for 14 days. The child is followed up after 5 days.

Fever

Body temperature should be checked in all sick children brought to an outpatient clinic. Children are considered to have fever if their body temperature is above 37.5°C axillary (38°C rectal). In the absence of a thermometer, children are considered to have fever if they feel hot or there is a history of fever.

A child presenting with fever should be assessed for common serious causes like malaria, meningitis and measles. The following information is important:

(a) Risk of malaria based on the geographic area endemic for it

(b) Presence of bulging fontanel or stiff neck suggesting very severe febrile illness such as meningitis

(c) Presence of runny nose, conjunctival congestion or rash suggestive of measles

A child with fever is classified as having **very severe febrile disease** if there is any general danger sign or stiff neck or bulging fontanel. He requires urgent referral to hospital. Prior to referral to a higher centre the child should be treated with first dose of IM quinine (10 mg/kg/dose) after making a blood smear; first dose of IV or IM chloramphenicol (40 mg/kg/dose or if not possible oral amoxicillin 15 mg/kg/dose), feeding to prevent hypoglycemia and one dose of paracetamol (15 mg/kg) for high fever (temp. 38.5°C or above).

**High malaria risk area**

Children with fever but without any danger sign or stiff neck or bulging fontanella are classified as Malariaand should be treated with antimalarials after making a blood smear. The antimalarials given are as follows:

(a) Presumptive treatment

(i) Oral chloroquine 10 mg/kg single dose on Day 1, 10 mg/kg single dose on Day 2 and 5 mg/kg single dose on Day 3.

(ii) In areas of high chloroquine resistance, give oral sulphadoxine (25 mg/kg) plus pyrimethamine (1.25 mg/kg) single dose.

(b) Radical treatment if P.vivax is positive on blood smear:

(i) Oral primaquin 0.25 mg/kg daily for 5 days.

**Low malaria risk area**

Children with fever but without any danger sign / stiff neck / bulging fontanella are classified as Malaria there are no symptoms of runny nose, measles or any other cause of fever. The antimalarials given after making a blood smear are as follows:

(a) Presumptive treatment:

(i) Oral chloroquine 10 mg/kg single dose on Day 1

(ii) In areas of high chloroquine resistance, give oral sulphadoxine ( 25 mg/kg) plus pyrimethamine (1.25 mg/kg)

(b) Radical treatment if P.falciparum positive on blood smear:

(i) Oral chloroquine 10 mg/kg single dose

(ii) Oral primaquin 0.75 mg/kg single dose

(c) Radical treatment if P.vivax is positive on blood smear

(i) Oral chloroquin 10 mg/kg single dose

(ii) Oral primaquin 0.25 mg/kg daily for 5 days

In a child being treated for malaria, the mother should be advised to return immediatelyif the child becomes sicker or is unable to drink or breast feed. The child should be followed up after 2 days if fever persists or recurs within 14 days. If fever is persists every day for 7 days the child should be referred for assessment.

Measles

A child with fever is assessed for signs of measles such as generalized rash with cough, runny nose and red eyes. If the child has measles or has had measles within the last 3 months, and there is any general danger sign or clouding of cornea or deep / extensive mouth ulcers, the classification is **severe complicated measles**. This child should be urgently referred to hospital after giving first dose of oral vitamin A, IM chloramphenicol and tetracycline eye ointment application.

If the child has measles now or has had measles within the last 3 months, and there is pus draining from eye or mouth ulcers are present, he is classified to have **Measles with eye or mouth complications**, and given first dose of vitamin A, tetracycline eye ointment and gentian violet for mouth ulcers. Follow up is done after 2 days.

If the child has **measles** now or has had measles within the last 3 months, with none of the above signs, only first dose of vitamin A is given.

Ear problem

Any sick child should be assessed for ear problems such as ear pain or ear discharge. If there is a tender swelling behind the ear, the child has **Mastoiditis**. He should be given first dose of IM chloramphenicol and urgently referred to hospital. If there is pus discharge or ear pain, the classification is **acute ear infection** and oral antibiotic

(cotrimoxazole) should be given for 5 days.

Malnutrition

Every sick child should be weighed and assessed for visible severe wasting and oedema of both feet. If there is visible severe wasting or oedema, the child is said to have **severe malnutrition** and given a single dose of vitamin A, kept warm and urgently referred to hospital. If the child has **very low weight** (malnutrition grade II, III or IV), the mother is counseled for feeding. The child is followed up in 5 days if there is a feeding problem or otherwise after 30 days.

Anemia

Palmar pallor is looked for in every sick child presenting to primary health care. If there is severe palmar pallor, the child has **severe anemia** and should be urgently referred to hospital. If some palmar pallor is present, the child has **anemia** and should be given iron and folic acid therapy in a single dose daily for 14 days (elemental iron 3-6 mg/kg/day and folic acid 100-200 mcg/day). All other sick children older than 6 months should be given prophylactic iron and folic acid (20 mg elemental iron + 100 mcg folic acid) for a total of 100 days in a year after the child has recovered from the acute illness.

Immunization

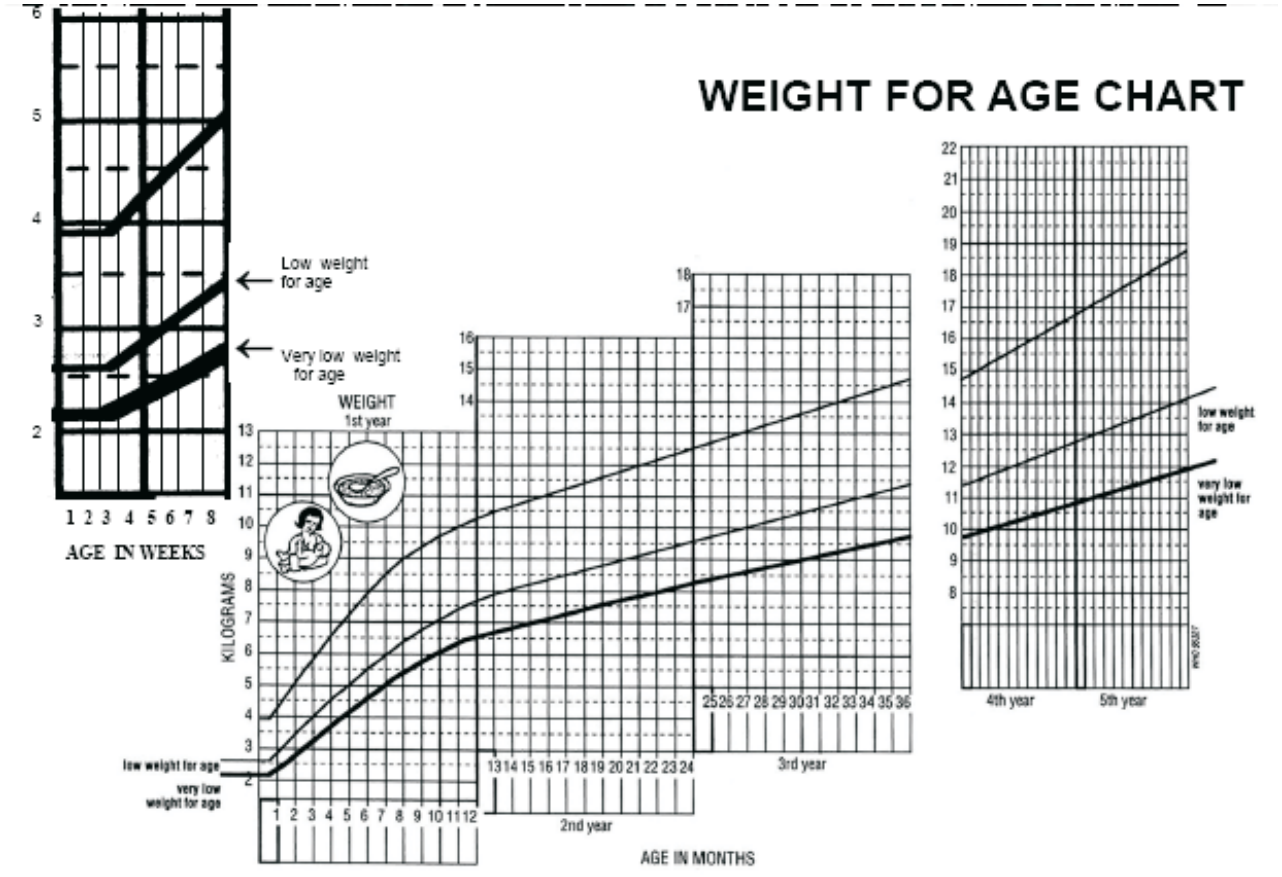
Immunization status of every sick child should be checked. Those being referred to hospital should not be immunized. All other children should be immunized as per schedule on the same day.

Assess other problems

Although the IMNCI guidelines focus on the main symptoms as enumerated above, every sick child should be assessed for other complaints, which can lead to severe or acute illness. In addition, the health of the caretaker should be also be addressed.

Case recording form for management of the sick child age 2 months up to 5 years is given on subsequent pages.

Fig. - 1: Reference weight for age chart from birth to 5 years age



# CASE RECORDING FORM FOR MANAGEMENT OF THE SICK CHILD AGE 2 MONTHS UP TO 5 YEARS

Col RajVir Bhalwar

# Planned Parenthood and Contraceptive Advise

As per the National population policy - 2000 and the RCH program in our country, the couples should be given a choice out of various contraceptive methods. Promotion of contraception purely on a voluntary basis, without any coercion, and with provision of due information about the various contraceptive alternatives is the central ethos of our national family welfare programme. The strategies and operational details of the programme and the various contraception facilities to the community are dealt with in the chapter on RCH program. The details of various methods of contraception are being dealt with in this chapter.

Broadly, methods of contraception would fall into the groups, viz. , "Natural Methods" and "Artificial Methods". Artificial methods are further grouped into Temporary and Permanent methods.

## Natural Methods of Contraception

These methods utilize either total avoidance of sexual intercourse (Abstinence) or by discharging the semen outside female genitalia (Coitus interruptus or withdrawal method) or else by utilizing methods which observe the naturally occurring signs / symptoms of fertile versus non-fertile periods of the menstrual cycle and avoiding sexual intercourse during the fertile period. These methods work on the principle that during one menstrual cycle, one ovum is discharged; very rarely, a second ovum can be discharged after 24 hours. Secondly, after intercourse, sperms stay alive upto 5 days (rarely 7 days) but can actually fertilize the ovum for at most 4 days. With this background the most fertile period of women is from 10th day to the 18th day, provided the cycle is of 28 days. Natural methods are based on detecting the fertile period and avoiding intercourse during the period. These are :

### (a) Rhythm Method

For women who have a regular 28 days cycle, the fertile period would be generally from day 7 to day 21.

### (b) Basal Body Temperature (BBT)

The woman should record her oral temperature first thing on getting up in the morning, daily and plot it on a graph paper with the day of menstrual cycle along horizontal axis and temperature along vertical axis. Immediately following ovulation there is increase in oral temperature by 0. 5 to 0. 8°F (0. 2 to 0. 4°C). Couples should avoid intercourse for 3 days, once the rise in temperature is noted.

### (c) Cervical mucus method

The woman notices daily, the quality of vaginal mucus discharge, by putting a finger into the vagina. Following cessation of menstrual flow, no mucus is felt in the vagina for couple of days. These are called the "dry days". Following the dry days, cloudy, white or cream colored mucus of sticky consistency with little moisture appears. This indicates that ovulation is approaching. Thereafter, just before and at time of ovulation the mucus becomes copious, clear and slippery, resembling the white of an egg and can be stretched into a thread if the thumb and finger on which the mucus is stuck, are gently moved apart. This persists for 3 days and is called the "wet days". Following this wet period, the mucus again becomes scanty, sticky and cloudy indicating the post ovulation phase, which persists till onset of next menstrual flow. The couple should abstain as soon as the first sign of mucus appears in the preovulatry phase, during the wet days in ovulatory phase and for 3 days after the completion of wet period.

### (d) Symptothermal method

This is based on combined observation of changes in BBT, mucus changes and also by palpating the cervix with a finger high up in the vagina. The cervix becomes softer and cervical os more open during the fertile period. If consistently and properly used, the failure rates per 100 women per year (HWY) (indicating the number of women who will become pregnant during one year out of 100 women who are using these method are :

(i) Calendar Method - 9 / 100 HWY (9%)
(ii) BBT Method - 1 - 2 / 100 HWY (1-2%)
(iii) Cervical mucus Method - 3 / 100 HWY (3%)
(iv) Sympto thermal Method - 2 / 100 HWY (2%)

### (e) Lactational Amenorrhoea Method (LAM)

Full or nearly full breast feeding means that at least 85% of the baby's food requirement is being provided by breast milk. For women who are fully breast feeding their infants, chances of pregnancy are very less for 6 months or when menstrual flow returns, whichever is earlier. If used correctly and consistently, the failure rate is 1 to 1. 5%. Chances of pregnancy are, however, more if the woman is not having full lactation or if not fully breast feeding the infant.

## Artificial Methods

The broad categories of contraceptives included in artificial (temporary) methods are Barrier methods, Spermicides, Intrauterine devices (IUDs), Oral contraceptives and Non-oral hormonal contraceptives.

### Barrier contraceptives

Condoms

Condoms are made of latex and are available as non-lubricated (Nirodh, Kohinoor), lubricated (Nirodh - Lubricated, Kamasutra, Kohinoor - Pink and Sawan) and more lately, coated with spermicidal jelly usually nonoxynol-9 (Share, Rakshak). The average shelf life is 5 years from date of manufacture and they should be stored in cool and dry place. If further lubrication is required then glycerin, K-Y jelly or a spermicidal jelly can be applied, but not Vaseline, oils or butter. Some couples may complain of initial reduction in pleasure due to slight decrease in sensations and interruption in sexual play (since the man has to put on the condom just before insertion). However,

it should be explained to them that this is only a transient phenomena, and most couples will adapt well with passage of time. Besides contraceptive effect, condoms are also very effective in preventing transmission of HIV, STDs, HPV infection (and amnionitic fluid infections while having sex during pregnancy).

The total "slippage" and "breakage" rate is 4% to 9%. The average failure rate is 12% to 14%, but if correctly used, it may be as low as 3%. Concurrent use of spermicidal jelly will further reduce the failure rate.

Condoms are very good choice as temporary method, especially for couples in whom use of hormonal contraceptives and IUDs is not indicated among the female partner. The only contra-indication to condom use is allergy to latex rubber in which case condom made of polyurethane or silicon rubber may be used.

Diaphragm, Cervical Cap (Check Pessary), Vault cap and Vimule

These are barrier methods to be used by the females but not much used now due to wide availability of other contraceptives.

Female Condoms

Available under trade name of "Femindon" and "Reality". The device is inserted like a vaginal diaphragm. At present it is not much used as contraceptive but has potential in prevention of HIV transmission.

Spermicides

Most commonly used spermicide is nonoxynol- 9. They are available as vaginal pessaries which are inserted high up in the vagina, 10 to 15mts before sex or as creams / jelly, as Delfen cream, Orthogynol jelly etc.

Foam Tablets

These are very commonly used. Marketed in our country as "Today" as a vaginal foam suppository containing nonoxynol-9. The tablet is to be inserted high in the vagina (may be moistened slightly with water if vagina is dry), 10 minutes before sex act and the action lasts for 1 hour after sex. If properly used, failure rates are as low as only 0. 5%.

**Intra Uterine Devices (IUDs)**

IUDs have been in use as contraceptives for many decades. However, their exact mode of action is still not clear. In all probabilities, they act by inducing mild inflammatory changes and foreign body reaction in the endometrium, which combined with alterations in prostaglandin levels, incapacitate the sperms and ovum, prevent sperm from fertilizing the ovum, and even if fertilization occurs, makes the uterine environment inhospitable for the blastocyst to be implanted.

The earliest IUDs, namely lippies loop, have now been almost phased out by copper-T and its subsequent variants.

Copper - T

Copper - T 200 (Gynae-T) is made of propylene impregnated with $BaSO_4$ and carries 120mg of 0. 25mm diameter copper wire wound around the vertical limb. The tail limb has a pair of threads (some variants have only one thread) which comes out of cervical os, into vaginal canal after the Copper-T has been inserted and can be felt with a finger to check that the Copper-T is in place. The copper has an exposed area of 200 sq. mm and hence the name Cu-T- 200. The US-FDA approved Cu-T-200 has an effective life of 4 years. Some additional variants available commercially in our country are Multiload ML Cu-T-250, ML Cu-T-375 and Nova Cu-T-200 (Nova T) which has a silver core added to the copper wire. The conventional Cu-T-200 has failure rate of 2%, while the newer variants have lower failure rate of 1-2%. In general Cu-T-200 is referred to a Group-I IUD; ML-250 and 375 as Group-II; while Nova-T and Cu-T-386A are referred to as Group-III IUDs.

The advantages of IUDs is the ease of insertion (can be inserted at Sub centre level by paramedical workers), the semi-permanency (Cu-T-200 can be left in place and remains effective for 3 years) and the ease of removal. However, before advising IUD, proper history should be taken from the couple and correct advice given as follows :

**Conditions which are absolute contra - indications to IUD insertion / continuation**

(a) Pregnancy
(b) Puerperal or Post abortal sepsis.
(c) Unexplained vaginal bleeding.
(d) Pelvic inflammatory disease within last 3 months.
(e) Known pelvic TB
(f) STD during the past 3 months.
(g) Suspected neoplasia of genital tract
(f) Uterine abnormalities

**Conditions which increase the risk due to IUD, and alternative contraceptive may be considered, if possible**

(a) Post partum 48 hours to 4 weeks (more chances of perforation).
(b) Women having increased chances of STD / HIV transmission (prefer condom).
(c) Age <20 years.
(d) Nulliparity
(e) Endometriosis
(e) Menstrual irregularities with increased bleeding or dysmenorrhoea.

Women who are best suited for IUD include those aged >20 years, who have given birth to atleast one child, have diseases or conditions like Obesity, Tobacco use, Headache, IHD, RHD, Diabetes, Thyroid disease, Benign breast disease and Irregular menstruation but without heavy bleeding and those who are breast feeding.

Timing of Insertion

(a) The best time to insert is during or soon after menstrual periods, post partum within 48 hours of delivery and after abortion.
(b) However, after delivery or abortion it is preferable

to insert IUD 6 weeks after the delivery / abortion and couple may be advised to use another method as condom for that period.

(c) It may be noted that as for as possible insertion should not be delayed just because of timing. In fact, the best timing is the one which is most convenient to the potential user, if it can be reasonably ascertained that she is not pregnant.

(d) It can also be inserted post coitus, even up to 5 days after coitus to prevent pregnancy.

Instructions to be given to the lady after insertion

(a) For the next few periods (at least for next 3 periods) she should watch her pads for any expelled IUD and, after the periods, should feel for the threads (tails) coming out of the cervical os, to ensure that the device is in place. She should report if she cannot feel the threads or sees the device on her pads, or feels the device to be in the vagina.

(b) She should come for a routine health check up after the next menstrual period.

(c) She should report in case of persistent irregular or heavy bleeding, severe pain in lower abdomen or abnormal vaginal discharge, or amenorrhoea (in which case pregnancy should be excluded).

(d) She should also report if she feels that she has been exposed to STD or HIV.

Indications for removal

(a) Abnormal or excessive bleeding.

(b) Persistent pelvic pain or cramping.

(c) Expiry of effective life span (3 to 4 years from date of manufacture for Cu-T-200)

(c) Pregnancy.

(d) Acute pelvic infection or neoplasm of genital tract.

(e) Displacement of IUD either inside the uterus or outside it.

(f) Personal reasons.

(g) After menopause (within one year).

Routine problems after insertion

The lady should be advised that she may face certain routine problems following insertion as follows, and she should not unduly worry about them :

(a) Some cramping abdominal pain for a few days

(b) Some vaginal discharge for a few weeks

(c) Heavier menstrual bleeding and possibly intra-menstrual bleeding for a few weeks

Complications of IUD

(a) Increased menstrual bleeding and sometimes inter- menstrual spotting.

(b) Cramping lower abdominal pain.

(c) Explusion: The overall expulsion rate is 2 - 8% in first year. It is commonest in first 3 months especially after the 1st period following insertion.

(d) Leucorrhoeic vaginal discharge

(e) Perforation of uterus (occurs in approximately 1 per 1000 insertion).

(f) Infection, especially during first month.

(g) Pregnancy due to failure (1 to 2%).

(h) Ectopic pregnancy (Rare, approximately 1 per 1000 women years. However, if pregnancy occurs with IUD in situ, then chances of its beings ectopic are very high, almost 30%).

**Oral contraceptives**

Hormonal Contraceptives have revolutionized the implementation of Planned Parenthood Programmes all over the world. Broadly, hormonal contraceptives could be either oral or parenterally administered. Oral contraceptives (OCs) can be further divided into two broad groups, viz, "Combined pills" (Containing both Estrogen & Progestogen) and "Progestogen only pills" (mini pills).

(a) **Combined pills** : These can be of two types, viz, Monophasic pill in which every pill has same amount of Oestrogen as well as Progestogen, and the multiphasic pill in which, in a given pack for one menstrual cycle, the pills will have variable amount of Oestrogen & Progestogen. An example is "Triquila" available in our country. Monophasic pills can be, in turn, low dose pills which contain less than 0. 05mg of ethinyl estradiol (EE) in each pill along with progestogen. The other variety, i. e. , high dose pills containing > 0.05mg EE per pill have been discontinued by now. Similarly, the earlier used sequential pills, which used only oestrogen in the tablets for first 14 days followed by combined Oestrogen & Progestogen for next 7 days have also been abandoned by now.

(b) **Progestogen only (Mini pill)** : These contain small amount of only a progestogen but no oestrogen. They are indicated for women >40 years age or who are lactating and not completed 6 months from delivery. They are available under trade names of Microval or Femulen; they are generally not available in our country.

(c) **Choice of pill** : Any of the low dose combined pill or else a triphasic pill (Triquilar) can be used. The choice will mainly depend on cost, since the triphasic pills are costly.

(d) **Commonly available pills** : In our country, the following pills are commonly available :

Common low dose pills

(a) Ovral-L or Mala-D - This contains L-norgesterol (L-NGL) 0. 15mg and EE 0. 03mg per pill. Mala-D is available at subsidized rates in our country under the FW program.

(b) Mala-N - This contains dl-NGL 0. 30mg and EE 0. 03mg per pill. This is available free of cost under the FW program in our country.

Triphasic pills

Triquilar contains L-NGL 0. 05mg and EE 0. 03mg for first

6 days, 0. 075mg and 0. 04mg for next 5 days and 0. 125mg L-NGL with 0. 03mg EE for the next 10 days.

Mode of Administration

(a) The day on which menstrual flow starts is taken as day-1. The first pill is taken on Day-6, one pill every day for next 21 days. Thereafter the pill is stopped and restarted after a gap of 7 days, irrespective of the onset or stoppage of menstruation during these pill free periods.

(b) **Very often the packet has 28 pills** - in such case the last 7 tablets are actually iron tablets. In this scenerio the next packet should be started on the very next day after the previous packet is finished, without any gap.

(c) **Action to be taken when a pill is missed** - If a pill is missed on a day, two pills should be taken on the next day, as soon as the woman remembers (preferably within 12 hours of last missed dose) and the other at bedtime; or else, if not remembered earlier, 2 tablets at bedtime on the next day. If 2 or 3 tablets are missed, the women should take 2 tablets on each of the consecutive 2 or 3 nights and continue with rest of the packet as usual. In all such cases, when the pills have been missed the next packet should be started as usual after a gap of 7 days from the time last 21 days packet is finished. In such cases where this prompt initiation immediately after 7 days is delayed by 1 or 2 days, the women should use additional barrier method till the time of starting the next normal course of 1 pill a day (from the 7th or 8th day). These rules apply to all OC users, whether using combined or triphasic pills.

(d) **Mechanism of Action** - Combined OCs produce contraceptive effect in different ways, viz. , inhibition of ovulation by bringing about changes in FSH & LH secretion, by altering the endometrium and by bringing about changes in cervical mucus.

(e) **Effectiveness** - Combined OC are very effective, with an overall failure rate of 0. 1% (1 per 1000 women year). Failures are maximum during first year of use and are mainly due to missed pills, delay in starting the next course exactly after 7 days of finishing the last 21 days pack, and due to stopping the pill abruptly due to side effects without taking any other appropriate contraceptive measure.

(f) **Side Effects** - These are of two categories, viz, minor side effects which are often temporary and the subject should therefore be properly counseled so that she does not unnecessarily discontinue the pills. The second category is the major side effects.

(i) Minor side effects include nausea vomiting and lack of appetite for the initial 2 or 3 months; breakthrough bleeding usually during first few months; menorrhagia, irregular bleeding or oligomenorrhoea; breast heaviness and tenderness; headache; weight gain; acne and oily skin; and rarely, depression and decline in libido.

(ii) Major side effects includes increased risk of IHD, and stroke especially if the woman is also a smoker or hypertensive or diabetic or has venous thromboembolism, raised blood pressure especially if age is >35 years; slightly increased risk of breast cancer and possibly cervical cancer; interference with insulin action in diabetics; execerabtion of existing hepatic conditions and reduction in lactation.

When to avoid OCs

(a) Smokers, especially if age >35 years.
(b) Breast feeding up to 6 months post partum.
(c) Hypertensive.
(d) Past H/o breast cancer.
(e) Unexplained vaginal bleeding.
(f) H/o stroke, thromboembolism or IHD
(g) Cirrhosis of liver or active hepatitis or liver tumors
(h) Using Rifampicin or anti-epileptics.
(j) Undergoing major surgery or prolonged immobilization.
(k) Diabetes with >20 years duration or with vascular complications.
(l) Hyperlipidaemia.

Warning Features

Women should be educated to watch out for following features and seek medical attention should they occur :

(a) Chest pain
(b) Shortness of breath
(c) Headaches which are severe or throbbing or occur on one side.
(d) Blurred or diminished vision.
(e) Swelling or severe pain in a leg
(f) Missed periods, especially if 2 periods are missed.
(g) Post coital or persistent irregular vaginal bleeding after 3 months of pill usage or excessive, white discharge especially if mixed with blood.
(h) Yellowness of eyes or urine.

Advantages of OC use

(a) Very effective, require minimal effort.
(b) Return of fertility on stopping the pills is very prompt.
(c) Can bring about relief in certain menstrual disorders as dysmenorrhoea.
(d) May be protective against endometrial cancer and ovarian cancer.
(e) May be protective against benign diseases of breast and ovaries.
(f) Likely to be protective against ectopic pregnancy,

PID, hirustism, acne, osteoporosis and progression of rheumatoid arthritis.

(g) At times, the increase in weight is quite welcome to women.

### Non-oral hormonal contraceptives

Non-oral Hormonal Contraceptive are of 3 broad categories :

(a) **Injectable** - These include the progesterone only (Depot Medroxy Progesterone Acetate - DMPA and Norethesterone Enanthanate - NETEN) or the combined ones (DMPA 25mg Plus oestradiol 5mg or NETEN plus oestradiol 5mg)

(b) **Contraceptive Implants** - These include Norplant (6 capsules of levo-norgesterol) and Implanon (single rod of 3-keto desogesterol).

(c) **Contraceptive Impregnated Devices** - as progesterone releasing IUD (progestinsert, LNG-20, Levonova); or contraceptive vaginal rings.

Of the above, DMPA (Depot provera) and NET-EN are often used and available in India. DMPA is given 150mg i. m. inj and remains effective for 3 months; NETEN is given 200mg as an oil based i. m. inj and remains effective for 2 months. These are most effective when given within first 1-5 days of menstrual cycle. The failure rate is only 0. 1 to 0. 4%.

Absolute contra-indications for their use are pregnancy, unexplained vaginal bleeding and current breast cancer. Relative contraindications include less than 6 weeks postpartum among breast feeding women, history of breast cancer, jaundice, cirrhosis, liver tumor, severe headache, undiagnosed breast disease, previous OC related liver diseases, and H/o IHD, hypertension or stroke. Fertility may take 6 to 12 months to return after discontinuation of this injection.

### Emergency (post-coital;morning-after) contraception

Emergency contraception pills (ECPs) are a very good method of preventing pregnancy likely to occur due to unprotected sex or else due to suspected failure, as rupture of a condom. The following are the salient features of ECPs :

(a) ECPs are hormonal oral contraceptives having the same hormones as used in OCs but in a higher concentration.

(b) ECPs come in a pack of two pills. The first should be taken as soon as possible, but certainly within 72 hours of an unprotected sex. The second should be taken 12 hours after the first pill.

(c) One ECP packet can protect only against one episode of unprotected sex.

(d) ECPs are available free of cost at PHCs and with ANMs at subcentres, under the name of "E-Pill". They are also commercially available under brand names like Ecee-2, Norlevo, E-P-72 and Pill72.

(e) ECPs are safe for all women including those who are breastfeeding.

(f) If the lady vomits within 1 hours of taking the pill, the dose should be repeated after taking an antiemetic as Meclizine HCL (Pregnidoxin)

(g) Some women may have minor side effects as breast tenderness, headache, nausea, vomiting, spotting, fatigue, and dizziness which may last for maximum of 24 hours.

(h) It should be clearly conveyed to the clientele that ECP is not an abortion pill since it cannot dislodge an implanted ovum.

(j) ECP is quite effective in that they may prevent up to 75% pregnancy which would have otherwise occurred following unprotected sex.

(k) After taking ECP, if onset of next menstrual cycle is delayed by more than 1 week of expected date, a pregnancy test should be done. She should also report if the period starts on time but the flow is scanty or is unusually foul smelling.

(l) ECP should not be used as a regular contraceptive method.

(m) In case E-pill or such ECP preparation is not available, the women can take 4 tabs of Mala-D at the earliest but within 72 hours of unprotected sex, followed by 4 Tablets of Mala-D after 12 hours of first dose.

(n) Reassure the women that her next period will start on the expected date or sometime 2-3 days earlier or later than expected date.

## Permanent methods

Permanent methods include male sterilization (Vasectomy) and female sterilization (Tubectomy). Any couple who has at least one child and is voluntarily motivated can be offered sterilization procedure. Medical officers should emphasize on the clientele that these procedures are perfectly safe and do not carry adverse effects like decline in libido, low backache, obesity and so on, as are commonly thought of. In fact the sexual performance and pleasure may improve since the fear of unwanted pregnancy is removed.

### Vasectomy

In the conventional procedure an incision is given on the scrotal skin and a piece of vas deferens 1 to 1. 5 cm long is removed. In the more recent technique of "No Scalpel Vasectomy" a puncture is made in scrotal skin using a reverse scissor and a hole of approx half a cm is created through which vas is ligated after removing a piece 1 cm long. The advantage of this method is that no stitches need to be given on the scrotal skin.

It must be emphasized on the acceptor that it will take 3 months for him to become completely sterile. For the duration, he or his wife should use an alternative temporary method. After 3 months seminal analysis should be done to confirm azoospermia.

### Tubectomy

In the conventional method, (Pomeroy's method) a piece of the loop of Fallopian tubes about 1 cm long on both

sides is removed. The same is done in minilaparotomy. In Laparoscopic tubectomy the tubes are either blocked by electrocoagulation or sealed with a silastic band.

The ideal time for tubectomy is soon after menstrual flow is over or in the post partum period. However, if it can be done in between the period at other times but the woman should continue to use alternative contraceptive till her next menstrual flow.

**Recanalisation**

For couples who have undergone sterilization operation but now need children, recanalisation operations are available. The success of recanalisation depends on many factors, the most important being the fertility state of both the partners. In case of tubal recanalisation it also depends on the original method by which tubectomy was done - if the original method was spring loaded clip, the pregnancy rate following recanalisation may be as high as 88%, while for Pomeroy method it is about 60%. As regards recanalisation of vas, in expert hands, the patency rate may be as high as 80% but actual pregnancy rate may be lower due to various other factors as fertility status of the husband and wife.

# Preventive Health Care of the Elderly

With improvements in health care, there have been resultant increases in life expectancy and increase in the percentage of "elderly population". For instance, the current estimates are that in our country the percentage of population who are aged 65 years and above, which was 3% a few decades back, is now 5% and is likely to increase to 10% by 2025AD and 18% by 2050AD. These demographic changes will require shifting our focus to cater to the special preventive health care needs as well as medical care needs of the elderly population.

### Peculiarities of elderly population in context of Health needs

The peculiarities of health needs of elderly people is that their health problems cannot be seen in isolation. There is a wide gamut of social, psycho-emotional and physical correlates which determine the medical problems and this entire gamut of factors (and not simply the treatment of concerned condition) needs to be addressed. The important ones of these factors are as follows: -

Social

As industrialization expands, it will be difficult for the children to stay on with their parents and carry on with the conventional family processions. As children move out and take up the vocation in other places, the problems of isolation and lack of physical support will come up. Even day to day requirement of life like going out to pay the electricity / telephone bills, buying fresh fruits and vegetables and even, cooking a proper nutritious meal would become difficult.

Psycho-Emotional

With loneliness at home, isolation will occur which would get aggravated if one of the spouses passes away. Friend circle will also get restricted because friends would also get old. The problem of isolation would get worse because of retirement when the old persons would find it difficult to keep themselves occupied. This, complex interplay will not only increase the risk of mental stress and its consequences but also aggravate the impact of stress related diseases as IHD and hypertension.

Financial

Unless backed up by adequate financial savings or personal plans or else financially assisted by children, there will be definite reduction in income, to the extent that it may interfere with bare needs of life as adequate nutrition, clothing and shelter.

Health care system

At present we do not have a very effective health insurance system in our country, which coupled with the inadequacies of public / Govt funded general health care system and inadequate training of medical, paramedical personnel in geriatric medicine would adversely affect the health care of the elderly.

## Medical problems of the elderly

A description of medical problems of the elderly is given in this chapter. However, as said earlier, these problems should not be seen as isolated medical issues but should be viewed in the larger context of socio-economic-emotive determinants as an overall health issue. For example, organizing an eye camp for the elderly would have little benefit if the transportation system, traffic control and street / domestic lighting is not improved.

Medical officers of Indian Armed Forces should make special efforts to understand both the preventive as well as curative aspects of health care of the elderly since a significant proportion of our clientele (the ex-servicemen and their dependents) would belong to this age group, and the proportion is likely to further increase, given the steady increases in life expectancy that are occurring in our population.

The health problems of elderly can be divided into 3 groups

(a) Problems which are important for both genders.
(b) Problems which mainly concern the elderly males.
(c) Problems which mainly concern the elderly females.

### Problems which are important for both the genders

Ocular Diseases

Age related diminution of vision and cataracts are major issues among elderly and significantly compromise the quality of life as well as activities of daily living (ADL). Glaucoma also is an important cause of suffering among elderly.

Hearing Defects

Reduction in acuity of hearing not only compromises the quality of life but even drives an old person into emotional isolation because they find it difficult to communicate.

Reduced Muscular strength and coordination

Reduction in muscular strength due to reduction in lean mass coupled with reduced flexibility and neuromuscular coordination occur with age and result in increased proneness to accidents and injuries.

Accidents and Injuries

There is marked increases in risk of accidents and injuries among the aged. The major physio-pathological factors which contribute to such increased proneness are diminution of vision and hearing, reduced muscular strength and neuro-muscular coordination, and various environmental factors, notably wet, slippery floors and poor lighting. The commonest areas of accidents are the toilet (due to wet floor, and a large number of fixtures in small space), kitchen (mainly due to open flames), staircases and roads.

Nutritional Deficiencies

Both macro and micronutrient deficiencies are common among elderly. They result due to interplay of four major reasons, viz., lack of financial resources to buy nutritious food items; reduced ability to go out to the market and buy nutritious raw items; reduced physical abilities with resultant reduced ability to cook nutritious meals; and physical ailments especially oro-dental problems causing difficulty in mastication and reduced sense of tastes.

Dental Problems

Reduction in number of teeth / edentulousness interferes with mastication, digestive process and also with the desire to eat. Ill-fitting dentures further aggravate the problem.

Cardiovascular Disease

The end result of atherosclerotic process becomes most evident in the elderly age group. The incidence (as well as mortality due to) of IHD, Stroke and Hypertension is significantly increased in this age group.

Increased susceptibility to adverse effects of physical environment

People aged >65 years are more susceptible to adverse effects of heat (heat stroke and heat exhaustion) as well as environmental cold (generalized hypothermia and local adverse effects of cold).

Increased susceptibility to infections

Age >65 years increases the susceptibility to nearly all infections due to decline in immunologic defenses. More particularly, lower respiratory tract infections (pneumonia) and urinary tract infections are an important cause of morbidity and mortality among elderly.

Degenerative neurological Diseases

Alzheimer's disease and Parkinsonism are almost exclusively encountered among elderly. Besides morbidity, these diseases substantially reduce the quality of life.

Complication of Diabetes

The micro vascular as well as macro vascular complications are more prominent during advanced age.

Cancers

Oral, gastric, lung and colorectal cancers are more common in elderly age group.

**Problems which mainly affect the elderly male**

Benign Prostate hypertrophy (BPH)

This is one of the commonest diseases affecting males >50 years, particularly >60 years age.

Prostate Cancer

The incidence shows a steep climb after 50 years age. Yearly Digital Rectal Examination (DDE) is a good screening tool for both BPH and prostate cancer. In addition, prostate specific antigen (PSA) could be useful screening test for prostate cancer after 50 years of age. Levels of <4ng/ml can be considered as normal, 4 to 10 ng/ml as suspicious and >10 ng/ml as strongly suspicious and need to be followed up with a biopsy.

Male Sexual Dysfunction

Male sexual dysfunction among elderly may manifest as either libido, erectile or ejaculation problems.

**Problems which mainly concern with elderly females**

Menopausal Problems

There are five areas when are predominantly affected by menopause - increased risk of cardiovascular diseases; genitourinary atrophy; skeletal bone loss; skin and hair changes; and neuroendocrine and vasomotor changes. Skin changes include loss of elasticity (apparent as lagging and wrinkled skin), dryness of mucosal surface, minor facial hirsutism and voice changes. Uro-genital changes include atrophic vaginitis, dysparounia, pruritis vulvae and irritable bladder. Neuroendocrine changes include hot flushes (which may sometimes interfere with quality of life) and psychological / mood problems.

Urinary incontinence

The impact is considerable both from medical as well as psychological point of view.

Cancers of female genital tract

The 3 major cancers of genital tract affecting the elderly women are uterine (endometrial), ovarian and cervical cancers.

Osteoporosis

Osteoporosis occurs in both sexes (Type-II Osteoporosis) but the incidence as well as the impact is much higher among females especially after menopause (Type – I osteoporosis). Osteoporosis represents only a small proportion of the problem, in any community, for every case of osteoporosis there would be additional 3-4 cases of osteopenia. Osteoporosis results in a large number of low-trauma fractures. The major fracture sites are hip, spine, wrist and pelvis. Risk factors for primary osteoporosis include low body weight, history of prior fracture, family history of maternal hip fracture, lack of dietary calcium and vitamin D, menopause, lack of weight bearing exercise, smoking and excessive alcohol use, tall and thin stature and white-race. Weight of <58 kg may indicate risk. In fact, a rough guide is to calculate an index as 0.2 X (Body weight in Kg – Age in years); if the result is less than 2, the same indicate increased risk.

## Prevention & control

Prevention and control of health problems of elders would need multifaceted approach. A well coordinated approach from health, social welfare, rural / urban development and legal sectors is desirable

**Social Measures**

Developing social ethos wherein children voluntarily take the responsibility of looking after their aged parents is important. In fact, young people need to be educated and motivated to utilize the experience and support of their parents / grandparents in day to day household matters before passing on the cultural heritage to the children. There is also a need to develop regulatory mechanisms which make it obligatory for the members of society to look after their aged parents.

Developing a Health Insurance Scheme

A large majority of the elderly are those who are not covered by any formal public sector health care support, unlike retired govt. servant. The need is to develop an affordable health insurance scheme in which people contribute, along with the employer and the government, to cater to subsequent expenses on medical care during old age.

Pensionary Benefits

Similar to the health insurance scheme suggested above, there is need to develop pension schemes based on contribution from employee, employer and government, so that old people can feed for themselves during old age, even if not supported by their children.

Proper construction of Roads, Walkways, Stair cases and houses

Accidents and injuries are an important cause of morbidity and mortality among the elderly. Proper designing of roads / walkways, and stair cases, along with adequate enforcement of traffic rules is a clear need. In addition, construction of "elderly friendly houses", giving particular attention to construction of toilets, kitchens, bedrooms and common galleries is important. In general, the principles of construction and maintenance are that the floor should not be slippery / wet; that the fixtures and furnitures should be adequately separated giving enough space for movement; lighting should be adequate; and open flames should be restricted to the minimum and, preferably, enclosed.

**Health Measures**

This includes the following:-

Need to initiate Primary Preventive measures in early adulthood

While a number of diseases finally manifest in elderly age (as cardiovascular disease, osteoporosis, cancers), the basic pathologic processes start during early adulthood, even during adolescence. Therefore, it would be wise for children / young people to start prevention at young age itself through healthy lifestyle (adequate and regular physical exercise, healthy diet, avoidance of tobacco and alcohol use). The details are discussed in the section on healthy lifestyle.

Information, Education & communication strategies

Health education should focus towards three broad groups – firstly, the elderly persons, secondly, the middle aged who would move into elderly age group in near future and thirdly the younger people who are the potential care provider for their elderly parents / relatives. The major areas of education should address the issue of hygiene, nutrition, physical exercise, avoidance of tobacco and alcohol, accident prevention measures, awareness about recognition of early signs / symptoms of common geriatric problems and motivation to seek treatment, and education regarding periodic health check-up.

Training and re-training of medical and paramedical personnel

Regarding the special health needs of the elderly and updating their knowledge regarding prevention and treatment of common geriatric diseases.

Periodic Health Assessment

Ideally, all people, males & females, should undergo a detailed health assessment once they are 45-50 years of age. Subsequently, a thorough health evaluation should be done once in every 5 years till 65 years age and thereafter every year or at least once in 2 years. Assessment should include general clinical examination, assessment of hearing & vision, assessment of Dental health, nutritional status including obesity, cardiovascular status, musculoskeletal system including spine, per-rectal examination for males and for females, gynecological and breast examination. Depending on availability, important investigation would include Hb%, GBP, urine routine and microscope, stool routine microscopy and test for occult blood, blood sugar estimation, lipid profile, renal function parameters and an ECG if required. Depending on the requirement, bone densitometry, PSA, Colonoscopy, USG studies and histopathological studies may be undertaken as indicated

Ensure effective communication

Elderly people need special efforts for communication. Hence, medical personnel dealing with elderly should very effectively communicate their findings and advise to the group and ensure a system of feedback to verify that their communication has been correctly understood by the elderly subject

# A Short History of Nutrition

***"Yuktahar Viharsya Yukt Chestsya Karmsu ;***

***Yukta Swapnav Bodhayasya Yogo Bhavati Dukh Ha."***

**"Yoga killeth out pain for him who is regulated in eating and amusement, regulated in performing actions, regulated in sleeping and waking"**

**~Shri Bhagavad Gita (1)**

No lesser book than the greatest of Hindu scriptures, Bhagavad Gita, highlights the importance of balanced, stable and regulated nutrition. The relationship between food and health dates as far back as the history of mankind. *Homo sapiens* and his predecessors *Homo erectus* and *Australopithecus* were primarily vegetarians. But over about a million years man gradually developed the art of hunting as he moved away from other primates and became omnivorous. There was no malnutrition, no obesity, no high cholesterol, no high blood pressure and no caries teeth. It was only about 10,000 years ago that the next stage of the 'technical' development of agriculture began. (2) Man started growing, rearing and consuming the 'concentrated' sources of energy - cereals, oilseeds and livestock! And with these, began the present era of nutrition and … disease.

The ancient Indians developed the discipline of life (Yoga), a system of medicine (Ayurveda) and a dietary philosophy of vegetarianism (Aahara), with one thing that was vital, common and central to each - diet. (3) Prudent food with a strict dietary discipline was the hallmark of ancient lifestyle and one of the secrets of a long and healthy life which the Indians enjoyed in the Vedic times.

6000 years ago, Imhotep, the ancient Egyptian father of medicine described the use of certain foodstuffs as prescriptions (4). It is amazing how close to modern scientific thinking these early historic practices were. Night blindness and xerophthalmia (called 'show' by ancient Egyptians) were treated by roasted beef liver or liver juice. Onion mashed with fat was described for the treatment of scurvy. The first report on the physiological effect of sunlight was given by Herodotus who reported that the skulls of Egyptian soldiers killed in wars, were stronger than their opponent, the Persian King Cambysus' soldiers, which were fragile. The reason given was that they go bareheaded since childhood exposing their skull to sunlight while the Persians have turbans on their heads (5). Ancient Egyptians advocated breastfeeding for 3 years to benefit from its virtues. If the mother was unable to nurse, wet nursing was advised (4).

A balanced diet for the wealthy was described in King Una's message (2600 BC), "eat good bread, ox flesh, wine, olive oil, fat, honey, figs, fish and vegetables everyday". Obesity was objectionable. Undernutrition and famine were described. A text in the 18th year of King Zoser's dynasty 5000 years ago recalls the holy book's story of Joseph; "I am overwhelmed with sorrow ... the Nile has not been full any time for seven years. Grain is lacking …there is a dearth of edible things ... children cry, young people waste, their legs give way to squatting on the ground." As a safeguard ancient Egyptians stocked grain in silos.

Later, Greek and Roman scholars started to write on the relationship between food and health. Scribonius Largus in the year 47 BC, insisted on the importance of diet for maintaining good health. Celsus classified foodstuffs and emphasized their role in maintaining health in his Latin treatise on medicine in the year 25 BC (3).

### Early pioneers of nutritional science

It is difficult to define the date when nutrition was recognized as a science and who exactly founded it. The term 'science of nutrition' was first used probably by Count Rumond in an essay on feeding poor people in 1795 (6). During the same period Lavoisier is also said to have founded nutrition as a science (2). Francois Magendi presented to the French Academy of Science his essay on "The nutritive properties of substances that do not contain nitrogen" in the year 1816, one of the first scientific works on nutrition (6).

The list of pioneers in the science of nutrition during the late nineteenth and early twentieth century is endless. The studies of Justus Von Liebig (Germany) in 1846 were basic for understanding the evolution of biochemistry and nutrition. Claude Bernard (France) in 1856 discovered glycogen and classified the digestive action of pancreatic juices. Marasmus was described in the year 1877 by Jules Poirot from France under the term "athrepesie". Sir Thomas Barlow (England) described infantile scurvy in 1883. Theodore Escherich (Austria) studied intestinal flora and discovered *E. coli* in 1885. Samuel Gee (England) described Coeliac disease in 1888. Otto Heubner (Germany) studied energy intake and expenditure in infants in 1903. The textbooks of Adalbert Czerny (Germany) in 1906 on child nutrition and of Heinrich Finklestein (Germany) on diseases of infancy in 1912 enjoyed great success. Lafayette B. Mender (USA) identified the nutritive value of proteins between 1909-1928. Casimir Funk (Poland) coined the name "vitamine" in 1912. Sir Archibald Garrod (England) wrote his path-breaking essay on "inborn errors of metabolism" in 1912. Clemens Von Pirquet (Austria) constructed the first percentile growth chart in 1913. Verner McCollum (USA) discovered fat soluble and water soluble factors that were essential for growth in l916 (6). Ciceley Williams (England) described Kwashiorkar in 1933.

### Nutrition science in the twentieth century

The science of nutrition bloomed during the 20th century. Vitamins and amino acids were discovered, human nutritional requirements were established and the relationship between diet, nutrition and the human body in health and disease were recognized. These scientific advances evolved through several phases. Initially knowledge of the various nutrients was attained. It was characterized by a great emphasis on vitamins and

mineral research.

An expansion of studies on proteins started in the 1960s the "protein era". Protein was considered as the critical factor required to overcome the prevalence of under nutrition. Autret, the head of FAO nutrition division stated that "deficiency of protein in the diet is the most serious and widespread problem in the world". Research on high protein yielding foods intensified; fortified cereals, fish protein concentrate, single cell protein, amino acid fortification all came into vogue. It was soon realized that energy is as important as proteins in the causation of malnutrition. Derrick Jelliffe, a pioneer in nutrition introduced the term 'protein- calorie' malnutrition, which was later modified to protein energy malnutrition and adopted by the FAO/WHO committee in 1971 to describe both kwashiorkor and marasmus.

Great debate started in the sixties and seventies on the causation and relationship between marasmus and kwashiorkor where eminent nutritional scientists; Waterlow, Gopalan, Scrimshaw, McLaren and others participated. Various studies on protein and energy requirements, the role of infection, metabolic and endocrine changes, adaptation were carried out and are still continuing.

The economic and sociopolitical dimensions of nutrition characterized the next phase. Studies on integrated nutritional planning, food resources, maldistribution and equity were reported. The relationship between nutrition and other disciplines was investigated. The effects of malnutrition on immunlogical, behavioral, cognitive and physical capabilities were documented. Nutrition was integrated into several United Nations programs; primary health care (WHO), GOBI, UNICEF programs, etc. Various integrated nutrition intervention programs were carried out at the national and international levels.

The role of nutrition in the development of chronic non-communicable diseases dominated the research work on nutrition during the later decades of the twentieth century. Diet was reported to account for more than one third of all cancers. The relationship between both overnutrition and under nutrition and various non-communicable diseases was studied. The relationship between obesity and cardio-vascular disease, diabetes and other chronic disorders was documented. Strong evidence suggested a relationship between in-utero under nutrition, adult onset diabetes and cardio-vascular disease (fetal origin hypotheses). Folate deficiency was reported to be associated with high levels of plasma homocysteine, one of the determinants of coronary heart disease.

Along with these advances the science of therapeutic nutrition developed. Drug and food companies contributed to research in this field. Great advances were achieved in dietetic prevention and management of non-communicable and/other chronic diseases. Pharmaceutical uses of certain vitamins, trace elements, other micronutrients and antioxidants were recognized. Interest in the science of genetics and molecular biology which was crowned by the decoding of the human genome is expanding and will be associated with great nutrition implications. Dietetic management of inborn errors of metabolism which started early during the twentieth century following Garrod's discovery of alkaptonurea in 1908 will witness great advances during the twenty first century. Enteral nutrition which dates back more 2300 years when ancient Egyptian physicians used enemas and rectal clysters to feed undernourished patients was revived in the latter half of the twentieth century. It became widely used during the last three decades following the introduction of successful procedures to deliver nutrients into high flow venous systems.

Great advances in agriculture were achieved since the green revolution in India. The introduction of genetically engineered food during the last decades of the twentieth century was followed by an ongoing international scientific debate. Parallel advances were achieved in animal nutrition and veterenary medicine, which increased animal food production. The relationship between mad cow disease and animal food as well as its relationship to Cruetzfeld Jacob disease in the humans is stimulating further research on animal nutrition, communicable disease and food safety. (7)

These and many other advances in nutritional sciences represent the ceaseless effort, genuine initiative and devotion of many pioneer scientists all over the world. Many pioneering studies were undertaken in the past century and stunning discoveries were made which revolutionized the field of medicine. To enumerate few studies of Burr on essential fatty acids, Goldberger and Spies on pellagra, McCollum and Moore on Vitamin A, Chick, Windaus and Hess on Vitamin D, Evans and Bishop on Vitamin E, King and Gyorgy on Vitamin C, Dam on Vitamin K, Mitchell, Snell and Williams on folic acid, Hodjkin on Vitamin $B_{12}$, McCance, Mac Kay, Widdowson, McLaren and Woodruff on iron deficiency, Ciceley Williams, Kerpel Fronuis, Gomez and Cravioto on protein calorie deficiency, Jelliffe on breast milk, Marriot and Jeans on infant feeding, Ylippo on feeding prematures (6) Pratt on food allergy, Guy and Kretchmer on lactose intolerance

# Body Composition and Energy

*"Tell me what you eat and I will tell you what you are. The destiny of a people depends on the nature of its diet."*

~Brillat Savarin (1)

From the nutritional point of view, mankind can be divided into four types:

(a) Primitive hunter gatherers
(b) Peasant agriculturalist
(c) Urban slum dwellers
(d) The affluent

India has the unique distinction of having all four types of communities. She is still predominantly a country of peasants but the rapidly growing towns have increasing number of poor slum dwellers and an ever increasing affluent society; even in the interiors of the country; few primitive hunter gathers still subsist in the jungles.(2)

These four groups have distinct and unique lifestyles, occupations, professions, emotions and mindset, so also, nutrition and diet. Across these four groups of people we, confront all the diseases known to mankind. Within these groups also, there are subgroups of infants, children, adults, elderly, the healthy, the pregnant, sick and infirm, vegetarians and non-vegetarians……. But, notwithstanding these variations, the basic principles of the science of nutrition remain the same whatever cultural or physiological group is being considered. The application through nutritional education is vastly different and has to be customized for the needs of a particular group. This chapter aims to put forth the basic principles of nutrition in brief.

At the very outset it is important to define the term nutrition. Nutrition is the branch of science that studies the process by which living organisms take in and use food for the maintenance of life, growth, reproduction, the function of organs and tissues and the production of energy. (3) Diet, on the other hand is what a person habitually eats and drinks.

## Composition of the body

### Chemical Composition

Normal chemical composition of a man weighing 65 kg is shown in Table - 1 (2). Most of the material listed in the table is part of the essential structures of the body, but a portion represents reserves or stores. Of the 9 kg of fat, not more than about 1 kg is essential, the remainder represents a store which can be drawn upon in times of need. In obese people this store may be very large and forms upto 70 percent of the body weight. Most of the protein is an essential component of the cell, but probably about 2 kg can be lost without serious consequences. By contrast, the body can be depleted at most by 200 g carbohydrate. During starvation the store of carbohydrate is continually replenished by synthesis from the large reserves of protein and fat. The body can lose upto10 percent of its total water and at least one third of the mineral content of the skeleton without serious risk to life.

Table - 1 :
Chemical composition of a man weighing 65 kg

| Constituent | Kg | Percent |
|---|---|---|
| Protein | 11 | 17.0 |
| Fat | 09 | 13.8 |
| Carbohydrate | 01 | 1.5 |
| Water | 40 | 61.6 |
| Minerals | 04 | 6.1 |

Various methods for estimating body composition are enumerated in Table - 2 (4, 5).

Table - 2 : Methods for body composition estimation

| Parameter | Method | Further application |
|---|---|---|
| **Anthropometry** | | |
| - Fat & Lean tissue derive fat mass | (BMI) | Quetlet's IndexTo and fat free mass |
| - % of body fat | Skinfold thickness, MUAC | |
| - Girth measurements | Arm, forearm, abdomen, waist, hip, thigh girths | |
| **Body fat** | Bioelectric-impedence analysis | To estimate LBM, body density & fat % |
| **Lean body mass** mass **(LBM)** | Bio-impedence analysis | To estimate fat |
| **Total body water** | Isotope dilution, Bio-impedence analysis | |
| **Total body** | Whole body | To estimate fat |

### Compartments of the body

At a meeting of the New York academy of science in 1963 the Professor of Surgery at Harvard, Dr Francis D Moore wrote on the blackboard:

Man = CM + EST + Fat

The body can be divided into three compartments, namely, cell mass(CM), extracellular supporting tissue (EST) and fat. Cell mass is the active tissue which carries out all the functions of the body. Extracellular supporting tissue supports the cells and can be divided into two parts - the extracellular fluid and minerals, and protein fibres in

**Newer techniques for body composition estimation**

While various methods are available, there is no 'gold standard' owing to wide variability in the human body compositions and 'assumptions' are made to account for them. Many newer techniques have therefore emerged. These are based on the following principles:

**(a) Near Infrared interactance**

A hand held instrument analyses near infrared light reflected from the skin on the biceps and analyses the spectrum of the reemitted light to indicate the fat and lean tissue. (5)

**(b) CAT Scan & MRI imaging**

Depict total tissue, fat and muscle areas. Can be used as a research tool. (6, 7)

**(c) DEXA (Dual-energy X-Ray absorptiometry**

A digital X-Ray image composed of individual pixels, produces rays of two defined energies. Beams are focused on the area of interest and energy spectrum of the emerging beams is analysed. This measures fat, LBM and bone mineral content. (8)

**(d) Neutron activation**

Neutron irradiation of the body results in production of short lived isotopes, analysis of which indicates the body composition. This requires expensive & costly equipment. (5)

**(e) Bio-Electrical impedence Analysis**

Analysis of a current passed through the body helps in

the skeleton and other supporting tissues. The extracellular fluid comprises the blood plasma and lymph. The living skeleton is a cellular organ in which minerals are laid down. Fat is the energy reserve held in adipose tissue beneath the skin and around the internal organs. In a healthy body the cell mass may contribute about 55 percent of total weight, the extracellular supporting tissue about 30 percent and the fat reserve about 15 percent. (2)

Food Constituents and Their Functions

Food is required for energy production, replacing the worn-out injured tissues and promoting tissue growth. In order to appreciate the influence of food on health and the factors which affect food requirements it is necessary to know the chemical composition of food and its metabolism in man. In order to appreciate these aspects of human nutrition, the biochemical and physiological qualities of food must first be considered. The constituents of food essential in human nutrition are the **'proximate principles'** which are the proteins, fats and carbohydrates. They yield energy and carry out tissue growth and repairs; **'the protective substances'** are the vitamins and minerals that are essential for normal tissue growth and function; and water which is an essential constituent of all tissues. These food constituents are described in detail in the subsequent chapters. The basics of 'energy' are briefly described hereunder.

**Energy**

Man gets energy from food in a chemical form, which is derived directly or indirectly from plants. This energy is bound in molecules of carbohydrate, fat, protein and alcohol. Whilst converting chemical energy into mechanical energy, man acts as an engine with measurable thermodynamic efficiency. Most of the energy is dissipated as heat. At best a man can convert 25% of the energy in his food into mechanical work. Energy is required for maintaining the body temperature and vital activity of organs, for mechanical work and for growth.

When an individual is at complete rest and no physical work is being carried out, energy is required for the activity of internal organs and to maintain the body temperature. This energy is required for maintaining the basal or resting metabolism. The basal metabolic rate (BMR) is determined experimentally when the subject is lying down at complete physical and mental rest, wearing light clothing in a thermo-neutral environment and at least 12 hours after the last meal. The BMR is more closely related to lean body mass (fat free body) than to the surface area but lean body mass is rarely used to estimate BMR. The reported value of BMR for Indians is 1 Kcal / kg/ hr.

**Units of Energy**

Calorie is the basic unit of energy. Kilo calorie is defined as the heat required to raise the temperature of 1 kg of water by 1°C from 14.5°C to 15.5°C. The joule (J) is now the accepted international unit of energy. It is defined as the energy expended when a mass of one kilogram is moved one meter by a force of one Newton (N). One Newton is the force needed to accelerate 1 kg mass by 1 meter per square second. Since joule is too small a unit to describe the energy value of diet, kilo joule (Kj) and mega joule (Mj) are of more practical use. One Kj is equal to 1000 J and one Mj is equal to 1000 Kj. However, the old unit of energy, namely, kilocalorie (Kcal) has been in use in nutrition for a long time and is still being used. (9, 10). The conversions of old and new units of energy are given below:

| | | |
|---|---|---|
| 1 cal | = | 4.184j |
| 1 Kcal | = | 4.184 Kj |
| 1000 Kcal | = | 4.184 Mj |
| 1 Kj | = | 0.239 Kcal |
| 1 Mj | = | 239 Kcal |
| 1 Kj | = | 1000 j |
| 1 Mj | = | 1000 Kj |

**Thermogenic Effect of Food**

Food intake itself increases heat production over the basal level even at rest due to its thermogenic effect. The intake of food raises the metabolic rate above the normal value (while fasting). This is known as the Specific Dynamic Action of food. The size of the effect is not closely related to the size of the meal. On normal diets, the overall effect amounts to no more than five to 10 % of the basal metabolism over 24 hours. (2).

Energy for basal functions, work metabolism and heat for

maintenance of body temperature is produced by the oxidation of carbohydrates, fats and proteins. Proteins are however, primarily needed for tissue growth, repair and maintenance. Fats serve as storehouse of energy, vehicle for fat soluble vitamins, as source of essential fatty acids and for maintenance of tissue structure. The intake of food is normally balanced by hunger which thus indirectly balances energy expenditure. Hunger may, however, not indicate this in various pathological states, notably in certain forms of malnutrition. Moreover, hunger can be modified not only by enough intake of food but also by doing less muscular work. Absence of hunger is not, therefore, necessarily an index of an adequate food intake.

# The Proximate Principles

## Proteins

These are large molecules made up of nitrogen containing amino acids that are united together by peptide linkage. In adults approximately 16% of body weight is attributable to proteins. Next to water, protein is the major component of body tissues. Proteins are indispensable constituents of living protoplasm as they participate in all vital processes. Proteins are macromolecules consisting of amino acid chains. The human body has a limited capacity of converting one aminoacid into another (1,2). Of the 22 aminoacids now known to be physiologically important, the body is capable of synthesizing some under proper conditions provided the supply of nitrogen is adequate. These amino acids are known as nonessential amino acids. Others cannot be synthesized by the body and must therefore be supplied in diet. These are the eight essential amino acids viz. leucine, isoleucine, lysine, valine, methionine, threonine, tryptophan and phenylalanine. To these may be added histidine which appears to be essential for the growth of infants. (3)

### Sources of proteins

There are two main dietary sources of proteins: -

(a) Animal Sources: These include eggs, milk, meat and fish

(b) Vegetable Sources: Pulses, nuts, cereals, beans and oilseed cakes

### Digestion and Absorption of Proteins

After ingestion, dietary proteins are acted upon by proteolytic enzymes (pepsin, trypsin and chymotrypsin) in the gastro-intestinal tract and broken down into amino acids. These amino acids are absorbed from lower duodenum and jejunum and are used for tissue synthesis or the formation of enzymes, certain hormones and other proteins of special significance. The ultimate fate of amino acids is the removal of nitrogen for the formation of urea and the direct or indirect release of energy. Proteins are in a constant state of transition of synthesis and degradation (4).

### Functions of Proteins

Proteins are needed for various functions in the human body:

(a) Proteins are important for body building, growth, repair and maintenance of body tissues.

(b) Proteins are required for the synthesis of plasma proteins, haemoglobin, enzymes and hormones.

(c) Proteins like collagen, actin and myosin form the structural tissues - skin and muscles.

(d) Proteins act as transport carriers for many molecules like iron, haemoglobin, lipids, etc.

(e) Antibodies are also proteins. Proteins are involved in the acute phase of inflammation as well.

(f) Albumin, a protein, acts as a buffer in the maintenance of blood pH. (5)

### Quality of Proteins

The nutritive value of a protein depends upon its aminoacid composition. A biologically complete protein is one which contains all the essential amino acids in adequate amounts to meet human requirements. Proteins from foodstuffs of animal origin, such as milk, meat and eggs are biologically superior to proteins of vegetable origin as animal proteins have all the essential amino acids present in them. Most of the vegetable proteins lack one or more amino acid and are thus classified as biologically incomplete proteins. The essential amino acid that is in shortest supply in a given food item is known as the limiting amino acid. The quality of vegetable proteins in a vegetarian diet can be improved by providing a suitable mixture of vegetable proteins. A relative lack of a particular amino acid in one protein can be compensated by simultaneous consumption of another protein, which contains that limiting amino acid. This is known as supplementary action. For example, the limiting amino acid in wheat is lysine and in pulses it is methionine. A diet combining wheat products such as bread (chapati) with pulses (dal) will compensate for these deficiencies and provide all the essential amino acids. Other similar examples from Indian diet are Idli-Sambhar, Wada-Pav, Rice & Dal, Khichri etc.

### Recommended dietary allowance

Adults: 1g/kg body weight. An additional allowance of 15g/day is recommended for **pregnancy**. During **lactation** an extra allowance of 25g in the first 6 months and 18g in the subsequent 6 months is recommended. **Children** have a higher protein requirement (2).

### Deficiency

Deficiency can occur when the diet does not provide enough protein. Secondly, if energy intake is insufficient proteins will be diverted to produce energy and thus causing a deficiency of proteins. Protein energy malnutrition (PEM) is a major cause for concern for children in our country. Childhood infections (esp. measles) also play an important role in triggering and sustaining a long term protein deficiency.

**Recent developments : The lysine debate**

*"Are predominantly cereal based diets in the developing countries protein adequate?"* There is a great ongoing debate: Is the protein deficiency because of lysine deficiency? Even the latest 'stable isotope studies' have not been able to settle this debate. One recommendation has been to replace about 22% energy with soya in order to overcome the protein inadequacy. (6)

## Carbohydrates

Carbohydrates are polyhydroxy aldehydes or ketones, or substances that produce such compounds when hydrolyzed. They contain carbon, oxygen and hydrogen in proportion approximating that of a 'hydrate of carbon' ($CH_2O$), hence the term carbohydrate. (7)

From the nutrition point of view, the carbohydrates can be divided into two categories.

(a) The first category comprises of available carbohydrates, which can be digested in the upper gastrointestinal tract, absorbed and utilized. These are the polysaccharides such as starch, dextrin and glycogen; disaccharides such as lactose, sucrose and maltose; and monosaccharides such as glucose, fructose and galactose.

(b) The second category comprises of unavailable carbohydrates or dietary fibre, which are difficult to digest.

### Sources of Carbohydrates

In agricultural societies the major source of the dietary carbohydrates is starch from cereal grains, millets, legumes, roots and tubers. With increasing prosperity as in industrial societies, sugar replaces complex carbohydrates as the main source. The presence of monosaccharides (free glucose or fructose) is limited to fruits and vegetables, otherwise they are not abundant in natural foods. Fructose is found in honey, fruits and vegetables. Sucrose and Lactose are the commonest disaccharides. Sucrose is extracted from sugar cane. Table sugar is 99% sucrose. Sucrose gets hydrolysed into glucose and fructose. Lactose is found in milk. It is hydrolysed to glucose and galactose. Maltose is present in malted wheat and barley. Other sources are nuts and seeds.

### Digestion of Carbohydrates

The available carbohydrates i.e. polysaccharides and disaccharides, are hydrolyzed by the action of digestive enzymes into monosaccharides and absorbed from the small intestine. After absorption, these monosaccharides are transported to liver via portal circulation where galactose is converted into glucose. The absorbed glucose may be utilized directly for providing energy to tissues, temporarily stored in the form of glycogen in liver and muscles or converted into fat. They are essential for the oxidation of fats and for the synthesis of non-essential amino acids.

### Functions of Carbohydrates

Carbohydrates are the most significant and cheapest source of energy in the diet. Carbohydrates provide 60 to 85% of energy in our diet. Various kinds of sugars (glucose, fructose, sucrose, etc), most literally, impart the sweet taste to life! Fibre has the important function of increasing faecal bulk, stimulating peristalsis and blocking cholesterol synthesis in the liver.

### Requirement of Carbohydrates

In a prudent diet carbohydrates should contribute to 60 to 70% of total energy (2).

Table 1

**Sugar Substitutes**

Sugar substitutes can be classified into two groups :

**(a) Nutritive sweeteners**

Sugar alcohols (Sorbitol, Mannitol, Xylitol) used as sugar substitutes in candies, chewing gum and beverages. These provide 4 Kcal / g of energy.

**Advantages**

(i) Not absorbed as rapidly as sucrose, so can be used in those who cannot tolerate a high blood sugar level.

(ii) Low risk of dental caries, as these alcohols cannot be used by oral bacteria.

**(b) Non-nutritive sweeteners**

These do not supply any calories. Examples are aspartane, sucralose, alitame and saccharin. These are several time sweeter than sugar, so small quantity is sufficient to sweeten the food. They must be used with caution as they are known to have carcinogenic

### Dietary Fibre

Denis Burkitt (a surgeon) and Hugh Trowell (a physician), served for 30 years, after the World War II, in Makareree University, Kampala, Uganda, before returning to Britain. They were struck by the great difference in the pattern and nature of disease affecting the affluent west as opposed to more primitive communities. In Uganda much bulky vegetable material was consumed and constipation was unknown. Their attention was focused on the unabsorbable material of the diet which they recognized as Dietary fibre. They concluded that this was not only responsible for the faecal bulk but was also directly or indirectly related to the difference in the pattern of disease. A 'fibre hypothesis' was thus formulated which suggested that unrefined complex carbohydrates protected against the 'western ailments' : colonic cancer, diverticular disease, appendicitis, constipation, hemorrhoids, hiatus hernia, varicose veins, diabetes, heart disease, gall stones, obesity, etc.

Definition

Dietary fibres are the remnants of the plant cell resistant to hydrolysis by alimentary enzymes and do not provide significant nourishment. They remain in the ileum but are partially hydrolyzed by the colonic bacteria. The term 'dietary fibre' is a broad term which includes Non Starch Polysaccharide (NSP) and related material such as resistant starch, lignin and complex assemblies of plant tissue where polysaccharides occur in close association with other molecules. The NSPs are normally present in cell wall, cement, plant gums, mucilages and algal polysaccharides. (8)

Classification

Fibre can be classified according to solubility in water, as soluble or insoluble. Insoluble fibre consists mainly of

cellulose, hemicellulose and lignin. On the other hand the natural gel forming fibres like pectins, gums and mucilages are soluble.

Sources and Losses

Insoluble fibres: Peas, beans, rye, granary bread, bran flakes, brown rice, maize, lentils and pulses, whole meal cereals (dalia), brown bread, sprouted grains and dals, whole meal flour and fruits with edible seeds are good sources of insoluble fibres.

Soluble fibre: Fruits in general (e.g. apples, citrus fruits, pears, straw berries) are good sources of soluble fibre.

Lettuce, grapes, canned orange, jams, white rice biscuits, white bread and corn flakes are poor sources of fibre. Milling of grains and polishing of rice removes the outer "bran layer" and thus greatly reduces the fibre content.

Functions

Dietary fibre stimulates chewing, improves flow of gastric juice and provides a sense of satiety. Insoluble fibre binds to water in the colon and swells. Hence it forms substrate for colonic bacterial fermentation. This stimulates peristalsis which increases transit time in the colon thereby reducing the risk of constipation and possibly that of colon cancer. (9)

Dietary fibre in disease

*"People with low incidence of coronary disease, atherosclerosis, diabetes and hyperlipidaemia obtain 85% of their energy from complex carbohydrates"*

**~ Prof William Connor**

In general soluble fibre slows gastric emptying, provides fermentable material for colonic bacteria and binds bile acids and cholesterols. Insoluble fibres hold water, reduce elevated colonic intraluminal pressure and binds minerals like zinc.

**Cardiovascular disease**

Fibre helps in achieving prevention of cardiovascular disease through various mechanisms :

(a) Soluble fibre binds with bile acids and other lipids interfering with micelle formation in the proximal intestine. This alters the quantity of cholesterol or fatty acids absorbed. The size of lipoprotein particles formed by intestinal mucosa is also altered.

(b) The re-absorption of bile acids is slowed by soluble fibre to increase cholesterol losses in faeces.

(c) Intestinal bacteria reduce soluble fibre to short chain fatty acids which block cholesterol synthesis in the liver. These effects of fibre reduce blood cholesterol levels which in turn reduces the risk of coronary artery disease (10).

**Diabetes Mellitus**

Fibres help in the maintenance of weight and prevention of obesity. Soluble fibre blunts the response of blood glucose. This helps in the control of blood glucose. Soluble and viscous fibres (pectin and gums) have the greatest hypoglycemic effect (11).

**Colorectal Cancer**

Fibre is considered to be an important contributory factor to the prevention of colonic cancer. The following mechanisms could be at play

(a) Fibre reduces the transit time in bowel and thereby reduces the time of exposure to potential mutagens and carcinogens that may be present in the diet.

(b) Fibre dilutes the carcinogens in the colon and alters the production of carcinogens in the stools.

(c) It alters the nature of faecal bile acids by altering the colonic (faecal) flora.

(d) It reduces the colonic pH by increasing fermentation of short chain fatty acid production.

(e) Diets rich in fibre also contains Vitamin A and C, which are strong antioxidants and are associated with lowering of the risk of colonic cancers. (12)

**Other GIT Disorders**

Fibre increases faecal bulk and relieves constipation. This reduces the incidence of colonic cancers, diverticulitis and appendicitis. The alteration in cholesterol production and further metabolism reduces the formation of gallstones as most of them are of cholesterol origin.

**Obesity**

High fibre diet contributes to bulk in food and satiety. It also reduces 'more' food intake and thus limits energy intake. An altered cholesterol homeostasis as brought out earlier, also contributes to obesity prevention (13).

Recommended Dietary Allowance

The diet should contain 35-40 grams of dietary fibre per day (2). Fibre content of selected food stuffs are given in

Table - 2 : Dietary fibre content of common foods (g/100g)

| Food Stuff | Fibre Content (g per 100g food) |
|---|---|
| Rice, raw, milled | 0.2 |
| Wheat flour, whole | 1.9 |
| Bengal gram, whole | 3.9 |
| Red gram (Dal arhar) | 1.5 |
| Peas dry, Rajmah | 4.5 |
| Cabage, cauliflower | 1 - 1.2 |
| Spinach | 0.6 |
| French beans | 1.8 |
| Coconut dry | 6.6 |
| Guava | 5.5 |
| Mango, Papaya | 0.7 |
| Pomogranate | 5.1 |
| Peach, Pears, Apple | 1 - 1.2 |
| Whole wheat flour | 10-13 |
| | |

## Fats

Fats are organic compounds, which are insoluble in polar solvents (water) but soluble in organic solvents such as ether, chloroform and benzene. These are actual or potential esters of fatty acids. Fats are only distinguished from oils by their different melting points; fats are solid and oils liquid at room temperature. 'Fats' and 'oils' are the ones which the housewife buys and 'lipid' is the term used by biochemists. However, the general term fat is commonly used to refer to the whole group and is used interchangeably with lipids. (4) They can be roughly classified into neutral fats and amphiphilic fats. Neutral fats include the triglycerides, cholesterol and other sterols. Amphiphilic fats consist of phospholipids such as lecithin and sphingo-lipids (eg sphingomyelin). Dietary fats are mainly triglycerides (over 90%) composed of fatty acids.

### Fatty acids

As a class fatty acids are the simplest of lipids. They are composed of a straight hydrocarbon chain terminating with a carboxylic acid group, therefore creating within the molecule a polar hydroplillic end and a nonpolar hydrophobic end that is insoluble in water. The carbon chain contains 4 to 24 carbon atoms. Fatty acids are components of the more complex lipids. Hydrogen atoms are attached to the carbon chain; the number of hydrogen atoms determines the degree of saturation (with hydrogen atoms) of the fatty acid. A fatty acid with hydrogen atoms on every arm is said to be 'saturated'. Unsaturated fatty acids contain double carbon bonds where there is no hydrogen. If there is only one double bond the fatty acid is termed as monounsaturated and when more than one double bond is present the fatty acid will be polyunsaturated.

### Saturated Fatty acids (SFA)

They have a relatively high melting point and tend to be solid at room temperature. These are obtained from animal storage fats and their products, e.g. meat fat, lard, milk, butter, cheese and cream. Fats from plant origin tend to be unsaturated with the exception of coconut oil and palm oil. A high intake of SFA is associated with an increase in LDL and total cholesterol and thus increases the risk of atherogenesis and cardio¬vascular disease. Some examples of SFAs are Myristic acid, Palmitic acid and Stearic acid.

### Monounsaturated Fatty acids (MUFA)

MUFA contain only one double bond and are usually liquid (oil) at room temperature. Olive oil and rapeseed oil are good dietary sources of MUFA. MUFA are also present in meat fat and lard. Dietary MUFA does not raise plasma cholesterol. They lower LDL cholesterol without affecting the HDL. Oleic acid is an example of MUFA.

### Polyunsaturated Fatty acids (PUFA)

PUFA contain two or more double bonds and are liquid at room temperature. They are easily oxidized in food and in the body. PUFA are involved in the metabolism of cholesterol, are components of phospholipids in cell membranes, and are precursors of biologically active compounds such as prostaglandins, interleukins, and thromboxanes. Therefore they have vital role in immune response, blood clotting and inflammation. PUFA are derived from the essential fatty acids linoleic acid (n6 or ω6) and α-linoleic acid (n3 or ω3) and are therefore divided into omega-3 (ω3) or omega 6 (ω6) groups of PUFA.

Omega-3 (ω-3) Polyunsaturated Fatty acids (PUFA) are found in fish and fish oils. The health benefits of these include reducing the cardiovascular risk factors. Research also indicates their beneficial role in cognitive function of brain. Some common omega-3 fatty acids are α-linolenic acid (linseed, soyabean, rapeseed, leafy vegetables), eicosepentaenoic acid (marine algae, fish oils) and docosahexenoic acid (fish oils).

Trans fatty acids (t-FA)

Trans fatty acids have been associated with adverse effects on lipoprotein status by elevating LDL and depressing HDL. They rarely occur in nature. These are produced during the partial hydrogenation of PUFA. In Indian homes this process takes place commonly when oil is heated over and over again as it happens during the process of frying puri, pakori or samosa, esp when the same oil is used again and again.

Essential fatty acids (**E**FA)

If fats are entirely excluded from the diet, retarded growth, dermatitis, kidney lesions and an early death might result. Studies have shown that feeding of certain unsaturated fatty acids eg linoleic and linolenic acid is effective in curing the condition. It is therefore evident that certain unsaturated fatty acids cannot be synthesized in the body and must be acquired from diet. These are essential fatty acids. EFA are commonly found in plant and fish oils. Deficiency of linoleic acid has been demonstrated in children although a deficiency of α-linolenic acid is not seen commonly in healthy people (8). Fatty acid content of different fats is given in Table - 3 (14)

Sources of **f**ats

Dietary fats are derived from two main sources:

(a) Animal Sources

They are milk and milk products (ghee, butter), lard, egg and fish oils. Animal fats in general are poor sources of essential fatty acids with the exception of certain marine fish oils such as cod liver oil and sardine oil, but they are good sources of retinol and cholecalciferol.

(b) Vegetable Sources

They include various edible oils such as groundnut, gingely, mustard, cottonseed, safflower, rapeseed, palm and coconut oil. Vegetable oils with the exception of coconut oil are all rich sources of essential fatty acids, but they lack retinol and cholecalciferol except red palm oil which is rich in carotenoids.

### Digestion and Absorption of Fats

Fats have to be reduced to small particles before digestion and absorption are possible. Bile salts and small quantity of fatty acids and monoglycerides liberated by pancreatic lipase emulsify fat in the duodenum with the formation of droplets smaller than 0.5 mm. Pancreatic lipase splits triglycerides into fatty acids, diglycerides, monoglycerides and glycerol. Fatty acids and monoglycerides pass into the cells of mucous membrane as very small particles. Within the cells further hydrolysis

takes place under the influence of intracellular monoglyceride lipase, and then the long chain fatty acids are re-esterified into new triglycerides. After re-synthesis, the triglycerides enter the lacteals of the small intestine as small particles known as chylomicrons. These pass into lacteals and the mesenteric lymph vessels, enter the thoracic duct and then join systemic circulation into the right subclavian vein. The major part of the absorbed fat enters the circulation through the thoracic duct, except for most short and medium chain fatty acids, which pass to the liver via the portal vein. After absorption from the alimentary canal, fats are carried in the blood either to storage depots or to the muscles and other tissues as a source of energy. Glycerol is oxidized to triose phosphate, a compound in the intermediate metabolism of carbohydrates. Normally the fatty acids undergo beta-oxidation ending in carbon dioxide and water. The long carbon chains of the fatty acids are also broken down in the liver into ketoacids. It must be appreciated that the normal break down of fats also needs simultaneous carbohydrate catabolism. Therefore, in diabetes, starvation or with a diet containing too much of fats and too little carbohydrates, incomplete oxidation of fats leads to an accumulation of aceto-acetic acid and ketones in the body resulting in ketosis. Approximately 2% of total plasma lipids are free fatty acids. The remainder of lipids are carried in the blood as lipoproteins. These are a complex of lipids with proteins. The protein component consists of peptide chains known as apoproteins. Lipoproteins are identified by the apoliprotein that is present (apo A, apo B, apo C, apo D and apo E). There are five classes of lipoproteins which vary in density and functions. The important characteristics of four main classes of lipoproteins are shown in Table - 4.

### Chylomicrons

Chylomicrons mainly consist of triglycerides and transport dietary lipids. Chylomicrons leave the enterocytes and enter the lymphatic system before entering the blood vessels. The triglycerides are hydrolyzed by lipoprotein lipase to release fatty acids that are used up for energy or stored in adipose tissue. The chylomicrons are cleared from the blood by the liver in 15-20 minutes.

### Very low-density lipoproteins (VLDL)

VLDL are synthesized in the liver and are large particles that are rich in triglycerides. They deliver fatty acids to adipose tissue, muscles, and heart where lipoprotein lipase facilitates their release from triglycerides. The enzyme in the heart has a high affinity for triglyceride and when triglyceride concentrations are low, they are preferentially released into heart tissue.

### Low-density lipoproteins (LDL)

LDL contains mainly cholesterol and cholesterol ester as they are the end product of VLDL metabolism. They carry approximately 70% of plasma cholesterol and are taken up by the liver and other tissues by LDL receptors.

### High-density lipoproteins (HDL)

The liver and intestine synthesize and secrete HDL. HDL is

Table - 3 : Approximate fatty acid composition of common fats and oils (g/100g) (14)

| Oil/Fat | Saturated | MUFA | Linoleic acid | α-linolenic acid | Predominant FA |
|---|---|---|---|---|---|
| Coconut | 90 | 7 | 2 | <0.5 | SFA |
| Palm kernel | 82 | 15 | 2 | <0.5 | SFA |
| Ghee | 65 | 32 | 2 | < 1.0 | SFA |
| Vanaspati | 24 | 19 | 3 | <0.5 | SFA (t-FA) |
| Red palm oil | 50 | 40 | 9 | <0.5 | SFA + MUFA |
| Palm oil | 45 | 44 | 10 | <0.5 | SFA + MUFA |
| Olive | 13 | 76 | 10 | <0.5 | MUFA |
| Groundnut | 24 | 50 | 25 | <0.5 | MUFA |
| Rape/Mustard | 8 | 70 | 12 | 10 | MUFA |
| Sesame | 15 | 42 | 42 | 1.0 | MUFA + PUFA |
| Rice bran | 22 | 41 | 35 | 1.5 | MUFA + PUFA |
| Cotton seed | 22 | 25 | 52 | 1.0 | PUFA |
| Corn | 12 | 32 | 55 | 1.0 | PUFA |
| Sunflower | 13 | 27 | 60 | <0.5 | PUFA |
| Safflower | 13 | 17 | 70 | <0.5 | PUFA |
| Soyabean | 15 | 27 | 53 | 5.0 | PUFA |
| | | | | | |

Table - 4: Important characteristics of plasma lipoproteins (15)

| Lipoprotein | Density | Protein (%) | Triglycerol (%) | Cholesterol (%) | Phospholipids (%) |
|---|---|---|---|---|---|
| Chylomicron | <0.95 | 1.5-2.5 | 84-89 | 1-3 | 7-9 |
| VLDL | <1.006 | 5-10 | 50-65 | 5-10 | 15-20 |
| IDL | 1.006-1.009 | 15-20 | 22 | 8 | 22 |
| LDL | 1.020-1.063 | 20-25 | 7-10 | 7-10 | 15-20 |
| HDL | 1.064-1.210 | 40-55 | 3-5 | 3-4 | 20-35 |

involved in the reverse transport of cholesterol from tissues to the liver or transfers it to other lipoproteins.

Lipoprotein (a)

This is a complex of LDL with apolipoproteins (a).

Unfavourable levels of these lipoproteins have adverse effects on health. High levels of LDL are associated with atherosclerotic risk so LDL is colloquially known as 'bad cholesterol'. A high level of HDL has favourable effect on the cardiovascular system and is termed as 'good cholesterol'. (8)

**Functions of Fats**

(a) They are concentrated sources of energy providing about 37.7 kj/g (9 kcal /g).

(b) Fats serve as vehicle for fat soluble vitamins (A.D,E & K)

(c) Fats are structural components of cell and cell membrane

(d) They are the sources of essential fatty acids. Linoleic acid and arachidonic acid are precursors of prostaglandins which are required for a wide variety of metabolic functions.

(e) Apart from their nutritional significance, fats improve the palatability of diet, delay gastric emptying and raise the caloric density.

(f) Some fats can be converted to biologically active compounds such as steroid hormones, interleukins, thromboxanes, and prostaglandins and bile acids (from cholesterol).

**Recommended Dietary Allowance**

The RDA for adults is 20g of visible fat per day. For pregnant and lactating women it is 30 and 45 g respectively. (2)

# The Protective Foods

*"Milk and leaves occupy a unique position, as they correct the defects of cereals, tuber, roots and meats. Thus…they be distinguished by the term 'Protective foods'."*

**~EV McCollum(1)**

## Vitamins

They are organic compounds required in very small but definite quantities for normal growth and the maintenance of a healthy life. They are not produced in the body and have to be supplied in the diet. They do not furnish energy and play no part in the constitution of the structure of tissues, but are essential for the transformation of energy and regulation of tissue metabolism. They are necessary for the efficient functioning of the organism as a whole, each in a specific manner. Deficiency of vitamins causes profound changes in structural and functional wellbeing, the picture of each deficiency being, specific. A few can be synthesized by the micro-organisms of the bowel, this biosynthesis shows great variations in different people on the same diet with the result that only certain members of a group consuming diet deficient in one of these vitamins may develop symptoms of vitamin deficiency while the other members of the same group remain healthy. Certain types of commensal bacteria sometimes under anaerobic conditions destroy the vitamins, particularly thiamine, nicotinic acid and ascorbic acid but a balance is normally maintained between biosynthesis and destruction. A disturbed balance by reduced intake, alteration in the intestinal bacteria, presence of parasites and intestinal infections may precipitate the vitamin deficiencies. This occurs particularly under stressful conditions such as toxaemia, pyrexia or gastro-intestinal conditions when the vitamin demand increases.

Vitamins are widely distributed in diet. Fresh milk, meat, eggs, fresh vegetables and fruits are rich sources. Cereals (esp whole unrefined cereals) which form the bulk of our diets are also important sources. Storage, processing and cooking of food may cause considerable vitamin loss, so that the maintenance of an adequate intake is more difficult when fresh food is scarce. The pharmaceutical use of vitamins should be restricted to rectify or supplement the envisaged or existing deficiency in the diet or to meet the increased physiological demands (eg in pregnancy). No physiological benefit, however, can be expected from a large dose of vitamins under normal circumstances. Vitamins have long been classified into two groups; water soluble and fat soluble. The water-soluble group comprises of vitamins B and C; the fat-soluble vitamins are A, D, E and K. This division is still useful, since it helps to understand the distribution of vitamins in foods and their absorption and metabolism in the body. There is also an important distinction in the handling of the two classes by the body. An excess intake of water soluble vitamins is excreted in the urine. Thus, there is virtually no danger in giving an excess of these vitamins. On the other hand, the fat soluble vitamins cannot be excreted in this way. Any excess of these vitamins, beyond the immediate requirement is stored in the liver. The storage capacity of the human liver is large and it normally holds a reserve of vitamins sufficient for many months; this is a useful provision for times when the dietary supply may temporarily be cut off. However the amount that can be stored is not unlimited. (2,3)

## Water soluble vitamins

### Thiamin (Vitamin B1)

Thiamine hydrochloride is a crystalline substance which is readily soluble in water. It is rapidly destroyed by heat in neutral or alkaline solutions. In acid solutions however, it is resistant to heat upto 120°C. It is mainly excreted in urine. Thiamine is present in the body mostly as thiamine pyrophosphate (TPP) but about 10 percent as thiamine triphosphate. TPP is the active form of thiamine in the body.

Sources

The important stores are seeds of plants. The germ of cereals, nuts, pea, beans and other pulses and in addition yeast is a rich source. All green vegetables, roots, fruits, nuts, flesh foods and dairy produce contain significant amounts of the vitamin. Pork has a higher content of thiamine than beef or mutton. Highly processed foodstuffs like white bread, polished rice and refined sugar are deficient in thiamine. In cereal grains, thiamine is found in highest concentration in the germ or embryo, less in bran and least in endosperm.

Losses

Milling of cereals below an extraction rate of 75 percent reduces the content of thiamine to a great extent. As thiamine is readily soluble in water, considerable amounts may be lost when foodstuffs are cooked in an excess of water which is afterwards discarded. It is relatively stable to heat upto boiling point, provided that medium is slightly acid, as in baking with yeast. But if baking powder is used, or if soda is added in the cooking of foodstuffs, almost all the vitamin may be destroyed.

Functions

(a) It forms part of the coenzyme thiamine pyrophosphate (TPP). This is a coenzyme of carboxylase, concerned with the oxidative decarboxylation of pyruvic acid which is an intermediate stage in the oxidation of glucose. In thiamine deficiency, the carbohydrate metabolism is interfered with, and pyruvic acid accumulates in the tissues and body fluids, and toxic effects result. It is needed in the transketolase reaction in the hexose monophosphate pathway. (4)

(b) It is also a coenzyme in 2-oxoglutarate dehydrogenase in central energy yielding

metabolic pathways and the branched chain oxo-acid dehydrogenase in the catabolism of leucine, isoleucine and valine. (5)

(c) It is essential for the health of the nerve tissue, and for normal cardiac, and gastro-intestinal functions.

Requirement

Since thiamin plays an important role in carbohydrate metabolism, its dietary allowance is related to energy intake. It is 0.5 mg per 1000 Kcal. (6)

Deficiency

Thiamin deficiency causes beriberi and Wernicke-Korsakoff psychosis. Three forms of Beriberi are known: Wet Beriberi (cardiac), Dry Beriberi (neurological) and Infantile Beriberi. The early symptoms and signs are common in both dry and wet Beriberi. The onset is usually insidious, though sometimes precipitated by unwanted exertion or a minor febrile illness. (4)

(a) Wet beriberi is the acute form. It is characterized by high output cardiac failure, bounding pulse, warm extremities, peripheral oedema and cardiac dilatation.

(b) Dry beriberi is the chronic form of disease and is characterized by progressive peripheral neuropathy. The tendon jerks are sluggish and anaesthesia of the skin (especially over tibia) is common. The muscles become progressively wasted and weak and walking becomes increasingly difficult. The thin, even emaciated individual needs at first one stick, then two and may finally become bedridden.

(c) Infantile beriberi occurs in the first few months of life (of an infant), if the diet of mother is deficient in thiamin. The infant remains constipated and appears plump due to water retention. The heart is enlarged, heart sounds are muffled. The infant may die of a heart failure if untreated. (7)

(d) Wernicke-Korsakoff psychosis is seen in chronic alcoholics with poor diet. It is characterided by confusion, low levels of consciousness and poor coordination (encephalopathy). Memory loss often follows the encephalopathy.

**Recent Advances (Thiamin)**

- Brains of Thiamin deficient animals reveal presence of Alzheimer-like amyloid. Although such pathology has not been seen in humans with Wernicke-Korsakoff syndrome, this has led to trials of thiamin for treatment of Alzheimer's disease. (8)
- While the classical forms of Beriberi from a predominantly dietary deficiency is on the decline, an increasing relationship is being seen between central nervous system damage caused by its deficiency in narcotic abusers and HIV/AIDS patients. Results from postmortem examinations and brain imaging indicate that Wernicke encephalopathy is significantly underdiagonosed. (5)

## Riboflavin

It is a yellow green fluorescent compound, soluble in water but not in fats. Though stable in acid solution, in alkaline solution it is readily destroyed by heat. It is also destroyed by short visible and ultraviolet rays.

### Sources & Losses

The best sources of riboflavin are liver, milk, eggs and green vegetables. Ceraels and yeast extracts also contain the vitamin. Riboflavin differs from other compounds of vitamin B complex in that it occurs in good amounts in dairy produce. Cooking does not destroy the vitamin apart from losses that occur when the water in which green vegetables have been boiled is discarded. If food, especially milk, is left exposed to sunshine, large losses may occur.

### Functions

In plant and animal tissues riboflavin gets linked with phosphoric acid to form flavin mononucleotide (FMN). This, with adenosine monophosphate (AMP) forms flavin adenine dinucloeotide (FAD). These two coenzymes, FMN and FAD are the prosthetic groups of flavoprotein enzymes involved in oxidation-reduction reactions within the cells in many metabolic pathways. The important functions of riboflavin include:

(a) Promotion of normal growth

(b) Assisting synthesis of steroids, RBC and glycogen

(c) Maintenance of mucous membranes, eyes, and the nervous system

(d) Aiding iron absorption (4)

### Requirement

The requirement of this vitamin is also related to energy intake. It is about 0.6 mg per 1000 kCal. The daily safe requirement ranges from 0.7 to 2.2 mg/day. (6)

### Deficiency

(a) The signs suggestive of riboflavin deficiency are cheilosis, angular stomatitis, glossitis, magenta tongue, nasolabial seborrhoea and genital (scrotal or vulval) dermatosis. Corneal vascularisation is also seen but is not a specific sign of riboflavin deficiency.

(b) Severe deficiency is rarely seen. But the elderly, anorexia nervosa sufferers and chronic dieters are at a higher risk.

(c) Certain secondary nutrient deficiencies are seen in Riboflavin deficient people. Hypochromic anaemia results due to reduced iron absorption and increased gastrointestinal loss modulated by altered cell morphology and cytokinetics. Vitamin B6 deficiency may occur because pyridoxine oxidase is a flavoprotein sensitive to riboflavin depletion. Pallegra may be precipitated because of impaired tryptophan metabolism due to impairment of kynurenine hydroxylase and

**Recent Advances (Riboflavin)**

- Marginal riboflavin status may be a factor in hyper-homocysteinaemia. Riboflavin supplements may be beneficial in lowering plasma homocysteine.(9)
- It has been studied that riboflavin deficient people are relatively resistant to malaria and have a lower parasite burden as compared to well nourished people. (5)
- Certain secondary nutrient deficiencies resulting from Riboflavin deficiency are being studied. For example, secondary deficiencies of iron, functional deficiency of vitamin B6 and impaired niacin synthesis, leading to pellagra are known. (5)
- The structural analogues of Riboflavin like phenothiazines, tricyclic antidepressants, anti-malarials and adriamycin inhibit flavokinase, leading

reduced synthesis of NAD. (5)

## Niacin (Nicotinic acid & nicotinamide)

Niacin is the generic term for a group of compounds that prevent pellagra. It is a white crystalline substance readily soluble in water and is resistant to heat, in solution or in a dry state. Although related chemically to nicotine it possesses very different physiological properties. It occurs naturally in the body in the form of an amide - nicotinamide.

### Sources

Nicotinic acid is widely distributed in plant and animal foods. Meat (especially the organs), fish, chicken, eggs, milk, whole meal cereals, groundnuts and pulses are good sources. In some cereals, especially maize, the greater part of the vitamin may be in a bound unabsorbable form. The human body is not entirely dependent on dietary sources of nicotinic acid as it may also be synthesized from tryptophan. On an average about 60 mg of tryptophan is needed to form 1mg niacin. In the assessment of this vitamin in diet, both the dietary content and niacin obtained from conversion of tryptophan are considered. The total niacin content can be expressed in terms of niacin equivalents (mg), which is the sum of niacin in diet + 1/60$^{th}$ of tryptophan content, in diet. (6)

### Functions

Nicotinamide is incorporated into the pyridine nucleotide coenzyme nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). These coenzymes are involved in numerous oxidoreductase reactions including glycolysis, fatty acid metabolism, tissue respiration and detoxification.

### Requirement and intake

Since this vitamin takes part in many reactions of energy metabolism, its requirement is also related to energy requirement. Its safe level is estimated to be 6.6mg niacin equivalents per 1000 kcal. The daily requirement varies from 8-26 mg. (6)

### Deficiency

Pellagra results from the deficiency of niacin. This is characterized by the three 'D's (4)

(a) **Dermatitis:** (Pellagrous dermatosis) Skin exposed to sunlight gets inflamed, that progresses to pigmentation, cracking and peeling. The neck is frequently involved and the distinctive distribution of skin lesions is known as Casal's Collar.

(b) **Diarrhoea:** This is often accompanied by inflamed scarlet tongue.

(c) **Dementia:** It may present as mild confusion and disorientation to mania and psychosis.

**Recent Advances (Niacin)**

- Nicotinamide protects against the autoimmune destruction of pancreatic b islet cells. Nicotinamide thus, can delay the onset of Type 1 diabetes in susceptible individuals. The trials conducted so far have been promising. (10)
- Nicotinic acid is used in pharmacological doses to treat hyperlipidaemia. (5)

## Folic Acid (Folate or Pteroyl glutamic acid)

It is a yellow crystalline substance, sparingly soluble in water and a stable molecule. When heated in neutral or alkaline media it undergoes rapid destruction. About three quarters of folate in foods is in polyglutamyl form. These are normally hydrolyzed to free folate by a conjugate present in small intestinal epithelium. Free folate is actively absorbed from the upper small intestine. It is stored mainly in the liver. Small amount is excreted in urine and faeces. Free folic acid is converted in the liver into tetrahydrofolic acid (folonic acid) which is the functionally active form in the body.

### Sources and losses

It occurs in green leaves, pulse, cereals, liver, kidney, mushroom and yeast. Food preparation can cause serious losses of folic acid in canning, in prolonged heating, when cooking water is discarded, and from reheating. Reducing agents in food tend to protect folic acid.

### Functions

(a) Folinic acid plays important role in the synthesis of purines, pyramidines, glycine and methionine. It is essential for the synthesis of DNA.

(b) The folate derivative 5-methyl tetrahydrofolate requires vitamin B12 to enable the use of methionine synthase in the synthesis of methionine and tetrahydrofolate.

(c) It is a potent anti anaemia factor in the treatment of megaloblastic anaemias of malnutrition, pregnancy and malabsorption. It is also effective in treatment of pernicious anemia.

(d) Cell mediated immunity is impaired in children

suffering from megaloblastic anaemia due to folic acid and Vit B12 deficiency.

**Requirement and intake**

The requirement of folic acid ranges from 50 µg to 100 µg. In pregnancy it increases to 150-300 µg. (6)

**Measurement**

Recent intake can be assessed by serum folate. Cellular status is assessed by red cell folate levels.

**Deficiency**

Dietary folate deficiency is not uncommon. Deficiency results in megaloblastic anaemia. Deficiency may be accompanied by depression, insomnia, forgetness, irritability and dementia. Low folate levels are also associated with neural tube defects. Lack of folic acid is known to cause accumulation of homocysteine (hyper-homocysteinaemia), which is a potential risk factor for coronary artery disease. High folate levels overcome the hyper-homocysteinaemia. Low folate levels can cause an altered methylation of DNA, increasing the risk of cancer. (4,5)

## Vitamin $B_6$ (Pyridoxine and Related Compounds)

**Recent Advances (Folic acid)**

- Various epidemiological studies indicated in the 1990s that elevation of plasma homocysteine is an independent risk factor for CVD and supplements of folates lower plasma homocysteine. A lot of work is being done to understand mechanisms involved. (9)
- Recent studies indicate that low folate levels increase the risk of colorectal & other cancers. It is being investigated if aberrant methylation of DNA results in the de-differentiation of genes & development of

Three naturally occurring pyridines - pyridoxine, pyxidoxal and pyridoxamine are collectively known as Vitamin $B_6$.

**Sources**

Meat, pulses and wheat are known to be rich sources while other cereals are fair sources of the vitamins. Fruits and vegetables are relatively poor sources. The extent to which processing of foods and cooking practices destroy vitamin $B_6$ depends largely on the food. In meat and milk, considerable amounts are lost, while in food of vegetable origin there are hardly any losses.

**Functions**

The three vitamins can be converted to the coenzyme pyridoxal 5 phosphate which is involved in the amino acid metabolism. These reactions include:

(a) Transamination of aminoacids to produce keto acids and synthesis of (non-essential) amino acids.

(b) Decarboxylation to yield biologically active amines eg neurotransmitters (adrenaline, nor-adrenaline, serotonin and GABA) and histamine.

(c) Porphyrin synthesis, including haemoglobin.

(d) It is also believed to have a role in the production of antibodies

**Requirement and intake**

The exact requirement for Indians has not been worked out but it is safe to believe that an intake of 0.6 - 2.5mg/day would meet the requirement. (6)

**Deficiency**

Deficiency of Vitamin $B_6$ is rare. It may be seen in patients suffering from malabsorption, patients on dialysis, or alcoholics. Symptoms include lesions of lips, corners of mouth and inflammation of tongue. Peripheral neuropathy is also a sign of vitamin $B_6$ deficiency.

## Vitamin $B_{12}$ (Cyanocobalamin)

**Recent Advances (Pyridoxine and related compounds)**

- Hyper-homocysteinaemia is most significantly associated with low folates, but there is also a significant association with low pyridoxine. High doses of this vitamin are shown to lower homocysteinaemia. (12)
- Inadequate levels of this vitamin are also likely to be associated with a higher incidence of hormone

Cobalamin is a complex molecule containing 4-percent cobalt, besides phosphorous and nitrogen. Cyanocobalamin is the commercially available form. Vitamin $B_{12}$ is the 'extrinsic factor' originally postulated by Castle. It requires the 'intrinsic factor', secreted by the parietal cells of the stomach, to be absorbed. It is freely soluble in water and resistant to boiling in neutral solution though unstable in the presence of alkalis.

**Sources**

It is unique among vitamins in that it is not present in any vegetable foods. It is present in animal products - milk, milk products, meat and fish. It is synthesized by the microorganisms in the gut and assimilated in the food chain.

**Functions**

(a) It recycles the folate coenzyme.

(b) Vitamin $B_{12}$ plays important role in the synthesis of DNA.

(c) It helps in maintenance of myelin in the nervous system.

(d) It has an important role besides folic acid in the treatment of pernicious anemia.

(e) It also helps in conversion of homocysteine to methionine.

**Measurement**

Serum $B_{12}$ is assessed by radioligand binding or microbiological assay. Absorption is assessed by Schilling test. (4)

**Requirement and intake**

The daily losses of this vitamin range from 0.25 mg to nearly 1mg. An intake of 2 mg per day has been recommended by FAO/WHO. The ICMR has, however, suggested a daily intake of 1mg of the vitamin for Indian adults. (6)

**Deficiency**

Since the vitamin doesn't occur in vegetable foods, vegans and strict vegetarians are at a high risk of its deficiency. Malabsorption, gastric atrophy, and reduced production of 'intrinsic factor' are some other causes of deficiency. Pernicious anaemia results which is a megaloblastic anaemia due to deficiency of this vitamin. Neurological symptoms characterized by loss of sensation and motor power in the lower limbs (due to degeneration of myelin) may also be seen. Since it is also synthesized in the gut many cases of vitamin $B_{12}$ deficiency are not seen very frequently.

## Pantothenic Acid

It is a pale yellow oily liquid that has never been crystallized, but its calcium salt crystallizes rapidly and this is the form in which it is generally available. Though stable in neutral solution, it is easily destroyed by heat.

**Sources and losses**

The best sources are liver, kidney, yeast, egg yolk, wheat germ or bran, peanuts and green vegetables. In most cooking and baking procedures there is little loss of the vitamin, but temperatures above, boiling point may cause considerable loss.

**Functions**

(a) This vitamin is a constituent of coenzyme A (CoA) which participates in pyruvate and fatty acid oxidation.

(b) It is also involved in acetylation of choline.

(c) It is also part of the prosthetic group of acyl carrier protein, which is important in synthesis of fatty acid, cholesterol and steroids.

**Requirement and intake:**

The exact requirement of Pantothenic Acid has not been ascertained. The average intakes are about 5 to 27mg/day, which seem to be adequate. (6)

**Deficiency**

Cases of 'burning feet' (parasthesia) responding to Pantothenic acid were seen during the First World War Depression, fatigue and muscle weakness were also known. Spontaneous deficiency is not seen now. (3,4)

## Biotin

Of the eight isomers of biotin only d-Biotin is biologically active.

**Sources and losses**

Yeast and colonic bacteria of many species either make or retain biotin. Kidney, liver, milk and dairy products are good sources. Raw egg white contains a protein, avidin that binds avidin and prevents its absorption. The effect is prevented by heating the egg white.

**Functions**

(a) It forms part of several enzyme systems; notably one that fixes $CO_2$ derived from bicarbonate ions and then incorporates the $CO_2$ in to the pathway of fatty acid synthesis. It participates in the pyruvate-carboxylase system.

(b) It is also involved in metabolism of branched chain amino acid.

**Requirement and intake**

There is little information concerning biotin requirements. Average intakes range between 15-70µg/day. (6)

**Deficiency**

Deficiency is rare but seen in patients on total parenteral nutrition. It is associated with exfoliative scaly dermatitis, glossitis, hair loss, anorexia, depression and hypercholesterolaemia. It is possible to induce deficiency by consuming a large number of raw eggs. B cell defects are also associated with lowered levels of biotin. (3,4)

## Vitamin C (Ascorbic Acid)

It is a water soluble, crystalline, white substance. Crystals remain stable in air and daylight. Ascorbic acid is very sensitive to oxidation, which is accelerated by heat, alkaline solutions, light and traces of metals, especially copper. The biologically active forms are L-ascorbic acid and L-dehydroascorbic acid. It is rapidly absorbed from the intestine. It is present in all body tissues but is found in a high concentration in the adrenal glands, pituitary gland, and intestinal wall. The white blood cells contain a higher concentration of ascorbic acid than the plasma. Excretion of ascorbic acid in urine depends on the blood and tissue contents.

**Sources and losses**

Its rich sources are citrus fruits (oranges, lemons), guavas, papayas, pineapple, mangoes, gooseberry (amla), kiwi fruit and green leafy vegetables. Root vegetables also contain vitamin C, esp. sweet potato. It is also synthesized in germinating seeds, pulses and grains.

The vitamin C content of fruits and vegetables is reduced by storage and damage to plant cells by rough handling, bruising or cutting, which results in release of enzyme ascorbic acid oxidase which oxidizes ascorbic acid. Also cooking of vegetables destroys vitamin C through the enzyme action and heat and by its extraction into cooking water. High pressure steaming as well as rapid frying of green vegetables destroys the enzyme thereby causing a greater retention of vitamin C than boiling.

**Functions**

Ascorbic acid is a powerful reducing agent (antioxidant) and is essential for many oxidation-reduction reactions.

(a) Ascorbic acid is required for the formation of collagen and is therefore necessary for the formation and maintenance of the normal structure of the intercellular ground substance (connective tissue), bone, tendons, skin, teeth and capillaries.

(b) It is important for hydroxylation of dopamine to nor-adrenaline

(c) It is required for the production of carnitine.

(d) It enhances the absorption of iron, through the conversion of ferric ($Fe^{3+}$) to ferrous ions ($Fe^{2+}$).

(e) It has anti-oxidant property like vitamins A and E, which has an important role in free radical scavenging, as an anti-aging and anti-cancer factor.

(f) It influences the maturation of the red blood cells, synthesis of bile and metabolism of drugs and carcinogens by the liver. (4)

**Requirement**

The requirement of vitamin C is 40 mg/day for adults. For lactating women 80 mg/day is recommended. (6)

**Deficiency**

Vitamin C deficiency is not common now. It causes defective formation of intercellular ground substance whose characteristic gross lesions occur in gums, bones and capillaries. Reparative process especially involving connective tissues, as in wound healing, are interfered in vitamin C deficiency due to the lack of the formation of collagen. Deficiency leads to a condition called as scurvy. The signs and symptoms include spongy and bleeding gums, perifollicular haemorrhages in the skin, sub periosteal haematomas and poor wound healing. Fatigue and muscle weakness is also reported. (4)

## Fat soluble vitamins

Vitamin A, D, E and K are the fat soluble vitamins. A brief description of each is given here.

**Recent Advances (Ascorbic acid)**

Vitamin C has assumed great importance as a free radical trapping antioxidant. It reacts with superoxide free radical (and a proton) to yield hydrogen peroxide or with hydroxyl radical to yield water. By its strong reducing property it reduces α-tocopheroxyl radical formed in cell membrane and plasma lipoproteins during oxidation of vitamin E, so sparing vitamin E. (5)

## Vitamin A (Retinol)

Hopkins conducted an experiment in young rats (1906-1912). These were fed on casien, starch, sugar, lard and inorganic salts. These rats failed to grow and died. An addition of only 3ml milk enabled them to thrive! An 'Accessory food factor' was thus demonstrated. Mc Callum isolated it in 1913 and was named as Vitamin A. Wald was awarded Nobel Prize for description of 'dark vision' and its association with Vitamin A. (2,13)

Vitamin A is a term for the biologically active compound retinol and its provitamin (precursor) carotenoids. Retinol is a fat soluble pale yellow compound. It is stable to heat at ordinary cooking temperatures but liable to oxidation and destruction on rancidity of fat. Retinol, consists of a hydrocarbon chain with a β-ionone ring at one end and an alcohol group at the other.

However, carotenoids cannot wholly be converted into retinol in the body and man absorbs and utilizes these pigments less efficiently. 6 microgram of β-carotene has the biological activity of 1 microgram. Other Carotenoids have even lesser vitamin A activity. (4)

**Sources and losses**

Retinol is found in foods of animal origin. The important sources of Retinol are meat, liver, kidney, milk, fish and eggs. Retinol can also be formed in the intestinal mucosa from the pigments known as carotenoids which are widely distributed in plants. Carotenoids are found in coloured fruits and vegetables. Only 50 of the approximately 600 naturally occurring Carotenoids get converted into vitamin A. Carotenes are found chiefly in association with chlorophyll, so that the green outer leaves of vegetables (e.g. cabbage) are good sources of carotene. One of these, β-carotene is by far the most important source of retinol (provitamin A) and is found in abundance in yellow-orange vegetables and fruits (e.g. pumpkin, papaya, mango, apricots, yellow peaches and green leafy vegetables). α-Carotene another carotenoid, is found in carrots, lutein in dark green leafy vegetables and β-Cryptoxanthin in citrus fruits. The pigments with **no** vitamin A activity include lycopene in tomatoes and zeaxanthin in sweet corn. (4)

Vitamin E protects it from oxidation. It is destroyed by exposure to sunlight. Foods which are heated for long period of time lose an appreciable amount of vitamin A. Boiling, canning or freezing of foods does not cause loss but drying and dehydration causes considerable loss.

**Retinol Equivalents**

Vitamin A activity of a diet is usually expressed in retinol equivalents. As mentioned, the term vitamin A is applied to both retinol (preformed vitamin A) and pro-vitamin A (beta-carotene). One microgram retinol is considered as 1 retinol equivalent (1RE). It is also known that the biological activity of 6 µg beta Carotene has an activity of 1 µg retinol (or 1 µg beta Carotene = 0.167 µg RE). International unit or IU is an old unit and is sometimes used.1 IU is equal to 0.3 µg of Retinol.

**Physiology**

After absorption retinol is carried from the intestines as retinol palmitate in chylomicrons and is taken up by the liver and stored there. Animals can store retinol sufficient to meet their needs for several months. It is released from the liver as retinol and circulates in blood bound to a specific transport protein, retinol-binding protein (RBP), the transthyretin (previously known as pre albumin) which forms complex plasma prealbumin. This serves to maintain the vitamin in aqueous solution, protects it against oxidation and also delivers the vitamin to target tissues (eye tissues, various epithelia, etc) (5)

**Functions**

(a) It is vital for the formation of retinal pigment rhodopsin in rods of the retina. Exposure to light results in a series of changes in its configuration, which leads to the adaptation of vision in dark. Retinol deficiency leads to impairment of dark

adaptation or night blindness.

(b) Retinol is essential for integrity of cellular structure esp. epithelial tissue respiratory, gastrointestinal, genitourinary and skin.

(c) It has a role in the immune defence mechanism of the body.

(d) Vitamin A has an anti oxidant property of free radical scavenging. (For details refer to section on antioxidants)

**Requirements**

The recommended intake is 600 mg of retinol equivalent per day per adult including children above 6 years and pregnant women. Lactating mothers require 950 mg. In converting the carotene figures to retinol, a conversion factor of 0.25 has been suggested by ICMR. (6)

**Recommended Dietary Allowance**

For vitamin A the RDA is given in terms of retinol (vitamin A alcohol). If the diet contains vitamin A and carotene, its content can be expressed as retinol using the following formula:

Retinol content =µg retinol + µg of β-carotene X 0.25

**Deficiency**

Deficiency of Vitamin A leads to ocular and extra ocular manifestations. The ocular manifestations are more common. The ocular manifestations resulting from vitamin A deficiency are termed as Xerophthalmia. Deficiency is often seen to be associated with weaning, protein energy malnutrition and a diet poor in vegetables, fruits, milk and butter. Socio-economic factors like educational status, income, poverty; cultural beliefs like misconceptions on breast feeding, faulty weaning practices and poor environmental sanitation /hygienic practices, infections and infestations contribute to vitamin deficiency.

## Vitamin D (Calciferols)

The term Vitamin D refers to two molecules ergocalciferol (Vitamin $D_2$) and Cholecalciferol (Vitamin $D_3$). Cholecalciferol is the natural form of vitamin and is produced by the ultraviolet irradiation of 7-dehydrocholesterol widely distributed in animal fats such as the oily secretions in mammalian skin. Dietary ergocalciferol & cholecalciferol are biologically inactive and are activated to 25 hydroxy-cholecalciferol in liver. Further conversion in the kidney results in the production of the more active form 1,25-dihydroxy cholecalciferol (Calcitrol). (13)

**Food sources**

Cod liver oils oily fish, milk, margarine, eggs, liver

**Functions**

Vitamin D regulates the absorption and excretion of calcium from the small intestine and also plays an essential part in the mechanism for mineralizing bone. It is considered as a hormone rather than a vitamin. (4)

**Measurement**

### Recent Advances (Vitamin A)

**Genomic action of Vitamin A**

Vitamin A performs certain genomic actions through nuclear actions or modulating gene expression by activation of nuclear receptors. In the presence of all-trans or 9-cis-retinoic acid the receptor heterodimers are transcription activators. In the absence of retinoic acid the heterodimers still bind to the DNA, but act as repressor of gene activator. It is therefore now understood that both deficiency & excess of retinoic acid causes severe developmental abnormalities (5).

**Vitamin A in cancer prevention**

Vitamin A acts as antioxidants, trapping singlet oxygen generated by photo between chemical reactions or lipid peroxidation of membranes. Many studies have indicated a negative association between Vitamin A intake and cancer incidence (5).

Vitamin D status can be assessed by the measurement of plasma 25-hydroxy-cholecalciferol. In severe deficiency plasma calcium and phosphate fall and alkaline phosphatase is elevated.

**Requirement and intake**

The vitamin D requirement for a child is placed at 100-400IU/day. This requirement can be obtained from exposure of the body to sunlight. ICMR expert group therefore has not recommended any dietary intake. Whenever this requirement is not met, a therapeutic supplementation may be needed. (6)

**Deficiency**

People who stay indoors and are fully covered (purdah system amongst women) are at a higher risk of deficiency due to lack of exposure to UV radiation due to sunlight. Malabsorption also increases the risk of deficiency. Severe deficiency results in rickets in children, characterized by reduced calcification of bone epiphysis. It results in skeletal deformities, bone pain and muscle weakness. In adults deficiency results in osteomalacia.

## Vitamin E (Tocopherol)

Eight naturally occurring forms of vitamin E are synthesized in plants; four tocopherols (α, β, γ and δ tocopherols) and four tocotrienols (α, β, γ and δ tocotrienols). Alpha tocopherol which is synthesized commercially has the highest biological activity, and is used as the standard against which activity of other forms is measured. Being fat soluble, vitamin E is found in all cell membranes. (4)

**Sources**

Vitamin E is widely distributed in foods and the richest sources are vegetable oils like groundnut, sunflower, safflower, cotton seed, corn, wheat germ, rape seed, palm and other oils. Nuts (like almonds and peanuts) are also good sources. Eggs, butter, whole meal cereals are moderately good sources. Meat, fruits, vegetables contain small amounts. Foods rich in PUFA are also rich in Vitamin E.

**Functions**

(a) Like vitamin A and C, it has a strong antioxidant property and protects cell membranes and lipoproteins from damage from free radicals. It also prevents the non-enzymic destruction of polyunsaturated fatty acids by molecular oxygen.

(b) It maintains the cell membrane integrity.

(c) It has a role in the DNA and prostaglandin synthesis.

**Requirement & intake**

The human requirement of vitamin E is not known with certainity. (6) The US authorities have recommended an intake of 12mg/day.

**Deficiency**

Deficiency of vitamin E in animals interferes with normal reproduction and causes a form of muscular dystrophy, but the effects if any, on human being are being studied. However a genetically inherited disease Familial Isolated Vitamin E (FIVE) deficiency is known. Patients develop reduced tendon reflexes by age 3-4, loss of touch and pain sensation, unsteady gait, loss of coordination and impaired eye movement in adolescence. (4) Deficiencies have also been seen in people with severe fat malabsorption. (5)

## Vitamin K

It exists in nature in two forms. Vitamin $K_1$ (phylloquinine), originally isolated from lucerine, is the only form that occurs in plants. It is a yellow oil, soluble in fat solvents, but only slightly soluble in water. Vitamin $K_2$ (menaquinone) is produced by bacteria in the lumen of large intestine.

**Food sources**

Green leafy vegetables, vegetable oils esp. soya bean oil, eggs, meat and dairy products are good food sources of vitamin K.

**Function**

(a) Vitamin K promotes the synthesis of γcarboxy glutamic acid (Gla) in the liver which is an essential for Prothrombin (or factor II) and also factors VII, IX and X. It is well known that these factors participate, in the coagulation of blood.

(b) Some other proteins also contain Gla and require vitamin K for their synthesis e.g. osteocalcin, a bone protein made by osteoblasts. (4)

**Requirement & intake**

No recommendations are given by the ICMR. The US authorities recommend an intake of 120µg for males and 90µg for females.

**Measurement**

Coagulation assays are traditionally used for screening of vitamin K deficiency. Under-carboxylated vitamin K dependent proteins that are produced when vitamin K is in short-supply or is blocked by antagonists e.g. warfarin, can be assayed.

**Deficiency**

This is characterized by poor blood clotting and results in low prothrombin activity. Neonates are born with very low stores of vitamin K due to sterility of intestines (and absence of bacteria producing vitamin K). So neonates are given an injection of this vitamin at birth. Adults rarely manifest the deficiency, but can be seen in cases of obstructive jaundice as lack of bile leads to poor absorption of vitamin K. The anticoagulants warfarin and dicoumarol can cause a deficiency.

Vitamin contents of common food items are given in Table - 1 on next page.

Table - 1 : Vitamin content of selected food items (per 100g) (2)

| Food stuff | Carotene (µg) | Thiamine (mg) | Riboflavin (mg) | Niacin (mg) | Folic acid (µg) | Vitamin C (mg) |
|---|---|---|---|---|---|---|
| Wheat flour | 25 | 0.49 | 0.17 | 4.3 | 35.8 | 0 |
| Rice polished | 0 | 0.06 | 0.06 | 1.9 | 8 | 0 |
| Bajra | 132 | 0.33 | 0.25 | 2.3 | 45.5 | 0 |
| Maize dry | 90 | 0.42 | 0.1 | 1.8 | 20.0 | 0 |
| Bengal gram | 189 | 0.30 | 0.15 | 2.9 | 186 | 3 |
| Soya bean | 426 | 0.73 | 0.39 | 3.2 | 100 | - |
| Beans | 187 | 0.10 | 0.06 | 0.7 | 45.5 | 24 |
| Spinach | 5580 | 0.03 | 0.26 | 0.5 | 123 | 28 |
| Carrot | 1890 | 0.04 | 0.02 | 0.6 | 15 | 3 |
| Groundnut | 37 | 0.90 | 0.13 | 19.9 | 20 | 0 |
| Guava | 0 | 0.03 | 0.03 | 0.4 | - | 212 |
| Amla | 09 | 0.03 | 0.01 | 0.2 | 600 | |
| Egg | 420 | 0.1 | 0.40 | 0.1 | 78.3 | 0 |
| Liver sheep | 6690 | 0.36 | 1.7 | 17.6 | 188 | 20 |
| Milk cow | 53 | 0.05 | 0.19 | 0.1 | 8.5 | 2 |
| Fish (Hilsa) | - | - | - | 2.8 | - | 24 |
| | | | | | | |

# Minerals

Minerals are required in small quantities and constitute only a small portion of the body weight but enter into the metabolism to a much greater degree than their mere weight indicates. A large portion of the ash of the body is composed of calcium, magnesium, sodium, potassium, phosphorous, sulphur and chlorine. The main functions of the minerals include: providing rigidity and relative permanence to the bones and teeth; providing essential elements for the formation and activities of the muscular, glandular, neural, and epithelial tissues; forming components of enzyme systems; and providing dynamic characteristics to the intra and extra cellular fluids for regulation of pH, osmotic pressure and electro-neutrality and those of secretion and excretions. (1)

## Classification

Minerals can be classified into macrominerals and microminerals. Macrominerals also referred to as major minerals are distinguished from the microminerals by their occurrence in the body. Taking this as criterion, various definitions of macrominerals have evolved, such as “those which constitute atleast 0.01% of body weight (5g in a 60 kg man)” ; or a more quantifiable and unambiguous definition like “mineral whose requirement is more than 100mg per day”. Calcium, phosphorous, magnesium, sodium, potassium, chloride and sulphur are the macrominerals. (2)

A precise definition of microminerals or trace elements has not been established. Some define trace elements as those that comprise less than 0.01% of total body weight or more appropriately those which are needed in a concentration of less than 1ppm. (3) These were initially known as trace because their concentration in tissues could not be easily ascertained by early analytic methods. (4) Iron appears to be the mineral that divides the macrominerals from microminerals. Thus a trace element (or micromineral) can be defined as one that is required by the body in the concentration equal to or less than that of iron. (5)

An element is termed 'essential' if a dietary deficiency of that element consistently results in a suboptimal biological function that is preventable or reversible by physiological amounts of the element. (6) Microminerals include iron, zinc, iodine, copper, manganese, molybdenum, selenium chromium and flourine. Cobalt, nickel, tin, silicon vanadium, arsenic and boron can be classified as ultra-trace elements. (2)

## Calcium

Calcium is essential for the building of bones and teeth. It is the most abundant mineral in the human body, maximum is deposited as hydroxyapatite, in bones and teeth. Constant levels of calcium in the body/ plasma is maintained under the influence of parathyroid hormone and calcitonin. Factors promoting absorption of calcium are vitamin D, proteins and lactose.

### Sources and losses

Rich sources of calcium are milk and milk products, ragi, fish which is eaten whole, custard apple (Sitaphal), dried fruits such as raisins, apricots and dates, and betel leaves with lime, pulses and tofu.

Calcium in food is not uniformly available to the body e.g. calcium in vegetables and fruits is poorly absorbed due to the presence of oxalic acid in these foods which forms insoluble calcium oxalate. Spinach is one of the foods which is very rich in oxalic acid. Phytic acid in the pericarp of cereal grains unites with calcium to form phytin, which is not absorbed. However, many cereals such as rye and wheat contain an enzyme phytase, which splits phytic acid so that it no longer binds calcium and makes it available for absorption. Excess of fatty acids, particularly saturated fatty acids in the small intestine may form insoluble soaps with calcium and may carry significant amount of calcium into faeces. Calcium in milk and dairy foods is more readily absorbed. (7, 8)

### Functions

(a) Calcium is essential for providing the structural rigidity to bones and teeth.

(b) It is responsible for the maintenance of optimum excitability of the nervous and muscular tissues.

(c) It has an important role in the coagulation of blood as factor IV.

(d) It acts as a co-factor for a number of enzymes e.g. lipase. (9)

### Requirement and intake

The suggested levels for calcium intake for adult men and growing children are 400 to 600mg/day.In case of pregnant and lactating women it is 1000mg/day. (10)

### Deficiency

Plasma Calcium levels are tightly controlled and are not usually affected by dietary insufficiency in healthy adults. Reduction in the level of circulating ionised calcium produces a clinical condition known as tetany. This is characterized by twitching of muscles of face, hand and feet. Cardiac arrhythmias may also result. A long term calcium deficiency during the bone formative age can cause stunted skeletal growth and a low bone density. Vitamin D deficiency leads to rickets in children due to poor calcium absorption. (9)

## Phosphorus

Phosphorus is the most important macromineral next only to calcium. Calcium utilization is closely linked to phosphorus as calcium is deposited as calcium phosphate. An adult human body contains about 400-700 g of phosphorus as phosphate, most of this occurs in

bones and teeth. (10)

**Sources**

Phosphorus is widely distributed in food stuffs and therefore, its deficiency rarely occurs. Milk, milk products, cereals, meat, fish, nuts, fruits and vegetables are good sources. A large part of phosphorus present in vegetable foods occurs in combination with phytin (fibre) and is available to the body only to the extent of 40-60 percent.

**Functions**

(a) It is essential for the formation of bones and teeth along with calcium as hydroxyapatite.

(b) It also plays an important role in all metabolism for derivation of energy from the phosphate bonds in adenosine triphosphate (ATP).

(c) It is an important constituent of nucleic acids, phospholipids and membranes. (11)

**Requirements**

It is suggested that phosphorus intake should be about 1 g per day that is about twice as great as that of calcium. (10)

**Deficiency**

Phosphorus deficiency is unlikely to occur as it is widely available in foodstuff. However hypophosphataemia may occur in pathological conditions (sepsis, liver disease, alcoholism, diabetic ketoacidosis) patients on prolonged parenteral nutrition, hypophosphataemic rickets and excessive use of aluminium-containing antacids. (9)

## Sodium

An adult male has total body Sodium of about 92 g, almost equally divided into the extracellular fluid and bone. In the blood and interstitial fluid it is found to be largely combined with chloride & bicarbonate. Intracellular fluid contains about a third of the sodium content of the extracellular fluid (9).

**Sources**

Sodium chloride is the best and most common source of sodium; 3 g salt is roughly equivalent to 1.2 g of sodium. Indian diet is particularly rich in sodium (pickles, chutneys, etc.). It is also present in food additives like monosodium glutamate, mainly used in Chinese cuisine.

Absorption takes place from the stomach and the entire alimentary tract rapidly. Excretion takes place through urine and sweat. (10)

**Functions**

(a) Sodium is the main cation in the extracellular fluid of human body.

(b) It is important in the blood pressure regulation

(c) Sodium is an important cation in maintaining the transmembrane electrolyte gradient.

(d) Acid-base regulation is a function of sodium. It also maintains the osmotic pressure

(e) It is a vital component of the electrophysiological control of muscles and nerves.

(f) It takes part in the structure of cartilage and muscle cells. (9)

**Requirement**

The daily intake varies from 2 to 20 gm/day. The recommended daily intake of sodium chloride is about 5 g. (10)

**Deficiency**

Excessive sweating as in hot and humid climates and extreme exertion, diarrhoea and dehydration can lead to sodium deficiency.

## Potassium

The adult human body contains about 250 g of potassium. Potassium occurs widely in foodstuffs, so there is little likelihood of its deficiency. It is the principal intracellular cation.

**Sources**

Most foods contain useful amounts of potassium, particularly those of vegetable origin. Fruits like banana, apricots, fruit juices, vegetables including potatoes, pulses, meat and whole grain cereals are good sources. Chocolates and coffee are also good sources.

**Functions**

Along with sodium, potassium too is involved in acid-base regulation and the electrophysiology of nerves and muscles. These two ions are essential for the cellular uptake of molecules through the sodium-potassium pump. (9)

**Requirements**

The daily requirement of potassium has not been determined accurately. (10)

**Deficiency**

Dietary deficiency is not common. However deficiency could be caused by diarrhoea, vomiting, dehydration, purgatives, chronic acidosis or alkalosis, diuretics, etc. Potassium deficiency affects the electrophysiology of cell. It may cause cardiac arrhythmias and muscle weakness. (9)

## Magnesium

All human tissues contain small amounts of magnesium. The adult body contains about 25 g of the metal and greater part of this amount is present in bones in combination with phosphate and bicarbonate. About one fifth of the total magnesium in the body is present in the soft tissues, where it is mainly bound to protein. Inside the cells, the metal is concentrated within the mitochondria.

**Sources**

Most foods contain useful amounts of magnesium, particularly those of vegetable origin. Green vegetables, pulses, meat, nuts and whole grain cereals are good sources. Hard drinking water may make a significant contribution to magnesium intake.

**Functions**

(a) Magnesium Is an integral part of bones and teeth.

(b) Within the mitochondria it is a co-factor for co-carboxylase and co-enzyme A and is concerned

with Intracellular energy metabolism.

(c) It is important in the replication of DNA, synthesis of proteins and RNA.

(d) It is essential for muscle and nerve cell function.

**Requirements**

Requirements are estimated to be about 350 mg/day for adults. (10)

**Deficiency**

It is unlikely that magnesium deficiency would arise in man from simple lack of food. Vitamin D appears to increase magnesium absorption from the intestine. Excessive losses of magnesium in the faeces or urine occur in many diseases e.g. renal or adrenal disease, malabsorption, use of some drugs (e.g. diuretics) and in re-feeding syndrome. Magnesium deficiency leads to apathy and muscular weakness and sometimes to tetany, convulsions, cardiac arrhythmias and cardiac arrest. (9)

## Iron

It is one of the most important micronutrients and is of fundamental importance to life. The body of an adult human contains about 4 g of iron, of which more than two thirds (about 2.4g) is present in haemoglobin. The rest of the iron in the body is present as a reserve store in liver and to a lesser extent in the kidney, spleen and other organs.

**Sources, Transport & Losses**

The sources of iron can be divided into two main groups:

(a) Haem iron sources

These are essentially the non-vegetarian sources of iron eg meat, fish and eggs. Milk is considered a poor source of iron but breast milk is an efficient source for the infant, as iron is absorbed well from it.

(b) Non-haem iron sources

These are the vegetarian sources, namely cereals, dark green leafy vegetables, pulses, nuts and dry fruits. Absorption of iron from these foods is only 10 to 20 percent.

Non-haem iron is poorly absorbed (1 - 20%) and is influenced by dietary constituents. Certain compounds like Phytic acid (in cereals, fibre), polyphenols (in plants), tannins (in tea), phosphates (in milk and eggs) present in foods of vegetable origin inhibit the absorption of iron. There are also factors in the diet that increase non-haem iron absorption, such as red meat, fish, chicken and liver. Ascorbic acid and low pH also enhance the absorption of non-haem iron. Haem-iron is absorbed directly into the mucosal cells where iron is released by haem oxidase and then bound to transferrin.

Maximum absorption of iron takes place in duodenum and upper part of small intestine. The amount of iron absorbed from a given meal depends to a large extent on the iron status of the individual. Iron absorption increases during growth and pregnancy.

When the body needs iron it passes directly through the mucosal cells and is transported by transferrin to the bone marrow. If iron is not required it is stored in the mucosal cells as transferrin. It will be lost in faeces when the mucosal cells are exfoliated. Excess iron is stored as ferritin or haemosiderin in the liver, spleen, or bone marrow. It can be mobilized from these stores when demand is increased.

It is lost mainly during menstruation and from the gastrointestinal tract. Physiological losses from all other routes (exfoliation from alimentary, urinary and respiratory tract and by dermal and hair losses and losses in the sweat) also occur. Excretion of iron is very low (about 1 mg/day in men).

**Functions (9, 11)**

(a) Iron is a component of haemoglobin and myoglobin.

(b) It is also a constituent of important enzymes like cytochromes, catalase, peroxidase, etc. As a part of these haemocomplexes and metallo-enzymes, it serves important functions in oxygen transport and cellular respiration.

(c) It is also involved in cellular immune response for appropriate functioning of phagocytic cells.

(d) Iron is known to play a part in imparting an optimum cognitive functioning of the brain.

**Requirements**

The requirement of iron is quite small, in the vicinity of 1 to 3 mg/day, depending on the age, sex and the physiological status. But since the absorption of iron is rather poor, diet should contain 10 to 25 fold iron. Hence the RDA of iron is about 28 mg for males and 30 mg for females (38mg for pregnant females). (10)

**Deficiency**

Iron deficiency anaemia is the most common nutritional deficiency in the world. It is estimated that up to half of all women and two-thirds of all pregnant women have anaemia esp. in developing countries. The common physical signs include: pallor, fatigue, breathlessness on exertion, insomnia, giddiness, anorexia and tachycardia and in severe cases oedema. (9)

## Iodine

*"Iodine-deficiency is a colossal public health problem in*

**Recent Advances (Iron)**

**Pro-oxidant activity of Iron**

There is no doubt in the fact that iron is an important mineral involved in various vital metabolic functions. But lately, a pro-oxidant role of iron is being studied. Excess iron promotes lipid per-oxidation and tissue damage in vitro. There is a possibility that, via these pro-oxidant effects, disturbances in iron metabolism play a pathogenic role in many diseases. Therefore iron may be potentially harmful in some situations, especially during preexisting inflammation and disease. (12) For more details section on 'Antioxidants' (Applied

*India. Survey upon survey has shown that out of the 26 million children born each year, as many as 13 million are at risk of suffering from iodine deficiency disorders."*

**- Union Health Minister Shri Anbumani Ramadoss (2005)**

It is an essential trace element because it is an integral component of the thyroid hormones: thyroxine and triiodothyroxine, both of which have important metabolic roles. Iodine deficiency is endemic in the mountainous areas with poor soil content such as the sub-Himalayan regions. This is due to iodine being washed from the soil. Its deficiency causes the widely prevalent preventable iodine deficiency disorders that affect all ages: abortions, still births, cretinism, mental retardation, deaf-mutism, dwarfism and goiter.

### Sources and losses

The presence of iodine in the food is a function of the iodine content of local soil. Among the natural foods the best sources of iodine are seafoods and vegetables grown on iodine-rich soils. Dairy products, eggs, cereal grains, legumes and green leaves (spinach) are also reasonable sources of iodine. Water contains traces of iodine which contributes to as much as 10% of our total iodine intake.

Certain vegetables of *Brassica* group such as cabbage, cauliflower and radish contain goitrogens such as thiocyanates and cynoglycosides. Consumption of large quantities of these foods may lead to the development of goiter by making the iodine present in food unavailable to the body. Goitrogens are inactivated by heating. Dietary iodine absorbed from the small intestine follows two main pathways within the body. Approximately 30 percent is used up by the thyroid gland for the synthesis of thyroxine hormone; the remainder is excreted in the urine. (9)

### Functions

(a) Iodine is a component of the thyroid hormones thyroxine ($T_4$) and triiodothyronine ($T_3$).

(b) Thyroid hormones maintain the body's metabolic rate by controlling energy production and oxygen consumption in cells.

(c) They are required for normal growth and development.

(d) In the fetus and neonate normal protein metabolism in the brain and CNS requires iodine.

### Requirement

The daily requirement of iodine is 150µg for an adult. (10)

### Deficiency

Endemic goiter of varying degree is found in a large proportion of the population in India, where the soil and thus food materials are deficient in iodine. Iodine deficiency of varying degree is found in almost all districts in India.

(a) **Adults:** Iodine deficiency disorder (IDD) in adults results in hypothyroidism and raised levels of TSH, which cause hyperplasia of thyroid tissues resulting in goitre. Hypothyroidism is characterized by lethargy, poor cold tolerance, bradycardia, and myxoedema.

(b) **Fetus & infants:** In the fetus, IDD results in cretinism. This is characterized by mental retardation, hearing, speech defects, squint, disorders of gait, and growth retardation.

(c) IDD is also linked to an increase in the rates of still birth, miscarriage, and infertility.

Fortification of salt with iodine is carried out to reduce IDD. The PFA act has specified an iodine concentration of 30 and 15 PPM in salt at source and consumer ends respectively thereby providing 150 mg of iodine in 10 gm of salt.

## Fluorine

It is normally present in the bones and teeth and is essential for the normal mineralisation of bones and formation of dental enamel.

**Recent Advances (Iodine)**

**Detection of iodine in salt**

It must be appreciated that mere iodination of salt does not ensure availability of iodine to the consumer. Iodine has a property to 'sublimate' and is thus constantly lost from its 'iodized vehicle (salt)' on keeping. It is therefore recommended to consume the iodized salt within a period of 6 months of iodization. There is a simple inexpensive rapid test (UNICEF) available to detect the level of iodine in salt. Test kits can be obtained by directing requests to MBI, 85 GN Chetty Road, III Floor, T

### Sources

Fluorine is widely but unevenly distributed in nature. It is found in many foods, but seafoods, cheese and tea are rich sources. However, the main source of fluorine to man is drinking water. The fluoride content of drinking water in India is about 0.5 mg/l but in fluorosis endemic areas, the natural waters have been found to contain as much as 3 to 12 mg of fluoride/l. A concentration of 0.5 to 0.8 mg/l in water is considered a safe limit in India. In temperate climate where the intake of water, is low, the optimum level of fluorine in drinking water is accepted as 1 mg/l. (14)

### Deficiency

Deficiency of fluoride in water below 0.5 mg/1 is usually associated with dental caries.

### Excess

Ingestion of large amounts of fluorine (>2-3ppm in water) is associated with dental and skeletal fluorosis. Skeletal fluorosis has been reported to be health problem in rural districts of Andhra Pradesh, Haryana, Karnataka, Kerala, Punjab, Rajasthan and Tamil Nadu. Scientists working at the National Institute of Nutrition Hyderabad found new form of fluorosis characterized by *genu valgum* and osteoporosis of the lower limbs in some districts of Andhra Pradesh and Tamilnadu.

## Zinc

Zinc is present in small amounts in all tissues of the body.

Total content of the body is over 2.0 g.

**Sources**

Zinc is widely distributed in food stuffs of both animal and vegetable origin. Good sources of zinc are meat, whole grains and legumes. Its bioavailability in vegetable foods is poor due to presence of phytate which impairs its absorption.

**Requirement**

The daily requirement of Zinc is about 15 mg in men and 12 mg in women. (15)

**Functions**

(a) It is part of over 100 enzymes including carbonic anhydrase, alcohol dehydrogenase, alkaline phosphatase, super oxide dismutase, collagenase, leucine aminopeptidase, aldolase, RNA polymerase and pancreatic carboxypeptidase; and is thus of importance in protein and carbohydrate metabolism, bone metabolism, and oxygen transport.

(b) Zinc is a powerful antioxidant.

(c) Zinc is important in the immune response and gene expression.

(c) Zinc stabilizes the structure of DNA, RNA, and ribosomes. (9)

**Deficiency**

A clinical syndrome characterized by small stature, hypogonadism, mild anaemia and low plasma zinc occurs in older children and adolescents in poor peasant communities in Iran and elsewhere in Middle East, where the staple diet is unleavened bread. The zinc intake is low and its absorption is impaired by phytate in the unleavened bread. However the common deficiency symptoms are:

(a) Severe deficiency results in growth retardation, failure to thrive, delayed sexual maturation esp in children.

(b) Deficiency of zinc impairs cellular immune mechanism while excess of it may depress neutrophils.

(c) Zinc deficiency may present as a tetrad of symptoms comprising of neuro psychiatric changes, dermal lesions, diarrhoea and alopecia (Acro - dermatitis Enteropathica). Zinc supplementation has been found useful in these conditions. (9,15)

## Copper

It is an essential trace element as it is a component of many metallo-enzyme systems and iron metabolism is closely dependent on it. The amount of copper in the adult body is estimated to be 80 -100mg. Copper is widely distributed in nature and therefore primary copper deficiency in adults has never been reported in adult man. Even poor diets provide enough copper for human needs.

**Sources**

Meat, nuts, cereals, fruits

**Functions**

Many metalloenzymes contain Copper. These enzymes have the following important functions: (9)

Caeruloplasmin (Ferrioxidase 1)- Iron oxidation & transport

| | |
|---|---|
| Superoxide dismutase | - Antioxidant |
| Cytochrome-c oxidase | - Electron transport |
| Dopamine hydroxylase | - Hydroxylation of Dopa in brain |
| Tyrosinase | - Formation of melanin |
| Clotting factors V and VIII | - Thrombogenesis |

**Requirement**

Suggested daily intake is 1-2 mg. (10)

**Deficiency**

Copper deficiency is rare. Hypocupraemia occurs in patients with nephrosis, Wilson's disease and sometimes in protein energy malnutrition. Neutropaenia is the commonest documented abnormality of copper deficiency. Infants, especially those who are premature, may develop copper deficiency which usually presents as chronic diarrhoea. Neutropaenia and later anaemia develop and they do not respond to iron. Menke's disease, a rare hereditary defect of copper absorption is invariably fatal. Copper deficiency may be a risk factor for coronary heart disease as it has been associated with raised plasma cholesterol levels and heart-related abnormalities.(9)

## Chromium

There is some evidence that chromium is an essential nutrient for man. Investigations of the relationship of the element to carbohydrate metabolism are suggestive of its possible role in human nutrition. Chromium is believed to be part of an organic complex known as the 'glucose tolerance factor' (GTF), which potentiates the action of insulin. The evidence for essentiality of chromium comes from observations of patients receiving total parenteral nutrition who develop diabetic symptoms. The symptoms respond to chromium treatment but not insulin. Studies on the use of chromium in the management of type 2 diabetes are not conclusive. Chromium may participate in lipoprotein metabolism.

**Sources**

The richest sources of chromium in the diet are meat, whole grains, legumes, and nuts. It is also present in significant amounts in drinking water.

**Requirement**

There are no RDAs for chromium. The average daily intake of chromium for adults is estimated as 0.1 mg. (10)

**Deficiency**

Chromium deficiency in man is evidenced by impairment of glucose tolerance, low tissue concentrations and low concentrations of glucose in urine and raised plasma cholesterol and triglyceride levels, weight loss, neuropathy, depressed respiratory quotient and abnormal nitrogen metabolism. Deficiency in humans has only been observed in patients receiving long-term total

parenteral nutrition. (9)

## Selenium

There is a resurgence of interest in the mineral selenium due to its antioxidant properties. It is an essential component of glutathione peroxidase, an important enzyme.

### Sources

Meat, fish, nuts and eggs are good sources. Lacto-ova vegetarians and vegans may be at risk of deficiency.

### Functions

Selenium is an integral part of over 30 selenoproteins; the most important of which are glutathione peroxidases and iodothyronine deiodinases. Glutathione peroxidase has an important role in the detoxification of peroxides and free radicals. Iodothyronine deiodinases are involved in the production of triiodothyronine from thyroxine. It also contributes to antibody responses, the production of eicosanoids as well as cytotoxicity of natural killer cells. (9)

### Requirements

Recommended daily intake is 70 µg. (11)

### Deficiency

Its deficiency has a wide range of symptoms, not all attributable to glutathione peroxidase. Its deficiency is associated with increased coronary artery disease. Keshan disease (endemic cardiomyopathy) in China and Kashin Beck syndrome, an osteo-arthropathy in children of 05-13 years age is seen in selenium deficient areas. (9,10)

## Molybdenum

**Recent Advances (Selenium)**

**Selenium and cancer prevention**

Epidemiological studies reveal an inverse relationship between serum selenium and cancers at several sites including prostate, colon, lung and non-melanoma skin cancers. (16)

Evidence that Molybdenum is an essential trace element is based on the fact that it is part of the molecular structure of the three enzymes; xanthine oxidase, sulphite oxidase and aldehyde dehydrogenase.

### Sources

Meat, nuts, cereals, bread, green vegetables are good sources. The amount of Molybdenum present in plants varies greatly depending on the soil, being relatively high in those grown on neutral or alkaline soil with a high content of organic matter and low in those grown on acid sandy soil. Consequently, dietary intakes vary but are usually within 0.5 to 2.0 mg/day.

### Function

Molybdenum functions as co-factor in xanthine oxidase, suiphite oxidase, and aldehyde oxidase and is involved in the metabolism of purines, pyrimidines, quinolines, and sulphites.

### Requirement

There are no recommended intakes but safe intakes are believed to be between 0.15 to 0.5 mg. (10)

### Deficiency

Primary deficiency is unknown in humans, but an inborn error of metabolism results in abnormal coenzyme production. It is characterized by abnormal urinary metabolites, neurological and ocular problems, and failure to thrive. The condition in the most severe cases can be fatal. Association between deficiency of Molybdenum and cancer of mouth and oesophagus has been recently reported.

## Cobalt

It is a constituent of vitamin $B_{12}$, an essential nutrient for man for methionine biosynthesis and propionate metabolism. It has been suggested that cobalt may be necessary for the first stage of thyroxine production i.e. capture of the iodine by thyroid. Cobalt is present in many foods, in cooking utensils, and even in atmosphere (at least in industrial cities). It is readily absorbed in the intestinal tract, but most of the absorbed element is excreted in urine.

# Nutritive Values of Commonly used Food Items

Our food comprises of many foodstuffs. The major foodstuffs are cereals, pulses, nuts, oilseeds, sugar, jaggery, fruits, vegetables, roots, tubers, milk, eggs and flesh foods. A brief description of the basic food items used is given here.

## Cereals

These form the staple food for human diet as they are cheap and have a high energy value. In an agricultural country like ours, rice, maize, wheat, and millets form the bulk of the diet. Thus the nutritive quality of the staple cereals is of great importance in India. Cereals are rich sources of carbohydrates and moderate sources of proteins. A predominantly cereal diet should invariably contain supplementary sources of protein; for vegetarians, pulses are very valuable in this respect.

Cereals contain no vitamin C and little carotene. Whole (unrefined) cereals are relatively good sources of the vitamin B complex, whereas refined cereals such as white flour and highly milled rice lose much of their vitamin content in processing. This is because the vitamins are concentrated in the outer layer of the whole grains, which are removed by machine milling. (1)

Machine milling and refining cause a considerable deterioration of nutritive value of staple human foods and of public health. For example, beriberi is endemic in countries where polished rice is habitually eaten. On the other hand, the absorption of nutrients decreases with an increase in the extraction rate. As a result the whole meal flour has lower energy value than white flour. Nevertheless, the lower digestibility of the protein of whole meal flour is compensated by higher contents and biological value of its proteins. (2)

Much of the phosphorus is present in the form of phytic acid in the fibrous part of the grain which forms insoluble phytates with calcium and iron, thus preventing absorption of these minerals. Atta produced for the Armed Forces is of 85 percent extraction, and not more than 5 percent bran is permitted to be removed during milling.

Parboiled rice is the only cereal which does not suffer appreciably when machine milled. The parboiling process consists of steaming the paddy after preliminary soaking so that the outer husk splits and becomes easier to remove. This also causes the B group vitamins in the outer layers to diffuse in to the interior of the grain. Rice supplied in Armed Forces rations is either undermilled or parboiled.

## Pulses

These comprise dried peas, beans, dals and grams. Dals are arhar, moong, urd massor or channa. They have high protein content, although with biological values inferior to foods of animal origin like meat, fish eggs and milk. They are, nevertheless very suitable for supplementing the vegetarian diet. Pulses are cheap and a valuable source of calcium, iron and vitamin B. Bengal gram (dal channa) and to a lesser extent green gram (dal moong) contain a small amount of ascorbic acid in the dry state. Soya bean is a pulse which has a high protein and fat content. The nutritive value of soya bean proteins is equivalent to milk proteins even though the protein quality is inferior. The consumption of unprocessed soya bean as dal is however, not acceptable to many. (1)

The ascorbic acid content of all unsplit pulses can be increased by germinating or sprouting. Whole unsplit dal or gram is first soaked in water for 12 to 24 hours and then spread on a damp blanket in a thin layer to allow access of air and covered with another blanket kept damp by sprinkling water. In a few hours small sprouts appear; when these are 10 to 20 mm long the process is complete. The vitamin C content is maximal after about 30 hours of germination. Boiling for 10 min causes a loss of vitamin C by 15 to 30%. Germination causes an important increase in vitamin B also. (3)

## Meat

It is a rich source of high quality protein and a good source of most B vitamins esp. nicotinic acid. It contains principles necessary for the prevention of nutritional anaemia and promotes haemopoiesis and thus has special blood forming properties. The protein of meat is qualitatively as good as that of fish, egg, milk, cheese and other dairy produce. Meat is rich in phosphorous but poor in calcium. Liver has first rate source of protein, vitamin A and the whole of the vitamin B complex. Meat extracts are of use in hospital dietetics on account of their mild stimulant action on the secretion of gastric juice. Meat extracts must also be regarded as a reasonably good source of vitamins of the B complex. The forms of preserved meat that may be issued in the Armed Forces rations are meat curried (mince and chunk), solid meat pack, dehydrated meat and accelerated freeze dried (AFD) meat.

## Milk

This being the sole food for growing young animals, it is as nearly complete a food as exists in nature. All the important nutrients are well represented in milk except iron, nicotinic acid and ascorbic acid. On the average, one liter of cow's and buffalo's milk respectively yield 32 g and 43 g of protein, 41 g and 88 g of fat, 44 g and 50 g of lactose, 520 mg and 480 mg of retinol, 670 and 1170 Kcal (2.8 to 5.02 Mj) of energy and 1200 mg and 2100 mg of calcium. (1)

Milk proteins are caseinogen (85%), lactalbumin (12%) and lactglobulin (3%). These proteins are of high biological value. Milk fat is an emulsion of extremely fine particles of

the glycerides of butyric, palmitic and oleic acid rendering it easily digestible and this is especially so in cow's milk. Newly drawn milk contains 2 mg of vitamin C per 100 ml but this readily disappears on storage, heating or processing in any other way.

### Curd

When lactose in milk is broken down to lactic acid by bacterial (lactobacilli) action, the proteins are coagulated by the acid and the curd is formed. Curd and whole butter milk have the same nutritive values as that of the original milk from which they are prepared and are easily digestible. Whole milk, curd and butter milk, are all very good sources of protein, calcium, vitamin A and riboflavin. They are indispensable for the feeding of children and adolescents up to young adult age, pregnant women, lactating mothers, patients and convalescing persons. Skimmed milk and butter milk made from it have less fat content than the whole milk due to extraction of butter.

### Cream, butter and ghee

Cream, butter and ghee are gradations of fat extracted from milk. Cream has nutritive value in between whole milk and butter. Good butter should not contain more than 16 percent of water and not less than 80 percent of fat. 100gm butter yields about 730 Kcal (3.05 Mj) and 960 mg of retinol. 100 g of ghee yields 900 Kcal (3.76 Mj) and 270 mg of retinol, which is, however, destroyed if ghee is used as a frying medium.

### Ration issue of milk

The milk issued in the ration is either a mixture of buffalo's and cow's skimmed milk, designated as standard milk, or a mixture of buffalo's whole milk and powder skimmed milk, designated as blended milk. The fat content of both these types of milk should be 3.7%, solids not-fat (SNF) 8.5 to 9.0%, and total solids not less than 12.5%. (4)

When fresh milk cannot be made available whole powdered or tinned milk is supplied. Tinned milk may be condensed, evaporated or homogenized; condensed milk may be sweetened or unsweetened. Condensed milk contains 50 percent cane sugar, which is a good preservative. Dried or powered milk is reconstituted by adding 7 volumes of boiled water just before consumption. Tinned milk should be reconstituted as per instructions given on each tin. Tinned or powered milk after reconstitution conforms to the specifications laid down for fresh standard or blended milk except that it is deficient in vitamin C.

### Eggs

Eggs contain all the nutrients required for the embryo. They have a high nutritive value. The proteins are of a high biological value. The NPU of egg protein is 100 and is taken as the standard protein, to compare other proteins with. The fat is present in the yolk. It is finely emulsified and hence easily assimilated. The minerals and vitamins exist in the yolk, which is also a valuable source of calcium, phosphorus, iron and vitamins A and D. The white of the egg is one of the best sources of riboflavin.

Eggs in rations are issued by number. For average estimations, the minimum weight laid down is not more than 25 eggs to a Kg, and not less than 35g per egg. Eggs are issued in hospital dietary and high altitude rations as well. In other rations they are issued in lieu of meat. Egg powder may be issued if fresh eggs are not obtainable.

### Vegetables

Vegetables esp. green leafy vegetables are rich in carotene, ascorbic acid, calcium, iron and riboflavin. The carotinoids and vitamin C possess antioxidant properties. The carotene of green vegetables like drumstick, amaranth and methi is better utilized than of yellow vegetables. A progressive loss of vitamin C occurs when vegetables are stored, bruised and cut. Cooking of green leafy vegetables in small quantity of oil increases the retention rate of carotenes to between 41 to 100%.

Gourds are generally of poor nutritive value; but the bitter gourd is relatively rich in ascorbic acid, and the yellow pumpkin is a fairly good source of carotene. Root and tuber vegetables are of variable nutritive value. Most of them contain moderate amounts of ascorbic acid. The carrot is outstandingly rich in carotene. Potatoes and sweet potatoes having high carbohydrate content have a good fuel value and contain moderate quantities of ascorbic acid. The tomato has good ascorbic acid and riboflavin contents. Onion has no outstanding nutritive properties, but is virtually irreplaceable because of its value as a flavouring agent and appetizer.

Canned vegetables have nutritive values almost equal to that of fresh, well cooked vegetables, except that 50% vitamin C is destroyed during processing. Dehydrated vegetables lose some ascorbic acid and vitamin A in processing and the remaining vitamin C is unstable. Vegetables processed through accelerated freeze dying process however retains most of the nutrients to a very high degree. (1)

### Fruits

Fruits are classified into citrus, non-citrus and dried varieties. They are inexpensive sources of antioxidants. Citrus fruits are rich in vitamin C. Guavas are a very rich source of vitamin C. Papaya and mango are rich in carotene and moderately rich in vitamin C. Banana and plantain have energy value but are not particularly good source of vitamins. Bottled lime juice supplied to hospitals and canteens are usually synthetic and completely devoid of vitamin C. The loss of vitamin C in cooking of fruits and in the process of canning and bottling is less than vegetables owing to the acids in fruit juices. Dried fruits contain neither thiamine nor vitamin C. Dried apricots, prunes and yellow peaches are a good source of carotene. (1)

### Nuts

Nuts have a high fat and protein content and hence a high energy value. Groundnuts are a good source of vitamin B complex. The protein of groundnuts is of low biological value. Multipurpose food (MPF) is flour made from a mixture of 75 percent groundnuts from which fats have been extracted and 25 percent roasted red gram. It is rich in protein and is fortified with vitamins and minerals.

## Fats and Oils

Vegetable oils such as mustard, groundnut, gingelly, coconut and safflower oils are widely used for cooking purposes. Vegetable fats (except red palm oil) are free of any vitamin A activity and contain predominantly unsaturated fatty acids. Coconut and palm oils are rich in saturated fatty acids. More details have been given in the section on lipids.

## Sugar

It is pure sucrose and is used for its sweetening effect and energy value. Excessive consumption of such purified food at the expense of energy provided in protective food lowers the vitamin, mineral and protein intake. On the other hand troops do benefit from a fairly liberal sugar ration: hot sweet tea is a traditional reviving agent for fatigued troops. Jaggery contains an appreciable amount of carotene and iron. Jams have the nutritive value of sugar & increase the palatability of diets. (5)

## Condiments, Pickles and Chutney

Most people use spices to flavour food and improve its palatability. They are essential to the culinary art and by stimulating the appetite improve health. They have little nutritional value as they are used in very small quantities. Green or dry chillies have a high carotene and vitamin C content. Pickles and chutney are appetisers. Tamarind has preservative effect on vitamin C if cooked along with vegetables. Turmeric, cloves and red chillies have been shown to have antioxidant properties.

## Beverages

By themselves tea, coffee or other non-alcoholic beverages have no special nutritive properties except for the sugar and milk added; but due to caffeine which is a stimulant for the higher centers of the brain, they help to relieve fatigue. If used in excess they may cause insomnia and tachycardia in some individuals. Recent studies show that they contain substantial amounts of antioxidants, which have distinct health benefits. Alcoholic beverages have an energy value of 6 to 8 Kcal (25.1 to 33.4 Kj) per ml. Authorization in ration scales is, however, not guided by its energy value but is considered from the point of view of its immediate psychological effects.

## Vitamin Concentrates

Vitamin concentrates are normally available through ASC sources for supplementing dietary deficiency to prevent diseases and preserve health; and through medical stores for therapeutic purposes to treat ailments. The multivitamin tablets available through ASC contain vitamin A 5000 IU, vitamin D 500IU, thiamine 2 mg. Riboflavin 3 mg. Nicotinic acid 20 mg and ascorbic acid 75 mg and other vitamins of B group, Zinc, Selenium etc. They should not be issued unless there are clear indications that the rations are deficient in vitamins. With special ration scales, when the tablets form a component part of the rations the tablets are incorporated in the pack or scales themselves and the issue is automatic.

When an outbreak of vitamin deficiency disease is anticipated through continued absence or severe shortage of supplies of fresh fruits and vegetables or of meat and milk and their substitutes, authority to recommend vitamin tablets is vested in the DDMS Command. The issue is done on the orders of the Army Commander. The scale of issue for prevention of disease is one tablet per man per day. The multivitamin tablets issued through medical stores are much costlier than the ration compound tablets issued through ASC sources and contain therapeutic doses of all vitamins, including 10 components of vitamin B group, and 8 important minerals. Therefore, the tablets obtained through medical stores should not be issued in lieu of the ration multivitamin tablets issued by ASC.

## Effects of Processing Foods

Processing of foods involves cooking, tinning, dehydration, freeze drying (pre-cooked or uncooked), pickling, bottling, smoking, or making jams. Variable quantities of nutrients are lost during processing. Processed foods, however, do not normally form the actual constituents of dietaries in the Armed Forces to any appreciable degree under normal conditions. Dried or tinned food stuffs have to be issued under adverse tactical or operational conditions or to tide over the temporary administrative /logistic breakdown.

### Cooking

Effects of cooking vary greatly according to the method of preparation, cooking and serving. The losses occur mainly due to destruction by heat and / or extraction into washing or cooking water which is not consumed. The latter is the more important of the two. The losses affect the vitamins and minerals. To minimize vitamin C destruction in green vegetables they should be used when fresh, stored in cool damp places; crushing and bruising should be avoided; the cooking time should be reduced to a minimum and cooking water be used up while cooking or added to other items being cooked at the time. Food should be served as soon as possible after it is cooked. It is better to allow it to cool and reheat when necessary rather than keep it hot; this conserves more vitamin C. Rapid frying before boiling leads to conservation of vitamin C by hydrolysis of oxidase enzyme. (1)

### Tinning

Generally speaking, tinned foods have the same nutritional values as cooked fresh foods and are good substitutes for fresh items. On the other hand, a diet based on fresh items offers a much greater variety than a tinned diet. For this and administrative and financial reasons a military ration composed of fresh foods is preferable to tinned rations.

### Dehydration, Drying and Freeze Drying

Dehydrated and dried foods are those from which

moisture has been extracted by evaporation. 'Dehydration' is a term used when the evaporation has been carefully regulated as part of the factory process under controlled temperature and moisture conditions, with the intention that the essential characteristics of the food should not be altered and perfect reconstitution should take place when moisture is replaced. 'Dried' food is generally prepared by exposure to sun, which doesn't reconstitute exactly to the original quality. Freeze-drying is carried out by subjecting the foodstuffs to freezing and

Table 1: Nutritive value of common foods* (per 100g) (1)

| Food stuff | Proteins (g) | Fat (g) | Fibre (g) | Carbohydrates (g) | Energy (Kcal) | Iron (mg) |
|---|---|---|---|---|---|---|
| Wheat flour | 12.1 | 1.7 | 1.9 | 69.4 | 341 | 4.9 |
| Rice polished | 6.8 | 0.5 | 0.2 | 78.2 | 345 | 0.7 |
| Rice parboiled | 6.4 | 0.4 | 0.2 | 79 | 346 | 1 |
| Bajra | 11.6 | 5 | 1.2 | 67.5 | 361 | 8 |

# Healthy and Unhealthy Diet

Not far back did we say "Eat drink and be merry!" Now the trend is changing, one tends to eat with caution. The notorious Roman banqueter was as uncomfortable as is the food over-indulgent of today. That, this truth was revealed to many is attested by the number of proverbs in various languages which instruct us the wisdom of moderation, for example :

'Eat only when hungry and drink only when thirsty, and never to leave the table with a feeling of satiety'

All this ancient wisdom prompts us to limit our food, then why does man eat or overindulge in eating? Why do we eat at all? The answer could be personal, philosophical, religious or merely a one liner 'because we feel hungry!'

## Why do we eat food: Functions of food

We eat to satisfy hunger, for satiety, to get energy for our day to day functioning. Food serves many functions in the body:

### (a) Food builds body tissues

The structural materials of food, proteins, minerals, vitamins and water are needed for growth and development. The food is also needed for the maintenance of the cells and tissues.

### (b) Food regulates body processes

Many a body processes are regulated by the 'fuel' supplied through food e.g. temperature control of the body, control of osmotic pressure, maintenance of hydrogen ion concentration of tissues, innumerable metabolic processes.

### (c) Food supplies energy

The macronutrients (carbohydrates, proteins and fats) supply energy. These provide constant source of fuel to the body. It is measured in terms of a kilo calorie or kcal, (the amount of energy required to raise the temp of 1kg water by 1°C).

### (d) Food gives us enjoyment

We want to enjoy food and entertain our guests with tasty food.

These requirements may be met by various combinations of the three major food constituents: carbohydrates proteins and fats, taken in different proportions. Although the actual distribution of each one of these nutrients in our daily diet is vital for good health, one hardly considers their proportion, as long as he enjoys the food. It must be appreciated that our lifestyle governs all facets of our life including our eating habits.

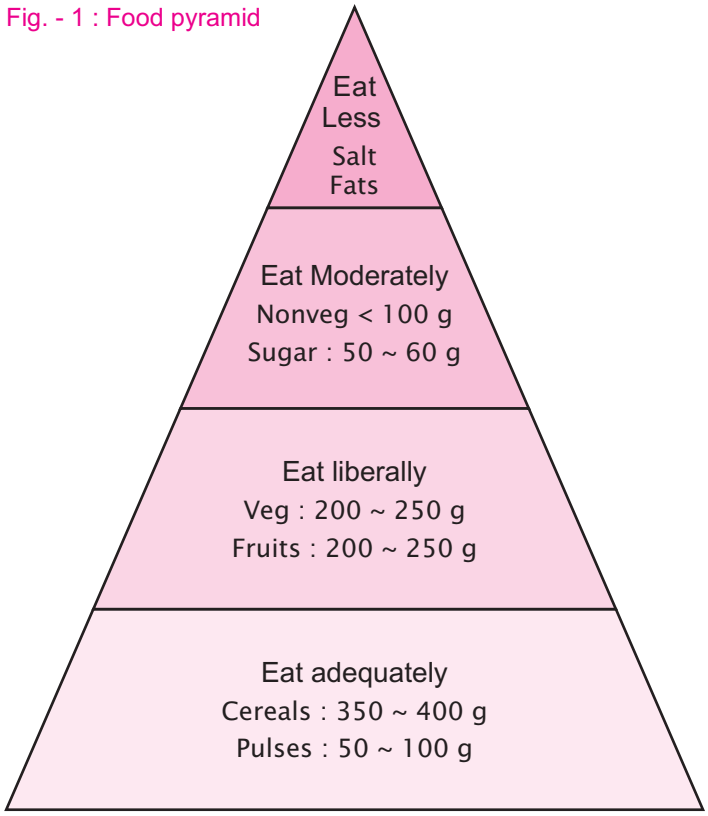
It is important to apply the knowledge of basic nutrition to real life situations to draw maximum benefits from it. We face some major nutritional problems in our daily life, both in the relatively healthy and those suffering from disease. Such situations arise mainly from the consumption of an unhealthy diet. Let us learn the basic principles of a healthy diet.

## Principles of a healthy diet

### Food Pyramid

The principles of a healthy diet for an average adult (2500 to 2800 kcal per day) can be summarized pictorially, through a food pyramid (Fig -1) (1). Foods depicted at the bottom of the pyramid (cereals, pulses, vegetables and fruits) are to be consumed in plenty. Foods in the middle of the pyramid, meat products and refined sugars, are consumed in moderation and the foods at the top (salt and oils) are sparingly consumed.

Fig. - 1 : Food pyramid



In other words, foods which give low calories (and low refined sugars), enough proteins, low fats and salts but lots of antioxidants, vitamins and natural fibre constitute a healthy diet. Such a diet is contributed to by whole grains, cereals, pulses, white meat, milk, low fat foods and plenty of fresh fruits and vegetables.

Besides fulfilling the biological requirement of

**Keeping bulk large and calories low ! An example...**

One liter of tomato soup and plain rice/dal will give the same satiety as one kg of butter chicken, but the former will give only 500 kcal while latter 4000 kcal. Therefore food items which are thin, watery, or made of grain, legumes & pulses give lesser calories than even much lesser quantities of fats and starchy foods. It is recommended to eat "low energy dense" items like fresh fruits, vegetables, raw salad or meals cooked with little amount of oil.

energy, food caters to the important psychological cue of satiety. So, one eats not only to meet the nutritional requirements, but also because one needs to be psychologically satiated each and every time he sits to dine. Such satiety depends on the "bulk" of food rather than the count of calories. Therefore the quantity of food, besides of course the quality also decides, as to which food is healthy or otherwise. Therefore one may aim to keep the bulk large and the calories low.

**How much oils and fat is healthy? (2,3)**

Let us recapitulate the basic principles with respect to consumption of fats and oils. It is recommended that:

(a) Not more than 20 to 30% of all calories should be obtained from fats.

(b) Out of this not more than 7% (of the total energy) should be from saturated fatty acids.

(c) The trans-fatty acids intake should be negligible (less than 1%) of daily energy intake.

(d) Adequate intake of PUFAs: 6-10% of daily energy intake, with an optimal balance of n-6 PUFA (at 5-8%) and n-3 PUFA (1-2%) levels of daily energy intake, respectively.

(e) Intake of MUFA should make up rest of the daily energy intake.

(f) Daily cholesterol consumption should be restricted to less than 300mg/day, mainly through restriction of dairy fats and red meat.

(g) Restrict intake of fats from dairy and red meat sources, avoiding use of hydrogenated oils and fats in cooking.

These dietary goals (with respect to fats) are translated into actual dietary intakes. Details of these are given in a subsequent section.

**Low Sugars**

Consumption of refined sugars must be restricted to less than 50-60 g of sugar per adult per day.

**Low Salt**

About 5 g of daily intake of salt is recommended for each individual. Low intake of sodium is helpful in the prevention of hypertension and other cardiovascular diseases.

**Plenty of fruits & vegetables**

A daily intake of 400 grams of a variety of fresh, seasonal fruits and vegetables (other than potatoes) is recommended for an adult. (2)

**High fibre in diet**

A daily intake of 35-40 g of fibre in diet is recommended. The fibre must be a combination of soluble fibre (pectin, gums, mucilages) and non soluble fibre (cellulose, lignin and hemicellulose). Unprocessed grains (cereals), seeds (legumes), green leafy vegetables, fruits and nuts contain plenty of fibre. (4)

**Avoid red meat**

Red meat contains high amounts of fat. High intake of preserved and red meat is also associated with high incidence of colorectal carcinoma. Heterocyclic amines, created by cooking, haeme-iron and specific fatty acids could be responsible. Therefore non vegetarians should prefer lean meat (fish or chicken) rather than mutton, pork and beef. (5)

**Low calorie foods**

As a general rule, food that is low in calories, but which can fulfill the daily requirements of energy in a balanced manner is considered as healthy. To keep the calories low in the diet the upper limit of calories intake must be limited to the recommended values for sex and activity level. Fats and oils are the most concentrated source of energy so intake of fats and oils must be restricted, as mentioned earlier. Similarly excessive intake of carbohydrates (cereals and starchy foods like potatoes) must also be discouraged. Some low calorie foods are given in Table - 1 (6).

Table - 1: Calories provided by one typical serving of some low calorie foods

| S. no. | Food item | Approximate quantity per serving | Calories per serving |
|---|---|---|---|
| 1 | Dalia | 1 plate | 80 |
| 2 | Khichri | 1 plate | 160 |
| 3 | Dhokla | 2 pieces | 100 |
| 4 | Poha | 1 plate | 120 |
| 5 | Biscuits | 4 numbers | 150 |
| 6 | Kheer | 1 katori | 120 |
| 7 | Bread | 2 slices | 125 |

## Unhealthy diet as a contributory factor to life style diseases

The changes in dietary patterns, as part of altered lifestyle in both developed and developing countries, have led to a markedly rising trend in chronic non-communicable diseases : obesity, diabetes mellitus, cardiovascular diseases, hypertension, stroke and various forms of carcinomas (e.g. oral cancer, lung cancer, breast cancer, colonic cancer, etc)

These are significant causes of disability and premature death. Most importantly, these can be almost completely prevented if correct diet is consumed.

**What is unhealthy diet?**

To put it in very few words: food high in calories, fats and salt and low in fibre is unhealthy food. What qualifies for such a food choice?

High calorie fatty foods

High calories are provided by food rich in oils and fats. These foods could be any 'oil dripping' preparations or fried foods like the deep fried puris, kachories, samosas, pakoras, parathas, matar paneer, malai kofta, cheese

balls, meat preparations (mutton curry, butter-chicken) or simply lot of ghee on the roti/dal, sweets, cakes and pastries, etc. Table - 2 gives calories provided by one typical serving of these 'unhealthy fatty foods' (6). The high calories present in these foods increase weight and cause obesity. These foods are high in fats, esp saturated fatty acids and cholesterol, which are strong risk factors for cardiovascular diseases (hypertension, ischaemic heart disease, stroke) and some cancers. Repeated cooking/frying of these fats (saturated or unsaturated), turns them into a dangerous variety of fats called as the trans fatty acids (t-fatty acids). The trans fatty acids are considered as extremely dangerous for the cardiovascular system, as they reduce the HDL-c and increase LDL-c, thereby further augmenting the risk (2).

Table - 2: Calories provided by one typical serving of some fatty foods

| Food item | Approximate quantity per serving | Calories per serving |
|---|---|---|
| Samosa | 1 number | 256 |
| Masala Dosa | 1 number | 360 |
| Kachori | 2 numbers | 500 |
| Mathri | 1 plate | 500 |
| Puri | 4 numbers | 250 |
| Ghee roti | 4 numbers | 360 |
| Cake | 1small piece | 250 |

### Sugary foods

Such foods contain excessive refined sugar. Chocolates, cakes, candies, halwa, laddoos, ice creams, soft drinks, etc are some examples of such foods. These foods are also considered unhealthy. These foods have high glycaemic index and their consumption causes sudden spurt in blood glucose levels, which may be deleterious for health. They also contain high calories (e.g. 1 small piece of cake provides 250 Cal), which leads to an increase in body weight causing obesity and other diseases. In addition to these calorie related drawbacks, since most of these foods are commercial products, they contain chemicals, artificial colours, flavours and preservatives, which are generally unnatural and harmful, many of them being carcinogenic. Moreover, excessively sugary foods are also liable to cause dental caries.

### Junk foods

Fast foods are served quickly and conveniently at a relatively low cost and so are very popular especially amongst young people. These include burgers, pizzas, chips, French fries, wafers, colas, etc.

Junk food is generally a fast food that is devoid of nutritional value. For example burger and cola are nutritionally only refined carbohydrates and sugar. It contains empty calories and hardly any vitamins, minerals or proteins. Some common problems with these foods are:

(a) Most such menus lack vitamin A, folate, biotin, pantothenic acid and other vitamins.

(b) They are deficient in iron, calcium and copper and other trace elements.

(c) The calorie content of one such meal could be about 900 to 1800 calories, which is 33 to 66% of the RDA. Excessive consumption of these is liable to increase weight and cause obesity.

(d) Their sodium content is very high and potassium content low.

(e) Contain chemicals, artificial colours, flavours and preservatives

(f) The fat content of some of these meals may be as high as 50% of the total daily calories consumed.

(g) The ratio of saturated to unsaturated fatty acids may be unfavourable.

(h) The method of cooking may not be acceptable (deep frying / grilling). Also, the temperature at which food is fried, and if the cooking fat is reused, affects fat quality.

(j) Very costly and less beneficial.

Regular and consistent 'addiction' to fast foods may therefore be deleterious to health. (7)

### Low fiber foods

The processed products of refined cereals such as refined flour and maida e.g. noodles, pasta, cake, white-bread, pizza, macaroni, etc are low in roughage and fibre. Their consumption may cause constipation as compared to a diet that is high in fibre. Such foods are also poor in vitamins and minerals as these important micronutrients are lost with the husk of the grains during processing and refining. Regular intake of low fibre food poses a risk of certain cancers, e.g. cancer colon.

### High salt foods

Some dishes contain very high amounts of salt, for example pickles, sauce, salted fish, chutneys, etc. High salt content in the diet is known to be an important contributory factor to hypertension and heart disease. Consumption of such food articles is therefore not recommended.

# Diet & Lifestyle Diseases

Lifestyle is the way we live or the way we would naturally live our lives, if not coerced by outside influences i.e. circumstances or persons. It is an outcome of genetic influences, early childhood developmental influences and certain acquired traits and attitudes as a result of our interaction with the society.

Over the past decade or so our lifestyle has witnessed a sea change. What has changed is the way we live, the way we work. Our habits, our physical activity, levels of stress, reaction to situations, attitude to time and our very behaviour has changed. These are the changes in our lifestyle.

Rapid changes in diet and lifestyle have resulted from industrialization, urbanization, economic development and globalization of the market. This has had a significant impact on the health of populations esp. in the developing countries undergoing rapid socio-economic transition. Standards of living have improved, there have been significant negative consequences in terms of inappropriate dietary patterns and reduced physical activity and a corresponding increase in diet related chronic disease.

With changing lifestyle, probably diet has suffered the most. People resort to fast foods, snacks, high calories - low nutrient foods, colas and burgers, all of which are basically unhealthy foods. This 'changed diet' coupled with an altered lifestyle is deleterious to health.

## Diet related behaviour and lifestyle disease

There are a variety of diet related behaviours and other host issues that have a potential effect on a population's level of lifestyle disease. Timely and suitable modification of these can go a long way in prevention of these diseases.

### Snacking

Taking frequent snacks (snacking) is a part of our culture. One tends to snack at home, on social functions, at the office, in the college canteen or simply while watching television. These snacks are always over and above the normal 3 meals. Therefore we do not account for the calories provided by them, and they are often ignored.

### Implications of one samosa a day

One samosa and a cup of tea adds up to 300 calories. Taken over a month would add up to about 9000 calories, which is good enough to add 1 kg weight in a month, i.e. 12 kg of extra weight in an year!

It is not only the calories or the weight gain that matters, samosa provides the unhealthy trans (t) fatty acids as well. t-fatty acids would increase the triglycerides and LDL-c, and reduce the HDL-c, thereby increasing the risk of heart disease.

To negate the weight gain, it is recommended that one must walk. Walking 1km burns 75 calories. To reduce the 1 kg weight gained one must walk for 4 km every day and to reduce the 12 kg gained over an year, one has to walk or 1500 Km in a year, that is the distance between Pune to

The two issues in snacking are the content and frequency of consumption of snacks. The occasions of snacking increase the density of energy and its contribution to total energy. Snacks contribute to 20-25% of all energy in the food in the USA and UK and the same trend is catching up in urban India. The truth with Indian snacks is that most of them are rich in fats and calories eg samosa, kachori and pakori.

The solution is to avoid high fat snacks like samosas and replace these with low calorie snacks like salads, vegetable dips, fruit based snacks, salt biscuits, poha, dhokla, etc.

Similarly soft drinks which are an inevitable accompaniment with snacks esp for the young generation, are also unhealthy. They contain excessive refined sugar, high calories, artificial flavours and colours and are devoid of micronutrients. These can be easily replaced with fruit juices or other natural drinks like lemon-water, coconut water, etc.

### Eating out

In modern societies, the frequency of eating food prepared outside the home is increasing. This rising trend of eating out has coincided with the increasing prevalence of obesity. These foods prepared outside, are richer in energy, fat, esp. saturated fat, cholesterol and sodium but are poor in minerals and fibre. So these foods are nutritionally poorer than home made food. A change in this practice might be an important positive lifestyle change.

The portion size in prepackaged, ready to eat and restaurant foods is also important. Large portion size builds on the consumers' desire of value for money. "Super-sized' portions potentially lead to increased energy intake and could therefore be significant contributor to obesity and other lifestyle disease.

### Restrained eating, dieting and binge eating patterns

Many selective and restrained eaters are at a risk of dieting-overeating cycles. A rigid restraint eating pattern is associated with a greater risk of weight gain. Binge eating disorder and night eating syndrome are examples of this pattern. Such a pattern needs to be discouraged.

## Potential etiological factors in relation to lifestyle diseases in population

An undesirable lifestyle may be responsible for contributing to the three major lifestyle diseases namely cancers, CVD and diabetes. (1,2,3)

### Cancers

Obesity is convincingly related to risk of carcinoma of breast, colorectum, oesophagus, endometrium, kidney, etc. Also, the excess risk of these cancers increases continuously with greater adiposity. Similarly alcohol also convincingly increases the risk of carcinoma of oral cavity, larynx, liver, breast and colorectum. High intake of salted fish (e.g. Chinese style salted fish) also increases the risk

of various cancers.

**CVD**

Due to lifestyle changes not only the incidence of cardiovascular diseases is increasing but is affecting more and more younger people. This is an alarming trend. Coronary artery disease, hypertension, stroke, etc are rising. 'Poor' diet with excessive saturated fat intake and low fibre is an important contributory factor along with sedentary and stressful lifestyle.

Diabetes mellitus

Diabetes mellitus has reached epidemic proportions in developing countries in the past few decades, and the incidence is rising. The lowest rates of this disease are seen in rural communities where people retain their traditional lifestyle. Dramatic changes have occurred in communities where there have been massive changes in the type of diet, from traditional to typical western. Such changes are associated not only with diet but also with other lifestyle factors e.g. physical activity.

## Dietary modifications for lifestyle disease risk reduction

Many studies indicate that a change in lifestyle can reduce the risk of obesity, diabetes mellitus, CVD and carcinoma. A weight loss achieved by dietary changes and increased physical activity can go a long way to achieve risk reduction. Lifestyle modification, as far as dietary modifications are concerned would concentrate on reduction in total and saturated fats, increased dietary fibre, low calories and plenty of fruits and vegetables. The practical modifications that should be made in our day to day diet to reduce risk of lifestyle diseases are discussed in the subsequent paragraphs:

### Recommendations on fats: The preventive prescription

Dietary intake of fats, esp the qualitative composition of fats in diet, strongly influences the risk of lifestyle diseases, through effects on blood lipids, thrombosis, blood pressure, endothelial function, arrhythmogenesis and inflammation.

The dietary goals with respect to various kinds of fats can be achieved by limiting the intake of fat from dairy and meat sources, avoiding the use of hydrogenated oils and fats and substituting saturated fats with unsaturated plant oils.

**The calculations**

Calculating a scale of 25% of energy to be obtained from fats, for a daily requirement of 2400 Kcal a sedentary man needs to obtain 600 Kcal from fats. Half of these come from invisible fats (which are mostly unsaturated variety) and the other half need to be provided through apparent dietary sources (300 Kcal/day or above 33g of oil / fat per day). So in a month, one would need to purchase (33g x 30 days = 990g) about 1 kg oil/fat. Saturated fats (butter, ghee) should account for not more than 7 % or 1/10$^{th}$ of total daily requirement. This works out to about 240g of butter or ghee per month. The rest 760g should be obtained from some unsaturated sources. It must be appreciated that an Army soldier is not really a sedentary worker, but a moderate or heavy worker, requiring atleast 2800 - 3000 Kcal per day. On recalculating, the fat requirement for him we find that he requires 42g oil/fat per day, or about 1260g per month. Saturated fats ( butter / Ghee) should not exceed 300g per month.

Different vegetable oils available in the market have varied saturated and unsaturated (PUFA, MUFA) compositions. One must therefore use different oils like mustard, soyabean, groundnut, safflower, sunflower, rice bran, cottonseed, sesame etc in rotation, to obtain all types of unsaturated fatty acids.

**The preventive prescription on fats for lifestyle diseases**

- One must cater for 1 Kg of vegetable oil and not more than 168g of butter/ghee per adult in the family per month.
- For a family of 4 adults it works out to 4 Kg of vegetable oil and about 670g of butter/ghee per month.
- Out of these 4 kgs of oil to be procured in a month, one may purchase different varieties of oils (or rotate the oils over few months) to get an all round benefit.
- Regular intake of fish (1-2 times per week) provides PUFA and MUFA, rich in omega 3 fatty acids, beneficial for heart.
- Non-frying methods must be resorted to, rather than deep frying and baking with lots of butter/fats.
- Puris, parathas rich in oils should be substituted by plain rotis.
- Sweets with plenty of ghee and oils must be shunned.
- Snacks (kachoris, pakoris, cheese-balls, namkeens, etc) which are rich in oils must be avoided.

### Recommendations on carbohydrates

Cereals

A maximum of 60% of total energy intake ie, about 1700-1800 Calories should be obtained from carbohydrates for a sedentary male. About 450g carbohydrates per day would provide these calories. Carbohydrates in excess of this amount would result in accumulation of surplus calories, eventually leading to obesity. Excess intake of starchy food (potato as vegetables, chips, wafers, french fries, etc) also provides plenty of 'easy' calories, liable to cause obesity. It is also recommended that different cereals must be consumed in one form or the other. One cereal could be the staple cereal say wheat, but it is advisable to consume one other cereal say rice as the second parallel cereal. In addition to this other cereals eg corn, millet (bajra, ragi), etc should be used as snacks.

Fibre

Intake of whole grain cereals must be encouraged. Excessive milling of cereals leads to loss of the outer layer of bran and fibre. Thus consumption of whole grains provide adequate fibre. These can be obtained from brown rice, flour with higher level of bran ie coarse atta,

dalia and porridge. To ensure maximum intake of fibre, the flour (atta) should not be strained with a thin strainer, so that bran is incorporated in the flour. The bran should not thus be discarded. Pulses, beans and other legumes also provide valuable fibre, so they must be consumed aplenty. The fruits and vegetables contain abundant amount of fibres and must be consumed regularly.

**Recommendations on salt**

Sodium

Many studies have proved that the amount of sodium in diet is a definite risk factor for hypertension and heart disease. Sodium is present in common salt which is generally consumed without a second thought. The use of sodium should be limited to reduce the risk of lifestyle disease. An upper limit of 5g of salt is recommended so its use should be restricted to less than this amount (5g/day).

Potassium

Dietary intake of potassium lowers blood pressure and is protective against stroke and cardiac arrhythmias. Potassium intake should be at the level which will keep the sodium potassium ratio close to 1, i.e. at the level of about 5g/day. This could be achieved by adequate daily consumption of fruits and vegetables, in the amounts given above. Potassium enriched low sodium salt substitutes can also help achieve this balance.

**The preventive prescription on salt**

At a rate of 5g/day, for a family of four, salt consumption works out to about (5gX4) 20 g per day; or about 600g per month. The following recommendations are made:

- For a family of four adults, buy a 1 kg pack of salt and about 1/3rd should be left at the month end, which should either be discarded or included for in the next months 'quota' of 600g.
- Avoid foods containing excessive salt like pickles, sauce, tinned and preserved food, processed cheese, etc.
- Consumption of fast foods like burgers, pizza, French fries, chat, bhel-puri which contain high amount of salt must be discouraged.
- Never add any salt to the food on the dining table.
- Remove saltcellars from dining table, to discourage sprinkling of salt on ready to eat food.
- Avoid sprinkling of salt on fresh salads.

The other sources of sodium consumption should also

**Recommendations for fruits and vegetables**

Fruits and vegetables are clearly an important part of a good diet. "Eat your fruits and vegetables" is one of the tried and true recommendations for a healthy diet. Eating plenty of fruits and vegetables can help ward off lifestyle diseases: coronary artery disease, stroke, hypertension, Alzheimer's disease, cataract, macular degeneration, etc and prevent many cancers.

Fruits and vegetables contribute to health through a variety of phytochemicals, antioxidants, flavanoids, potassium and fibre. A variety of seasonal fruits and vegetables should be consumed. Adequate intake of fruits and vegetables (400-500g) every day is recommended to reduce the risk of lifestyle disease. A family of 4 must consume 1.5 - 2 Kg fruits & vegetables in a day or about 10 - 15 kg in a week.

Variety is as important as quantity. No single fruit or vegetable provides all the micronutrients needed to be healthy. The key lies in the variety of different fruits that one eats.

Quantity

An average Indian takes a maximum of just three servings of fruits / vegetables a day. The earlier dietary guidelines called for about 100g of fruits to be taken per day. However the guidelines have been changing with the stronger emerging inverse relationship between lifestyle diseases and fruits. Now the American authorities recommend as many as five to thirteen servings of fruits and vegetables a day, depending on one's caloric intake. For a person who needs 2,000 calories a day this translates to nine servings, or about 5 cups/portions per day. And this doesn't count potatoes (as potatoes are mostly starch). A typical portion can be defined as :

| | |
|---|---|
| (a) Melon, Pineapple | Large slice |
| (b) Fresh corn on the cob | 1 whole cob |
| (c) Apple, banana, orange | 1 fruit |
| (d) Small tomatoes | 6 tomatoes |
| (e) Grapes, cherries or berries | 1 cupful |
| (f) Fresh fruit salad | 2-3 heaped tsbp |
| (g) Dried fruit - raisins, apricots, dates, figs | 1/2-1 heaped tbsp |
| (h) Fruit juice | 1 glass (150ml) |
| (j) Vegetables, raw, cooked, frozen or canned | 2 heaped tbsp |
| (k) Salad | 1 dessert bowlful |

Variety

Since different fruits and vegetables have different nutritional benefits a wide variety must be chosen. A rough public health guideline could be to choose fruits of different colours. Moreover, seasonal fruits are recommended, as they are not only cheap but also available fresh.

How to meet this requirement

This requirement can be met by simply including some fruit and a couple of servings of vegetables at each meal i.e. lunch and dinner. For example: a glass of orange juice (freshly squeezed or from concentrate) at breakfast, together with a banana is equal to two portions. Similarly, a piece of fruit or some salad with lunch is equal to one portion. Vegetables included in the dinner, together with a fruity pudding are equal to at least two portions.

Role of frozen, dried or canned fruits

Fruit and vegetable intake can be augmented by including fresh, frozen, canned, dried or juiced fruit as well. The main aim is just to eat more of them! Although cooking reduces the level of some nutrients, there will still be useful amounts left. Dried fruits generally have less vitamin C and, although a concentrated source of sugar, they are usually high in fibre and other vitamins and minerals. Frozen vegetables are often frozen quickly after harvesting so they retain a good level of their vitamin content.

**Other Recommendations**

Sugar

Excessive intake of refined sugar is deleterious to health. Therefore its use must also be limited by all in general and by patients of diabetes, hypertension and heart disease in particular. The following recommendations are made:

(a) The recommended sugar intake is about 60-75g per adult per day.

(b) For a family of 4 the maximum sugar consumption works out to about (60gX4) 250g per day.

(c) Thus, for such a family composition, maximum sugar purchase should not be more than 7 kg per month.

Fish

Regular fish consumption is protective against CVD, stroke, etc. Fish is therefore recommended to be taken once or twice a week.

Alcohol

While regular low or moderate consumption of alcohol is protective against CVD, concerns about other cardiovascular and health risks associated with alcohol (stroke, hypertension and carcinoma) do not favour a general recommendation for its use. Moreover, alcohol is an energy dense nutrient (7kcal/gm) and because of its place at the top of oxidative hierarchy, its potential for sparing fat oxidation and promoting fat storage is significant. Generally, the snacks consumed with alcohol are also energy dense, which add to the calorie consumption. If consumed one should not exceed 2 units of alcohol per day. Complete cessation of cigarette smoking is a must.

Meat & eggs

Meat contains high amounts of fat so their use must also be limited quantitatively and qualitatively. The following recommendations are made:

(a) Non-vegetarians should restrict the consumption of red meat (beef, pork, mutton).

(b) Preserved meat (ham, bacon, salami, sausages) must also be limited.

(c) Prefer lean meat (chicken and fish) to red meat.

(d) Prefer marinated / baked / grilled dishes to oil dripping fried ones.

(e) Discourage high fat meat / cooked in thick gravies.

(f) Let meat be a part of meal, not the full meal.

(g) Egg yolk too contains high cholesterol so its use should also be restricted.

Hot foods

Consumption of very hot drinks and foods typically consumed in some cultures probably increase the risk of carcinoma of oral cavity, pharynx and oesophagus. It is recommended not consume foods/drinks when they are very hot (scalding hot).

# Antioxidants, Minerals and Diseases

## History

*Jules Verne*, the famous French author and visionary, author of the famous book '*Twenty thousand leagues under the sea*' wrote in 1865, in another of his novels *"From the earth to the moon"*, that "Oxygen... this gas without a smell, eminently vital, can cause the most serious disorders in the organism." No one believed him then, or even dreamt of the fact that oxygen could "cause the most serious disorders in the organism".

Oxygen toxicity in laboratory animals was however, first described in 1878 and was established in 1899. The first experiments investigating a free radical reaction were reported in 1894 by Fenton. But the attributability of retrolental fibroplasia among premature newborns to oxygen, had to wait till as late as the 1950s. And it was not until the 1960-70s when bronchopulmonary dysplasia in the new-born and the adult respiratory distress syndrome were appreciated by the medical community. It was thus only towards the later part of the last century that the free radicals and the role of antioxidants was scientifically well understood with the discovery of superoxide dismutase in 1969 (1).

The issue on which the present research is concentrated, the world over, is the role of micronutrients in lifestyle diseases. Even though a final word on the issue has not yet been said, there are epidemiological indications that the antioxidants and trace elements have a major role to play in the causation, modification and prevention of these diseases.

## Role of micronutrients

In context of the lifestyle diseases, the micronutrients can be grouped into two: the antioxidants and metals including the trace elements. Micronutrients are the key to optimal macronutrient metabolism because of their essential role in metabolism. Invariably, metabolic steps require the concomitant involvement of one or more vitamins and minerals. Chronic degenerative disease etiology and rate of pathogenesis are intimately associated with micronutrient imbalances. Although precise mechanisms remain to be identified, antioxidant status is critical in the pathogenesis of such diseases (2).

### Mechanism of oxidant injury

Reactive species like those of oxygen (reactive oxygen species), nitrogen (reactive nitrogen species) and chlorine (reactive chlorine species) are produced during normal metabolism: a certain amount of production of these reactive species is, in fact, necessary for proper health: for example, it helps the body's immune system to kill microorganisms. Reactive oxygen species are mainly produced in mitochondria and are formed in much larger amounts during activity than during rest (3,4). These species are oxidants - i.e., molecules or atoms which can oxidize a substrate and are reduced in this reaction. They are able to damage several key cellular components like membrane lipids, nucleic acids, carbohydrates and proteins, thereby severely disturbing major cellular and organic physiologic functions. This type of damage occurs when the host defenses against oxidants (for this reason called antioxidants) are quantitatively and/or qualitatively unable to counteract the production and effects of oxidants themselves. This state is referred to as oxidative stress and is known to be associated with a number of disease states in humans (5,6). To date, compelling evidence supports the important role played by oxidative stress in the pathophysiology of lifestyle diseases and the aging process.

### Antioxidant defence system

The antioxidant defence system provides protection against oxidative reactions and is organized at three levels namely prevention, interception and repair (7).

The interplay of all these processes and compounds in the network provides optimal protection to the organism. In oxidative stress related disease states and during aging the antioxidant micronutrients are consumed and their levels may fall below normal range (8,9,10).

Several components of the antioxidant defence system are micronutrients (e.g. vitamins C and E) or are dependent upon dietary micronutrients (e.g. copper, zinc and manganese, superoxide dismutase, etc). The antioxidant defences act as a coordinated system where deficiencies in one component may affect the efficiency of the others. Oxidative stress may be an important factor as much in infection as it is in chronic disease, if micronutrients are deficient (11).

### Sources of micronutrients

A wide range of natural sources have been shown to contain antioxidants. These include fruits, vegetables, nuts, plant extracts, herbs and spices. As is well known, antioxidants range from various vitamins including tocopherols, carotenoids, ascorbates, etc, whose sources are well established (fruits, vegetables and cereals) to various trace elements, eg Selenium. (12, 13)

Work is now being concentrated on other specific plant products namely polyphenols, which have significant antioxidant properties. Evidence for their role in the prevention of degenerative diseases such as cancer and cardiovascular diseases is emerging. A summary of polyphenols in food is given in Table - 1 (13).

### Implications to lifestyle diseases

Free oxygen radicals may be involved in several pathologic conditions. Oxidation of LDL-c is thought to play an important role in the development of atherosclerosis. Free oxygen radicals are apparently involved at different stages of cancer development. Free radicals may contribute to the autoimmune destruction of ß cells, leading to diabetes and may impair insulin action. Reactive oxygen species have also been proposed as mediators of inflammatory damage in asthma and in joints in rheumatoid arthritis. Furthermore, it has been suggested that the oxidation of lens proteins by free radicals play an important role in the process leading to cataract. (14)

Table - 1 : Polyphenols in foods (13)

| Polyphenol | Source |
|---|---|
| Protocatechuic acid | Raspberry |
| p-Hydroxybenzoic acid | Strawberry |
| Chlorogenic acid | Cherry |
| Coumaric acid | Plum |
| Sinapic acid | Apple, Pear, Coffee, Flour, Potato, Corn |
| Delphinidin | Black grape |
| Malvidin | Cherry, Strawberry, Red wine, Plum , Broccoli, Tea, Apricot, Apple, Beans, Black grape |
| Flavanones | Orange juice |
| Naringenin | Lemon juice |
| Isoflavones | Soy flour |
| Daidzein | Soybeans, boiled |
| Monomeric flavanols | Chocolate |
| Catechin | Beans |
| Epicatechin | Apricot, Cherry, Grape, Peach, Apple, Tea, Red wine |

## Antioxidants and cardiovascular diseases

### Atherogenesis

Several lines of evidence support a role for oxidative stress in atherogenesis. Epidemiological studies suggest that low levels of antioxidants are associated with increased risk for CVD,(15) while high vitamin E plasma levels have been shown to be associated with the absence of atherosclerosis in the elderly (16). The oxidation of LDL by the oxygen free radicals result in the unregulated uptake of modified LDL by macrophages in arterial walls, accelerating the atherosclerotic process. α-tocopherols, β-carotene and ascorbic acid can directly scavenge free radicals and help prevent the condition. These mechanism suggest that increased dietary intake of these nutrients would be protective against atherosclerotic vascular diseases. This was supported by the evidence from observational studies on vitamin E and β-carotene but the results of clinical trials have been variable. (17)

### Coronary Heart Disease

Antioxidant micronutrients have been postulated to exert protective effects against coronary heart disease (CHD). A meta-analysis has indicated that the relative risk reduction of ischaemic heart disease in high consumers of fruit and vegetables may be in the order of 15% (18).

#### Vitamin E

Vitamin E is thought to prevent atherosclerotic disease not only by its antioxidant effects, but also through its inhibitory effects upon smooth muscle proliferation and platelet adhesion. In supplementation studies in humans, á-tocopherol decreases lipid peroxidation, platelet aggregation and adhesion and is anti-inflammatory in nature. (19)

#### Flavonoids

Flavonoids are polyphenolic antioxidants, which occur in a variety of foods of vegetable origin, such as tea, onions and apples. Data from several prospective studies indicate an inverse association of dietary flavonoids and CHD (20). Benefit on stroke risk has also been reported(21).

#### Isoflavones

A composite analysis of 38 clinical trials found that an average consumption of 47 g of soy protein per day led to a 9% decline in total cholesterol and a 13% decline in LDL-c, in subjects free of CHD. Cholesterol lowering of this magnitude could potentially lower the risk of CAD by 20-40%(22). This effect of soy proteins was attributed to isoflavones, compounds that are structurally and functionally similar to estrogen. Several animal studies too suggest that intake of these compounds may provide protection against CVD(23). Besides their estrogenic activity, other suggested modalities of action are their thyroxine like activity, antioxidant activity and their effect on arterial compliance(24).

#### Folates

Homocysteine has been incriminated as an independent risk factor for CHD and probably stroke(25). There is also evidence which suggests that homocysteinaemia results in endothelial dysfunction, an effect that is reversed by oral folate supplementation(26). Folic acid is required for the methylation of homocysteine to methionine. Reduced plasma folate has been strongly associated with elevated plasma homocysteine levels and folate supplementation has been demonstrated to decrease those levels(27).

#### Sodium

High blood pressure is a major risk factor for CHD and stroke (both ischaemic and haemorrhagic)(28). Of the many risk factors associated with high BP, the dietary exposure most investigated has been daily sodium consumption. Sodium (salt) intake has been directly correlated with mean blood pressure and prevalence of hypertension in many populations. Comprehensive epidemiological evidence was provided by the INTERSALT study (29). The results of low sodium DASH trial further strengthen the conclusion that reduction of daily sodium intake, through salt restricted diets lowers BP effectively and is additive to the benefits conferred by the DASH diet (30).

Based on the observational and trial data so far available it would be justified to recommend a daily salt intake of less that 5g/d. Such a recommendation holds good even in tropical countries as sodium homeostasis regulates sodium excretion in sweat and urine (30).

#### Potassium

Cardioprotective effects of dietary potassium have been hypothesized as the basis for low CVD rates in populations consuming traditional diets and in vegetarians in the industrialized countries. The INTERSALT study provided evidence of an inverse association between urinary potassium excretion and BP

levels, across diverse populations (31).

**Cardiovascular Accidents (CVA)**

After a stroke (ischaemic or haemorrhagic) or trauma, the production of reactive oxygen species may increase, sometimes drastically, leading to tissue damage via several different cellular molecular pathways. It was shown that the plasma levels of vitamin C - but not of vitamin E, were inversely correlated with the size of the brain lesion. Also the plasma levels of vitamin C and of lutein were shown to be associated with functional outcome in patients with stroke of recent onset. In these individuals, lipid peroxidation was shown to be significantly higher compared to controls. It was also shown that short-term and long-term vitamin C supplementation increases the resistance of plasma to lipid peroxidation (7).

**Diabetes mellitus**

Diabetes mellitus represents a state of increased oxidative stress, which is based on evidence of increased peroxidation, glycoxidation and reduced antioxidant reserve (32).

It has been shown that oxidative stress has an adverse effect on glucose metabolism. Development of the disabling chronic complications of diabetes mellitus has also been attributed to oxidative stress (33). Recent research suggests that reactive oxygen species (including free radicals) may also be involved in the initiation and development of vascular complications in diabetics. Free radicals meet many of the criteria required for a role in the pathogenesis of diabetic vascular disease: they are present in tissues affected by the diabetic process, they have a direct toxic effect on tissues, under certain condition glucose molecules can induce free radicals production(32).

Vitamin E

Two cohort studies conducted in Finland reported that a low plasma level of vitamin E is associated with a 3.9 fold elevated risk of developing the disease. A nested case control study carried out within a cohort study reported that subjects with a high serum vitamin E level had a 39% lower risk of Diabetes compared to those with a low level of vitamin E. While the relationship between vitamin E and the risk of diabetes should be further investigated, there is insufficient evidence that an increased intake of this nutrient will prevent the disease (34).

Magnesium

Three large American cohort studies have reported a strong negative association between intake of magnesium and risk of type-2 diabetes. In the absence of any evidence regarding the mechanisms of action, it seems inappropriate to offer recommendations regarding intake (34).

Chromium

The relationship between chromium and glucose metabolism is being studied since the late 1950s. Anderson et al reported that subjects with mildly impaired glucose tolerance showed an improvement in glucose tolerance and a lower level of blood insulin after receiving chromium supplement (35). Another study in patients with type-2 diabetes showed improved glycaemic control with chromium supplements, compared with placebo (36).

Flavonoids

Recent research focussed on flavonoids shows a trend toward a reduction in risk of type-2 diabetes with higher intakes of flavonoids (fquercetin and myricetin) (29).

Although there is scarcity of data from controlled studies, anecdotal reports indicate that the use of these antioxidant vitamin and mineral supplements may be beneficial as an adjunct therapy in the management of diabetes and its complications. In particular, it has been reported that high doses of single micronutrient antioxidant supplements, such as vitamin E, may be beneficial to patients suffering from this disease (33).

**Cancers**

Even though it has been reiterated many times that fruits and vegetables probably reduce the risk for cancers of the oral cavity, oesophagus, stomach and colo-rectum, but role of specific micronutrients in the prevention of various cancers is still under study. Some of the probable mechanisms relating micronutrients to cancer are enlisted below:

Prevention of cancer by micronutrients: Mechanism

(a) Several phytochemicals like flavanoids, isothiocyanates and allyl sulphides derived from fruits and vegetables are potent modulators of the enzyme systems responsible for metabolizing carcinogens, which can decrease the incidence of cancer (37).

(b) Antioxidants such as vitamin C, vitamin E, phytic acid and polyphenols inhibit formation of N-nitroso compounds, which are potential carcinogens (38).

(c) Lignins and phytoestrogens in soy have weak estrogenic activity and have been shown to lower the risk of hormone dependent cancers (39).

(d) Some plant starches e.g. oligosaccharides have growth promoting effects on bifidobacteria that are important for the health of colon, decreasing the risk of colonic carcinoma (40).

(e) Phytochemicals in the whole grains and legumes have the ability to block initial DNA damage and suppress post initiation, which halts the carcinogenic process(41).

There is evidence that the consumption of cereals, fruits, dairy products, and added lipids (especially olive oil) are found to be associated inversely with the risk of oral carcinoma(42).

**Alzheimer's disease and other age related diseases**

Neuro-degenerative diseases including Alzheimer's Disease, Parkinson's disease, Huntington's disease and amyotrophic lateral sclerosis share, in common, both aging as a major risk factor and oxidative stress as an

important pathophysiological mechanism. Collectively, there is enough evidence to suggest that oxidative damage plays an important role in brain dysfunction seen in dementias, especially in Alzheimer's disease. Antioxidants appear to be specifically associated to particular biomolecular damage. This is, for instance, the case of lutein, lycopene, ß-carotene, whose plasma levels have been found to be inversely related in Alzheimer's disease patients(7).

### Human immuno deficiency virus

Low plasma or serum levels of vitamins A, E, $B_6$, $B_{12}$ and C, carotenoids, Se and Zn are common in many HIV infected populations. Micronutrient deficiencies may contribute to the rapid progressive pathogenesis of HIV infection through increased oxidative stress and compromised immunity. Low levels or intakes of these micronutrients have been associated with adverse clinical outcomes during HIV infection, and new studies are emerging which suggest that micronutrient supplementation may help reduce morbidity and mortality during HIV infection (43).

### Conclusion

A large body of scientific evidence doubtlessly indicates that an association exists between inadequate antioxidant status and increased risk for or poor outcome of several lifestyle diseases, including CAD, stroke, cancers, diabetes, Alzheimer's disease degenerative diseases of the eye, and even injuries. Antioxidant micronutrients do also show beneficial effects in the prevention of several of these diseases. This effect, however, is much stronger and consistent for antioxidant-rich fruits and vegetables than for single vitamin supplements. In addition, fruits and vegetables contain other polyphenolic phytochemicals, which help in detoxifying many kinds of carcinogens

# Obesity and Diet

Obesity is a condition of excess body fat accumulation to an extent that increases the risk of causing or complicating diseases. It is generally defined as a body mass index of more than 30kg/m$^2$ (1, 2). Industrialization and urbanization have played a vital role in determining the nutritional status of the population. Those living in cities are more prone to the problems of overweight and obesity. Overweight and obesity contribute to the development of diabetes, heart disease, hypertension and many other illnesses. Obesity is largely preventable through changes in lifestyle.

Over the past two decades there has been a dramatic rise in the prevalence of obesity throughout the world. It is estimated by the WHO that globally, over 1 billion (16%) adults are overweight and 300 million (5%) are obese. The highest rise in the number of obese is noted in the countries with fast growing economies esp of South East Asia. 250 million people in the third world countries suffer from obesity. In India alone there are more than a 100 million obese individuals. We are truly in the midst of an obesity epidemic, which has serious health ramifications (3).

## Causes of obesity

Obesity results from an excess of dietary energy intake over energy expenditure and thus both an increase in intake and a decrease in expenditure will lead to excess calories being stored as fat and, ultimately to obesity (3).

### Increased energy intake

An increased energy intake due to lifestyle changes and affluence as seen in urban areas seems to be fuelling the obesity epidemic.

### Decreased energy expenditure

There is a rapid decline in manual labour resulting from car ownership, availability of labour-saving devices, shunning outdoor sports and watching television and computer use for long hours. These factors contribute to obesity.

### Metabolic factors

In some individuals endocrine disorders such as Cushing's syndrome and hypothyroidism, Prader-Willi syndrome etc are the causes of obesity.

### Genetic factors

Obesity tends to run in families. Obesogenic genes are under study, which alter the metabolism or alter the response to obesity limiting hormones like Leptins, etc.

### Obesogenic environment

The shared environmental factors like lifestyle, meals, home environment, family traditions of eating and exercise, level of activity, affluence, etc substantially contribute to obesity than mere genetic factors.

### Fetal programming

The Barker hypothesis proposes that undernutrition during pregnancy may increase the susceptibility of that individual to obesity in adulthood.

## Implications of urban life on obesity

Till recently, obesity was understood in fairly simple terms and was believed that excess body weight results from eating too much and exercising too little! But today it is understood that obesity results from a complex interaction of the factors discussed above: genetic, metabolic, psychological and environmental, causing an imbalance between energy intake and expenditure.

The varied lifestyle and dietary habits of people play an important role in the causation of obesity. In India one important factor, which has ignited the obesity epidemic, is the '*nova-rich*' culture. This is marked by a sudden increase in income, having more disposable income at hand, higher purchasing power and being able to spend more on food. Stress, time crunch, sedentary lifestyle and excessive television viewing add fuel to fire. Non-traditional foods and snacks are considered as more and more mainstream. Easy availability of fast foods, falling prey to food fads, pub and junk food culture and aping the west make the problem more complex. Aggressive advertising, marketing and universal accessibility of chips, wafers and colas have made them not only a household item but a must for any outing or birthday party! These are some of the reasons of urban obesity. Subconsciously we are imparting the same 'unhealthy' eating-behaviour to our children, ensuring that the next generation too falls in the same vicious cycle of no return.

## Quantifying obesity

### Body Mass Index (BMI)

Overweight is usually determined by the Body Mass Index (BMI), which compares the person's weight to his height. BMI is computed by taking the body weight in kilograms and dividing it by the square of the height in meters.

BMI does not measure the body fat but relates well with the

$$\text{BMI} = \frac{\text{Weight in kilograms}}{\text{Height}^2 \text{ (in meters)}}$$

degree of obesity. The categories of obesity as pronounced by the WHO are depicted in Table - 1.

Table - 1: Grades of obesity based on BMI (4)

| BMI | Classification | Risk of comorbidities |
|---|---|---|
| < 18.5 | Underweight | Low |
| 18.5-24.9 | Healthy/normal weight | Average |
| 25 - 29.9 | Pre-obese (Overweight) | Mildly increased |
| 30 - 34.9 | Obesity Class I | Moderate |
| 35 - 39.9 | Obesity Class II | Severe |
| > 40 | Obesity Class III | Very severe |

The guidelines have been revised lately for Asians, considering the fact that Asians (esp South East Asians including Indians) are more susceptible to metabolic syndrome. These are summarized in Table - 2.

Table - 2: Grades of obesity for Asians (1)

| BMI | Classification | Risk of co-morbidities |
|---|---|---|
| < 18.5 | Underweight | Low |
| 18.5 - 23 | Normal weight | Increasing but acceptable |
| 23 - 27.5 | Pre-obese | Increased |
| >27.5 | Obese | High |

**Waist circumference**

Measurement of the waist circumference is a practical method to assess obesity, esp. the degree of abdominal adiposity and the cardiovascular disease risk. Waist is measured at mid point of lower border of rib cage and iliac crest (a more practical method is to measure it at the level of lower edge of umbilicus). A measure of less than or equal to 90 cm for men and 80 cm for women is considered normal.

**Waist-Hip Ratio**

It is another measure of abdominal adiposity and the cardiovascular disease risk of the individual. A ratio of <0.9 for men and <0.8 for women is considered normal.

## Critical periods for weight gain

Weight gained during certain critical periods, usually lead to an increased number of fat cells and makes obesity difficult to treat (5). These periods include:

(a) Age range of 12 to 18 months
(b) Age range of 12 to 16 years
(c) Gain of 60% (or more) of his ideal weight by an adult
(d) Weigh gain during pregnancy

It is important to be on guard during these critical periods, with an aim of preventing almost irreversible weight gain.

## Clinical consequences of obesity

Obesity is associated with a higher risk of mortality and morbidity. The life expectancy of a morbidly obese individual is about a decade lower than one with normal BMI. Most overweight and obese individuals exhibit certain symptoms like difficulty in walking, heavy breathing while walking, joint pains, snoring, morning headaches and shortness of breath. Some specific clinical consequences are listed below:

**Metabolic**

Diabetes type 2 (50 to 100 times more common in obese), hyperlipidaemia, hypertension (5 to 6 times commoner), stroke (2.5 to 6 times commoner), gall stones, breast and colon cancer, infertility (men and women) and polycystic ovary syndrome are seen more often in the obese.

**Physical**

Osteoarthritis, chronic back pain, respiratory problems, limited mobility, higher accidents, sleep apnoea and skin problems.

**Psychological**

Depression, low self-esteem, social isolation, poor employment status, impaired relationships.

## How to reduce weight?

The aim should be to maintain a BMI of 18.5 to 25 kg/m2 and avoid weight gain in adulthood. Details are discussed in subsequent sections. It is important to follow the height weight chart so that one could follow his BMI.

**Preventing / treating obesity in the conventional manner : Role of dieting**

Being overweight, a high BMI or an overt obesity is probably the first indication of the fact that our diet is off - course and needs correction. If ignored at this stage other more sinister lifestyle diseases might soon follow. The origin of obesity could however be multifactorial. Many modalities for treatment/prevention of obesity are available. The dietary therapy (commonly known as 'dieting') remains the most practical and effective measure. Other measures are:

(a) Behaviour therapy
(b) Drug therapy
(c) Surgical intervention
(d) Genetic approach

In the present chapter we shall concentrate only on the dietary therapy.

**Reducing weight through dietary therapy (dieting)**

The first step to adopt a healthy lifestyle is to get educated on nutritional and health aspects. Understanding the nutritive values of Indian foods is perhaps a good beginning. One must learn about calorie content of different foods, food composition (fats, carbohydrates and proteins), nutrition labels, types of foods to buy and details on cooking procedures. Correct dieting technique involves instructions on how to make safe, sensible and gradual change in eating patterns. Moderate reduction in calorie intake is essential to achieve a slow but steady weight loss. This strategy also helps in maintaining this weight loss.

People should be encouraged to increase the intake of complex carbohydrates (unrefined cereals and sugars, fibre rich foods) and to decrease the intake of fats and simple carbohydrates (refined sugars, excessively milled cereals e.g. white bread, etc). Intake of low calorie and low fat foods must be emphasized. Fruits and vegetables must be made an integral part of the diet.

There are four areas to be considered in the use of dieting and nutritional education in treating obesity. These are

(a) Ascertain the activity status: sedentary, moderate or hard worker. Assess the present BMI and the desired BMI (20 to 25 kg/$m^2$). This would indicate the weight (in Kg) to be reduced.
(b) Set a practical time frame for weight reduction. It has to been achieved at a rate of around 1 - 1.5 kg per month.

(c) Assess the daily calorie intake from fats, proteins and carbohydrates. The weight to be reduced is then translated to the calorie restriction. These calories are distributed between carbohydrates, protein and fat so as to cut down calories preferably from fats and carbohydrates (in that order). This also helps balance all nutrients.

(d) Suitable substitutions should be made. The frequency with which the foods are to be eaten and the situation in which the food is ingested is also to be looked into.

**Reducing weight: An example**

Let us take a 1.66 m tall, sedentary male, weighing 80 kg.

**Step 1:** His present BMI works out to 29 kg/m$^2$. Let us presume that his desired target BMI is 25 kg/m$^2$. To achieve this BMI his weight must be about 69 kg i.e. he must reduce 11kg.

**Step 2:** It is recommended that he reduces 1.5 kg weight per month, i.e. he would be able to reduce 11 kg in about 7 months.

**Step 3:** Assess his total daily calorie intake. As a rule, generally, a daily reduction of about 500 kcal brings about a weight loss of about 500g per week. Conservatively, let us assume that a reduction of say, 1.5 kg per month can be achieved. 500 kcal per day can be reduced by cutting down 16 g oil (150 kcal), and about 85 g carbohydrates per day. Suitable modifications must also be made to other lifestyle factors like alcohol, junk foods, parties, snacks, physical activity, etc.

**Step 4:** Make suitable substitutions as applicable (see next para). For example, replace saturated fats with PUFA/MUFA, replace whole milk with skimmed milk, and refined flour with whole-wheat flour. More fruits and

### Food substitutions that help in weight-loss

It is well known that one must try to eat a variety of foods, especially whole-grains and lots of fruits and vegetables. These foods can be filling and satisfying and are lower in calories than foods full of oils or fats. Some times it is not only scientific but easy and more palatable too, to substitute one (set of) food item with other, which is less fattening or healthier. While cooking, try to replace undesirable ingredients with healthier alternatives. Some such examples are given here. This list is, by no means comprehensive. Many more such substitutions can be worked out provided they are nutritionally correct and acceptable to the individual (6).

Complex carbohydrates take longer time to digest, so they contribute to prolonged satiety. Foods that are rich in complex carbohydrates, low in fat and high in fibre are very beneficial for an individual's health and well-being. In addition, these foods help to maintain a low body weight. Therefore, refined carbohydrates (milled rice, white bread, biscuits) must be replaced with preparations of complex carbohydrates e.g. brown rice, whole-wheat atta and whole-wheat bread, etc

Potatoes, rice, beans and some vegetables (like yam, sweet potato, turnips, beet-root and carrots) are rich in complex carbohydrates. But one must consume even these with caution as their starch content is fattening. It is advisable to choose starchy foods that are high in fibre, like whole grains.

Nuts are good source of proteins, fibre, unsaturated fatty acids and certain antioxidant polyphenols. In small amounts they can be part of a healthy weight loss programme, however if consumed in large quantities their calorie content may add on to the weight. Use of fried nuts must be avoided to inhibit intake of undesirable oil.

Low fat and non-fat dairy products are as nutritious as whole milk dairy products, but they are lower in fats and calories, so it is advisable to substitute whole milk with skimmed milk.

Similar substitutions can be worked out for meats. Mutton and beef must be substituted with lean meat (e.g. chicken & fish). Prefer non-fried meats (e.g. stews, soups, etc) to 'tasty' oil dripping meat preparations.

One must cut down on sugar and fried / baked food, especially fast foods like chips, wafers, burgers, samosa cutlets and cakes! Such foods may have plenty of harmful 'unseen' fat. These can be replaced with some light biscuits, nuts, plain toast, fruits, salad and fruit juices.

Choose fats and oils wisely. Shun saturated fats like ghee and trans-fatty acids found in fried and baked foods. Replace these with oils having higher contents of PUFA and MUFA e.g. vegetable oils sunflower, safflower, groundnut, linseed or cotton seed oils. But one cannot consume these in an unlimited quantity. The total intake of fat has to be restricted to not more than 30% of total energy intake, (ideally at about 20%). Fish and fish oils are also healthy additions to the diet.

### Some more tips on dieting

(a) To reduce weight many people skip meals with an aim of reducing calories in their diet. But this is not the correct practice, because during the course of the day one is likely to make up for those 'missed' calories by snacking or eating more during the next meal. Do not eat food left over after the meals.

(b) A healthier way to lose weight is to eat many small but measured meals or to eat a minimum of three meals, which include a variety of nutritious, low-fat and low calorie foods. So the best way to lose weight is to cut back on the number of calories on a sustained basis and be more physically active.

(c) Try not to snack while doing mundane things like watching television, playing video games or using the computer. If you want to snack while watching TV, then keep small and fixed amounts of food with you.

(d) One should not shop when hungry because impulse buying of 'junk food' is likely to occur

which is fattening in the long run.

(e) Stress must be reduced. Find relaxation methods that work for you to limit excessive eating triggered by stress. Meditation is an excellent relaxation method. Develop an attitude of positive thinking and be cheerful. One must exercise regularly. It helps burn the body fat, strengthens the muscles and reduces stress.

(f) Slow and steady weight loss of about 0.5 to 1kg per week is the safest way to lose weight. Very rapid weight loss in a short while means you may be losing water rather than fat, so such a weight loss would not last long. On the other hand a very rapid weight loss for a relatively sustained period can cause you to lose muscles rather than fat, which again is harmful.

Other cautions

(a) There are certain other factors that should not be lost sight of. For example some food labels may claim 'low-fat' or 'no-fat'. But these foods may still have a lot of calories. Food labels claiming 'zero cholesterol' may not mean 'zero oil'. They may not have 'cholesterol' in the technical sense, but may still have oil, excessive consumption of which may not always be healthy. Often these foods have extra sugar, flour or starch thickeners to improve their taste and appearance. These ingredients add calories, which in turn can lead to weight gain.

(b) It is also important to drink enough water each day. One needs to drink a minimum of 8-10 glasses of water daily. Alcohol has high calorie content and apart from endangering health, it may act as a causative factor for obesity. The snacks taken along with drinks are often not counted by the individual as part of their daily diet. These in fact could be full of fats and calories, since, more often than not; these are fried foods, e.g. nuts, wafers, kebabs or cheese balls.

(c) Fruits and vegetables are the main sources of nutrients in vegetarian diets. Most fruits and vegetables have negligible fats and calories. Fruits and vegetables offer the additional but vital advantage of being the important source of antioxidants.

(d) There are certain nutrients (like iron, calcium, vitamin D, B12 and zinc) that are more commonly found in animal products rather than in vegetarian diets. Here are some vegetarian foods that contain useful nutrients (6,7)

(i) **Iron** : Whole grain cereals, pulses especially soybeans, chickpea, Dark green leafy vegetables, jaggery, dried fruits especially figs, raisins, apricots, certain seeds like pumpkin seeds and sunflower seeds, etc

(ii) **Calcium** - Dairy products, custard apple, ragi, broccoli.

(iii) **Zinc** - Whole grains (especially the germ and bran of the grain), dairy products, nuts, leafy vegetables and root vegetables (onions, potatoes, carrots, radish).

(iv) **Vitamin $B_{12}$** Cereals, dairy products.

(v) **Vitamin D** Milk, soyamilk and exposure to sunlight.

### Fad diets and their role in weight reduction

Fad diets stress either the absence or presence of particular foods or combination of foods. These are commonly aimed at weight reduction. A fad diet is a set of menus advocated generally by people who have little or no knowledge of nutrition or on the basis of inadequate evidence by nutritionist as well. Such diets have short lives and persons addicted to dietary fads shift from one such diet to other rapidly. These diets exist because of ignorance and gullibility. People clutch to almost any straw to lose weight or regain health.

The secret of the short-lived success of such diets is that, weight is rapidly lost, but is regained little later, once the former eating habits are resumed (8).

### Commercial 'Weight reducing' diets

Either the sheer number of obese and weight conscious people is so high or there is such a glamorization of good physique that today dieting is not only 'commercialized' but dieting and 'slimming centres' have attained industrial proportions. Visiting a well-known slimming centre is considered a prestige symbol for the affluent.

Popular diets have become increasingly prevalent and controversial. More than 1000 diet books are now available, with many popular ones departing substantially from mainstream medical advice. Public interest is being fuelled by cover stories of popular magazines and televised debates.

Out of the thousands of structured commercial diets, probably the more popular ones are the **Atkins diet, Ornish diet, Weight watchers diet and the Zone diet.** These are based on different 'principles' to reduce weight. For example, Atkins diet, the most popular of the lot, restricts intake of carbohydrates to less than 30 g a day and permits ad-libitum, the consumption of fats (fatty meat, butter, and other high-fat dairy products). The Ornish diet restricts fat, Weight watcher's diet restricts portion size and calories, Zone diet modulates macronutrient balance and glycemic load (9).

Since all these diets are not natural, they have their own associated disadvantages, risks and controversies.

Atkins diet : A critical analysis

One such diet warrants a more detailed discussion and a critically analysis. Let us take the most popular of these, the Atkins diet (10).

The Atkins diet books have sold more than 45 million copies over 40 years all over the world. In the present obesity epidemic, this diet and accompanying Atkins food products are popular. The diet claims to be effective at producing weight loss despite ad-libitum consumption of fatty meat, butter, and other high-fat dairy products, restricting only the intake of carbohydrates to under 30 g

a day.

It eliminates carbohydrates from food without restricting protein and fat intake. Deprived of carbohydrates, the body uses fat for fuel. A small part of metabolized fat is eliminated in the urine as ketone bodies, and this is why such diets are called "ketogenic".

Caloric loss due to ketonuria does not exceed 100 Cal/day in the non-diabetic. It is maximal during total fasting and cannot be increased further by a ketogenic diet. In the short run, such diets produce rapid weight loss due to polyuria. The apparent paradox that ad-libitum intake of high-fat foods produces weight loss might be due to

(a) Severe restriction of carbohydrate depleting glycogen stores.

(b) This leads to excretion of bound water causing weight loss

(c) The ketogenic nature of the diet being appetite suppressing

(d) The high protein-content being highly satiating

(e) High fat / protein diet reduces spontaneous food intake

(f) In the absence of carbohydrates the food choices are limited, leading to decreased energy intake

On the other hand in the long run, re-feeding carbohydrates causes water retention and weight gain. The diet decreases appetite: patients eat less without feeling severe hunger and without measuring their food intake. Orthostatic hypotension, fatigue and nausea are

**Some benefits of weight loss**

**Losing 10 kg is associated with :**

- A reduction in total mortality by 20%
- A reduction in systolic blood pressure by10 mmHg
- A reduction in diastolic blood pressure
- A reduction in fasting glucose
- A reduction in total cholesterol by10%
- A beneficial rise of 8% in HDL cholesterols
- An improved self-esteem

# Major Non-communicable Diseases and Diet

After having swept the Western world, cardiovascular diseases have now assumed epidemic proportion in South East Asian countries, including India. It is extremely important to modify the lifestyle to prevent these dangerous diseases. Diet is an important aspect of the lifestyle which can be easily modified to prevent CVD. The details of CVD, its risk factors and prevention are described in another section on Non-Communicable diseases.

## Dietary recommendations for a healthy heart

### Fats

Quality of fats

Fats affect the risk of cardiovascular disease by virtue of both their quantity and quality. Various types of fats came under disrepute at different points of time. *Desi ghee* was once considered ideal food for health. It came under disrepute in the 1970s when the 'cholesterol theory' took shape and cholesterol was declared the biggest 'villian'. So *Dalda,* a hydrogenated fat replaced ghee in our diet. In a decade or so it was realized that *Dalda* too was 'not' healthy as it contained saturated fats. It was then thought that unhydrogenated vegetable oils were healthy. This was followed by the emergence of the 'omega 3 fatty acids' and the 'linolenic acids'. The scientific data apart, even the history tells us that the 'quality' of fat has a lot to do with the risk factors of CVD.

Quantity of fats

It must be realized that ad-libitum consumption of even the so called 'good' fats is not acceptable. The total quantity of fat consumption has to be kept in check and excessive consumption is certainly deleterious to the heart. It is well understood that both quantity and quality of fat strongly influence the risk of CVDs like the Coronary Heart Disease (CHD) and stroke, through effects on blood lipids, thrombosis, blood pressure, endothelial function, arrhythmogenesis and inflammation. For promoting cardiovascular health diets must provide the following: (1,2)

Total fat intake

The total fat intake should be less than 30% of total energy intake. (Note : 1g fat provides 9 Kcal)

Type of fat

Restrict intake of fats from dairy and red meat sources, avoiding use of hydrogenated oils and fats in cooking. Prefer plant oils (e.g. groundnut, sunflower, soyabean, ricebran, etc.). It is best to use these different oils in rotation to have the benefits of each.

Saturated fatty acids

These should not contribute to more than 7% (of the total energy).

Trans-fatty acids

The trans-fatty acids intake should be negligible (less than 1%) of daily energy intake.

PUFA

Intake of PUFAs should be adequate, ie. 6-10% of total daily energy should be from PUFA. There should be an optimal balance of n-6 PUFA (at 5-8%) and n-3 PUFA (1-2%) levels of daily energy intake, respectively.

MUFA

Intake of MUFA should make up rest of the daily energy intake from fats, i.e. about 10% of daily energy.

Cholesterol

Daily cholesterol consumption should be restricted to less than 300mg/day, mainly through restriction of dairy fats, red meat and eggs.

### Fruits & vegetables

Fruits & vegetables contribute to cardiovascular health through a variety of phytochemicals, antioxidants, potassium and fibre. A daily intake of 400-500 grams of a variety of fresh, seasonal fruits and vegetables (other than potatoes) is recommended for an adult.

### Sodium

Current evidence suggests that an intake of 70mmol or 1.7g of sodium per day, is beneficial in reducing blood pressure. This is equivalent to about 5 g of daily intake of salt. Low intake of sodium is helpful in the prevention of hypertension and other cardiovascular diseases. Other forms of sodium (food additives or preservatives, such as monososium glutamate and sodium benzoate, etc should also be guarded against (1).

### Potassium

Dietary intake of potassium lowers the blood pressure and is protective against stroke and cardiac arrhythmias. Potassium intake should keep the sodium to potassium ratio close to 1.This may be achieved through adequate daily intake of potassium, in the form of fruits and vegetables (1).

### High fibre in diet (Non starch polysaccharides)

A daily intake of 35-40 g of fibre in diet is recommended. The fibre is protective against CHD. Unprocessed grains (cereals), seeds (legumes), green leafy vegetables, fruits and nuts contain plenty of fibre (2).

### Fish

Regular fish consumption (once or twice a week) is protective against CHD and stroke. As brought out earlier fish is a rich source of omega-3 fatty acids (4).

### Alcohol

While low to moderate consumption of alcohol is protective against CHD, concerns about the other cardiovascular and health risks associated with alcohol consumption (like stroke, hypertension and cancers) do not favour a general recommendation for its use.

### Low calorie foods

As a general rule, food that is low in calories, but which

Reduce fat in your diet : Facts on fats & how to ensure right quantity and quality (3)

- **Fats are necessary but excess is dangerous.**
  ~Moderate total fat intake. Limit visible fat and cut down invisible fat from animal foods.
- **Saturated fats present in animal foods increase blood cholesterol and worsen blood clotting.**
  ~Select low fat milk, limit/avoid cheese, meat, butter, ghee and hydrogenated oils.
- **Trans fatty acids increase blood cholesterol.** ~Limit/avoid hydrogenated oils and repeated frying.
- **Vegetable oils and plant foods do not have cholesterol. MUFA and PUFA decrease blood cholesterol and suppress clot formation in blood.**
  ~ Prefer plant foods and vegetable oils.
- **The ratio of saturated to polyunsaturated fats should be roughly 0.8 to 1.0.**
  ~This can be achieved by a judicious combination of cereals, pulses, vegetables, milk & vegetable oils.
- **A good balance of linoleic (n-6) and alpha-linolenic (n-3) acids is essential.**
  ~Use of mustard oil or soyabean oil along with other oil(s) will help to achieve this.
  ~ Also eat plant foods that are good sources of alpha-linolenic acid (Table 1).
- **Long chain n-3 PUFA found in fish lower blood cholesterol, triglycerides and prevent clot formation. They also lower blood pressure and have several other beneficial effects.**
  ~Those who like fish should take 100-200g twice a week.
- **Carbohydrates esp. refined sugars, increase triglycerides.**
  ~Prefer natural food; reduce refined sugars (sucrose, sweets, candies etc.) in diet.

Rich sources of α-linolenic acid (2)

| | |
|---|---|
| Cereals and Millets | Wheat, *Bajra* |
| Pulses and Legumes | Blackgram, cowpea (*lobia*), *rajmah*, soya bean |
| Vegetables | Green leafy vegetables |
| Spices | Fenugreek (*methi*), mustard (*rai*) |
| Oils | Mustard, soyabean |
| Animal foods | Fish (Rich in n-3 PUFA) |

can fulfill the daily requirements of energy in a balanced manner is considered as healthy. To keep the calories low in the diet the upper limit of calories intake must be limited to the recommended values for sex and activity level. Fats and oils are the most concentrated source of energy so intake of fats and oils must be restricted, as mentioned earlier. Similarly excessive intake of carbohydrates (cereals and starchy foods like potatoes) must also be discouraged.

## Diabetes mellitus and diet

Diabetes is a metabolic disorder characterized by chronic hyperglycaemia with disturbances of carbohydrate, fat and protein metabolism resulting from defects in insulin secretion, insulin action, or both (5). The details of the disease, its risk factors and prevention are discussed in the section on Non Communicable diseases.

We will concentrate on the dietary management of diabetes in this chapter.

### Objectives of dietary management (5,6,7)

(a) To remain healthy using appropriate foods.
(b) To achieve and maintain optimal metabolic outcomes:
(c) Reduce blood sugar
(d) Maintain ideal body weight
(e) Reduce serum lipids
(f) To avoid any complications
(g) Avoid acute complications – hypoglycaemia, ketoacidosis, etc.
(h) Prevent vascular complications

### Diet in Diabetes

Dietary advice should be placed within a comprehensive context of care which includes supporting patients to manage their diabetes and make decisions; it should also complement other treatment including drugs, physical activity, etc. Dietary advice must take account of the individual's personal preferences, cultural background, and lifestyle.

The diet should not be a complete deviation from his existing diet. People with diabetes do not need to follow a 'special diet' or comply with narrow restrictions or measured portions of food, as thought earlier. However, eating well is important for good diabetes control and can contribute to improved well-being. The optimum healthy choice of food for people with diabetes is the same as for the general population and ideally should be low in fat, sugar, and salt, include plenty of fruits and vegetables and base meals on carbohydrate foods such as bread, potatoes, and rice. In fact a typical Indian diet is very close to such a diet! Patients with newly diagnosed diabetes should be referred for individual advice to a dietitian and

afterwards receive an annual dietetic review (6,7)

Calories

It is recommended that the patient should take that many calories which help him to maintain his body weight to 10% lower than the ideal body weight. A rough measure of the ideal body weight can be obtained by subtracting 100 from his height; or else height-weight charts can be used.

**Recommended Calorie Intake**

Recommended Calorie Intake is based on the current body weight of the patient and is given in Table - 1. (7,8)

The distribution of calories in the diet for a diabetic is given in Table - 2

Table - 1 : Recommended Calorie Intake for Diabetics

| Body weight | Recommended calories |
|---|---|
| Ideal | 30 kcal/kg/day |
| Overweight (> 20% of ideal weight) | 20 kcal/kg/day |
| Underweight (< 20% of ideal weight) | 40 kcal/kg/day |

The composition of optimum diet above must be translated into practical advice through the following tips on major foods / nutrients :

Table - 2 : Distribution of calories in the diet

| Nutrient | Percent of total calories |
|---|---|
| Carbohydrate | 60-65% |
| Protein | 15-20% |
| Fat | 15-20% |

Carbohydrates

Eat regular meals based on starchy carbohydrate foods such as bread, potatoes, rice, and chapattis. Choose wholegrain foods where possible, e.g. wholemeal bread and whole grain cereals.

Sugars

Reduce refined sugars and sugary foods. However, following a very strict sugar-free diet is not necessary. Some sugar can be used as an ingredient in foods e.g. in many wholegrain breakfast cereals (dalia, cornflakes). Sugary drinks should be replaced by sugar-free or diet alternatives.

Fats

Reduce intake of fat, especially animal fat. Eat less butter, cheese and red meat. Prefer low fat dairy foods like skimmed milk. Replace fried foods with steamed or oven baked items. Prefer small quantities of PUFA (plant oils) to saturated fats (butter/ghee).

Proteins

A liberal intake of proteins is recommended (except in associated kidney disease). Intake of 1 to 1.5g protein /kg body weight is recommended.

Vitamins & minerals

Eat more fruit and vegetables to get optimum vitamins and minerals. Five portions per day would suffice.

Salt

Cut down on salt. Spices, lemons, etc can be used as an alternative.

Alcohol

Avoid alcohol. Limit alcohol to not more than two units per day.

Fenugreek seeds

A lot of work has been done on fenugreek seeds (Maithi), which is used as a condiment in Indian diet. They suppress the urinary excretion of sugar and relieves symptoms of diabetes. Fenugreek leaves do not show such effects.

Fibre

A liberal intake of dietary fibre is helpful in the contol of diabetes.

Weight

Weight is a good indicator of diet and diabetic control. Lose weight if overweight by trying to reduce at a rate of 0.5-1.0 kg/ week, as discussed in the chapter on obesity.

**Glycaemic index**

Every carbohydrate when consumed increases the blood sugar. Those carbohydrates that get absorbed quickly raise the blood sugar fast. Such foods are deleterious to health esp for diabetics as they induce an abrupt insulin response. This immediate effect of foods and carbohydrates on the blood glucose levels is measured in terms of glycaemic index. Foods with a high glycaemic index are readily absorbed and raised blood glucose quickly. Low glycaemic index foods are digested and absorbed slowly and raise blood glucose levels slowly. The glycemic index of Glucose is taken as 100. The glycemic index of various common Indian

Table - 3 : Glycaemic Index of Common Foods (7)

| Item | Glycaemic Index | Item | Glycaemic Index |
|---|---|---|---|
| Bread | 70 | Apple | 39 |
| Millets | 71 | Banana | 69 |
| Rice (White) | 72 | Potato | 70 |
| Wheat (Paratha) | 70 | Potato chips | 51 |
| Soya beans | 43 | Idli | 80 |
| Dals | 48 | Groundnuts | 13 |
| Glucose | 100 | Milk | 33 |
| Sucrose | 59 | Fructose | 20 |

In general, all foods can be classified into the following three categories for diabetics: (7)

**(a) Foods that can be used freely**

(i) Vegetables ( including green leafy vegetables) and low sugar fruits (banana, mango, dates are high sugar content fruits)

(ii) Spices

(iii) High-fibre foods

(b) Foods to be used in moderate amounts

(i) Fats

(ii) Cereals/Roots/Tubers

(iii) Pulses

(iv) Nuts

(v) Milk products

(vi) Eggs & Meat products

(vii) Artificial sweeteners

(c) Foods to be avoided

(i) Sugar / Sweets /Honey

(ii) Jam and jellies

(iii) Cakes and pastries

(iv) Sweetened juices and soft drinks

(v) Fried fruits, *ghee*, butter

# Common Nutritional Deficiency Disorders

There are serious deficiencies in the diets of our population particularly among the poor. As a consequence of this dietary deficiency, several nutritional deficiencies with clinical manifestations and disabilities are encountered in our country. Most important of them being:

(a) Vitamin A deficiency
(b) Iron deficiency anaemia
(c) Iodine deficiency disorders (IDD)
(d) Protein energy malnutrition (PEM)

These four are often referred to as *'Nutritional giants'* and have been the concern of health authorities in the country. PEM and vitamin A deficiency occur mostly among preschool children. Goitre due to iodine deficiency results in thyroid insufficiency, impaired metabolism and mental retardation. Anaemia is prevalent in all groups. Fortunately our troops and families are in receipt of good nutrition and so, except for anaemia, the other three nutritional deficiencies are not commonly come across. Hence they are dealt with in brief (1).

## Vitamin A deficiency

Vitamin A deficiency is a major nutritional problem affecting young children and leading to blindness.

### Magnitude of the problem

It is one of the major nutritional public health problems in India and other developing countries. Millions of children (esp preschool children) are at risk of xerophthalmia. About 36 countries in South East Asia, Western Pacific & Africa are most affected. World-over 256 million people suffer from preclinical xerophthalmia and 2.7 million from xerophthalmia. 7,00,000 patients develop corneal lesions and 3,50,000 become blind of xerophthalmia.

In India it is commonest amongst preschool children esp from rice eating states (Andhra Pradesh, Tamilnadu, Karnataka, West Bengal and Bihar). The prevalence of Bitot Spots in the 1to 5yrs age group is about 1-5%. Very few studies report corneal lesions in India (0.05-0.1 per 100 preschool children in South India) (2)

### Xerophthalmia

Xerophthalmia is the manifestation of vitamin A deficiency in various clinical forms. Xerophthalmia assumes extreme importance because it is seriousness, may lead to blindness and is preventable. Public health problem of Xerophthalmia can be ascertained by the levels of prevalence of various conditions amongst the preschool children in the community (Table - 1)(3).

### Clinical Features (4)

Night Blindness

It is classically associated with vitamin A deficiency. Seen more commonly in the pre-schoolchildren, mother of the child typically complains that in the evening child strikes against a stone while playing and falls down frequently, he can't see the contents of his food plate and gropes for food especially at dusk time and he is unable to see what's written on the black-board. Night blindness usually responds rapidly to vitamin A tablets/oil or injections.

Table - 1 : Xerophthalmia as a public health problem

| WHO Classi-fication | Clinical condition of xerophthalmia | Prevalence among preschool children |
|---|---|---|
| XN | Night blindness | >1% |
| X1A | Conjunctival xerosis | |
| X1B | Bitot's spots | >0.5% |
| X2 | Corneal xerosis | |
| X3A | Corneal ulceration/keratomalacia (involving <1/3 of cornea) | >0.01% |
| X3B | Corneal ulceration/keratomalacia (involving >1/3 of cornea) | >0.01% |
| XS | Corneal scar | >0.05% |
| XF | Xerophthalmic fundus | - |
| Biochemical | Plasma retinol <0.35 mmol/l | >5% |
| | | |

Conjunctival Xerosis

It is one of the earliest detectable signs of vitamin A deficiency. It manifests as thick, wrinkled (vertically folded) conjunctiva with a tendency to dryness. It is resticted to 'exposed' bulbar conjunctiva. The dryness looks like “Waxy Paint” as there is loss of transparency and no shine in the affected conjunctiva. It is unwettable, classically referred to as a “Receeding tide” of the tear drop. The unwettability is because of reduced goblet cells/mucin secretion from the lachrymal glands, due to affected epithelium. The 'break-up time of tears' is also reduced

Bitot's spots

These are white triangular patches present on the conjunctiva. They resemble flakes of foam or plaster on the surface of the conjunctivae, due to hyperkeratinizing metaplasia of the epithelium and accumulation of seborrhoeic excretions.

**Site :** Bulbar Conjunctiva, on either side of cornea, generally temporal and bilateral

**Shape :** Classically triangular (but not always)

**Color** : Pearly white/creamy-yellowish/cheese

**Texture**: Foamy, soapy

**Symmetry**: May be bilateral

**Characteristic feature** : Unwettable

**Importance:** Usually indicates Vitamin A deficiency, esp in children.

Corneal xerosis

If not treated at an early stage, the cornea too, becomes pale, lusterless and looses its sheen, corneal xerosis. This may progress to a state of **corneal ulceration** and subsequently **keratomalacia** may ensue. There may be an eventual perforation through which the contents of the eye may extrude out and the patient looses his sight.

Extra-ocular manifestations

Follicular hyperkeratosis, growth retardation and anorexia are some of the extra-ocular manifestations of vitamin A deficiency.

**Treatment of xerophthalmia (2)**

(a) 2,00,000 IU (110mg) of Retinol Palmitate (oil miscible vitamin A) is administered orally for 2 days. In cases of persistent vomiting/diarrhea, water miscible vitamin A 1,00.000 IU is administered IM Injection, followed by 2,00,000 IU 1-4 wks later

(b) For infants less than 1year old or less than 8 kg weight, use half the dose

(c) Refer case to Eye specialist, if active corneal lesions are there

(d) Monitor severe cases of Acute Respiratory Infections, diarrhoea, measles and protein energy malnutrition carefully, as vitamin A deficiency is likely to be precipitated in them.

(e) Avoid large doses in pregnant women

**Prevention**

It is one of the simplest preventable nutritional disorders. The following actions must be taken.

Dietary modifications

Dietary modifications to promote production & consumption of Vit A & beta-carotene rich foods. Include rich sources of vitamin A, like dark green leafy vegetables, Deep yellow/ orange coloured fruits, eggs, milk, meat in the diet.

Nutrition education

Educate the troops on the importance of vitamin rich diet, its regular intake and the harmful effects of its deficiency. Importance of home gardening, consumption of fresh fruits and vegetables, food preservation techniques must also be emphasized. *Sainik sammelans*, family welfare meets and mass media can be used to the fullest to disseminate this message.

Periodic massive dosage (2)

(a) Vitamin A administration is now integrated with immunization program

(b) 1st dose 100,000 IU is given at 9 months of age along with measles vaccines

(c) Thereafter the second and subsequent doses of 200,000 IU are given at 6 monthly intervals till 3 yrs of age

(d) Fortification of ghee and butter are being done as a government policy to augment the vitamin A status of people.

Long term action

Constant nutritional education emphasizing good diet (including fruits & vegetables), importance of immunization, environmental sanitation, breast feeding, early treatment of infections and good maternal and child health care would go a long way in the prevention of this condition.

## Anaemia

Anaemia is another important nutritional problem affecting all segments of the population in general and children, women and pregnant women in particular.

Anaemia is defined as a condition in which the haemoglobin content is lower than normal as a result of deficiency of essential nutrients, regardless of the cause of such deficiency. As per the WHO, normal haemoglobin levels are (5)

| | |
|---|---|
| Males | 13g/dl |
| Females | 12g/dl |
| Pregnant female | 11g/dl |
| Children | |
| 6m-6yrs | 11g/dl |
| 6yrs-14yrs | 12g/dl |

Any levels below those specified above are considered as anaemia.

In pregnant women prevalence of anaemia may be as high as 60-70%. Anaemia in our country is essentially due to iron deficiency although in children and pregnant women, folate deficiency also plays a part. Although our diets contain fairly good amount of Iron, its absorption is very poor (2-3%). Anaemia can be aggravated by environmental factors which lead to blood loss e.g. poor sanitation, hookworm infestation, etc.

**Prevention**

Anaemia can be prevented by increasing iron intake in the population. Two approaches are used to achieve this.

One is by improving the diet by incorporating iron rich foods like meat, green leafy vegetables, jaggery, etc. Vitamin C sources (lime, *amla*, guava, etc.) should also be encouraged, as they augment the absorption of iron.

Therapeutic supplementation of iron and folate tablets is also resorted to. A public health programme of distribution of iron folate tablets to pregnant women (during last trimester) and preschool children is in operation as a part of MCH services. This approach is designed to achieve results in a limited time, like in pregnancy. Details are given in the chapter on RCH programme.

Besides enriching the diet with iron it is also important to limit iron losses. Therapy and prevention of helminthiasis including hookworms is achieved through health

education, improving hygiene and sanitation, use of drugs and provision of safe drinking water. Excessive menstrual losses and blood loss due to IUDs (or any other pathological causes as piles, bleeding peptic ulcers, etc) should also be attended to. Good ante-natal care leading to early diagnosis and sustained treatment of anaemia is important not only to keep the pregnant mother anaemia free, but also to keep the next generation healthy (6).

## Iodine deficiency disorders (IDD)

The major nutritional deficiency leading to goiter and cretinism is iodine deficiency. Iodine deficiency disorders (IDD) are endemic in Sub-Himalayan belt in North India affecting nearly 120 million people. Recently new pockets of IDD have been identified in other parts of India particularly in tribal belts, in Gujarat, Madhya Pradesh, Andhra Pradesh, Maharashtra, Kerala and Karnataka, bringing the total affected population to 200 million. Although goitre is mainly due to iodine deficiency in some areas, goitrogens present in some of the habitual foods, may be contributing to the precipitation of iodine deficiency when iodine intake is marginal (1,7).

### Clinical features

IDD may presents as a spectrum of disorders and illnesses throughout the life cycle (8)

Foetus and neonate

Abortions, stillbirths, congenital anomalies (umbilical hernia, large anterior fontanel), high unexplained perinatal and infant mortality, lethargy, poor feeding, prolonged physiological jaundice.

Infancy & early childhood

Signs of cretinism (mental deficiency, deaf-mutism, squint, short stature, hoarseness of voice)

Child & adolescent

Poor scholastic performance, juvenile hypothyroidism, retarded mental and physical development.

Adult

Mental and physical underdevelopment. People appear to be slow and rather sleepy.

Prevention and control

Control and prevention of goitre has been principally based on providing extra iodine to the population through iodised salt distribution or iodised oil injection in hyperendemic areas. Iodisation of all salt is undertaken 30 ppm at source so as to give at least 15 ppm at the consumer end.

The importance of iodized salt in prevention of IDD has to be emphasized repeatedly to the community. It must be reiterated that only iodized salt must be consumed by all. It must be consumed within 6 months of iodization, as the concentration of iodine diminishes with time. The community must be made aware of the fact that selling of uniodized salt may attract legal action. All health education methods must be resorted to, for effective dissemination of this information eg through lectures, road shows, audiovisual aids, schools and women groups, etc. (9,10)

## Protein Energy Malnutrition (PEM)

Malnutrition is a range of conditions occurring when intake of one or more nutrients doesn't meet the requirements. PEM is a malnutrition resulting from the deficiency of protein and/or energy in diet. Protein energy malnutrition (PEM) is an important nutrition problem among preschool age children. This leads to various degrees of growth retardation. When growth retardation is severe, functional deficiencies, like resistance to infection and poor intellectual development may result. The main cause of PEM is food inadequacy ie the deficiency of energy or proteins or both. In these cases deficiency in other nutrients like vitamin A, iron, calcium and riboflavin is also seen. It is also known that infections like measles and diarrhoea aggravate PEM (1).

Protein Energy Malnutrition classically manifests as Marasmus or Kwashiorkor. Marasmus results from a continued restriction of both dietary energy and proteins. It is most common in children aged less than 5yrs (most cases < 1yr, in urban areas). In adults it may be said to be similar to a clinical manifestation of 'starvation'.

The term Kwashiorkor was introduced by Cicely Williams. It comes from language of 'Ga' tribe of Ghana, meaning “Sickness the other child gets when the next baby is born”. In 1959, Jelliffe introduced the term PEM, as there was close association between Kwashiorkor and Marasmus (4,11)

### Prevalence

The prevalence of clinical forms of PEM is estimated to be about 1% is in India. The prevalence of Marasmus is higher than Kwashiorkar. A mixed picture of Marasmic-Kwasiorkar is commonly seen. More than 80% cases are mild to moderate grade (12).

### Importance

Malnutrition is an important public health problem as it involves many children. It is a self perpetuating problem as the vicious cycle of malnutrition and PEM persists. It has got long term effects in the form of growth retardation and mental deficiency and mortality.

### Etiology

The old concept of 'protein gap' (deficiency of proteins in diet) has now given way to the new etiological theory of 'Food gap'(1). Inappropriate food (low in energy density, protein & micronutrients - Vitamin A, Iron, Zinc) which is poor both quantitatively and qualitatively is the chief cause of PEM. Under-nutrition in fetal life, esp last trimester, lactation failure, low energy dense weaning foods, incorrectly constituted formula, contaminated water and infections (Diarrhoea Measles, Acute Respiratory Infections, Intestinal worms etc.) also play important role in the causation of PEM.The other associated social factors are poverty, poor environmental conditions, large families, poor MCH services and poor cooking practices. Ignorance and the inability to provide adequate food also seem to be important contributory factors.

### Clinical features

Marasmus

**(a) Constant features**

(i) Growth retardation

(ii) Wasting of muscles & subcutaneous fat- 'Wizened old man's look'

**(b) Other features**

(i) Hair changes - Easily pluckable hair

(ii) Infection

(iii) Vitamin deficiency

(iv) NO psychomotor changes

Kwashiorkor

(a) **Constant features**

(i) Oedema

(ii) Growth retardation

(iii) Muscular wasting

(iv) Retention of some subcutaneous fat

(v) Psychomotor changes

(b) **Other features**

(i) Hair changes Flag sign

(ii) Diffuse pigmentation of skin and dermatoses- Flaky paint dermatosis

(iii) Moon face

(iv) Anemia

(v) Hepatomegaly

(vi) Associated vitamin deficiencies (Retinol, Tocopherols, Folate, Pyridoxin, Vitamin K)

(vii) Associated mineral deficiencies (Iron, Potassium, Zinc, Copper, Selenium, Magnisium)

(viii) Associated acute infections

**Assessment**

**Causation of edema in PEM (13)**

Due to a predominant deficiency of proteins hypoalbuminaemia results which leads to lower intravascular oncotic pressure, causing edema. In other words a low amino acid supply in diet causes a reduced hepatic synthesis of proteins leading to low circulating plasma proteins and edema. Another newer theory attributes edema to the imbalance between free radicals and antioxidants. Infections trigger inflammation and free radical injury. This leads to an oxidative damage to structural lipids of the cell membrane which becomes permeable to sodium and potassium and thus the fluids leak into the extracellular spaces causing edema.

The level of antioxidants is already low in infections which further aggravate the PEM being precipitated by poor diet. So it is a vicious cycle between infection, high free radical load, low antioxidants and PEM.

The condition can be assessed by using any of the 'malnutrition' classifications. The Gomez Classification is simple and is commonly used. It is a 'weight for age' classification. The weight of the given child is compared with a 'normal child'. 'Normal child' is defined as the 50th centile of Harward (Boston) standard.

**Prevention**

Health promotion

The following issues are vital:

(a) Good ante-natal care

$$\text{Wt for age (\%)} = \frac{\text{Wt of child}}{\text{Wt of 'normal child' of same age}} \times 100$$

Table - 2 : Interpretation of Gomez Classification

| Weight of child as compared to a 'Normal child' | Interpretation |
|---|---|
| 90-110% | Normal |
| 75-89% | 1st degree/mild malnutrition |
| 60-74% | 2nd degree/moderate malnutrition |
| < 60% | 3rd degree/ Severe |

(b) Education on food, hygiene and family planning

(c) Education on the importance of colostrum, diet during lactation

(d) Various measures under the ICDS initiative, like good nutrition, immunization, education, hygiene and sanitation etc.

(e) Promotion of breast feeding

(f) Good weaning practices, correct time of weaning, importance of low cost weaning foods

(g) Prevention and control of infections during weaning

(h) Improve family diet

(j) Correct knowledge on balanced diet

(k) Using of family planning practices

(l) Hygiene & sanitation

Specific protection

**(a) Diet**

Protein & energy rich food should be consumed by children. Special attention must be paid to diet during weaning. Adequate quantities of fruits and vegetables must be included in the diet.

**(b) Immunization**

The child must be immunized as per the national schedule.

Early Diagnosis & Treatment

**(a) Growth monitoring**

Vulnerable children must be identified. Children must be monitored through growth charts. Early diagnosis of growth failure must be done and treated as appropriate.

**(b) Early diagnosis and treatment**

Early diagnosis and treatment of infections is also vital. To achieve this, health worker must be alert and mothers should be aware of the signs and symptoms of common infections. Preparation and use of ORS should be known to all mothers.

(c) **Medical advise**

In extreme and serious cases early medical advice must be available. Hospitalization of the case remains the only choice in complicated cases.

## Conclusion

These four nutritional giants, if not prevented, may lead to many long lasting disabilities. PEM results in poor growth and development among children. Vitamin A deficiency leads to nutritional blindness. Anaemia leads to impaired work capacity, impaired resistance to infection and poor pregnancy outcome. IDD results in thyroid insufficiency, impaired metabolism, mental retardation and cretinism which may be irreversible. Therefore it is of utmost importance to take all preventive measures against them.

# Rations, Catering and Food Inspections in the Armed Forces

## History of military nutrition

*'An army marches on its belly'*

**~Napoleon**

This dictum only crystallizes the fact that troops must be given enough to eat and are more efficient when well fed. The old armies were dependent largely on the efforts of foraging parties for their rations; if the land was barren of food, they faced starvation as had happened with the German forces advancing into Siberia in the II World War. Most armies in the olden times did not pay much attention to the nutritive value of different foods. Navies, on the other hand, were familiar with the fact that on long voyages, crews were decimated by scurvy. As early as in the 16th century the cure for scurvy with oranges and lemon juice had been described. During his second voyage to the South Seas (1772-75), *Captain Cook* kept his crew entirely free of scurvy -- an unprecedented feat. He used a variety of substances, including germinating seeds and lime juice. Perhaps, the earliest controlled human clinical trial ever undertaken was the one conducted by *James Lind* on prevention of scurvy in 1742 and published in 1752. Beriberi was the scourge of the Japanese Navy prior to 1882, when it was eliminated by *Admiral Takaki* who increased the allowances of vegetables, fish, meat and barley.

The science of nutrition was applied to military affairs in the modern sense only in the second decade of the 20$^{th}$ century. No convincing explanation of the influence of diet on diseases was available until the concept of vitamins was placed on a sound footing by *Hopkins, McCollum, Funk* and others between 1906 and 1913. In the First World War nutritional science was used for the first time in military medicine, in the true sense. Both the quantity and quality of rations were intensively studied. Shortage of food and limitations of shipping necessitated the observance of utmost economy in rations in 1916. Another instance of effectiveness of vitamins is that the health of *Allenbys'* troops improved considerably after entry into Palestine, with less wastage due to sickness and rapid healing of wounds. This has been attributed to the availability of citrus fruits and green vegetables in abundance in that area. (1, 2)

The state of nutrition of troops determines their potential fitness, that is, their capacity to overcome hardships and disease. Troops may be called 'fighting fit' when their nutrition is optimal, they have positive health, are adequately trained, and when all possible measures against disease have been taken. Unless nutrition is optimal, full benefit from training and minimal wastage from diseases cannot be expected. Nutrition is also a basic factor in morale; only well-nourished troops can show vitality and keenness at its highest.

## Responsibility of Medical Officers

Nutrition not only aims at preventing deficiency diseases but also at maintaining the highest possible level of fitness. To achieve this all medical officers should be acquainted with these factors: Nutritional characteristics of food, requirements under varying conditions (including war), ration scales, manifestations of malnutrition, organization of supply, inspection of rations, scope of catering and cooking etc.

## Feeding of Armed Forces personnel

### Principles

(a) During war or peace, the issue of rations in kind must be the mainstay.

(b) The standard ration scales must fulfill nutritional requirements under various circumstances.

(c) It must make every possible allowance for the habits and tastes of the consumers.

(d) Flexibility should be attained by authorizing substitutes through which fluctuations in supply and catering can be met and variety can be achieved.

(e) Where true nutritional equivalence is not possible, issues of substitutes should be limited so that the total nutritional balance of the ration scale is not seriously impaired.

(f) Ration scales should, as far as possible, be composed of fresh foods.

(g) Processed substitutes may be inevitable in war, but tinned and dehydrated foods should be treated as a means to an end and not as a perfectly satisfactory method of feeding troops.

(h) The importance of any given food in a ration is related not only to its absolute nutritive value but also to the quantity in which it is consumed. It is therefore, quite justifiable to sometimes use a food of limited nutritive value for the sake of variety, or to eek out short supplies.

(j) Canteens should serve more as places for providing diversion and an interlude to break the inevitable monotony of unit catering & not as a substitute for it.

The armed forces present diverse situations and problems as far as nutrition of the troops is concerned. Nutritional requirements and challenges for the armed forces personnel are not only different from the normal population but even within the armed forces they vary during training, stay in peace areas, exercises, field areas, high altitude and operations. These issues are discussed in the subsequent sections.

## Armed Forces Rations

Before the First World War, Indian troops received a cash allowance from which each man purchased his own food, with the result that no control on nutrition was possible. Experience in Mesopotamia in 1916 underlined the

danger of such a system. After the war the system was so modified that a cash allowance was made to units and not to individuals. Certain foodstuffs were also supplied in kind. Under the peace scale *atta* / rice 24 oz, *dal* 3 oz, potatoes and *ghee* 2 oz each, sugar 1½ oz and salt ½ oz were issued in kind. The field service ration scale included the same items as issued at present except that the quantities of meat and *dal* were less by an oz, vegetable by 2 oz and the milk issued was almost half of the present quantity. The *ghee* was supposed to be pure animal *ghee*, a fact which is still remembered by some old soldiers with nostalgia.

During World War II, the army expansion and rise in the cost of living brought difficulties in food supplies. In 1943, a modified field service scale was authorized in 'peace' areas, which was converted into a basic ration scale for all Indian troops in 1944. However, in 1945, due to shortage of food, further changes were made to overcome the food shortage in India.

**Administration**

A variety of rations have been formulated for different purposes and are published in 'Scales of Rations and Supplies' (SRS) issue by the ASC which are frequently amended to suit the supply position and requirements. The fundamental regulations regarding ration scales, provisioning and supplies are contained in DSR paras 884 to 901. In addition to the ordinary services ration scales, special rations are available for road and rail journeys, hospitals, and for special operational purposes. Ration scales are drawn up or amended by the respective HQs in consultations with their Medical Directorates. Policy matters regarding ration scales are dealt with on an inter services basis by the Armed Forces Health Sub Committee of the Medical Services Advisory Committee.

The fundamental consideration is to satisfy the quantitative and qualitative nutritional requirements of Armed Forces personnel working under different conditions. The bases for this consideration are the human requirements of energy, proportion of proximate principles in the diet, optimum quantities and proportions of vitamins, minerals and trace substances. These requirements are drawn out of various tasks required to be performed by the consumers. Various administrative, tactical and operational contingencies are also considered. The supply position is assessed and taken into consideration. The durability (shelf life) of various items is considered. The habits and tastes of various categories of personnel and acceptability of the items are also considered. Substitutes for short supply items and to relieve monotony are recommended with appropriate restrictions against continuous use. In drawing up ration scales the medical services, the ASC, purchase organizations and the food inspectorate actively collaborate.

**Routine rations**

Armed Force rations normally contain fourteen basic items- atta, rice, pulses, potatoes, onions, meat, vegetables, milk, sugar, tea leaves, oil, salt , fruit and condiments; firewood for cooking is also included in the ration scales. To provide variety and to meet the market fluctuations of availability of items, substitutes like fish, pork, eggs, fowl, nuts, and dry fruits are also included in the provisioning schedules. Not less than 40 percent of the vegetables are required to be green leafy vegetables. Tinned, dried, dehydrated or AFD (Accelerated Freeze Dried) items are provisioned for use under field conditions when the supply of standard fresh items becomes logistically difficult or impossible. When such an issue is unavoidable for more than two weeks and/or nutritional deficiencies jeopardizing the health of the troops are envisaged, the rations are fortified by authorizing synthetic vitamins under orders of Army Commanders with the advice of the DDsMS. The intention of controlling this is twofold; to restrict unnecessary use of the expensive item and to incidentally keep the Army Commander informed of the fresh rations breakdown.

**Energy value**

The energy value of the usual Armed Forces ration scales ranges from 3700 to 5000 Kcal (15.51 to 29.9 Mj). Values of rations for any special circumstances i.e. physical emergencies as in combat and training may vary according to the needs. The peace service scale for army personnel provides 3710 Kcal (15.54 Mj), field service scale 4040 Kcal (16.9Mj), high altitude ration scale 5080 Kcal (21.25Mj), the composite pack ration 3500 Kcal (14.64Mj) and emergency or survival rations still less. The usual peace scale ration for Army personnel contains about 120 gm of protein of which 21 gm is of animal origin, retinol 1206 mg, thiamin 4.9 mg, riboflavin 2.8 mg., nicotinic acid 32 mg, ascorbic acid 130 mg and iron 85 mg. Carbohydrate is mainly from cereals, pulses, sugar, and potatoes; animal proteins are drawn from meat and milk; vegetable proteins are drawn from cereals, pulses and a few vegetables; fats are drawn from vegetable oils and milk. 20g of salt evaporated is supplied to satisfy the salt demand and 20g of salt can also be issued extra in summers.

Field service rations contain more cereals, milk, meat and oil but less vegetable. The high altitude ration scale has a high carbohydrate and high protein proportion. High protein contained in a high altitude ration has been achieved by addition of extra meat, egg, gram flour (baisan) and milk powder; while higher carbohydrates are supplied as jam and extra sugar. Air force and Navy rations are richer in animal protein than Army rations.

**Various ration scales**

The summary of ration scales at present in force in the Armed Force is given in appendices 'A' to 'J'. These appendices show only the standard items and not the alternative/ substitute items. The authorities are :

(a) Scale of ration for troops in Peace/Field area (SAI 7/S/74)

(b) Scale of ration for Officers in Peace/ Field area (Annexure to Govt of India, Min of Defence letter no 3(I)-83/D(QS) dated 12 Mar 1983.

(c) Scale of ration for troops at high altitude of 9000

ft. (2700 m) and above (SAI 3/S/72)

(d) Scale of ration for officers in Jammu and Kashmir and NEFA area (SAI 3/S/72).

(e) Scale of ration for Indian Navy (NI 06/86)

(f) Scale of ration for Indian Air Force (AFI 18/S/68)

(g) Scale of ration for cadets of the National Defence Academy Khadakvasla and Indian Military Academy, Dehradun (AI 8/S/74 and AI 33/91- Same scales are also applicable for cadets at OTA, Madras, CME and AFMC Pune, MCTE, Mhow, MCEME, Secunderabad.)

(h) Ration scale for cadets at the Rashtriya Indian Military College, Dehradun (AI 10/S/74).

(j) Extra/ration for edentulous cases (AI 10/S/76).

(k) Hospital diets and extra (AI 94/76).

In addition to the above ration scales there are operational rations consisting of an emergency ration scale and composite pack rations (AO 157/73) and also survival rations.

## Provisioning and supply of rations

### Functions of Medical Services

Medical services are responsible for advice on the composition of ration scales and on any other matters relating to rationing which have a bearing on the health of the troops. The DGsMS (Army, Navy and Air force) are the advisers to their respective Chiefs of Staff. The DGsMS are assisted by ADG (H and P) and JDsMS(H) Navy and Air. Administrative Medical Officers at lower levels have the same responsibilities towards local commanders, their technical advisers being the ADsH at command and Corps and DADsH at Division and Area HQ levels. Officers of the equivalent appointments in Navy and Air force administrative HQs are advisers to their commanders. However, any medical officer may be consulted by Commanders on some aspect of food and nutrition. The information in this chapter should enable him to deal with most questions. Medical Officers act in an advisory capacity; the discretion of accepting or otherwise of medical advice rests with unit/ formation commanders. The provision, supply and handling of food are functions of the ASC. Medical officers should ascertain the effect of their advice and its implementation by checking the rations received, cooked and consumed. Hospital dietary is in a special category. The specialists should advise regarding hospital rations.

### Functions of ASC

The Quartermaster General (QMG) is responsible for provisioning and supplying rations. The Director General of Supplies and Transport (DG S & T) assists him. This organization has five main functions: provisioning; supply; inspection of food stuffs; training of cooks; and catering. Provisioning and supply is based on ration scale drawn up by the Service Headquarters in consultation with the Medical Services. Foodstuffs are ordered centrally through the Food Ministry or purchased from local markets. Local purchase requires less organization and is eminently suitable for perishable and fresh foodstuffs or for those with only localized distribution. Before finalizing the contracts for provisioning, representative samples of items are inspected by the Food Inspections Organization of the S & T directorate. Supplies are organized according to ration scales, strength of unit/formation and availability of articles. When the food has been passed as fit for acceptance it is held in supply depots for issue to troops in accordance with unit indents.

## Catering in the Armed Forces

### Army

At the Army HQ a catering cell with a specially trained catering officer and the Deputy Assistant Director (Catering) as its head, functions under the Directorate General of Supply and Transport. At the Command level the officer commanding of the Command School of Catering functions as the Advisor in Catering. In a Mountain Division, a catering JCO is appointed in its ASC battalion. At ASC School, Bareilly, there is catering wing for training of unit cooks. The IMA and NDA are authorized catering officers/ JCOs. At Command Hospitals there is an ASC catering JCO while at other large hospitals an AMC JCO is trained to carry out the duties of a catering JCO.

In each station there is a Station Messing Committee with the Station Commander as the Chairman; OsC of units, unit messing officers, the manager of the dairy farm, Naval and Air Force representatives and the formation/station catering officer/JCO as members and the ASC officer as the secretary. They assemble every month to discuss matters concerning rations, the supply position and catering. In each unit there is a similar unit messing committee with 2 IC as chairman and Coy JCOs, MO, messing officer, QM, senior cook and Mess NCOs as members. They also assemble once a month to discuss messing problems. A unit messing officer is appointed to ensure proper catering in all the JCO/OR messes. The catering officer/JCO from the formation HQ advises units on all matters.

### Navy

The Director of Supply is responsible for laying down the policy at Naval Headquarters. Under his direction the logistic officers on the staff of the senior administrative authorities afloat and ashore take steps to implement the various aspects concerning catering, by giving proper guidance and direction to other senior logistic officers of ships/establishments under them. At large establishments and for the fleet, commissioned store officers (catering) are responsible for carrying out the policy under the direction of senior supply officers.

### Air Force

There is a staff officer in charge of catering at the Air Headquarters. Under the AOC command there is a command catering officer who is responsible for detailed supervision of the policy as laid down by Air Headquarters. Station administrative officer is

responsible to the commanding officer for general administration of messing and supervision of rations at various air force stations. He has a station catering officer (when authorized) to advise him, otherwise a messing officer is detailed to carry out these duties. The station catering officer is assisted by WO (catering assistant) of catering.

**Functions of the Catering Establishments**

(a) Station Messing Committee

(i) To acquaint units with the current supply policy, matters regarding turnover of stocks and matters connected with free and payment issues.

(ii) To discuss matters concerning popularity, quality and variety of ASC supplies.

(iii) To discuss suggestions from Unit Commanders on improving supplies.

(iv) To discuss and give out a monthly/fortnightly forecast issue programme prepared by the OC supply depot.

(v) To hear and meet particular preferences of units within the authorized scales of rations.

(b) Duties of Station Catering Advisers

(i) To ensure that the men get the full benefit of authorized rations.

(ii) To advise unit commanders on all points in connection with the messing, cook houses and dining halls.

(iii) To see that the 'bill of fare' is prepared intelligently to provide variety and a balanced diet.

(iv) Training and welfare of cooks.

(v) Maintaining close liaison with medical, engineer and ordnance services on matters concerning nutrition, hospital diets, designing of cooking equipment, cook houses and dining hall equipment.

(vi) Liaison with ASC officers

(c) Unit Messing Committee

(i) To ensure that men are properly fed on the rations available.

(ii) To acquaint members of the unit messing committee with the current supply position.

(iii) To hear and remedy complaints and consider suggestions put forward by the members.

(iv) To draw up the 'bill of fare'.

(v) To see that adequate facilities exist in dining halls and there is no wastage of food.

(vi) To suggest alternate dishes.

**Unit Responsibility**

It is the responsibility of the OC unit / ship to see that the meals provided to troops under his command are satisfactory. The provision of good food is one of the most important factors for the promotion and maintenance of positive health and welfare of a unit. Unit should insist that rations supplied to them conform to the quality and quantity laid down in the regulations. Medical officers should advise accordingly. If there is a legitimate cause for dissatisfaction, the matter must be taken up by the OC with the local ASC officer; the procedure is laid down in DSR- Para 893 A.

The processes of drawing, storage and cooking of the rations are equally important for satisfactory nutrition. The commanding officer is assisted in efficient execution of these responsibilities by the unit messing committee and the unit messing officer/JCO. All rations should be drawn in suitable clean containers and stored in appropriate stores.

**Messing Arrangements**

Rations are issued daily to the kitchen NCO according to the 'bill of fare'. The unit catering officer is responsible for the messing arrangements and should always consult the medical officer and accompany him on his inspection rounds.

Vegetables should always be obtained fresh and cooked in a minimum quantity of boiling water. Fruits and vegetables which are eaten raw, should be first washed thoroughly in running water or in several changes of fresh water, then immersed for not more than three or five minutes in clean WSP solution made by adding one scoop full (2 gm) of WSP to 10 liters of clean water and again washed in clean running water. Cooking must be so timed that food is ready only few minutes before time of distribution. If the food is not cooked and served well it causes wastage and adversely affects the nutrition of troops. An examination of the table waste and swill bins should indicate which items of food are unpopular.

## Sanitation of Cookhouses and Dining Halls

A brief account of sanitation of cook house and dining hall is given here. A detailed description of hygiene aspects of receipt, storage, processing, cooking of food items including meat, milk, eggs, rice, tinned food, water etc. is given in relevant Army Order (AO) on prevention of food & water borne diseases. AO also deals with hygiene of food handlers, control of vermin, responsibilities of various authorities and investigation of outbreak (Refer AO 25/2004/DGMS) .

A high standard of tidiness and cleanliness of all premises used for cooking and serving the food should be ensured. The following important aspects must be considered:-

**(a) Cookhouse premises**

The entire cookhouse premises should be spacious, lighted, fly proof, rat proof, airy and spotlessly clean at all times. The cookhouse should have a separate kitchen or cooking room, a storeroom for fresh provisions, a preparation room, a scullery and a room for the cooks' clothing. Sinks should be provided in preparation room, kitchen and scullery and washing rooms. The floor, wall, ceiling, sinks tables, shelves, cooking appliances and utensils should be spotlessly clean. Fly proofing should be carried out by the use of wire gauze fitted to windows and

doors or use of old mosquito nets / camouflage nets.

**(b) Kitchen**

The kitchen should be spacious and sufficiently large. Properly constructed cooking range is recommended. This will not only economize the consumption of fuel but also keep the cookhouse clear of smoke and afford maximum comfort to the cooks. The kitchen should be fly proof and well ventilated. It should be meticulously clean and tidy. The floor should be well cemented and free from cracks and crevices.

Two flit guns are authorized for each cook house and dining hall for spraying a solution of pyrethrum extract just before the cooking starts. The cooking range should be flanked with platforms for cooks to sit and for prepared food to be kept, awaiting removal to a food serving hatch, racks or hot-plates. Chapati baskets must be lined with clean cloth which is washed daily. All food should be kept covered.

**(c) Preparation Room**

Provision of fly proof and ventilated preparation room for the preliminaries of cooking such as peeling, cutting and washing of food before they are cooked is necessary. The practice of preparation of vegetables on the floor or gunny sacking must be prohibited. This should always be done on a zinc-toped table or granite slabs fitted with a chopping board on it. The peeling and refuse should be deposited directly in a covered refuse bin specially kept for the purpose. The provision of meat chopping block is essential. The block should be washed immediately after use and covered with a layer of powered salt and kept in the sun.

**(d) Store Room**

A separate fly proof and airy store-room for raw fresh food stuffs should be provided. Fresh rations should be kept in baskets/ crates ensuring free circulation of air and stacked on shelves. Fresh fruits and vegetables should under no circumstances be kept in gunny bags. Meat, milk and curd should be kept in a fly proof meat and milk safe or cupboard. Dry rations should be kept in racks, away from the walls, either in neatly tied bags or in tins, on dunnage, preferably in a separate well ventilated store-room. Condiments, tea, oil and salt should be kept away from each other. Rations are issued daily to the kitchen NCO according to the 'bill of fare' and proper accounts maintained. A room for equipment and utensils and for the cooks clothing and other necessaries should be provided separately.

**(e) Scullery**

The scullery should be dry, clean and tidy. Sinks should be adequate, and draining boards should be sufficient and clean. If a proper scullery cannot be provided, as on field service, a properly constructed washing platform with a cement top or PBX top draining into a properly constructed soak-pit through a grease trap must be provided. Maintenance of the grease trap and soak-pit is extremely important to avoid fly, mosquito, cockroach and sand fly nuisance. All utensils after use should be thoroughly cleaned, washed, dried and kept in clean places. Tables should be scrubbed with washing soda and water twice a day using a hard brush.

**(f) Dining Room**

The dining room should be clean, fly proof, well lit, ventilated and cozy in winter and cool in summer. It should be close to the cook-house and afford about one square meter of floor space per man, including passages, for 85 percent of the strength in units and 90 percent in depots. In the field, camouflage netting can provide reasonable fly proofing and a condemned mosquito net can be utilized for protection of cooked food. While serving food, care should be taken to ensure that it is not exposed to flies or dust. It should be presented in a manner that will enhance the acceptability or appeal, and reduce wastage. An effort should be made to supply hot food at all meal times. To achieve this aim, a hot plate should be incorporated in the serving hatch or platform.

All necessary equipment including water jugs and drinking vessels should be presentable and attractively laid out. Water should be taken out by a ladle without dipping the hands. An occasional visit at meal time to see the arrangements for the protection, service and state of food is desirable. Provision should be made for the collection of inedible portions of the meal i.e. bones, peelings, cores etc. Salt and pepper containers should also be provided on each table. Dining tables must be scrubbed with hot water and washing soda after each meal. Officers, JCOs and NCOs messes should also conform to the same standards.

**(g) Cooks' Hygiene**

All men employed as cooks and in the handling of food should take a thorough bath before starting daily work, keep their hair and nails clipped short and invariably scrub and wash their hands with brush, soap and water after every visit to the latrine or urinal and before handling food or raw rations. They should be medically examined at regular intervals, vaccinated against the enteric group of fevers and inspected daily for personal hygiene. The list showing the names of the cooks, date of their employment, dates of immunization, details of medical examination and remarks of the medical officer should be displayed. If civilian cooks are employed, each should have an identity card bearing his photograph to prevent impersonation. They must also be subjected to similar medical examination procedures.

Cooks should be provided with special clothing consisting of 4 aprons, 4 caps (or pugrees), 4 shirts, 2 shorts, 2 trousers to wear while on duty. A clean set of jharons (mops) should be available to the cooks every morning. Facilities for scrubbing hands with brush and washing with soap and running water should always be available. Even in the field, improvised arrangements for provision of running water (tap fixed to a drum) is preferable to a basin of water, which should always be available in the cookhouse at all times.

**(h) Washing Arrangements**

Arrangements to clean and wash the mess tins or plates and hands should be made adjacent to the dining hall. Covered swill bins should be provided and kept on

impervious cement platforms. In the field service, mud platforms properly rammed down after mixing crude oil and covered over with PBX sheeting should be constructed. The lid of the swill drum should always be kept shut. A cement platform or sink should be provided for washing hands. A platform with three open drums containing coarse ash and fine ash (or sand) and for putting used ash should be provided A third platform with three drums for washing and sterilizing mess tins or plates should also be provided. Mess tins and plates should first be cleaned with coarse and then with fine ash, and then washed and rinsed in three drums placed over a kettle-trench. The first 'washing' drum should contain hot water and soap; the second, 'rinsing drum' should contain hot water and soda; the third, 'sterilizing' drum should contain water kept constantly boiling during the period it is being used. The drums should be clearly marked WASH/STERILISE. Utensils should be cleaned with sifted ash or sand before treating in the three containers successively. They may be washed with clean water if the arrangements to boil water are not feasible.

**Rules of the cookhouse and dining hall hygiene**

Rules of the cookhouse and dining hall hygiene as under should be incorporated in all unit standing orders and displayed in a prominent position in all messes, cookhouses and dining halls.

Unit Standing Orders for Cookhouse and Dining room Hygiene

(a) Any one who may be suffering from or under treatment for dysentery, diarrhea or any other communicable disease (a carrier of typhoid or para-typhoid) will not be employed in any capacity in the cookhouse untill certified fit by a medical officer.

(b) An up-to-date nominal roll of all men employed in the cookhouse showing the immunization record and the date of medical inspection will be maintained and displayed prominently in the cookhouse.

(c) Personnel employed in cooking of food will be provided with the authorized special clothing. Aprons will always be worn at work, kept clean, and changed and washed when dirty.

(d) Running clean water (hot during winter), soap, nail brush and clean towel will be provided in each cook-house. Cooks should keep their nails clipped short and invariably wash their hands before they handle the food and after visits to latrine.

(e) No personal clothing, accessories or private property of men employed in the cook-house will be permitted to be kept there; nor will they perform their toilet or washing or drying of their under-clothing in the cookhouse. Personal clothing on the body will be removed and kept in the place provided for the purpose and overalls are put on.

(f) Smoking in the cookhouse is prohibited.

(g) The NCO in-charge will be responsible to ensure that there is always a sufficient supply of clean jharons (mops) available for drying washed dishes and cooking utensils. The jharons used for handling hot and sooty vessels will be separate and distinct. After the last meal these cloths must be boiled in water containing washing soda and hung up to dry.

(h) All pots and pans will be freed from grease, cleaned and dried after the last meal and placed on a shelf on their sides with their interiors exposed to the air and to view.

(j) The cookhouse sinks, tables, chopping blocks, cutting-up boards, pastry slabs, mincing machines, knives, forks, spoons and all other utensils will be kept clean when in use and will be thoroughly cleaned after the last meal. All utensils when not in use, will be kept in the places allocated for them and will be available for inspection at any time.

(k) Only food which is to be used during the current day will be kept in the cookhouse. When not in the process of cooking or in preparation for cooking it will be protected from flies in fly proof food safes.

(l) Food scraps, vegetable peelings, etc will not be thrown on the floor, but directly deposited in covered refuse bins provided for the purpose.

(m) All cutting up of meat will be done on the cutting blocks/boards provided for the purpose.

(n) The bill of fare for the week will be displayed in the cookhouse.

(o) Adequate arrangements will be made for the washing, rinsing and sterilizing of eating and drinking utensils.

(p) Any defect in the cooking apparatus or in the utensils will be reported at once by the NCO in-charge to the unit quartermaster, who will take the necessary steps to have the defects remedied.

(q) The floors of cookhouse will be scrubbed daily and excess water must be dried up by mopping.

(r) The cookhouse and dining hall should be sprayed daily with 0.1 percent pyrethrum solution, preferably between 1000 to 1200 hours.

**Ration Stores**

It should be a fly proof and rat proof concrete building. Grains and flour should be stacked on racks placed away from the wall. In field camps, grains should be stored in iron or tin containers. Regular turnover of reserve rations should be ensured and their condition should always be examined by the medical officer to ascertain whether they are infested with weevils and other food pests. Vegetables such as potatoes, onions and tomatoes should be stored in ventilated shelves and not in gunny bags. Tinned foodstuffs should be periodically examined for damage to tins and the expiry of the date.

## Inspection of Food stuffs

The prevention of the Food Adulteration Act (1954) as amended, is meant to control the quality of foodstuffs offered for sale to the general public. The inspection of

foodstuffs is necessary to ensure that they are of adequate nutritive value, will not cause food borne diseases and conform to contract specifications. This is the responsibility of an ASC organization known as the Food Inspection Organization. The Deputy Director of Food Inspection (DDGFI) is responsible to the QMG for food inspection. He is a medical officer (specialist in PSM) appointed by the DGMS (Army) and has under him a number of technically qualified ASC officers along with other technical personnel.

Composite food laboratories (CFLs) are established for special tests and food analysis. The services of food inspection officers, at the CFL may be utilised if the quality of supplies is in doubt. However, all medical officers should know the elements of food inspection as they are frequently consulted. Medical officers in units should inspect periodically the rations at the ration stand, in food stores, cookhouses, and dining halls. They are also required to inspect slaughter houses, dairies and bakeries under military control. In addition they may expect to receive occasional appeals from units for a decision in respect of food thought to be unfit for consumption. In the vast majority of cases, an opinion regarding fitness can be given after an intelligent use of the senses. Chemical analysis may be required. The following notes on individual commodities have been compiled with the objective of serving as a short guide to the inspection of ration articles by medical officers. Further details may be obtained by consulting a standard text book on food inspection (3,4,5,6) the Prevention of Food Adulteration Act / rules (7,8) and the official army publication on ASC (9). This publication also gives comprehensive working information on the specifications and inspection procedure of various food articles (Chap X), various ration scales and their nutritive values and hospital rations (chap XI), hygienic requirements in butcheries, and inspection of meat, poultry and fish (chap XII) and pest control in ration stores (chap XV).

**Principles of Inspection**

Sampling of the products requiring inspection is the first important procedure if large consignments of food are involved. Samples should be adequate in quantity and fully representative of the consignment. For example, if tinned milk is being examined, it may be necessary to sort the consignment into different brands, and thereafter each brand into groups (rusted tins, 'blown-up' tins) and representative number of tins from each group examined in detail. Only by systematic sampling can the quality of large consignments be accurately assessed and suitable instructions for disposal formulated. In the analysis of the sample obtained, the following factors should be considered:-

(a) The appearance, physical condition, taste and /or smell of the commodity in relation to its normal characteristics and keeping qualities.

(b) For the foodstuffs in cans, bottles, cartons, the external and internal condition of the container, the date of manufacture, the date of expiry or the warranty period and the manufacturer's name or proprietary brand.

**Disposal of Food materials after Examination**

Food may be considered as fit for issue without conditions, fit for issue within a limited period, or unfit for issue. The procedure to be followed is laid down in para 900 of DSR. If a unit takes rations on charge, the ASC is absolved from further responsibility and the unit must adjust any loss, if the medical officer subsequently condemns the article. Any queries regarding fitness for issue or consumption of rations should therefore be raised before rations are accepted by units. If the ASC officer agrees with the unit's complaint, he will immediately replace condemned articles. If he does not agree, the OC station will give a final decision, usually after a formal board of enquiry has been convened to examine the disputed rations and to make recommendations as per instructions issued from time to time.

**Atta and Flour**

The only difference between these two wheat products, from the point of view of inspection, is that atta contains a larger proportion of the pericarp or bran and the germ of the wheat grain. It, therefore, has a grayish appearance as compared with the dead whiteness of refined flour. Fresh flour or atta smells sweet, is of uniform consistency and has a bland taste devoid of sharpness. Deterioration usually results from prolonged storage or from adverse storage conditions. The main reasons for rejection are as follows:-

(a) Poor Baking Quality

The baking qualities of bread are due to gluten, the wheat protein. If a small quantity of flour is made into dough and the starch thoroughly washed out under running water, the sticky mass remaining is gluten. With good quality flour and atta this is golden yellow and is sufficiently elastic to be stretched for several inches without breaking. Gluten from old flour is dull grey and is friable. The change is associated with an increase of rancidity in the flour due to splitting of fats by enzymes in the wheat grain. The ultimate criterion on which a decision to reject flour as unfit for baking purposes may be made, is the quality and palatability of a sample loaf, baked by a competent baker.

(b) Rancidity

It is due to oxidative changes in the fat of atta or flour, and gives rise to a distinctive flavour which is easily detected. It is not a cause for condemnation unless the commodity is definitely unpalatable.

(c) Mustiness

It is due to infestation with the flour-mite, a tiny 8 legged creature which is invisible to the naked eye. If the surface of some infested atta/flour is smoothened with a knife, the mites will, in a few minutes, raise small heaps on the smooth surface. A distinctive odour is present. A mild infestation with a slight musty odour may be ignored, but in the majority of cases infestation develops rapidly, and

by the time it has become obvious, the flour is usually unfit for human consumption.

(d) Larval infestation

It is common, especially during the monsoon. The usual agent is the weevil, a small beetle that is easily visible and lays eggs from which larvae hatch. Infestation with the larvae of certain moths may also occur and this condition can be detected by the webs of silky material produced. Such flour or *atta* can be cleaned by sieving through muslin provided infestation is not unduly heavy. With heavy infestation the excreta of larvae renders the flour objectionable

(e) Mouldiness

It may occur under moist conditions. The flour becomes lumpy owing to the network of mycelia produced. If such lumps are carefully removed without breakage by sieving, it is usually possible to retain much of the flour as fit for immediate consumption.

**Bread**

Ordinary bread is made from white flour and should be risen, evenly aerated, free from large cavities and has an elastic crumb. The commonest defects in bread are sourness, soddenness and heaviness, all of which may be due to bad baking or poor storage. In the examination of bread, the chief guides are its general appearance, colour, smell, taste, texture and the presence or absence of moulds and animal parasites. The loaf or loaves should be broken open, a chunk should be taken from the middle of the loaf, rolled into a tight ball and examined for resilience by dashing it against the wall or the floor. Good bread will rebound.

**Biscuits**

These are made of flour, sugar, oil, salt water, milk and bicarbonate of ammonia. On examination of biscuits, note should be made of appearance, color, odour, crispness, hardness, palatability and the presence or absence of insects. The commonest defects are rancidity, mustiness, softness and the presence of moulds.

**Rice**

The appearance of rice varies greatly according to the variety, the degree of milling, and any other treatment to which the rice may have been subjected, such as parboiling or polishing. The rice for consumption by troops shall be lightly milled or parboiled. Ration rice, therefore does not have the white appearance of highly milled rice but may be of greyish colour. Parboiled rice has a characteristic translucent appearance. Under good storage conditions, rice will not deteriorate, or may even improve in quality upto about 2 years. The chief defects are an undue degree of milling, infestation or mouldiness.

(a) Milling

Normally all ration rice is inspected before being purchased, but there are occasions when apparently highly milled rice may be issued to troops. Its thiamine content can only be assessed by laboratory assay for thiamin content (specified as not less than 2 mg/g) and for phosphorus pentoxide content (specified as not less than 0.4 %). Thiamine assay cannot be carried out as a routine but the phosphorous test gives a fairly safe indication of the degree of milling and of the thiamine content.

(b) Infestation

The condition is similar to that in *atta* and flour.

(c) Mouldiness

Under damp storage conditions, or if rice is exposed to rain while in transit, the growth of mould is likely. The mould may develop only in the layers of rice adjacent to the sack container especially if the dampness has been caused by rain, and in that case the rice in the centre of the sack may be perfectly good and sound.

**Milk and Milk Products**

Fresh milk should be inspected as described in chapter 15. Tinned milk may be either sweetened or unsweetened, and is condensed by means of evaporation to about half or one-third of its original volume. Sweetened tinned milk contains about 50 percent of added cane sugar which is an important preservative. The inspection of tins and their contents should be carried out as follows:

(a) Tins

One type of tin has ends soldered to the body without crimping, though the side seam is crimped and soldered. This type is fragile and with rough handling is liable to develop leaks. The other type has crimped and soldered seams and is less likely to develop leaks. Etching on the insides of tins is not a sufficient cause for the rejection of contents. The contents of leaking tins are liable to rapid deterioration. Bulging, badly dented and leaking tins should be rejected.

(b) Unsweetened Tinned Milk

The chief defect likely to be found, other than obvious deterioration within a leaky tin, is an increase in acidity. If this is high and an unpleasant sour taste is present, the milk is unfit for human consumption. A milder degree of acidity is not harmful but it is an indication for immediate use. In some tins the fat may have separated, leading to an appearance like clotted cream. Sometimes a deposit of calcium lactate takes place. Such milk is quite wholesome if sourness is not present.

(c) Sweetened Tinned Milk

It is not liable to deterioration due to bacterial action. But in hot climates caramelisation tends to occur resulting in a brownish discolouration or even separation of sugar crystals. This is harmless and is not a cause for rejection.

(d) Butter

It should contain not more than 16 percent of water and not less than 80 percent of fat. Adulteration in a small quantity is difficult to determine accurately even by chemical analysis. The smell, taste, color and consistency must be taken into account on ordinary inspection. The commoner defects are rancidity, too much salt and too much water. A decision whether or not to reject it must depend on the degree of fault in each case. Butter on bacteriological examination may show large number of bacteria found in milk, if it has not been prepared from pasteurized cream. Tinned butter will melt during hot

whether with the curds settled at the bottom of the tin. It is perfectly wholesome in this state and can readily be reconstituted by stirring thoroughly. The slight lumpiness in such reconditioned butter is not an adequate cause for rejection.

(e) Cheese

The most important guides to its fitness for consumption are the smell, general appearance, taste and presence of mould. Surface mould on cheese does not render the interior unfit for consumption.

**Oil**

Hydrogenated oil was being provided earlier. It has now been replaced with refined vegetable oil (cotton seed, groundnut, palm kernel or seasame oil). The product should be clean and wholesome. It must be free from unpleasant taste, smell and rancidity.

**Eggs**

Fresh eggs should not be less than 35 g each and not more than 25 eggs per kg. In the candling test an egg is fitted into an opening cut in a shield (e.g. a piece of cardboard) behind which is placed a bright light. Viewed in the dark, a fresh egg will appear uniformly pink and translucent, while a bad egg will show cloudy dark patches, or even opaque, owing to the presence of gases resulting from decomposition. In the floating test, an egg is placed in a vessel containing 10 percent sodium chloride solution. A sound egg slowly sinks while a bad egg floats.

**Fresh Vegetables and Fruits**

'ASC Specifications' lay down that fresh vegetables shall be freshly gathered, sound, crisp and free from discolouration. The vegetables shall be of good average size for their class and not coarse, stringy or old. Potatoes must be of good quality, free from disease and of such a size that they average not more than 32 to a kg and must not be capable of passing through a 2.5 cm circular mesh. Fruits must be in good order, sound, freshly plucked, free from mould and all unpleasant taste and smell, of good average size, ripe and in a suitable condition for consumption and not over-ripe, bruised or otherwise damaged. Deterioration in fruit and vegetables must be judged on the merits of each case, but all rotten products should be rejected. Freshness is of nutritional importance, since old, limp or bruised fruits and vegetables have lost much ascorbic acid through the action of oxidases.

**Tinned Fruits and Vegetables**

Tinned fruit and jam keep well because the sugar in them acts as a preservative. The can as well as its contents should be inspected. The can may be 'blown' when the ends bulge and cannot readily be pressed in. On puncturing, a hiss of escaping gas is heard. With tinned fruit and jam (and less commonly with other tinned products), blown cans may be due to hydrogen formed by the action of the acid of the fruit on the tin coating, which lays bare pin points of the underlying steel and may catch fire if the tin is punctured near a lighted match. So long as the can remains intact, the contents remain perfectly sound and wholesome but at a late stage the acid erosion may produce small perforations and spoil the contents by bacterial action. If the gas in the blown can is carbon dioxide due to fermentation of sugar, small bubbles will be seen throughout and an alcoholic smell will be present. Advanced fermentation renders a product unfit for consumption.

**Dehydrated Vegetables**

If no advanced deterioration e.g. attack by mould is present, no judgement can be passed until the product has been reconstituted, cooked and compared with the cooked fresh product as regards appearance, smell and flavour. A good dehydrated product should resemble the fresh product when cooked. Dehydrated potatoes frequently have a somewhat dark yellow color which disappears almost entirely on reconstitution and cooking, and is no cause for rejection. The condition of the container is of utmost importance for the keeping quality of all dehydrated foods. If tins are not hermetically sealed, the contents will deteriorate rapidly by becoming damp and mouldy and in some cases, fermented. The freeze-drying process produces dried products of a much better nutritive and keeping quality and the reconstituted freeze dried products resemble more closely to the cooked fresh food than do the dehydrated products.

**Peas, Beans and Dals**

Pulses of all kinds are liable to attack by certain insects, the larvae of which develop within the seed and eat away its substance until nothing but a hollow shell is left. One species of larva makes a neat circular hole in the pulse, through which it escapes. This is preceded by the appearance of a circular mark. However, in the absence of the mark or the hole, the pulse is not necessarily uninfested. The only sure method of estimating the extent to which a consignment is infested is to take a sample and cut each individual seed into half. A grossly infested consignment should be condemned. If pulses have been exposed to rain, germination may occur. In the absence of fungus infection this is harmless. The decision regarding whether to accept or reject should be based on the palatability of cooked samples.

**Sugar**

The commonest defects are dampness, dirt and the presence of animal parasites. In examining it, colour, solubility and sweetening power must be considered. Sugar may be considered sound, if it is sweet and is readily soluble in half its weight of water to form clear bright syrup with no parasites.

**Condiments**

Condiments such as mustard, pepper, turmeric and ginger do not normally deteriorate. If however, they are not properly packed and become damp, they ultimately develop mould growths and are spoilt. Garlic, and to a lesser extent chillies, contain a higher percentage of water than other raw condiments, and if not properly dried before storage, may deteriorate rapidly. Garlic tends to germinate, rot and become black. Chillies become mouldy. Parasite infestation is not uncommon in condiments.

### Tea

Tea should be blend of medium quality with good colour and a fair size leaf producing good liquor. It should be dry and free from impurities and adulteration.

### Salt

Salt is of two types. 'Edible common salt' is pale pink, light gray or white in colour and may contain a small quantity of insoluble matter. The sodium chloride content should not be less than 96 percent. Refined salt is a white crystalline powder. It should dissolve freely in water with not more than a trace of insoluble matter. The 'running quality' in table salt is produced by blending it with bee's wax. Iodised salt protects from Iodine deficiency disorders. As per PFA act specifications, the concentration of Iodine at source and at consumer end should be 30 and 15 PPM (mg/ Kg) respectively.

### Meat

Inspection of meat, fish and poultry is described in subsequent chapters.

# Milk Hygiene and Military Dairy Farms

## Fresh Milk

### Inspection of milk

The main objectives of inspecting fresh milk supplies are to detect visible dirt, deterioration and adulteration; assess nutritive quality and keeping quality; and ascertain efficiency of pasteurization. The important points to remember are:-

(a) Visual Inspection

Ropy milk or slimy milk may be due to a disease of the udder or contamination by Lactis vascosus. Blue milk, may be due to the poor condition of the animal (e.g. due to tuberculosis) or occasionally to infection by Pscyanogena. Red milk may be due to a crushed udder; but milk for the first few days after calving is highly coloured owing to the presence of colostrum. Dirty milk is due to manurial dust from the flanks and tail of the cow, or dirt in the container. The measurable amount of dirt on standing should be less than 100 ppm and when this residue is diluted with water and centrifuged, the insoluble dirt should be less than 50 ppm of the milk. Ropy milk or excessively dirty milk or red milk, other than that due to the presence of colostrum, should be condemned at once. Blue milk should not be accepted as sound whole milk.

(b) Taste

Bad taste in milk may be due to the feeding of the cow (e.g. with turnips). Medicinal taste may occur if the cow is being administered some drugs. Rejection is justified if the taste is definitely unpalatable. Ordinary souring of milk, though not harmful, is not acceptable. Souring of milk is not necessarily indicative of feacal contamination by pathogenic organisms; they are lactose non-fermenters and hence do not make milk sour. Therefore, non-sour milk is not necessarily always safe either.

(c) Laboratory Tests

The specific gravity of milk should be 1.029 to 1.033 but watered milk can be readily restored to its normal specific gravity by adding sugar or cornflour. A further analysis is necessary to detect adulteration. Most military dairy farms possess the Gerber's apparatus for simple qualitative laboratory test on fresh milk. Tinned or powdered milk should be sent to Composite Food Laboratories. Fresh milk, for detailed analysis chemical and bacteriological tests and to assess the efficiency of pasteurization, may be sent to the Command Path Lab.

**(i) Gerber's Test**

In this test fat estimation is carried out by thoroughly mixing 10 ml of sulphuric acid, 1 ml of amyl alcohol and 11 ml of milk in special tube provided with the apparatus and centrifuging it for 5 to 7 min when milk fat separates as a clear supernatant layer. This is read off from graduations on the tube, which shows the percentage of fat in the sample.

**(ii) Total Solids**

These are estimated by the evaporation of whole milk in a water bath and then weighing the dried residue or by using Richmond's formula viz. Total solids= 0.25 G + 1.2 F + 0.14 (G means specific gravity above thousand i.e. 28 or 30 and F means percentage of fat). Solids not fat (SNF) are estimated by deducting the fat value from the total solids.

**(iii) Methylene Blue Test**

It is carried out for testing the keeping quality and bacterial contamination in the milk. The basis of the test is that the dye is reduced and decolourised by the bacterial enzymes. The rate of reduction is an index of the extent of bacterial contamination. One ml of methylene blue solution of 1:300,000 strength is added to 10 ml of milk sample in a test tube and then incubated at 37 ºC in a water bath or incubator. The mixture should not decolourise within 5½ hours. If kept at room temperature above 37 ºC it should not decolourise within 4½ hours.

**(iv) Phosphatase Test**

This test is meant for ascertaining the efficiency of pasteurization and depends on the fact that the enzyme phosphatase is destroyed by the pasteurization temperatures; but not completely destroyed at a lower temperature, or in a shorter period than that required for pasteurization. Milk containing as little as 0.25 percent of raw milk in the properly pasteurized milk still contains detectable quantities of enzyme. The test is performed by addition of disodium phenyl-phosphate to pasteurized milk. The enzyme phosphatase, if present, splits up the phenol by means of a phenol test reagent which gives different shades of blue colour depending upon the amount of phosphatase enzyme present. The colour is matched against the standard colours in a Lovibond colorimeter. Pasteurized milk must not contain more than 2.3 Lovibond units.

**(v) Bacteriological Tests**

These are rarely carried out as a routine but when indicated, are used for detection of *M tuberculosis* or *B abortus.* Under such circumstances 100 ml of milk is centrifuged at 3000 rpm for half an hour. The deposit is mixed with a little saline and injected into two guinea pigs. One of them is sacrificed after 4 weeks and the other after 8 weeks. Lungs and other organs are examined for tubercular granulomas. Serum from these guinea pigs can be used for agglutinating B abortus culture, or the spleen of the killed guinea pigs can be cultured in a liver extract-agar medium containing gentian violet of concentration of 1 in 250,000 in the presence of 10 percent CO2. Deposits of centrifuged milk also can be cultured for other organisms in appropriate media such as the Wilson Blair medium for the enteric group of organisms and the tellurite medium for *C diphtheriae.*(1)

## Military Dairy Farms

Military dairy farms have been established for the purpose

of ensuring a pure, wholesome and protected milk supply for the military population. The buildings should conform to the principles mentioned here under. A dairy consists of the farm, the milk depot and the pasteurization and bottling / packing plant, milkers changing rooms, and a manure disposal yard. The 'milk depot' or the dairy proper has milk receiving, pooling and cooling rooms and the blending room. The plant contains the boiler house, the bottle and churn sterilizing rooms, pasteurization plant, bottling / packing and cooling plant, the butter and cream separation room. All of these are housed in permanent, solid, fly and dust proof structures.

Milk can become a good nidus for non lactose fermenting organisms of *salmonella* and *shigella* group, of *streptococci* and *staphylococci,* a vehicle for viral hepatitis and poliomyelitis virus and transmitting medium for bacilli (*Brucella abortus*, *tuberculosis*) and *Rickettsia burnetti.* Organisms of cholera, salmonella and shigella group and viral hepatitis and poliomyelitis can be transferred to the milk extrinsically through a milkman's contaminated hands or through water, flies, dust or containers and cause dysentries, diarrhoea, cholera, typhoid, paratyphoid, bacterial type of food poisoning, viral hepatitis and poliomyelitis. *Mycobacterium tuberculosis* and Brucella abortus are transmitted intrinsically to the milk from the infected cow and cause tuberculosis and brucellosis. *Coxiella burneti* infection can be transmitted to man by handling of animals and their products, consumption of infected milk and meat and also by aerosol spread. *Streptococcus and staphylococci* can be transmitted to milk both extrinsically by the milk man suffering from a hand infection, an open sore or boil any where in the body , a running nose or ear and also intrinsically from the cow suffering from mastitis and cause a toxin type of food poisoning, septic tonsillitis, nasopharingitis or scarlet fever like syndromes. Diphtheria is known to have occurred in hostels due to infected milk. Table - 1 depicts the diseases conveyed through milk. (2)

Milk borne outbreaks of acute infection like food poisoning, typhoid or viral hepatitis may occur where milk from various sources is pooled to provide to large community-feeding establishments like students' hostels, Armed Forces Personnel, or large hotels and restaurants. The outbreaks are explosive, affecting persons in a circumscribed area with a common milk supply from a common source. Such outbreaks occur through consumption of ice creams or puddings, etc made of milk or cream. In order to assess the nutritive standard and initial purity the raw milk should be subjected to various tests, described above. To prevent outbreaks of milk borne diseases hygiene of cattle, personnel, equipment, process (of milching and pasteurization), packing and delivery should be ensured.

A periodical medical examination of personnel, inspection of premises and equipments, veterinary inspection of cattle, scrutiny of the process in the dairy, inspection of functional efficiency of the farm, depot and plant, and laboratory tests for purity and quality of pasteurization are required to be carried out. These measures should ensure the following:-

(a) The live stock of milching cattle is healthy, free from infections and protected against any illness; ill animals are isolated and contacts are segregated to prevent spread of infection; ill animals are not milked.

(b) High sanitary standards of the surroundings are maintained.

(c) Milk handlers are healthy, free from and protected against infections and are prohibited from handling milk if evidence of ailment is seen.

(d) Water supply is pure and protected.

(e) Containers are clean, regularly washed, sterilized and protected from contamination.

(f) Milk is protected against contamination by flies, dust or other extraneous matter.

(g) Milk is treated to destroy pathogenic organisms and thereafter kept protected.

Table - 1 : Diseases conveyed through milk

| Disease | Organism | Reservoir/Source |
|---|---|---|
| Tuberculosis | *M tuberculosis (bovine)* | Cattle |
| Brucellosis | *B abortus / melitensis* | Cattle, Goat |
| Q Fever | *Coxiella burnetti* | Cattle |
| Septic Sore throat | *Streptococcus pyogenes* | Cattle, milk handlers |
| Food Poisoning, toxin type | *Staphylococcus aureus* | Cattle, milk handlers |
| Diarrhoea and dysentries | *Shigella,E hystolytica* | Milk handlers |
| Cholera water, milk | *Vibrio cholera* | contaminated |
| Enteric fever | *Salmonella species* | Milk |
| Viral hepatits, polio | *Hepatitis A, Polio viruses* | Milk |

### Care of Cattle

The quality and the quantity of milk depend upon the particular breed and also on the care that is devoted to the cattle. The milk yield is also sensitive to their comfort, feeding, watering, and cleanliness; hence a clean, airy, cool and spacious cattle shed is of prime importance. Ample water supply to wash the cattle sheds and bathe the cattle should be available. There should be adequate arrangements for storing the fodder and water. Facilities for cleaning the stalls, gang-ways, gutters etc. should exist. Adequate arrangements for bathing the cattle should be there. It is healthier to bathe the cattle daily with cool water (or warm water during severe winter), but in any case a bath must be given at least twice a week. Cattle should be groomed and their udders washed, and then wiped with a damp cloth every time the animal is milked. Ample water supply for drinking is absolutely essential. Fodder and other victuals like cottonseed, oilcake, bran and meal consisting of a coarsely crushed

mixture of grains, according to the scales laid down must be given to each animal. Meal, cottonseed and fodder stores should be rat proof. Rat and flea nuisance are as much detrimental to the health and comfort of animals as they are for human beings. Measures to keep them under control must be taken and maintained throughout the year. Salt blocks for cattle to lick should be kept at vantage positions.

Sick animals must be immediately isolated and contacts segregated. In order to ensure this, the cattle should be inspected by a veterinary surgeon at least once a month, or as often as required. Segregation and isolation sheds must be available. Preventive inoculation against common diseases must be ensured. In well developed farms, tuberculin tests followed by segregation, examination, treatment or sacrificing of the infected and sick animals according to their stage of disease, is resorted to. Thereby herds free from tuberculosis can be raised. Each cow or buffalo must have a history card showing the date of birth, state of parity, milk yield since the first milking day, medical history, immunization given, any test for absence of tuberculosis and a history of brucellosis and mastitis at any time during its milking life. When the milk yield consistently shows a fall, the reasons for it should be investigated. Unless it is due to seasonal, periodical or prenatal waning, appropriate action to treat the animal or if due to senility, to dispose off the animal, should be taken.

### Cow Sheds

A properly constructed cow shed and its cleanliness is one of the important requirements for production of safe milk. The site should be well drained, higher than the surrounding ground and the building should run North-South. The approaches to the shed should never cross a manure yard. The best layout is a double range shed with a 2 meter broad para-central dunging passage with a central channel, a 3 meter cow standing on either side of the passage, and 1 meter broad mangers flanking among the sidewalls. The floor area per cattle head should be minimum 6 $m^2$. The space allowed per cow should be 18 $m^3$ if the cows are allowed to graze, or 24 $m^3$ if the cows are not turned out. The walls should be of reinforced concrete and whitewashed inside. Good cross ventilation is essential and should be secured by hopper windows on opposite walls and by air inlets along the walls near the floor with outlets along the ridge. The shed should be well lit by not less than 1/3 $m^2$ of window per animal, but should be capable of being darkened during the heat of the day. The whole flooring should be of impervious concrete. No inaccessible drain or trapped gulley should be allowed in the shed. An isolation shed for sick cattle must be provided. The sheds should be washed every day and cleaned twice a day. They should be sprayed with insecticide once a week.

### Disposal of Cattle Dung and Sullage

All channels carrying sullage and liquid cattle dung should always be made of concrete and continue for some distance beyond the shed to a suitable place for disposal, such as a septic tank with large soakage pits or central sewerage system. Semisolid cattle dung is a potent source of fly breeding and pollution of milk in dairy farms. It should be removed daily to a cow dung depot made of concrete and situated at least 200 m away from the cattle sheds. In large dairies a suitable method of removal is in wheeled iron tubs running on a length of small gauge rail line. In small dairies iron wheel barrows may be used but the path from the shed to cattle dung depot should be of concrete. The cattle dung can be either sold to the contractor or converted into manure and used in the farm. All cattle dung should be removed daily from the cattle dung depot. When regular removal from the dung depot is not possible, a system of 'tight packing' on concrete or impervious platforms and proper composting, about 400 m away from dairy farm and buildings should be adopted. The cattle dung under such circumstances should be removed direct from the sheds to the place of final disposal without the intervention of a cow dung depot. Antifly measures by the use of camouflage nets impregnated with dieldrin or organophosphorus insecticides should be carried out at the cattle dung disposal yards and dung depots. These places should be on the leeward side of the farm as the breeze may carry dried cattle dung to milk.

### Health of Workers

There are three categories of personnel i.e. those working on the farm outside the plant houses, those working inside the plant, and the administrative staff including those engaged in grooming the cattle or disposal of manure etc. but not coming in direct contact with milk. All employees of the first two categories should be permanent, selected after a thorough medical examination and should be issued identity cards. Medical inspection of the employees should be carried out very regularly and frequently, strict attention being paid to personal cleanliness. Exclusion of carriers of communicable diseases should be rigidly enforced. A regular immunization against enteric group of fevers and when so advised by the MO, against cholera should be ensured. Record of medical inspection and immunization should be maintained for all personnel. The manager should keep a daily list of all those absent without adequate reasons. They should not be allowed to return to work until medically inspected. The manager is responsible for reporting to the MO, all cases of illnesses, especially diarrhoea, dysentery, enteric fever, infected fingers or boils, running nose or ears, sore throat or cough among his employees.

All indoor workers should remove their clothes on arrival for work and these should be kept in a cupboard. They should then be made to scrub their hands thoroughly with soap, hot water and a nail brush and put on their working clothes which should be clean and suitable to each man's particular duties. Milkers should similarly change into their milking suits and overalls and should wear cotton milking caps; workers handling milk should wear masks made of gauze. All workers should have adequate sanitary and bathing facilities and should be made to use them consciously and through regulations. After using the sanitary annexe, they should be made to wash their hands

with soap and water before entering the processing premises or milking. They should be provided with clean sheets and should use milk pails with baffles and covers. As soon as a pail is full it should he covered as a protection against flies and dust and immediately removed to the milk room, without transferring it to any other vessel.

**Milk Depot and Dairy**

The dairy and milk depot should be adjacent to but entirely separate from the cowsheds and should be sited with a view to avoid contamination of milk by flies, dirt dust and manure. The whole block should be well ventilated, well lighted and fly proof. All ceilings and interior walls should be smoothly plastered with cement and lime washed frequently. The lower one meter of the walls may be paved with glazed tiles. Floors should be made of concrete and should be drained by shallow surface channels, leading to a suitable drain outside the building. The dairy and milk depot should have a milk receiving room, milk pooling and cooling room, a fat assessment room, a sterilizing room for bottles and cans, a storeroom and a change room for workers.

In certain stations especially in semi-permanent field stations, where military dairies cannot be established, milk depots are organized under the orders of the Station HQ and ASC control. In these depots, milk brought from local contractors is pooled, tested for fat contents and keeping quality and distributed to units without boiling or sometimes after boiling and immediately cooling. In some places blending is also carried out. An extremely strict hygienic control is necessary. Raw milk must be subjected to tests before being accepted under the following circumstances: -

(a) A milk receiving room should be used only for receiving milk from the sheds and for which special racks should be provided. A fly-proof hatch fitted with a jet steaming device should be provided, through which each milker hands in his full pail and receives in exchange an empty pail; under no circumstances should any milker or other outside worker be allowed to enter the receiving room.

(b) Milk straining, pooling and cooling rooms should open off the receiving room but should be entirely separate from it. A metal milk strainer with removable cotton wool discs which can be burnt after use, should be used. The milk cooling apparatus should be capable of cooling milk to below 7 ºC.

(c) Sterilizing Room : A piped supply of pure water, hot water in abundance and steam for sterilizing is essential. Separate galvanized iron washing tanks for washing bottles, cans and churns are required with emptying plugs leading to a proper drain. Sterilizing apparatus are required separately for bottles and cans. Cans and churns should be thoroughly washed with soda ash, scalded by exposing to steam for 20 min. In smaller dairies cans can be sterilized separately by inverting them over a steam jet, which emerges from the center of wooden block over which the mouth of the cans fit. This must, however, be considered as only an improvisation. For sterilizing bottles, a galvanized iron tank with the inside of the lid padded with an asbestos gasket and into which current steam can be blown, is the only satisfactory type of sterilizer. The sterilized bottles, cans and churns should be stored in metal racks.

**Pasteurization Plant**

This includes a pasteurization room, packing/bottling room, and cream and butter separation rooms. The premises should be fly and dust proof.

(a) Pasteurization Room

The pasteurization plant should receive milk directly from the milk straining and cooling room without being exposed to outside environment. Equipment in the pasteurization room should be made of stainless steel and protected from dust, flies and human nasopharyngeal droplets. The room should be fly and dust proof.

(b) Bottling /packing Room

The mechanical bottling / packing and sealing machines are necessary and should be insisted upon whenever pasteurization plants are provided. There should not be any likelihood of the contamination of milk while bottling / packing and sealing.

(c) Creamery

The hygienic standard of the butter room and of the methods of separating cream and butter making must be high. The personnel employed should be reduced to a minimum and should be permanent and under direct and close supervision. All cream should be pasteurized before being churned and the butter should not be touched by hand at any stage in its manufacture.

(d) Blending Room

Milk for issue to troops as daily ration is 'standardized' or 'blended' in a separate room with all precautions necessary to prevent exposure to pollution, flies dirt & dust. Water must be properly clarified and chlorinated but must also be boiled prior to blending. Standard or blended milk samples are tested for their fat content, which should be 3.7 percent. Skimmed milk powder should be from an authorized and approved source. Blended & standard milk should be subjected to pasteurization before packing / bottling or delivery from cans (3,4).

## Pasteurization

Boiling kills the microorganisms in any liquid but is likely to adversely affect its quality, taste and flavour, if the components of such liquid are heat-labile, such as are found in milk. Pasteurization involves rapidly heating a liquid (to less than the boiling point), maintaining it uniformly over a definite period and subsequent rapid cooling. This destroys most of the pathogenic microorganisms, reduces the total quantity of all the microorganisms and makes all of them less viable without affecting its inherent qualities unduly or its taste and flavour unfavourably. It may not sterilize the liquid but makes it non-infective, retains its nutritive and aesthetic

qualities and improves its keeping quality. The important pathogens that are destroyed by pasteurization of milk are *M tuberculosis, B abortus, Streptococci and Staphylococci* and the non-lactose fermenting pathogenic organisms of the *Salmonella-Shigella* group. The subsequent rapid cooling of the heated milk inhibits the multiplication of any viable residual microorganisms or of the ones subsequently gaining access to the liquid. The low temperature must be maintained till the milk is consumed.

The nutritive value of pasteurized milk remains reasonably satisfactory. Its fat, protein, calcium, phosphorus, and vitamins A and D contents are not affected. There is a 10% loss of vitamins B and 20% loss of vitamin C. Pasteurization improves the keeping quality of milk, reduces the number of bacteria, and destroys tuberculosis bacilli and other pathogenic organisms except spores and thermoduric bacteria. However, milk with a high bacterial count in a raw state will not pasteurize so efficiently as clean milk. Pasteurized milk can be preserved for 8 to 12 hours at 18˚C.

**Methods of Pasteurization**

The methods of pasteurizing milk are as follows :

(a) Holder (Vat) method

This method consists of heating the milk to the temperatures between 63ºC and 65.5º C and holding it in large tanks at that temperature for 30 min before cooling it rapidly to 5˚C. None of the milk escapes heating, and the pathogenic bacteria are killed with certainty. There are leak-proof inlet valves with an air relief, leak proof and close coupled outlet valves, air space heaters, accurate thermometers and automatic temperature controls. From the holding tank the milk runs directly to the cooler and then to the packing / bottling machine through a closed system.

(b) Continuous Flow Method

This method is the modification of the Holding method. The milk is first heated to 63ºC or more and then led through a series of heated metal coils so that the milk remains at that temperature in the apparatus for 30 min.

(c) High Temperature Short Time (HTST) Method

In this method milk is heated to 72˚C for 15 seconds and then rapidly cooled to 4ºC.

(d) Ultra high temperature (UHT) Method

Milk is rapidly heated usually in two stages, the second stage being under pressure, between 125º to 150º C for a few seconds only. It is then rapidly cooled and packed / bottled as quickly as possible.

(e) Pasteurisation in Bottles

The filled bottles should be well sealed with an effective stopper and heated by a shower of hot water or by steam. The simplest method is to place the milk bottles in water-bath brought to 63ºC held there for 30 min and then chilled. Several types of machinery are in use for this purpose. One type consists of a revolving drum in a metal cylinder, in which the filled bottles are subjected to a spray of hot water, and before completing the revolution are chilled. In another type of device the endless conveyors carry the bottles through a trough of hot water and then they are cooled. The theoretical risk of contamination after pasteurization is entirely eliminated. However, the temperature stratification occurs in heavy glass bottles.

The pasteurization process needs constant supervision and the following are the most important factors to ensure efficient pasteurization:-

(a) Raw milk must be clean and free from extraneous matter.

(b) A pasteurization chart should show the range of and the period for which the temperature, as specified for the method, was maintained.

(c) Milk must be protected from contamination during cooling and bottling / packing; unprotected open coolers are undesirable.

(d) Excessive foaming of milk must be avoided during pasteurization. In excessive foaming the temperature of the foam is too low to kill pathogens and may even encourage the growth of thermophilic organisms.

(e) The apparatus must be efficiently cleaned and sterilized after each day's work

(f) Besides ensuring efficient supervision, the process of pasteurization should be checked from time to time by the colorimetric phosphatase test as described earlier.

(g) If there is any doubt, about the effectiveness of pasteurization, the issue of such milk must be reconsidered. It is much safer for the consumer to assume that the milk he receives is untreated and is therefore boiled rather than to enjoy a false security.

## Inspection of Dairies and Milk Depots

These are carried out by the administrative departmental, technical, veterinary and medical officer. The medical officer should inspect the dairy in a definite sequence and with a view to scrutinizing all details in the process of production of milk and milk products, their wholesomeness, quality and safety for consumers. He should cover all the points described above. All recommendations and comments should be verbally conveyed to the manager of the dairy and important ones conveyed in writing to the higher medical authorities with intimation to the manager, if so indicated. Sampling of milk may be carried out periodically at the dairy farm or milk depot and also at various points on the consumer line. The tests for nutritional ingredients, adulteration,

# Inspection of Meat and Slaughter House Sanitation

## Fresh Meat

Medical officers are sometimes asked to give an opinion whether meat kept for sometime after slaughtering is fit for human consumption or not. Smell is the most reliable indication of decomposition but consistency and general appearance are also important considerations. The outside of the carcass and the skewer thrust into the substance should be smelt. Meat with an unpleasant smell is unfit for consumption. Decomposed meat loses its firm elastic consistency and tends to become soft and slimy. The fat becomes pale and the muscle appears dark brown to black. However, the smell is always a good indicator.

## Fresh Fish

The common signs of deterioration are as follows:-

### (a) Smell

It is probably the most important test of soundness. Fish with an unpleasant smell should be rejected, even if all other tests are in its favour.

### (b) Appearance

When freshly caught the gills are bright pink, but after death they rapidly become darker and in a matter of an hour or so assume a liver colour. The longer the fish is kept, the darker are the gills. This is not, however, a completely reliable sign of deterioration.

### (c) Firmness

The flesh should be firm to touch, not rapidly separated from the bones, and should not tear easily. If flesh pits readily under pressure, early decomposition must be suspected.

### (d) Colour

It should be uniform. There should be no evidence of discoloured patches on the skin. These are usually seen first along the line of the backbone.

### (e) Eyes

These should be prominent and not sunken, collapsed or dull.

### (f) Floatation Test

If not eviscerated, a sound dead fish sinks in water while an unsound one floats, belly up.

## Tinned Meat and Fish

The interior of the tin and its contents are subjected to heat, though an absolute sterility is not achieved, but the growth of remaining live organisms and spores is so inhibited that hermetically sealed cans should normally remain sound for several years. Under tropical conditions, the rate of deterioration is somewhat accelerated and spoilage may result even in an intact tin. The date of packing and the recommended last date for usage, must therefore always be kept in mind. Sardines packed in oil have an exceptionally good keeping quality. Fish packed in tomato sauce may deteriorate if the acidity of the sauce causes erosion of the tin and eventually results in pin point leaks. Cans and contents should be systematically examined before giving a final opinion. Cans should not be condemned as a result of external inspection only. It is essential to verify conclusions by examination of the contents.

### (a) Inspection

Damaged, dented or rusted tins must be viewed with suspicion. Dents near a seam may indicate a leak. Tins should be of normal contour. If they are excessively convex (in the absence of marked denting), the tin is 'blown' owing to the formation of gas from decomposition. The pressure inside may be tested by putting a little water on the end of the tin (preferably near the edge, in a hollow) and carefully puncturing through it. If the pressure is negative, the water is sucked into the hole; if positive, a stream of bubbles rises through the water. A positive pressure is due to gas formation and indicates bacterial action which may make the contents unfit for use.

### (b) Palpation

A sound tin has a solid 'dead' feel. One in which for any reason the negative internal pressure has been destroyed is under pressure and is known as a 'springer'. Springers should be tested by perforating through water and then opened for inspection of the contents. The latter may or may not be fit for consumption.

### (c) Percussion

A sound tin, when tapped by the fingers, or by a piece of wood, gives a dull note, while one with gas is definitely tympanic. A tympanic tin must always be viewed with suspicion.

### (d) Contents

All tins showing external defects should be opened and the interior of the tin and its contents examined. The interior of the tin is normally somewhat blacked and this is not a cause for rejection of the contents. Tinned meat which has been exposed to tropical conditions may show varying degrees of softening or liquefaction of the fat. This may not be a cause for rejection unless definite decomposition indicated by tainted smell and taste, is present. Any tin, the contents of which are perceptibly tainted, should be condemned.

### (e) Laboratory Tests

The above routine indicates whether or not decomposition has occurred. The salmonella group of organisms, which are responsible for the large majority of food poisoning outbreaks, do not cause any alteration in the physical appearance of the food. Food appearing perfectly sound, may produce severe poisoning. When considered necessary, the tins should be sent to a laboratory for bacteriological and chemical analysis, and for feeding tests on animals. Such food should not be used till cleared by lab tests.

## Dehydrated Meat and Fish

The same general principles as discussed in the preceding para apply. Dehydrated meat and fish tend to become acidic after a short time. There may be a slight odour which disappears when the tin is opened or on cooking. This may not indicate the 'unfitness' of food for consumption. At a later stage when marked rancidity or decomposition occurs, the product should be condemned. Dehydrated meat and fish are liable to infestation by insects especially *Dermestes* (the larder beetle). If it has been present for some time, adult beetles will be seen on opening the tin, together with the discarded skins or larvae but in more recent infestations only the larvae will be found. In heavily infested meat the muscle tissue is largely eaten away, leaving mainly fibrous tissue. Infested meat or fish should be destroyed. The accelerated freeze-drying process, now employed, results in better quality of dried products without loss of its nutrients and keeping quality.

## Refrigerated Meat

### (a) Chilled meat

It is preserved at a temperature of 14 ºC to 16 ºC. It can only be relied on to remain sound for a few weeks after slaughter, extendable to six weeks if the air in the cold storage space contains 10% carbon dioxide. The carcass is cold to touch and stiff, but is not frozen solid; and if carefully and slowly thawed before jointing, it is difficult to distinguish from fresh meat. As a rule, however, the bark has lost the characteristic shine of fresh meat and may be even dirty looking or torn in places. Mould may be present but is harmless unless it has penetrated deeply. The cut muscles surface loses the marbled pink appearance of fresh meat and assumes a uniform dark-red, or even brick colour, due to extravasations of pigment from muscle cells (ruptured by freezing) into the interfibrillar fat. If the carcass is thawed too rapidly the surface 'sweats', and the meat becomes sodden and water logged.

### (b) Frozen Meat

It is preserved at a temperature below 8° C. The carcass is frozen solid and can only be cut with a saw and keeps indefinitely so long as it remains at this temperature. The exterior is white and the bark is often torn and has completely lost its bright appearance. Ice crystals are apparent on the surface and after sawing in the interior. Moulds are frequently present on the surface. On thawing, the appearance closely resembles chilled meat, but the colour is usually somewhat darker, the fat more stained, and the meat more sodden and moist. Putrefactive and pathogenic bacteria are inhibited but not killed by freezing. When frozen meat is thawed, decomposition sets in very rapidly.

## Poultry

Although it is the custom in temperate climates to allow poultry and game to hang for some days in order to improve flavour and tenderness, this is usually not practicable in India. Fresh poultry have bright prominent eyes, the feet are limp and pliable, the flesh moderately firm and the skin pale. Staleness is shown by stiff and dry feet, dull & collapsed eyes, soft & flabby flesh and probably a greenish discolouration around the crop.

## Inspection of Animals and Carcasses

In stations where a veterinary officer of the RVC is available the responsibility of ante and post-mortem examination of all meat issued, as rations to troops will devolve on the veterinary officer. Where a veterinary officer is not available, an ASC officer trained in meat inspection carries out this duty. A medical officer may have to carry out the meat inspection, if neither of them is available or after the rations have been received in the unit and there is doubt regarding fitness of the meat for consumption. Every animal should be examined prior to slaughter and in this task the medical officers must rely on its general appearance. If the animal looks well and has no obvious signs of disease, it can be passed as fit for food in the vast majority of cases. On the other hand, one should hesitate before passing a poor looking animal, even if presenting no obvious signs of illness. In general, the thin diseased body, rough and staring coat, hanging head, quick laboured breathing, injected conjunctivae, dribbling saliva, diarrhoea, a raised temperature and a high pulse rate are signs of disease. To prevent substitution, all animals examined ante-mortem and passed, as fit should be suitably branded. The normal temperature of sheep is 40 ºC, of swine is 38.8 ºC and of cattle 38.6 ºC; and pulse rates are 40, 75 and 75 respectively.

The carcass should be examined for its nutritional condition; evidence of bruising, haemorrhage or discolouration; local or general oedema; the efficiency of bleeding; swelling or deformities of bones or joints; or abnormalities in musculature. The pleura and peritoneum should always be examined and their removal or tampering with, before examination, is never permitted. After the carcass is split (those of bovine are always split those of swine only if disease is suspected), the sternum, ribs, vertebrae and spinal cord should be examined. The head including the tongue, the palate, the retropharyngeal, sub maxillary and parotid glands should be examined and the cheek muscle incised by a linear incision parallel to the lower jaws for evidence of actinomycosis, foot and mouth disease, cysticercosis and glandular tuberculosis.

All viscera should be examined as they are removed from the carcass, or after ensuring that the viscera are of a particular carcass. Every organ and its associated lymph glands should be examined visually and by palpation. If any abnormal condition is observed, the nature and significance of which cannot be determined by such examination, the organ and/ or glands should be incised, care being taken to avoid soiling the rest of the carcass with infective material. The examination of lymph of glands should be by multiple incisions into their substance. Very often the slaughtering takes place in the middle of the night or in the early hours of the morning when a veterinary officer is not available on the spot. To identify viscera of the particular animal with a view to enable the veterinary officer to carry out a postmortem

examination, the viscera of individual animals must be hung alongside the carcass. This will enable the veterinary officer to trace the infected carcass in the event of tuberculosis being later revealed in the viscera.

**(a) Stomach, intestine and Spleen**

The outer and where necessary, the inner surfaces together with the omentum and glands should be examined. The spleen is commonly the site of pyaemic and tubercular abscesses.

**(b) Liver**

The liver and its associated glands should be examined. Lumps in its substances may be tubercular, pyaemic or hydatid in origin. The bile duct should be examined for flukes.

**(c) Kidney**

The renal and adrenal glands should first be examined and then the kidney should be inspected. If necessary the organ may be split by an incision. The kidney should be smooth, uniform in consistency and of an even brown colour. Tubercular abscesses are not uncommon.

**(d) Uterus and Ovaries**

The inner and outer surface of the uterus and the substance of the ovaries should be seen for infection and new growths.

**(e) Lungs**

The lungs should be examined, together with the bronchial and mediastinal glands, by inspection, palpation, and unless obvious disease renders this unnecessary, by incision. Tuberculosis, pneumonia and in the sheep, strongyloides infection are common.

**(f) Heart**

The pericardium should be opened and the heart examined. If necessary it may be incised. The base of the heart is a common site for tuberculosis and cysticercus infection.

**(g) Udder**

It should be examined by inspection, palpation and incision at the base of the teats. Incisions should also be made into any indurated regions and into the supramammary gland.

**(h) Scrotum**

The testicles, penis and superficial inguinal glands should be examined.

**(j) Lymph glands**

These must be examined as a matter of routine. The important groups are the bronchial, mediastinal, hepatic, mesenteric, retropharyngeal, submaxillary, popliteal and the prescapular glands.

## Common diseases of meat yielding animals

A brief description of two important conditions Anthrax and Foot and mouth disease is given here:

**(a) Anthrax**

It is a disease rapidly fatal to animals and usually diagnosed only after death. Post-mortem appearances are: muscles - pale with blackened areas due to haemorrhages; blood - black and tarry; organs - haemorrhages into the substance paranchyma; Lungs - pulmonary congestion; spleen - greatly enlarged, dark purple in colour and intensely engorged with blood. In pigs there is usually oedema of the glottis but enlargement of the spleen is absent. Blood tinged discharges from the nose and rectum are seen. When the animal is suspected to have been died of anthrax, it should be opened for post-mortem examination. The examination of an animal suspected to have anthrax should be carried out with the greatest care to avoid self infection and contamination of the surroundings. The usual plan is to take a sample of blood from the ear of the dead beast and examine it microscopically. If an examination of the direct smear leaves any doubt, a mouse is inoculated. The carcass should be destroyed by burning in a meat destructor or by proper burial.

**(b) Foot and mouth Disease**

It is most common in cattle and pigs but other animals may be affected. It is intensely infectious. The disease begins with small clear vesicles on the toothless border of the upper jaw which then spread to the nasal septum, the tongue, the skin above the hoof and the skin in the cleft of the hoof. The udder and external genitals may be affected. Later the vesicles enlarge, coalesce and burst, leaving pale watery looking erosions or septic ulcers. At a late stage septicaemia may occur. It is also called epizootic eczema or aphthous fever. When generalized, the whole carcass must be condemned. When strictly confined to the mouth and feet, only those parts need be condemned.

Judgement regarding fitness for human consumption or otherwise depends upon the nature of the disease and the extent to which the carcass is affected. Broadly speaking if animals show evidence of generalized pathological conditions (including pathological emaciation) the whole carcass should be condemned. If a pathological condition is localized and obviously not liable to be because of systemic infection (e.g. simple abscesses, benign tumours, cirrhosis of the liver etc.) only the affected organ or portions of the carcass and portion contiguous there to, should be condemned. In the absence of obvious pathological conditions, meat which is well cooked will not give rise to disease; but since thorough cooking is not invariably carried out, a careful inspection of carcasses and raw meat is necessary. If any doubt still exists, and expert advice is not available, it is better to condemn and be safe than to take a risk.(1,2)

## Slaughter House Sanitation

Slaughter house may be private or public. The private ones are not encouraged as it might be difficult to monitor them. They are not only a source of very serious nuisance but also facilitate the slaughter of diseased and dead animals. Nuisance in a slaughter house arises from the unhygienic way animals are kept, slaughtered and managed. The removal of carcasses and garbage is delayed which decompose there itself. Filthy slaughter houses are always a menace to the public health due to large collection of offal undergoing putrefaction and the

continuous flow of blood, urine and faecal matter in the surrounding areas. A poorly managed slaughter house emanates rotten smell and it becomes a source of disease. Fly breeding and contamination of meat are the two major health hazards. Thus, for proper sanitary control, all slaughtering should be carried out in licensed public slaughter houses (abattoirs) wherein hygiene rules must be followed strictly. It therefore becomes imperative for the AMA to inspect the abattoir regularly and thoroughly.

The salient points pertaining to a good slaughter house are enumerated below:

**Design**

The slaughter house should be well ventilated and totally fly proof. It should have sufficient running water supply. Adequate provision should be there to deal with blood, offal and waste animal products. It should be fitted with scaffolding having chrome plated hooks for dressing of animals.

**Building**

The slaughter house should be built with brick and concrete and well protected against rodents, cats and dogs. A concrete boundary wall is desirable. Adequate toilet/wash and hand-washing facilities (with soap and water) must be available.

**Floor and walls**

Special notice should be taken of the floor and general cleanliness of the place where the carcasses are dressed. Floor should be made of impervious concrete. The interior walls should also be of smooth concrete, which should be lime washed frequently.

**Drains**

Concrete channels should drain all liquid waste from the lairs and the slaughter room to a place of disposal outside, through covered drains. All the drains must be cleaned frequently. The manholes must also be frequently checked. Drains must be in a good state of repairs as damaged/broken drains are unhygienic.

**Waste disposal**

The liquid waste should be run into a water carriage sewer, and all solid refuse should be burnt in an incinerator. In case the above measures are not possible (as when slaughtering under unit arrangements, or in the field service when meat-on-hoof is supplied), the best method of disposal then is daily burning of all refuse and offal in the beehive incinerator. On rare occasions when burial has to be adopted, the pits should be well limited and covered with the rammed oiled earth. Special covered receptacles made of non absorbent material with close fitting lids should be provided for holding blood and offal, pending incineration or burial. This offensive material must be hygienically disposed off at the earliest. Semisolid manure should be dealt with in a similar manner as the manure from a dairy.

**Employees**

Preferably the employees must be permanent. They must wear clean clothing and be free from communicable diseases. They must undergo initial and periodical examination. They must also take routine immunization.

It need no further emphasis that the sanitation of slaughter house extremely important. In very large commercial establishment mechanism of functions is necessary. A regular inspection of slaughterhouses is essential to ensure cleanliness in the production of meat for human consumption and to ensure that it does not become a center for the spread of infections. (3)

The most important points to note are: -

(a) The method of disposal of offal, blood, animal excreta and discarded animal tissues.

(b) The fly proofing, rat proofing and dog proofing of the premises.

(c) The sanitation of the lair, the structural soundness of the building. The construction of the floor which should be made of cement concrete and provided with rat proof drains.

(d) The spaciousness of the separate slaughtering, skinning and hanging rooms and their ventilation.

(e) Availability of water for maintaining the sanitation.

# Nutrition during Training and Operations

Under normal conditions, maintenance of adequate nutrition can be attained to a large extent by the provision of rations in accordance with well-designed ration scales and of suitable facilities for messing. But the same may not be possible during training and operations.

## Training

The nutritional requirement of recruits under training is high. An average new recruit, who is recruited during the peace time may be reasonably well nourished but one who is recruited during war time may not be so. When troops are put on arduous administrative or operational tasks under active field service conditions or under intensive training for a task force assignment, their nutritional requirements increase and are the same as of recruits under training.

## Operations

During operations conditions are often different and more or less abnormal as far as the logistics of provisioning, supply and cooking of food is concerned. The following problems may be faced during operations:

(a) Expansion of armies may require enrolment of men with poor constitution necessitating special feeding to make them fit

(b) Shortage of food may necessitate the modification of normal ration scales;

(c) Limited logistics may result in failure to supply

(d) Consideration of climate and distance may make impossible the use of certain valuable but perishable foods

(e) Tactics may dictate the use of rations not exceeding a given weight and bulk

(f) The unusual physical stress or exposure to diseases may cause important changes in nutritional requirements.

Unless these difficulties are tackled effectively and on a sound nutritional basis, the 'fighting fitness' of troops will be impaired, possibly to a degree, which will jeopardize the success of operations.

### Depleted feeding during operational situations

When ration meets three quarters of the full requirement, no serious effects are noticed for 6 to 10 days. Thereafter the energy output will tend to fall off until intake and output are balanced, but no specific deficiency effects appear if the diet is balanced. If forced hard work is continued, slow inanition may ensue. If the period exceeds about 10 days, a well-balanced ration, meeting full nutritional requirements is essential for continued efficiency. When rations meet half the daily requirements, there is severe hunger after two or three days; serious diminution of efficiency follows and slow starvation dominates the picture.

Nutritional requirements are affected by the operational, tactical or training conditions. For example, if rations are required to be carried on a man-pack basis or while under seige, ration issue may have to be restricted or reduced in bulk and weight. When reduction in rations is visualized as a probable operational necessity, nutritional reserves should not be depleted during training. Good pre-feeding may be the best possible prelude to underfeeding and men should go into battle with ample bodily reserves. However 'excess feeding' must be guarded against to avoid obesity!

When shortage of rations is due to the tactical situation as during a seige or logistic blocks, preservation of fitness for the longest possible time is vital. Under such situations restricting physical activity to an essential minimum can lower requirements; infections which raise nutritional demands should be prevented.

Steps to replenish the depleted reserves of men by good feeding and rest should be taken early after the operations. However, after a period of insufficient feeding, small easily digested meals at frequent intervals should be given initially rather than copious and indigestible meals. Possibility of inanition, malnutrition and infections among troops recovered or escaping from enemy custody should be remembered.

### Principles of feeding during operations

Special pack rations are devised for operations when transport is limited, normal cooking and catering arrangement are not available, limitations on weight and bulk are severe, and a compromise has to be reached between what is nutritionally desirable and what is practicable. Such special ration packs are not the normal method of feeding troops. There are three operational ration scales and also the composite pack rations and the survival rations. The design of a special pack is influenced by the following factors:-

(a) Concentration

The highest possible energy value must be put into a given weight packed into the smallest possible space. It is extremely difficult to concentrate food beyond 418 kj per 30 g of weight (including packing material) without serious loss of palatability; so a normal ration should be expected to weigh about 1 kg. Energy value can be increased for a given weight by utilizing high energy value of fat, excluding low energy foodstuffs and dehydrating or freeze drying the pre-cooked foods.

(b) Nutritive Value

It may not be possible to consume the concentrated ration for a long time continuously as the nutritional requirements may not be met in a balanced manner. Extra vitamin supplements should be provided in such a food.

(c) Palatability

Variety and attractiveness can be achieved beyond a certain point only at the expense of weight. Consideration of customs and habits and the availability of facilities for

cooking are also important.

(d) Keeping Quality

The ration must retain its nutritive value as well as its keeping quality. The latter is largely a question of devising a pack which will withstand the rough handling, humidity and heat

**Composite packs & "Meals Ready to Eat"**

The composite packs contain multivitamin tablets, matchboxes, hexamine cooker, water sterilizing outfit and tin opener. The use and role of composite pack rations is given in the pamphlet 'Operations Feeding -Use of Special Rations Pack India'. These rations provide food of adequate variety and nutritive value of about 3500 Kcal (14.6 Mj) which does not require cooking and which is packed so as to facilitate easy handling. Their principal use is in the operations, 'between' the initial assault and the establishment of a normal chain of supplies and cooking facilities, in jungle operations, or for air dropping. The type 'A' ration pack is meant for meat eaters and type B contains cooked dal for vegetarians. These rations are not to be used when basic rations can be provided. The use of Composite Rations will be restricted to a maximum period of two weeks at a stretch. The present container has 5 men's ration for one day.

Another type of pack rations are "Meals Ready to Eat" (MRE) for individual persons. Each pack weighs approx 2.32 Kg and contains one person's breakfast, lunch and dinner. It contains ready to eat suji halwa (300 g), veg pulao (300 g), veg peas and mushrooms curry (300 gm) dal makhani (330 g), chapaties or parathas (320 g), tea mix (tea, sugar and dairy whitener), soft bar (110 gm), hexamine cooker and tablets, matchbox, paper plates etc These packs are stocked in selected supply depots to be issued to troops when necessary and as ordered by the authorities.

**Emergency rations**

The emergency rations are normally issued to the 'teeth' part of the field force before going into operations, to be carried by each individual on his person in the tin or cardboard container provided for the purpose in the WET of the unit. It is consumed by the troops under specific orders only when the other types of rations cannot be made available. It is intended to be substituted only for 24 hours. The pack consists of 230 g service biscuits and 110 g raisins providing about 1200 Kcal (5.09 Mj) without any special regard to the nutritive value as a whole or its requirement for any special task.

## Appendix A

**Scale of Rations for Officers in Peace / Field**

(Annexure to Govt of India, Ministry of Defence letter No 3 (1) 83 1 D (QS) Dated 12 Mar 1983)

| S.No. | Commodity | Scale per officer per day in grams |
|---|---|---|
| 1 (a) | Atta or Rice (Undermilled or parboiled) | 450 |
| (b) | Atta | 200 |
| 2. | Dal | 40 |
| 3. | Oil hydrogenated | 80 |
| 4. | Milk fresh / standard / blended | 250 ml |
| | OR | |
| | Milk tinned sweetened or unsweetened | 92 |
| | Whole milk powder | 36 |
| 5. | Sugar | 90 |
| | OR | |
| | Gur | 110 |
| 6. | Tea | 09 |
| | OR | |
| | Coffee soluble powder | 03 |
| 7. | Vegetables fresh | 170 |
| | OR | |
| | Vegetables tinned curried | 90 |
| | OR | |
| | Dal whole or germinating | 90 |
| | OR | |
| | Peas dried or beans dried | 90 |
| 8. | Potatoes fresh | 110 |
| | OR | |
| | Potatoes tinned | 80 |
| | OR | |
| | Dal | 60 |
| | OR | |
| | Vegetable fresh | 110 |
| 9. | Onions fresh | 60 |
| | OR | |
| | Onions spring green | 90 |
| | OR | |
| | Onions dehydrated | 07 |
| 10. | Fresh fruits citrus | 110 |
| | OR | |
| | Fresh fruits non-citrus | 230 |
| | OR | |
| | Fruit tinned | 90 |
| | OR | |
| | Fruit dried | 28 |

| 23. | Vitamin C tablets | 100 mg |
| | OR Lemon orange powder | 17 |
| 24. | Kerosene | 378 ml |
| | OR LPG | 150 |
| | | |
| | | |

*25 issues in a month. Substitutes will be issued to non-drinkers on all days and to drinkers on days when rum is not issued.

## Appendix D

**Rations for Officers in Jammu & Kashmir and NEFA Area (SAI 3/S72)**

| S.No. | Commodity | Scale per Men per day in grams |
|---|---|---|
| 1. | Atta / Rice | 450 |
| | Not more than 230g of bread and 60g of flour may be drawn for equivalent quantity of atta/rice. | |
| 2. | Dal | 40 |
| 3. | Oil hydrogenated | 80 |
| 4. | Sugar | 90 |
| 5. | Milk fresh | 250 ml |
| | OR Milk tinned | 100 |
| | OR Whole milk powder | 36 |
| 6. | Meat fresh dressed | 260 |
| | OR Meat on hoof | 640 |
| | OR Fish fresh | 430 |
| | OR Fowl including duck/chicken (dressed) whichever is economical | 175 |
| To be issued in lieu For vegetarian | | |
| | Milk fresh | 500 ml |
| | OR Whole milk powder | 73 |
| | OR Milk tinned | 200 |
| Either of the following may be drawn in lieu of 30g of meat once a week: - | | |
| | Ham | 28 |
| | OR Pork lunchen meat | 30 |
| | OR Bacon | 30 |
| | OR Sausages | 28 |
| | OR Liver fresh | 30 |
| | OR Kidney | 30 |
| 7. | Potatoes | 110 |
| | OR Potatoes tinned | 80 |
| | OR Vegetables fresh | 110 |
| 8. | Vegetables fresh | 170 |
| | OR Vegetables tinned or curried | 90 |
| 9. | Onions | 60 |

## Appendix E

**Scale of Ration for Indian Navy standard scale of Ration for Sailors (N I 6/86)**

| S.No. | Commodity | Scale per Men per day in grams |
|---|---|---|
| 1. | Bread / Atta / Rice / Biscuit / Flour / Suji | 600 |
| 2. | Oil hydrogenated | 80 |
| 3. | Sugar | 70 |
| 4. | Tea | 08 |
| | OR Coffee | 05 |
| 5. | Salt evaporated | 20 |
| 6. | Dal | 90 |
| 7. | Condiments | 16 |
| 8. | Meat fresh (with bones) | 180 |
| | OR Meat tinned | 110 |
| | OR Fowl (live weight) | 240 |
| | OR Fowl (dressed) | 125 |
| | OR Fresh Fish | 160 |
| | OR Eggs | 03 no |
| | OR Fish tinned | 130 |
| For vegetarian | | |
| | Milk fresh | 350 ml |
| | OR Milk tinned | 140 |
| | OR Whole milk powder | 50 |
| 9. | Potatoes fresh | 110 |
| | OR Potatoes tinned | 80 |
| 10. | Vegetables fresh (other than onions and Potatoes) | 160 |
| | OR Vegetables tinned | 80 |
| 11. | Onions | 60 |
| | OR Onions spring green | 90 |
| 12. | Milk tinned (sweetened or unsweetened) | 76 |
| | OR Milk fresh | 190 ml |
| | OR Whole milk powder | 27 |
| 13. | Fruit fresh citrus | 50 |
| | OR Fruit fresh non-citrus | 100 |
| | OR Fruits tinned | 40 |
| 14. | LPG | 95 |
| | OR Steam coal | 1400 |
| | | |

## Appendix F

**Scale of Ration for Indian Air Force (AFI 18/S/68 *)**

| S.No. | Commodity | Scale per Men per day in grams |
|---|---|---|
| 1. | Bread / Atta / Rice / Flour | 600 |
| 2. | Dal | 90 |
| 3. | Ghee / Oil cooking<br>(In lieu of 30g of ghee/oil cooking 20g of butter and 30g of jam/Marmalade/honey may be given) | 80 |
| 4. | Sugar | 70 |
| 5. | Tea | 08 |
| 6. | Salt evaporated | 20 |
| 7. | Condiments | 16 |
| 8. | Meat fresh (with bones) | 180 |
| | OR Meat dehydrated | 70 |
| | OR Meat tinned | 110 |
| | OR Fresh Fish | 160 |
| | OR Fowl / Chicken (live weight) | 240 |
| | OR Fowl / Chicken (dressed) | 125 |
| | OR Eggs | 03 no |
| For vegetarian | | |
| | Milk fresh | 350 ml |
| 9. | Potatoes | 110 |
| 10. | Vegetables fresh (other than onions and potatoes) | 160 |
| 11. | Onions | 60 |
| 12. | Milk fresh / blended | 150 ml |
| 13. | Fruits fresh (citrus) | 50 |
| | OR Fruits fresh (non-citrus) | 100 |

- Additional Ration for Air crew is also given in the same AFI.

## Appendix G

**Scale of Ration for Cadets of NDA, IMA, OTA, CME, MCTE, MCEME and AFMC (AI 8/S/74)**

| S.No. | Commodity | Scale per Men per day in grams |
|---|---|---|
| 1. | Bread / Atta / Rice / Flour (not more than 340grams of bread will be issued, balance being atta/rice/flour) | 510 |
| 2. | Dhallia (three times a week) | 30 |
| | Cornflakes (once a week) | 28 |
| | Semolina (three times a week) | 30 |
| | Sago (once a week) | 28 |
| 3. | Cornflour (thrice a week) | 07 |
| | Custard powder (thrice a week) | 07 |
| | Jelly (once a week) | 07 |
| | Ice cream powder (once a week) | 07 |
| 4. | Milk standard / fresh / blended | 550ml |
| | OR Milk tinned | 220 |
| | OR Whole milk powder | 81 |
| 5. | Butter fresh | 28 |
| 6. | Eggs (thrice a week at the scale of 2 ½ eggs per cadet per diem and four times a week at the scale of 1 ½ eggs per cadet per diem) | 2 ½ / 1 ½ |
| | Bacon (fresh or tinned) issued twice a week | 30 |
| | Sausage / Salami (fresh or tinned) issued twice a week | 30 |
| | Liver / Kidney (issued once a week) | 60 |
| For Vegetarians | | |
| | Milk standard / fresh / blended (for preparation of curd) | 210 ml |
| | OR Cheese | 28 |
| 7. | Meat fresh (four times a week) | 340 |
| | Fish fresh (two times a week) | 600 |
| | Chicken dressed / Fowl dressed (once a week) | 255 |
| For Vegetarians in lieu of Meat fresh and its alternatives | | |
| | Milk standard / fresh / blended | 660 ml |
| | OR Oil hydrogenated | 30 |
| | And Vegetables fresh | 340 |
| | OR Eggs | 08 no |
| 8. | Oil hydrogenated | 85 |
| 9. | Dal-four times a week | 40 |
| | Baked beans / dried beans- once a week | 40 |
| | Kabuli Channa- once a week | 40 |
| | Mothi red- once a week | 40 |
| 10. | Potatoes fresh | 110 |
| **S.No.** | **Commodity** | **Scale per Men per day in grams** |
| 11. | Onions fresh | 60 |

Contd. ....

## Appendix G

**Scale of Ration for Cadets of NDA, IMA, OTA, CME, MCTE, MCEME and AFMC (AI 8/S/74) (Contd.)**

| | | |
|---|---|---|
| | OR Onions spring (non-citrus) | 90 |
| 12. | Vegetables fresh | 230 |
| 13. | Cheese tinned or cream- thrice weekly | 14 |
| 14. | Sugar | 100 |
| 15. | Tea | 09 |
| | OR Coffee soluble powder- six times weekly | 04 |
| | Chocolate drinking- once weekly | 14 |
| 16. | Salt | 20 |
| 17. | Condiments and spices | 20 |
| | OR Pickles / chutney / vinegar | 20 |
| 18. | Jam / Marmalade | 14 |
| | OR Jam / marmalade- thrice weekly | 14 |
| | And Golden syrup- once weekly | 14 |
| | And Fruit fresh- thrice weekly | 20 |
| | And Sugar | 10 |
| 19. | Firewood split | 500 |
| | OR Steam Coal | 700 |
| | OR LPG | 150 |
| | | |

**Scale of Ration for Cadets at Rashtria Indian Military College, Dehradun (AI 10/S/74)**

| S.No. | Commodity | Scale per Men per day in grams |
|---|---|---|
| 1. | Atta / Rice / Flour<br>(not more than 280grams of bread will be issued, balance being atta/rice/flour) | 430 |
| 2. | Dhallia (four times a week) | 10 |
| | Cornflakes (once a week) | 14 |
| | Semolina (twice a week) | 10 |
| 3. | Cornflour / Custard powder and other cereals for pudding | 08 |
| 4. | Milk standard / fresh / blended | 500ml |
| 5. | Butter fresh | 28 |
| 6. | Eggs | 21 / 2 no |
| 7. | Meat fresh (with bones) four times a week | 200 |
| | Fish fresh- twice a week | 340 |
| | Chicken dressed / Fowl dressed- once a week | 140 |
| **For Vegetarians in lieu of Meat fresh and its alternatives** | | |
| | Milk standard / fresh / blended | 390 ml |
| | OR Milk tinned | 160 |
| 8. | Oil hydrogenated | 80 |
| 9. | Dal | 10 |
| 10. | Potatoes | 110 |
| 11. | Onions fresh | 60 |
| 12. | Vegetables fresh | 200 |
| 13. | Fruits fresh (citrus) | 110 |
| | OR Fruits fresh (non-citrus) | 230 |
| 14. | Cheese tinned or cream- thrice weekly | 14 |
| 15. | Sugar | 90 |
| 16. | Tea | 07 |
| | OR Coffee soluble powder | 03 |
| 17. | Salt rock | 20 |
| | OR Salt evaporated | 30 |
| | | |

## Appendix J

**Scale of Ration for Edentulous Outdoor Cases (AI 10/S/76)**

| S.No. | Commodity | Scale per Men per day in grams |
|---|---|---|
| 1. | Rice | 230 |
| 2. | Bread | 230 |
| 3. | Dal | 60 |
| 4. | Sugar | 90 |
| 5. | Tea | 09 |
| 6. | Salt evaporated | 10 |
| 7. | Milk standard / fresh / blended | 660 ml |
| 8. | Butter fresh | 30 |
| 9. | Eggs | 02 no |
| 10. | Potatoes fresh | 110 |
| 11. | Vegetables fresh | 110 |
| 12. | Fruit fresh citrus | |
| | To be issued on Medical Recommendations | 60 |
| 13. | Compound vitamin tablets | 01 no |
| | | |

NOTE: - Following category of persons who are entitled for free rations will be issued above scale of rations for maximum period noted against them :

| Category | Maximum period |
|---|---|
| a) Edentulous patients who are awaiting the fitting of artificial dentures. | 90 days |
| b) Cases of maxillo facial injury after discharge from hospital. | 60 days |
| c) Edentulous cases where dentures have been withdrawn by authorities for remaking. | 4 weeks |

# Occupational Health

## Introduction

Rapid industrialisation of the country has led to a sharp increase in the labour force in the twentieth century. The expansion of the workforce has taken place more in the unorganised sector. Today a staggering 92.5% of the Indian labour is employed in this sector (1). It comprises largely the needy small and marginal farmers, the contract labourers and the agricultural workers. However, precious little seems to have been done to combat the health hazards associated with their workplace. This is primarily because their "unorganised" nature fails to put pressure on agencies to enforce legislation for their safety and welfare.

The organised sector, considered better off, employs 280 lac employees. Out of these 195 lacs are in the public sector and 85 lacs in private sector. By definition, the organised sector includes all the establishments in the public sector and non agricultural establishments employing 10 or more persons (1) It is this 'unionised' sector that has made the State enact legislation for Health and Safety at the workplace.

Industrial enterprise in India began during the Industrial revolution in 1850. The conditions of the working class during this period were abysmal. Their salaries and working conditions were determined by market forces. There was absolutely no legislation for protection or compensation from occupational diseases and injuries. With the organization of industries, the laws regarding their working became necessary and were enacted from time to time (2). Social Security legislations were framed to protect and compensate the worker from Occupational diseases and injuries.

The concept of Industrial health has undergone considerable changes in the last century. Earlier the term implied occupational diseases of workers employed in the classical occupations like foundries, textile mills, mines, etc. Gradually the term "Industrial Health" has been replaced by a broader word viz "Occupational Health". This embraces all occupations- ranging from the humble housemaid (Hunter describes them as having housemaid's knee- a type of chronic bursitis) to the most sophisticated software engineers (suffering from eye strain or repetitive strain Injury due to prolonged use of the key board similar to the erstwhile Telegrapher's Cramps). Infact, the peculiar problems faced by Armed Forces personnel categorise them into a separate occupational group. Two health disciplines viz Aviation Medicine & Marine Medicine have specialised institutes & personnel dedicated to cover health problems faced by pilots & submariners. Occupational Health is thus a comprehensive subject comprising the health, safety and welfare of the workers in the "workplace" and "off work" environments. Consequently in occupational health, the teamwork of several disciplines such as medicine, engineering, administration, physics, nutrition etc. have to be integrated for high industrial production and well being and contentment of the workers (3).

### Role of Medical Officers

Medical officers are frequently required to extend medical supervision to ordnance factories, Armed Forces workshops, unit workshops and other mechanical units and to provide medical care to the personnel working there. Moreover, Air Force and Naval MOs have to deal in their day-to-day duties with personnel who are virtually industrial workers as they are to function under similar circumstances. The following paragraphs may serve as a guide to them when called upon to carry out inspection of such places and extend medical supervision and care to workers in these units and establishments.

### Historical Perspective

The workmen were neglected in ancient medical practice & occupational diseases ignored in medical science. Ramazzini (1633-1714) is known as the father of occupational medicine. His textbook 'De Morbis Artifactum Diatriba' is a masterpiece that describes vividly the diseases of miners of metals, potters, tinsmith, glassworkers, cleaners of privies & cess pits, millers, well diggers & 50 other occupations. He advises rest for long duration work, spacious workplaces and good housekeeping for prevention of occupational diseases - a concept that no modern industry can afford to neglect. Infact, Ramazzini brought in the concept of occupational physician by cajoling all doctors to add to the Hippocratic Art by asking each patient- 'What is your occupation?' Hutchinson's Clinical Methods has further amplified this by stating that no history is complete without a detailed occupational history. Doctors need to ask their patients the exact nature of his occupation including past occupations. Merely recording say "Hyderabad Industries" as occupation gives no indication of the nature of work. On probing further one would know that this factory is an asbestos unit & only then can one suspect the symptoms to be of asbestosis (a type of pneumoconiosis). In case an occupational history was not taken the patient would probably have been diagnosed as "Tuberculosis" which is not an occupational disease. Thus, a proper occupational history can not only help in treatment & control of the

| Stalwarts in Occupational Health | |
|---|---|
| Bernardino Ramazzini | Father of Occupational Health |
| Charles Turner Tackarrah | First Practitioner of Industrial Medicine |
| John Simon | First Medical Officer of Factories |
| Karl Marx | Rise of Trade Union Movement |
| Sir Thomas Morrison Legy | First Medical Inspector of Factories |
| Philippa Howerday | First Industrial Nurse |
| Donald Hunter | Wrote "Diseases of Occupations" |

disease but also assist the worker in getting his entitled compensation from the employer.

The introduction of machinery during the Industrial Revolution (1760-1830) gave a great fillip to the concept of occupational health. As the steam engine was invented, so the test for colour blindness was made obligatory for Railway Drivers (1876). This concept is today called Periodic Medical Examination. Rapid industrialisation led to mass migration from villages to cities as workers were needed to run the factories & mills. This led to the creation of "Shanty Towns" - a term used to describe the resultant overcrowding, filth & cholera & typhus outbreaks in these labour colonies.

The first man documented to practice Industrial Medicine was Charles Turner Tackarrah. His book had a really long name viz "The Effects of the Principal Arts, Trades & Professions & of Civic States, habits of living on health & longievity with suggestion for the removal of many of the agents which produce disease & shorten the duration of life". This however, is considered superior to the work of Ramazzini. It has vividly described postural deformities, tuberculosis in tailors & lung disease in miners & grinders of metal (silicosis). Tackarrah has documented that knife grinders who did dry stone grinding lived for only 28 years whereas their counterparts who did wet stone grinding survived for 40-50 years. These deaths were attributed to silicosis. John Simon, the First Medical Officer of Factories has clearly spelled out that "Tackarrah's work in Industrial Medicine is like Jenner's is to Small Pox".

Occupational Medicine has found a place in fiction also with Charles Dickens in his famous "Oliver Twist" describing scrotal cancer in chimney sweeps. Thereafter, the popular novel "Alice in Wonderland" immortalised mercury poisoning by using the term "Mad as a Hatter" to describe the psychotic symptoms of the mercury felt hat.

Later Karl Marx in his famous book "Manifest De Komunistein" stated "Proliterans have nothing to lose but their chains. They have a world to win. Working men of all countries unite". This practically laid the foundation of the Trade Union movement. Rise of socialism led to legislation in industry as workers got more bargaining powers by forming Trade Unions. This promised not only better wages but also more Safety, Health & Welfare for the industrial workers in the organised sector. The first Medical Inspector of factories Sir Thomas Morrison Legy (1870-1932) did pioneering work on lead poisoning. Philippa Howerday (1878) was appointed as the fist Industrial Health nurse. She divided the day in looking after the workers during the morning & visiting their houses in the evening to look after the families. Donald Hunter is credited with writing the book "Diseases of Occupations" which remains the Bible of Occupational Health till date.

## Occupational health and the Armed Forces

The Armed Forces by virtue of its diverse role in varying climatic conditions, terrain and often uncongenial psycho-social environment is exposed to peculiar physical, chemical, biological, mechanical and psychosocial factors in the workplace and off it. Occupational health is thus of prime importance for optimising the efficiency, well being and contentment of the personnel of our three services. Occupational health aspects peculiar to the Navy (Marine Medicine) and Air Force (Aerospace Medicine) have been dealt with separately in this manual. The focus of our discussion in the succeeding paras will pertain to the common occupational health problems of the Armed Forces.

The occupational health hazards, may be grouped into: -

(a) Physical Hazards
  (i) Effects due to heat and cold.
  (ii) Effects due to altitude.
  (iii) Effects of noise especially during firing of heavy weapons.
  (iv) Mechanical factors injuries, accidents.
  (v) Effects of excessive blindness or glare - Snow blindness.
  (vi) Effects of ultraviolet radiation especially in high altitude and snow-bound areas.

(b) Chemical Hazards
  (i) Hazards due to Chemical Warfare.
  (ii) Dusts especially while travelling through unmetalled desert tracks.

(c) Biological Hazards
  (i) Vector-borne diseases esp malaria and zoonoses due to frequent movements and living outdoors.
  (ii) Fungal infections due to prolonged use of uniform and boots.
  (iii) Potential for rapid spread of airborne infections due to living in barracks.
  (iv) Common source food and water-borne disease outbreaks.
  (v) STD/HIV infection increased chances of personnel visiting CSWs as they stay for long without their families.
  (vi) Nosocomial infections & needlestick injuries in health workers.

(d) Psychosocial Hazards
  (i) Long periods of deployment in operational situations away from families may result in heightened emotional stress, frustration, alcoholism, hostility, anxiety, depression and psychosomatic disorders.
  (ii) Long periods of isolation in high altitude or other areas resulting in psychosomatic problems.

(e) Hazards due to Warfare
  (i) Conventional warfare-deaths /injuries due to bullets, shells, bombs, mines etc.
  (ii) Psychological problems "shell shock"

(f) Accidents

The occupational hazards specific to certain Arms and

Services of the Army are discussed in the succeeding paragraph. Though, it may be kept in mind that certain trades are common to all Arms or Services and as such the occupational hazard discussed under a particular head may be applied to a similar trade in another Arms/Services.

(a) Army Service Corps (ASC)

Personnel from this service are employed in supply, transport and clerical duties. The peculiar hazards of occupation are: -

(i) Drivers

- Poor ergonomics in vehicles may lead to various musculoskeletal disorders esp backache.
- Long hours of driving leading to increased eye, mental and physical fatigue and thus enhancing the proneness to accidents.
- Effects of vibration (Raynaud's phenomenon).
- Risk of acquiring STD due to staying away from their families and hence proneness to visit CSWs.

(ii) Clerks

- Musculoskeletal disorders like backaches.
- Repetitive Strain Injuries (RSI) due to typing.
- Working with computers for long hours may lead to eyestrain (due to glare) and other effects of radiation.

(b) Medical Personnel

(i) Increased risk of Hepatitis B, HIV, etc due to accidental needle stick injuries.

(ii) Long hours of standing during surgeries, dental and other procedures may lead to varicose veins.

(iii) Risk of acquiring various infections esp airborne infections during the course of patient care.

(iv) Effects due to radiation amongst personnel working in radiology and radiotherapy.

(v) Contamination hazard due to improper handling of cytotoxic and bio- medical wastes.

(vi) Increased risk of infections among lab workers dealing with blood and other body fluids.

(c) EME

(i) Effects of high noise levels in the workshop floor resulting in deafness.

(ii) UV radiation effects due to arc welding leading to blindness.

(iii) Effects due to inhalation of various fumes and gases.

(iv) Irritant dermatitis due to repeated exposure to various chemicals like grease, oil etc.

(v) Musculoskeletal disorders amongst vehicle mechanics due to awkward postures and excessive bending at work.

(vi) Effects due to prolonged exposure to vibration.

Injuries during handling of various types of machinery.

(vii) Electrical injuries.

(d) Engineers

(i) Injuries during blasting, mine-laying/removal, construction work.

(ii) Effects of prolonged exposure to vibration during drilling and handling of heavy machinery.

(iii) Injuries during handling of heavy equipment during earth moving and bridging.

(iv) Drowning while assisting in river crossings.

(e) Armoured Corps and Mechanised Infantry

(i) Claustrophobia due to cramped spaces in armoured vehicles.

(ii) Effects of excessive heat inside their vehicles.

(iii) Effect of noise due to firing of guns.

(iv) Effect of dust.

(f) Artillery

(i) Effects of high levels of noise generated during firing of artillery guns may lead to rupture of tympanic membrane and conductive deafness.

(ii) Injuries during handling of heavy equipment.

(iii) Effect of dust.

(g) RVC

(i) Risk of acquiring zoonoses.

(ii) Animal bites.

(h) Signals

(i) Injuries among linemen due to fall from telephone poles.

(ii) Long hours of work under the sun esp among linemen resulting in heat stress disorders.

(j) Infantry

The occupational hazards in the Army discussed in the preceding paras are mostly applicable to Infantry, more so due to their repeated participation in CI Ops.

(k) Recruits/Regimental Training Centres

(i) Stress fractures.

(ii) Psychosocial stress.

(iii) Overcrowding having the potential for explosive disease outbreaks like meningococcal meningitis, exanthematous fevers, etc.

(iv) Common source outbreaks - Food poisoning, viral hepatitis.

(l) Troops on foreign mission

The specific hazards are discussed elsewhere in a separate Chapter.

## Occupational lung diseases

### Pneumoconiosis

The concept of using the term Pneumoconiosis has undergone a change. Earlier, this term was used to describe all lung related problems caused by any kind of dust (4). However, the term should only be used for all dust damage to the alveolar part of the lung, including the airways that have no mucociliary lining (5). Therefore, by convention Pneumoconiosis does not include bronchitis, asthma or cancers. In other words, basically it is the inorganic dusts like silica, asbestos & coal that cause Pneumoconiosis since they affect the lung parenchyma, rather than the airways. On the other hand, organic dusts like cotton dust or cane sugar principally cause 'bronchitic' changes in the lungs & so do not qualify to be called Pneumoconiosis. Nonetheless, the control measures for both organic dust & inorganic dust remain the same.

Standard distance, full size, posterior-anterior films taken & processed as recommended by ILO (6) play an important role in the prevention & early detection of occupational diseases of the alveolar part of the lung. For epidemiological purposes, the classification of individual X-rays of pneumoconiosis is a difficult task and even those experienced in radiography vary in their judgement. In general, rounded opacities are fairly specific for pneumoconiosis due to mineral dusts. Other changes such as irregular opacities (which are frequently seen after exposure to asbestos dust) are less specific. In exposure-response epidemiological studies it is recommended that random groups of X Rays be examined by atleast three experienced medical workers independently, using standard ILO X Rays for comparison. In order to ensure repeatability, a certain number of X rays should be re-examined & use should be made of trigger films. However, it should be pointed out that this approach may not be suitable for long term serial studies because film processing techniques change over a period of time. It is therefore, not surprising to note that most cases of Pneumoconiosis in India are diagnosed as Tuberculosis.

### Silicosis

Silicosis is a disease caused by breathing air containing silica in its free state, as quartz (SiO2) .The pathological result is a generalised fibrotic change and development of miliary nodules of variable sizes in both lungs. The clinical manifestations are shortness of breath, decreased chest expansion, a lessened capacity for work, and chronic bronchitis with the absence of fever and characteristic X-ray findings. There is an increased susceptibility to tuberculosis. The diagnosis of the disease mainly depends upon occupational history, symptom complex and the radiological findings. The pathological process starts only when the dust particles, which contain silica in a free state such as quartz (SiO2), reach the alveoli. Most of the dust inhaled is expelled by the ciliated epithelium and some part is eliminated by phagocytosis, which brings up the particles and discharges them to the ciliated epithelium and the cough mechanism expels them. However, when the fine particles are present in the atmosphere in a large quantity, some find their way to the finer air passages. They first cause the inflammation of the ciliated epithelial cells with their subsequent destruction, reducing the first line of defence. Epithelial cells crowded with silica dust get aggregated into definite clumps around which fibrosis occurs. This damage produced in the lung is permanent. It is liable to activate the preexisting tubercular focus and develop tuberculosis. The disease finally produces emphysema and corpulmonale. The factors of importance in the causation of the disease are dependent upon the nature of the work process and the environmental working conditions. They are as under: -

(a) The dust must contain silica in a free state as quartz (SiO2) and the particles must be of respirable size.

(b) These must be present in sufficient concentration in the atmosphere and must be breathed for long periods.

(c) The larger particles tend to flocculate and settle out of the atmosphere. Particles of 0.5 to 5 microns are dangerous as they are capable of getting into the lungs.

(d) Therefore, the dust, which cannot be seen by the naked eye, is much more dangerous than the dust, which is visible.

(e) The work in enclosed places is more dangerous than in open places.

(f) Wet processes carry less risk or none at all but dry processes are definitely dangerous.

(g) It is generally held that 10 years or longer is necessary for the development of a significant degree of silicosis; but in more severe exposures, such as in sand blasting and rock drilling under ill-ventilated conditions, it may occur early (7,8,9,10).

#### Prevention

Very little can be done once the disease has set in and, therefore, prevention is most important. Preplacement & periodic health examinations of the worker are important. Chest X Ray is to be taken to see if the individual has pulmonary tuberculosis or any other lung disease. Basic lung function tests should be carried out, including measurement of the Vital Capacity & Forced Expiratory Volume in one second. Dust control is the most important engineering procedure to reduce risk as shown in Table 1. If a significant number of workers develop silicosis within 20-25 years of first employment, the dust control measures should be suitably revised.

### Asbestosis

Asbestos is a fibrous material. These are silicates; silica combined with bases like magnesium, iron, calcium, sodium and aluminum. These are of two types-serpentine and amphibole. However, 90% of production is of serpentine variety. Asbestos used in the manufacture of asbestos cement, fireproof textiles, roof tiling, brake lining, gaskets, and such other items.

Asbestos fibres are inhaled and fine dust gets deposited in the alveoli. These are insoluble and cause chronic irritation resulting in pulmonary fibrosis of lungs. It can also cause carcinoma of bronchus and mesothelioma of

pleura and peritoneum (more due to amphibole variety). These possibilities are more when exposure is coupled with smoking. The disease appears after an exposure of 5 to 10 years. The fibrosis is peribronchial, diffuse and more near the bases in contrast to fibrosis due to silicosis. Clinically, patient gets cough, pain in chest and dyspnoea disproportionate to the clinical signs in lungs. In advanced cases there may be clubbing of fingers, cardiac failure and cyanosis. Sputum shows asbestos fibres coated with fibrin called "asbestos bodies". X-ray chest shows a ground glass appearance in lower parts of lungs. Disease is progressive even after removal from exposure.

Prevention

(a) Adopt all measures for dust control. The legal exposure limit in India is 2 fibres/ml of air.

(b) Substitute it with safer materials like glass fibres, calcium silicate, plastic foam etc. where feasible.

(c) Use safer varieties of asbestos (chrysotile & amosite).

(d) Periodic medical examination of workers and elimination of susceptibles from workforce.

(e) Use of personal protective measures.

(f) Good housekeeping & the use of vacuum cleaners.

(g) Use of respirators & protective clothing is to be encouraged.

(h) Health education of the workers.

(j) Continuing research to find safer substitutes (7, 8, 10-16).

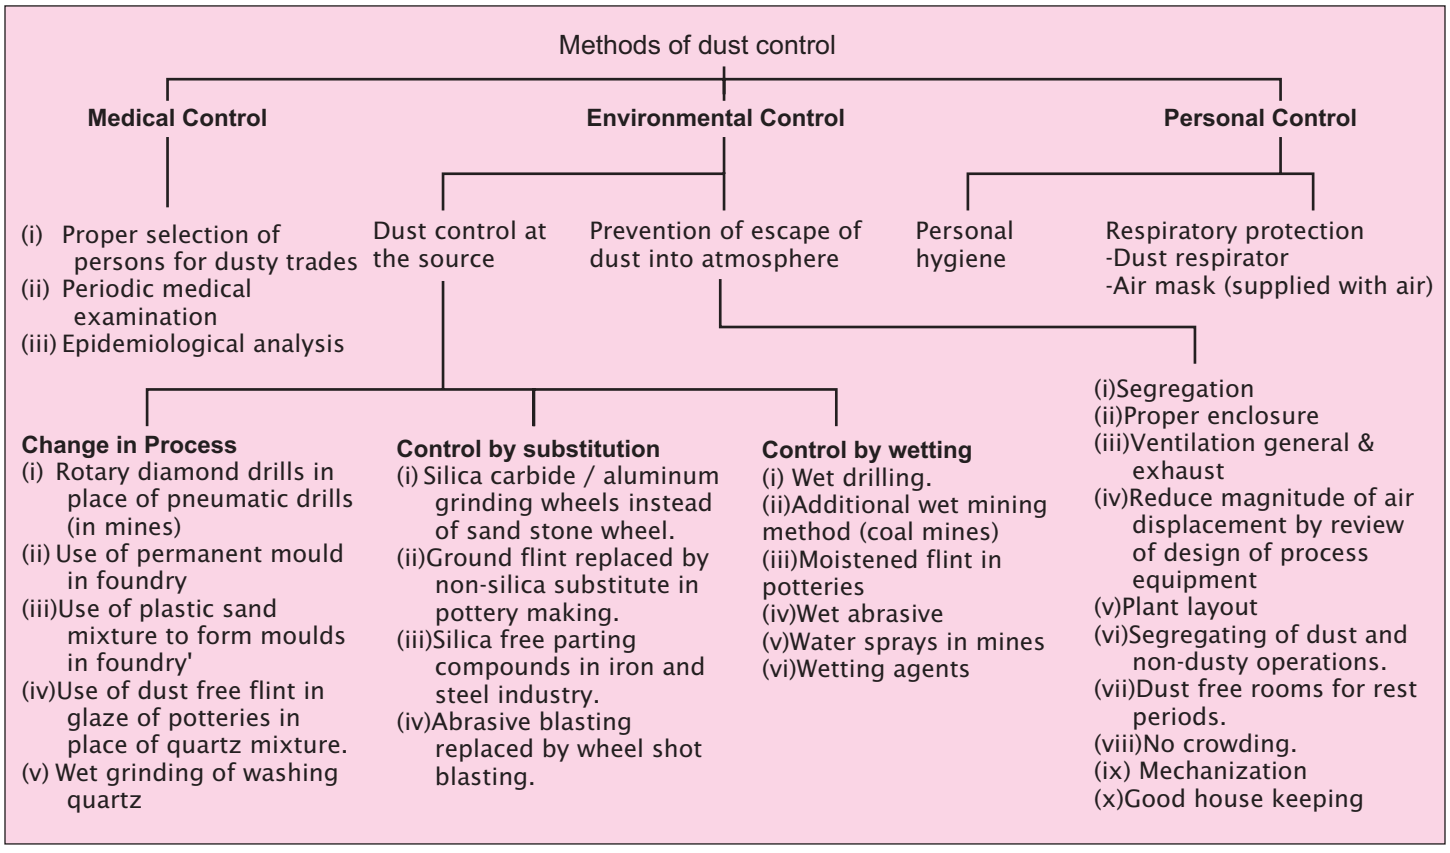
**Bysinossis**

Bronchopulmonary diseases caused by exposure to airborne dust of cotton, flax & soft hemp leads to Bysinossis. It is a chronic respiratory disease characterised by tightness of the chest & breathlessness at work after the weekend or other absence. It is also called 'Monday Fever". This is probably due to a histamine releasing substance. In addition to histamine release, exposure to cotton dust causes irritation in the upper respiratory tracts & bronchi, which after prolonged exposure slowly progresses to chronic obstructive pulmonary disease. In early stages there may be decline in FEV1, which may be symptomless in some workers. Within, one or two days, most symptoms tend to disappear except for irritation in the upper respiratory tract. As the disease progresses, the chest tightness is accompanied by breathlessness, the symptoms becoming worse & persisting for a longer time. In its late stages the disease resembles chronic bronchits & emphysema, except for the history of chest tightness & decline in ventilatory capacity, characteristically worse at the beginning of the work week. Chest X rays do not show any specific changes.

Prevention

Preplacement examination should include Chest X ray, VC and FEV1. Periodic medical examination is recommended every year. In groups of workers, a drop of more than 10%

Table- 1: Methods of dust control



## Work Environment

### Design of Building

All buildings, permanent or temporary should be structurally safe and sound to withstand the stress and strain of machinery. Single storey construction is the usual rule as it allows flexibility of layout. Any intensity of natural light can be obtained in it by a combination of wall and roof lighting and it is easier to manage natural ventilation. By careful orientation, direct exposure to the tropical sun can be avoided. Protection from conducted heat can be achieved by a choice of suitable material. Asbestos lining of the walls and ceilings will reduce the noise or machines by controlling the reverberation, resonance and sympathetic vibrations. This will also make the building fireproof.

### Space Requirement

A floor area of 3.8 sq.m. and 14.2 cu.m. of space per worker should be provided. The height of the work rooms should not be less than 3 m. In calculating the space, no deduction need be made for furniture, machines and material, but a height above 4.2 metres should be excluded. The floor should, however, not be crowded with machinery. Individual machines or process units should have sufficient space around them to permit safe operation.

### Lighting

Workrooms should be adequately provided with natural and / or artificial lighting. Any special type of work should have special, extra or spot lighting suitable for the operations. In all places where persons work or pass through, enough diffuse background lighting should be ensured. Natural lighting is ensured by the provision of skylights and windows located and spaced with devices to avoid glare. Artificial lighting should be provided where the daylight illumination is insufficient. It should be uniform and free from sharp and contrast shadows and direct or reflected glare. Supplementary lighting specifically designed for particular visual task should be so arranged as to avoid glare, flicker or after-image. Emergency lighting should be provided in all important stairway exits and passages, to and from work places and windowless buildings. The fluorescent tube in strip lighting is being increasingly used. Their efficiency is high and running costs are low. They give uniform illumination and there is low heat formation with absence of shadows. However, in course of time when the tube gets exhausted it develops a flicker, which is irksome to the eyes and also produces a stroboscopic effect (7,8).

### Ventilation

Modern concept of ventilation requires replacement of vitiated air by supply of fresh outdoor air. The quality of the incoming air should be such that its temperature, humidity and purity are conducive for healthful working. Clean fresh air should be supplied to enclosed work places and it is recommended that in work rooms and assemblies there should be 4 to 6 air changes in one hour. If the air is changed more frequently, i.e. more than 6 times in one hour, it is likely to produce a draught which should be avoided. Where an adequate supply of fresh air cannot be obtained by natural ventilation, mechanical ventilation should be provided. All dust, fumes, gases, vapours or mists generated and released in industrial processes should be removed by local exhaust ventilation at their point of origin (7, 8).

### Thermal Comfort

Temperature and humidity should be maintained in enclosed work places suitable to the kind of work performed. In localities subject to high or low seasonal temperatures appropriate means such as heat insulation of roofs, walls and floors, and even of doors and windows should be adopted. All employees should be protected against radiant heat and excessive temperature from heated machines or hot processes by heat insulation of the equipment and / or by suitable protective clothing. In industries involving exposure of workers to high or low temperatures, 'transition rooms' should be provided so that the workers can gradually adjust themselves to the external climatic environments. Roof-shelters and windbreakers should be provided for yard-workers where necessary. Measurement and indices of thermal comfort have been dealt in detail in another chapter.

### Working Comfort

Seats and workbenches of suitable shape and height should be provided for workers. The seats should be so placed that working material can be reached easily without strain or having to bend forward unduly. Seats should also be provided for all workers who have to work in a standing position, for rest during occasional short interruptions in their work.

### Sanitary Conveniences

These should be conveniently located: -

(a) Latrines

Scale of latrine accommodation is 4 for the first 100 workers and 2 for subsequent 100 workers or part thereof.

(b) Urinals

Two urinals for every 100 workers upto 500 and there after one for 100 workers are to be provided. For female workers separate sanitary conveniences are to be provided.

(c) Wash Basins

Adequate hand washing facilities should be provided. For persons whose work involves contact with any injurious substances, there should be at least one tap for every 15 workers.

(d) Bath-rooms

Adequate number of bathrooms for bathing and washing of clothes should be provided.

(e) Spittoons

Sufficient number of spittoons should be placed at convenient places.

(f) Cloak Rooms

Well-ventilated rooms with individual lockers should

be provided for dressing purposes and storage of personal clothing (17).

### Drinking Water

An adequate supply of cool and safe drinking water should be provided in a readily accessible place. Water coolers are ideal and most hygienic. Proper precautions to prevent contamination of water in tanks, pails and other containers must be enforced, Section 18 of the Factories Act lays down that every factory having more than 250 workers will provide cool drinking water during hot weather (17).

### House-keeping

It implies general cleanliness and orderliness of the plants, the tools and the products. Cleaning and sweeping should be done during non-working hours; vacuum cleaning or wet mopping should be adopted. Effective drainage should be maintained where wet processing is carried out. False floors, platforms, mats or other dry standing places along with suitable footwear should be provided in oily and greasy places. However, 'house-keeping' means much more than merely keeping the working places clean. That there is a place for everything and everything in its right place, is a tried and true axiom of industrial safety. Stumbling and tripping due to improper house-keeping is another potential cause of accidents.

### Miscellaneous Requirements

Infestation with rodents, insects and vermin should be eliminated by suitable measures. Workrooms and work places should not be used as living or sleeping quarters. No food, drink, betel nut or leaves or tobacco should be consumed or brought by any worker into any workroom in which dangerous and obnoxious materials, particularly lead and radioactive substances, are in use. Anyone suffering from communicable diseases should be at once isolated and preventive and control measures instituted.

## Industrial Toxicology

Industry uses and manufactures wide variety of substances, which are either known or suspected to cause toxic effects in the persons working with them. Industrial toxicology is concerned with the study of various substances used in industry either as media for processing some other materials or as raw materials or the finished product. The genesis of toxic effects is shown below in a schematic manner:

| | |
|---|---|
| Things used or manipulated → | Solids, liquids, gases |
| may produce | dusts, fumes, gases, rays |
| which may be → | inhaled, swallowed, absorbed by or attack |
| the | skin, |
| and cause | harmful effects, (Occupational hazards/ diseases) |

### Permissible Exposure Limit (PEL)

It is defined as exposure to a maximum time weighed average (TWA) of concentration of a toxicant for an 8-hour work. The PELs of some important substances as recommended by Factories Act 1947 (modified in 1987) are given in Table 2.

Table - 2 : Permissible Exposure Limit (PEL) of gases and vapours

**(Factories Act 1948 as amended 1987)**

| Substance | Parts per million of air by volume |
|---|---|
| Acetone | 750 |
| Ammonia | 0.25 |
| Arsine | 0.2mg/$m^3$ |
| Benzene | 10 |
| Bromine | 0.7 |
| Carbon disulphide (skin) | 10 |
| Carbon monoxide | 50 |
| Formic acid | 5 |
| Hydrogen cyanide(skin) | 10 |
| Nitrogen dioxide | 3 |
| Phenol(skin) | 5 |
| Phosgene | 0.1 |
| Pyridine | 5 |
| Sulphur dioxide | 2 |
| Toluene | 100 |
| Trichloroethylene | 50 |
| Vinyl chloride | 5 |
| Xylene | 100 |

### Prevention - Engineering Measures

General rules for prevention/reduction of hazards from dangerous and obnoxious substances are as under :

**(a) Substitution**

Wherever practicable the use of offending substances should be prohibited. Failing that, a harmless substance should be substituted for the harmful one e.g. the use of yellow phosphorus substituted by phosphorus sesquisulphide in the match industry, sand-blasting may be substituted by shot blasting; and acetone may be used in place of benzol as solvent.

**(b) Total Enclosure**

Through airtight enclosure, personal contact with harmful substances such as dusts, fibres, fumes, gases, mists or vapours can be prevented.

**(c) Local Exhaust Ventilation**

Where an airtight apparatus cannot be used, the harmful products should be removed at or near their point of origin by means of fume chambers or suction hoods

properly connected to efficient exhaust systems.

**(d) Dust Suppression**

Where practicable the materials should be used in a moist or wet state to prevent the evolution of dust e.g. lead.

(e) **Duration of Exposure**

Limitation of the duration of exposure or employment should be compulsory in certain trades e.g. in radioactive processes.

(f) **Restriction of Employment**

Children below 14 years are not permitted to work in any industry. Women and young persons between 15-18 years are prohibited from working in hazardous industries.Women are prohibited from working underground in a mine.

(g) **Personal Hygiene**

Provision of adequate washing facilities and insistence on washing / bathing e.g. for workers in lead, chromes and radioactive processes. Prohibition of the preparing or taking of meals and smoking in workrooms.

(h) **Environmental Monitoring**

The atmosphere of workrooms should be tested periodically to ensure that the concentration of irritating or toxic dusts, fibres, fumes, gases, mists or vapours is kept within safe limits.

(j) **Health Education**

By far the most important safety factor is the co-operation of the worker in obeying the given safety orders and instructions. Too often, the safety notices / posters are couched in purely negative terms; the worker is exhorted not to perform one or other action and is left in doubt as to the reason for the prohibition. A positive approach has been found to be more effective. If the notices give an indication of the nature of the hazards to which the workman would be exposing himself, there could be less temptation for disobeying the restrictions.

## Legislation - Notifiable Diseases

Occurrence of any of the diseases listed here under should be notified under "The Factories Act, 1948 as modified in 1987" (17).

(i) Lead poisoning including poisoning by any preparation or compound of lead or its sequelae.

(ii) Lead tetraethyl poisoning.

(iii) Phosphorus poisoning or its sequelae.

(iv) Mercury poisoning or its sequelae.

(v) Manganese poisoning or its sequelae.

(vi) Arsenic poisoning or its sequelae.

(vii) Poisoning of nitrous fumes.

(viii) Carbon bisulphate poisoning.

(ix) Benzene poisoning including poisoning by any of its homologues, their nitro or amino derivatives or its sequelae.

(x) Chrome ulceration or its sequelae.

(xi) Anthrax.

(xii) Silicosis.

(xiii) Poisoning by halogens or halogen derivatives of the hydrocarbons of the aliphatic series.

(xiv) Pathological manifestations due to radium or other radioactive substances and X- rays.

(xv) Primary epitheliomas of the skin.

(xvi) Toxic anaemia.

(xvii) Jaundice due to hepatotoxic substances.

(xviii) Oil acne or dermatitis due to mineral oils and compounds containing mineral oil base.

(xix) Byssinosis.

(xx) Asbestosis.

(xxi) Occupational or contact dermatitis caused by direct contact with chemicals and paints. These are two types, that is, primary irritants and allergic sensitizers.

(xxii) Noise induced hearing loss (exposure to high noise levels).

(xxiii) Beryllium poisoning

(xxiv) Carbon monoxide

(xxv) Coal miners pneumoconiosis

(xxvi) Phosgene poisoning

(xxvii)Occupational cancer

(xxviii)Isocyanates poisoning

(xxix) Toxic nephritis

Medical Examination

A proper pre-placement medical examination followed by periodical medical inspections at appropriate intervals for workers exposed to hazardous occupation should be enforced.

## Chemical Hazards

**Lead**

Lead is ubiquitous in industry and poisoning due to absorption of lead and its compounds is still common.

Table - 3 : Categories of lead absorption

| Test occupation | Normal population | Acceptable absorption in occupation | Excessive absorption in with signs & symptoms |
|---|---|---|---|
| Blood lead | 10ug/dl | 10-80ug/dl | >80ug/dl |
| Urinary lead | 10-65 ug/g Cr | upto 150 ug/g Cr | >150 ug/g Cr |
| Zinc protoporphyrin | 16-35 ug/dl | Upto 100 ug/dl | >100 ug/dl |

Hazardous processes are lead smelting, burning and making paint, painting, welding, riveting, battery manufacture, and lead baths connected with heat treatment of metals, specially when carried out in confined spaces. Inhalation of lead dust and fumes is the chief route of poisoning; the next common route is ingestion; cutaneous absorption is rare. It is rapidly absorbed into general circulation when inhaled and produces ill effects much more rapidly and probably in a more severe form than when ingested. Young persons are more prone to lead poisoning than adults. Lead concentration in the working atmosphere should be kept below 2.0mg per 10 cu m of air ( 7,8, 18-22).

(a) Symptoms

The commonest manifestations of lead poisoning are blood changes and lead palsy. Lead makes the RBC fragile and causes haemolysis, which results in anaemia with compensatory stimulation of the bone marrow. So immature RBC or reticulocytes appear in the blood. The RBC count is generally below 3 million with haemoglobin under 70 per cent (Sahli). In 'Lead palsy' there is a typical degenerative neuritis and subsequent fibrosis. In acute lead encephalopathy, there is involvement of the meninges with oedema and increased intracranial pressure. There, may be some capillary damage as well. The lead line showing blue discolouration of the margins of the gums is a classical sign. A diagnosis of lead poisoning should be based on clinical findings, biochemical evidence of excessive lead absorption and by evidence of unusual exposure. Table-3 lists biochemical tests for estimating the degree of lead absorption and Table-4 show signs and symptoms of lead poisoning.

(b) Prevention

It depends on good housekeeping, personal protection and education of workers and medical supervision for the detection of hazards before the occurrence of poisoning followed by its rectification.

(i) Exhaust ventilation measures so arranged that whatsoever position the worker assumes the lead dust and fumes are drawn away from his face.

(ii) Strict periodical inspection of the exhaust system; all ducts and their angles should be cleaned periodically.

(iii) Avoidance of crowding in the workrooms where metallic lead is heated.

(iv) The floor should be impervious to water, and smooth so that no lead dust can accumulate.

(v) The floor should be constantly kept wet and swept before and after the day's work with a vacuum cleaner.

(vi) Workers should wear special work clothes which should be removed before leaving the factory and deposited in specially provided lockers in

Table 4 : Table showing manifestation of lead poisoning

| System | Evidence of absorption | Evidence of incipient poisoning | Evidence of definite poisoning |
|---|---|---|---|
| General appearance | Restive, moody, easily excited, emotional, lead line. | Pallor, leadline, jaundice. | Anaemia, leadline, jaundice, emaciation, “premature ageing”. |
| Digestive System | Persistent Metallic taste, slight anorexia, slight constipation. | Metallic taste, definite anorexia, slight colic, constipation. | Metallic taste, increasing anorexia, nausea and vomiting, marked colic, rigid abdomen marked constipation, blood in stool. |
| Nervous system | Irritability, unco-operativeness. | Slight headache, insomnia, slight dizziness, palpitation, increased irritability, increased reflex. | Severe headache, increased insomnia, increased dizziness ataxia, confusion, marked reflex changes, tremor, fibrillary twitching, neuritis, visual disturbances, encephalopathy hallucinations, convulsions, coma, paralysis. |
| Miscellaneous | | Muscle soreness, easily fatigued. | General weakness, arthralgia, hypertension. |
| Urine examination | Abnormal lead content. | Abnormal lead content, albumin, casts. | Abnormal lead content, albumin, casts, porphyrinuria, haematuria |
| Blood changes in increase in cells showing | Polycythemia, polychroma-tophilia, increased platelets, | Normal red cell count and | Decrease in haemoglobin, decrease haemoglobin, reticulocytosis,RBC, |

order to ensure the prevention of contamination of private clothes.

(vii) Suitable respirators against lead dust and fumes should be used and inspected regularly.

(viii) No food, drink and tobacco should be taken in a place where there is a risk of lead poisoning; special rooms should be provided for this in factories.

(ix) Personal cleanliness should be ensured by providing bathing and washing facilities.

(x) Health education to avoid dusts and fumes of lead being inhaled or ingested.

(xi) Medical Surveillance : Pre-employment medical scrutiny of the prospective workers in the hazardous process should include the history of previous exposure to lead and elimination of those with a positive history of symptoms of lead poisoning. Quarterly medical examination during employment with attention paid to the loss of weight, gastro-intestinal symptoms, weakness of wrist muscles and blood picture. Removal from exposure should be followed by active treatment

(c) Treatment

When lead poisoning is diagnosed, the further exposure should be discontinued. The use of penicillamine and Ca-EDTA, chelating agents, help in bringing down the blood lead levels by promoting lead excretion in urine. A saline purge will help to remove unabsorbed lead from the gut and also will relieve constipation.

**Tetraethyl Lead**

Exposure to high concentrations of vapour of leaded petrol, especially in hot weather, is responsible for an acute form of lead poisoning (lead encephalopathy). In industry this hazard occurs by spillage in petrol filling sheds/holds/barges with inadequate ventilation, inhalation from clothing saturated with petrol from spillage and splashing and absorption through the skin, which is relatively slight. In some cases a chronic form of lead poisoning occurs. Spillage should be prevented by use of filling apparatus. Proper ventilation of the shed is important. The operation of filling should be carried out in the open air. Exhaust fans may be necessary. Special precautions must be adopted when containers are loaded in the holds of the barges. Only containers in sound condition should be accepted for loading and care should be taken in the storage of the containers. The holds of the barges / tanks should be provided with adequate ventilation. Short shifts at frequent intervals during the work and overall turnover of the labour, so that each man is employed for one week in four on this work, are essential preventive measures. Other precautions are the same as have been described under lead poisoning. With the current trend on use of unleaded petrol, it is presumed that toxicity due to this cause will be on the decline.

**White Phosphorus (WP))**

White phosphorus (WP) is being used in smoke producing ammunition. After white phosphorus exposure burnt skin is washed with 5% sodium bicarbonate and 3% copper sulphate in 1% hydroxyethyl cellulose. Phosphorus particles become coated with black cupric phosphide allowing easy identification. Copper Sulphate also decreases rate of oxidation of phosphorus particles, limiting damage to underlying tissue. Since blackened particles continue to elicit tissue injury, they can be removed. Of late, copper sulphate is found to be toxic and systemic copper poisoning can manifest as vomiting, diarrhoea, oliguria, haematuria, hepatic necrosis and cardio- pulmonary collapse. Thus presently the following treatment is followed: -

(a) Self Aid

(i) If burning particles of WP strike and stick to clothing, take off the contaminated clothing.

(ii) If burning WP strike the skin, smother the flame with water/ a wet cloth. Keep the WP covered with wet material to exclude air until the particles can be removed.

(iii) Try to remove the WP particles with a knife, stick or available object. It may be possible to remove some particles with a wet cloth.

(b) Treatment

(i) At the earliest opportunity, all WP particles must be removed.

(ii) Affected area is bathed in a bicarbonate solution to neutralise phosphoric acid which will then allow removal of visible WP particle. In dark surrounding, fragments are seen as luminescent spots.

(iii) Do not apply oil based ointments until it is certain that all WP has been removed as WP is readily soluble in oil. Following complete removal of the particle, treat the lesion as thermal burn.

(iv) If eye is affected, treatment must be started immediately. The most effective treatment is to neutralise any phosphoric acid by irrigating with 5% bicarbonate solution. Continue irrigating for 10-15 min with copious amount of normal saline or water at room temperature. On completion of irrigation, a wet dressing/cloth should be applied to stop WP burning by depriving it of oxygen. All WP particles easily accessible should be removed promptly. The lids must be separated and a local anaesthetic instilled to aid removal of embedded particles. Once all particles have been removed from the eye, atropine eye ointment should be put and patient be transferred to care of an Ophthalmologist as early as possible (7, 8, 18 21).

**Mercury Fulminate**

It is a brownish yellow, heavy, crystalline solid prepared by the action of alcohol on mercuric nitrate. The chief hazard is dermatitis affecting those who are employed in filling

operations where a fine dust is raised, which comes in contact with the naked skin. The susceptibility of some individuals may not enable them to withstand exposure even for a day. The exposed parts of the body become erythematous. accompanied by violent itching, swelling and oedema of the face, eye-lids, ears, neck and forearms. Teeth become black owing to the formation of mercuric sulphide. Cleanliness of the plant is important. All precautions as for a lead factory should be taken. Exhaust ventilation should be fitted, and all persons should be provided with well fitting overalls, aprons, rubber gloves, and if necessary, respirators as well. Additional hand washing facilities should be provided (8, 18-22). Details of occupational dermatitis are given in Table - 5.

**Chromium**

Chromic acid and bichromates of sodium and potassium are used in chromium plating of metals, manufacture of explosives and for tanning of leather. Characteristic chrome ulcers occur on nail beds and the nasal septum. They are small, deep ulcers varying in size from the head of a matchstick to the end of a lead pencil. The tissues around the ulcers are heaped up and are covered by crusts. They may cause perforation of the nasal septum. The ulcers are as a rule not painful but heal very slowly (7,8, 18-22).

(a) Prevention

Mechanical lateral exhaust ventilation should be provided for the removal of the vapour and spray at the point of origin. The floor of rooms containing chrome baths should be impervious, maintained in good condition and flushed out daily. Suitable rubber gloves, aprons and other protective clothing should be provided and maintained properly. Water taps should be installed in workplaces, to enable the workers to wash hands frequently. Shower bath and a change of clothing should follow the day's work. All cuts, abrasions and other injuries on hand and forearm should be protected by adhesive strapping before starting work. The hand and forearm should be inspected twice a week and any breach of continuity of the skin should be immediately reported to the factory doctor. A protective ointment should be applied in the nostrils.

(b) Treatment

Chrome holes are only slightly painful and tend to heal spontaneously but may be troublesome if secondarily infected. They can however be treated adequately with a 10 % solution of Calcium EDTA. For ulceration of nasal septum use of liquid paraffin on plugs of cotton wool is enough. The man should be removed from the exposure until completely cured.

**Metal Fume Fever**

It is an acute transient illness and is commonly known as 'Brass Founders Ague', 'Zinc Fever' or 'Metal Chill'. It follows the inhalation of high concentrations of finely dispersed zinc or brass fumes, usually in the form of oxides. After heavy exposure, the nose and throat feel dry and sore giving rise to a dry cough. In a few hours, the symptoms appear. There is shivering which may last for

TABLE 5 : Occupational Dermatitis

| Predisposing Factor | Machine causes | Physical causes | Chemical causes | Biological causes | Preventive measures |
|---|---|---|---|---|---|
| Type of Skin<br>Age<br>Personal hygiene<br>Weather conditions<br>Pre-employment conditions of skin<br>Nutritional state<br>Environmental conditions<br>Protective clothing<br>Mechanical factors<br>Excessive sweat<br>Emotional status | Repeated friction<br>Sand, dust, coal particles<br>Metal particles<br>Glass fibres<br>Fish scale / bone pricks | Heat<br>Humidity<br>Sunburn<br>Radiation (U.V.Rays, X-rays)<br>constant exposure to water | Primary Irritants:<br>Alkali soap (dissolve keratin)<br>Organic solvents (Dissolve fats)<br>Inorganic acids (Dehydrate tissues)<br>Heavy metal salts (Precipitate tissue proteins)<br>Chromates and bleaches (oxidation of tissue)<br>Coal tar and petroleum (Keratogenic action)<br><br>Cutaneous Sensitisers:<br>Combine with tissue proteins and forms complex antigens<br>Acridine compounds (acriflavin, mepacrine)<br>Dyes (Diamine, Rosamine, Chrysodine)<br>Solvents (Petrol, TNT)<br>Developers (Metol, hydroquinone)<br>Antioxidants (Guanidine)<br>Resin, perfumes, waxes<br>Miscellaneous group (fluorides, mercury fulminate, bichromates, insecticides, fungicides, streptomycin, penicillin). | Bacteria<br>Parasite (Mite)<br>Plants (Liliaceae)<br>Vegetables (Asparagus, spinach, beans, pyrethrum)<br>fruit (Orange, lemon, tulip) | Selection of workers<br>Health education<br>Periodic inspection<br>Plant design<br>Substitution<br>Personal protection<br>Thermal comforts<br>Barrier cream<br>Keeping up morale of workers |

some time and this is followed by profuse perspiration, the picture simulating that of an attack of malaria. Considerable prostration follows the attack, but by the next morning recovery is almost complete. Some degree of insusceptibility is produced by low-grade inhalation but is lost in 48 hours. Workers therefore, are likely to suffer more on Monday mornings. Metal fumes should be eliminated by proper exhaust ventilation. When conducting replacement or transfer medical examinations, cases with a history of chronic bronchitis, asthma or any other respiratory trouble should be withheld.

**Mineral Oils**

Mineral oils are insoluble and soluble. The insoluble ones are used mainly as lubricants for cutting tools and the soluble ones are used as cooling agents. Cutting oils have the property of defattening the skin. They also plug the pores of the skin and form comedones. After some days of use they may contain steel slivers, which may injure the skin and thus start dermatitis affecting the forearm and thigh. Small blackheads due to blocking of the sebaceous glands appear in these areas.

(a) Prevention

Cleanliness of persons, their clothes and machines should be ensured by the provision of adequate washing and shower bath facilities. Suitable industrial cleaners should be placed at convenient locations in the washroom. Clean rags or cotton waste free from sliver should be provided. Time should be allowed for workers to carry out thorough cleansing, change of clothes and dressing. Those who give a previous history of dermatitis should be excluded by preplacement examination. Persons suffering from seborrhoea, acne and excessive sweating should be prohibited from employment in such jobs (Table-5). If the dermatitis occurs or comedones appear, the person should be temporarily withdrawn from the process and re-employed when the skin condition clears up.

(b) Treatment

The treatment is usually by soothing lotions or cream like calamine. Barrier creams may help in getting the skin of the beginners slowly conditioned to the contact with cutting oils but cannot serve as a permanent protective measure for persons whose skins are excessively sensitive.

**Benzene**

This is a colourless aromatic hydrocarbon with a characteristic pleasant smell. It is extensively used as a solvent and as a starting material in the synthesis of numerous chemicals (7,8, 23-27).

(a) Acute Poisoning

Clinically, acute poisoning is of three general types, depending upon the severity of its anaesthetic effects on brain centres. Very high concentrations of benzene inhalation may result in unconsciousness, followed by death from respiratory failure. With somewhat, lower concentrations there may be dizziness, weakness, apprehension, collapse and unconsciousness. Death may occur from respiratory failure. In the third type of poisoning death occurs in several days usually without recovery from coma.

(b) Chronic Poisoning

The haemopoetic system is mostly affected but degenerative changes are also observed in the kidneys and heart. There is weakness, dizziness, rapid pulse, persistent headache, malaise, loss of appetite, shortness of breath, undue fatigue, decreased resistance to infections, and ulcers in the throat. Due to decrease in platelets, there is bleeding from the mucous membrane and haemorrhage in tissues. Macrocytic anaemia gives more reliable indication of the poisoning than leucopenia, especially in the early part of the disease.

(b) Prevention

The ventilation of the workroom should be improved by mechanical exhaust ventilation. A monthly examination of the employees should be carried out including a complete blood count, and findings recorded in a special register. There should be a rotation in duties of the personnel. Worker's showing an altered blood picture should be removed from exposure. They should report for medical examination, if bleeding from the nose, gums or other mucous membranes is noticed. Toluene, xylene, cyclohexane or trichloroethylene can be used as comparatively safer and satisfactory substitutes for benzene.

(c) Treatment

Penicillin should be given in adequate doses if infection is suspected. Repeated blood transfusions may be necessary. Since anaemia is frequently of the macrocytic type - folic acid and vitamin B12 should be given. The diet should be rich in protein, especially animal proteins and in vitamin C and Vitamin B group.

**Trinitrotoluene (TNT)**

It is a yellowish crystalline solid, which looks like brown sugar. It is used extensively as an explosive. TNT is mainly absorbed by the skin and to a certain extent by inhalation. It forms methaemoglobin, which decreases the oxygen carrying capacity of the red blood corpuscles. It has a deleterious action on the bone marrow and can also cause massive necrosis of the liver. Breathlessness, cyanosis, and dermatitis of the hands and forearms are the early symptoms of poisoning which appear 7 to 14 days after exposure. Later jaundice and aplastic anaemia may develop. Control of the dust at the point of generation and dissemination by local and general exhaust ventilation and dilution with uncontaminated air by the plenum system of general ventilation together with good housekeeping reduce the danger of TNT poisoning. Workers should be subjected to a rigid pre-placement medical examination. Habitual alcoholics, mouth breathers and particularly persons showing any indication of anaemia, and those with liver, kidney, and chronic respiratory and skin diseases should be eliminated. Subsequent to employment they should be examined at monthly intervals with special attention paid to the blood

picture. If anaemia develops, repeated blood transfusion might be needed in addition to a high protein diet and anti-anaemia therapy (7,8,23).

**Tetryl**

It is a light yellow crystalline powder used as an important propellant in conventional military missiles. It causes dermatitis, beginning on the face. There may be blisters on the skin, and eyes may become oedematous. Hands or the parts of the body coming in contact are discoloured yellow. As a rule there are no constitutional disturbances. Exhaust ventilation, protective clothing, barrier ointments and personal cleanliness reduce the incidence. Sodium sulphate incorporated in soap quickly removes the stain caused by tetryl (7,8,23).

**Nitroglycerine**

Nitroglycerine is prepared by adding glycerine to a mixture of nitric and sulphuric acids. It is principally used for making dynamite. It is absorbed mainly by inhalation and to a lesser degree through the skin. It is a strong vasodilator. The symptoms of poisoning are flushing of the face, throbbing in the head, intense headache, palpitation, and nausea, vomiting and fainting. All operations where nitroglycerine is washed and neutralised should be enclosed as completely as possible and exhaust ventilation should be provided. Since it is also absorbed through the skin, it is essential that special attention is paid to housekeeping (cleanliness of workshops) and personal hygiene, which should include changing of working clothes daily, washing of hands and wearing of protective clothing as, described above.

**Trichloroethylene (Trilene)**

It is a colourless liquid with chloroform like odour. It is largely used in the metal industry as a degreaser. When the exposure is sudden,the worker may die and the post-mortem examination may reveal oedema of the lungs and petechial haemorrhages. Fatty degeneration of the liver, kidneys and heart is present if death is delayed. Repeated exposure affects the central nervous system leading to paralysis of the hypoglossal nerve, sensory fibres of the fifth nerve, second cranial nerve and polyneuritis in the limbs. Mild poisoning may cause various grades of unconsciousness as occurred in the past in laundry workers. Trichloroethylene should be used only in closed systems or in rooms with a downward exhaust ventilation system. Workmen with dry and fissured skin should not be permitted to handle the chemical. Inhalation of a mixture of 95 per cent carbon dioxide is of great value in the treatment of poisoning. Artificial respiration may be necessary (7, 8, 22, 23, 27).

**Carbon-Monoxide**

It is a colourless and odourless gas formed from the incomplete combustion of materials containing carbon. It is encountered in various industries such as foundries, gasworks, coke-ovens, blast furnaces and in automobile garages. It is a chemical asphyxiant. It forms a relatively stable compound, carboxyhaemoglobin when it combines with haemoglobin, as its affinity for the haemoglobin is about 300 times that of oxygen (7,8).

(a) Symptoms

Acute poisoning causes a sudden onset of unconsciousness, rapidly developing cyanosis and death. Initial symptoms of subacute carbon monoxide poisoning, which are more likely to be encountered in industry than the acute poisoning are shortness of breath, palpitation on exertion accompanied by slight headaches which tends to increase in severity. With the increased concentration of this gas in the blood, judgement becomes fogged and the affected individual may not realise his own danger. If the exposure continues mental aberration is followed by unconsciousness resulting in death from respiratory failure. Chronic poisoning shows all these symptoms coming on gradually and then continuing for longer periods.

(b) Prevention

Minimising its leakage by ensuring efficient ventilation, and finally by observing the rules of personal protection can prevent carbon monoxide poisoning. No person should be allowed to work single handed in a place where there is a danger of production of this deadly gas. No workman should enter or approach a place until the gas has been flushed out by fresh air and a suitable breathing apparatus is used. Safety posters in common languages should be displayed at strategic points explaining the deadly nature of symptoms of poisoning and means of rescue and first aid. Workmen should be given practice drill in rescue operations, artificial respiration and resuscitation. A cylinder containing a mixture of 95 per cent oxygen and 5 per cent carbon dioxide with a close fitting mask, should be available at all times for immediate use.

(c) Treatment

The victim should be removed immediately into fresh air and should not be made to walk even if he is conscious. The oxygen and carbon dioxide mixture should be administered or oxygen should be administered under positive pressure if available. If the breathing has stopped or is shallow, artificial respiration must be started and continued until normal breathing returns. If the heart has stopped beating, cardiac massage and stimulants should be given. Absolute rest in bed and warmth are essential. A close vigil should be maintained because of the tendency to relapse. Artificial respiration, administration of oxygen-CO2 mixture and cardiac massage should not be stopped until it is quite certain that heartbeat cannot be revived.

**Hydrogen Cyanide**

It is a colourless gas, with a penetrating bitter almond odour. Sodium and potassium cyanide baths used in the heat treatment of steel and iron are potential health hazards (7,8).

(a) Symptoms

Hydrogen cyanide like carbon monoxide is a chemical asphyxiant and prevents the tissue from using the oxygen carried in the blood. When inhaled in high concentration it

causes sudden collapse and almost immediate death. In lower concentration symptoms are delayed; the patient complains of headache, dizziness, vomiting, general weakness; slow and irregular respiration and pulse is almost imperceptible. There is a smell of bitter almonds in the breath, and if inhalation continues for some time coma supervenes, followed by death from respiratory failure.

(b) Prevention

Efficient plenum and exhaust ventilation, respiratory devices, protective hoods and respirators ensure safety.

(c) Treatment

Immediate first aid measure comprises of removing the patient to fresh air, keeping the patient warm and at rest and removing contaminated clothing. Contaminated skin is washed well with water. Treatment consists of inhalation of amyl nitrite for 15-20 secs every 2-3 mins along with Oxygen inhalation and artificial respiration. If patient is comatose or becomes drowsy then Dicobalt edetate (300 mg in 20 ml glucose sol) should be given by slow IV injection over 3-4 mins. If there is no return to consciousness then give Sodium thiosulphate (12.5 gm in 25 ml of 50% sol) IV over 5-6 mins. If the symptoms reappear or persist, half the dose of the antidotes should be repeated one hour later. If cyanide has been swallowed, gastric lavage is essential.

### Nitrous Fumes

The chief constituents of nitrous fumes are nitrous oxide, nitric acid, and two forms of nitrogen dioxide, $NO_2$, $N_2O_4$; the last two lend a brown colour to the fumes. Nitrous fumes are present in industries where sulphuric and nitric acids are manufactured, and in the manufacture of explosives. The fumes are also a hazard in certain operations e.g. welding, metal cleaning and electroplating. Toxicologically nitrogen dioxide $NO_2$ is the most important of the oxides of nitrogen (7,8).

(a) Symptoms

The principal symptoms of nitrogen dioxide poisoning are vertigo, headache, tightness in the chest, nausea and cough. In high concentration it may produce bronchitis, pulmonary oedema and death. It is one of the most insidious hazards in industry. When a workman happens to inhale some fumes, for a time he is little inconvenienced. He goes home and has his meal, still suffering from no ill effects. During the night, pulmonary oedema develops and he may be dead by next morning or noon.

(b) Prevention

The fumes should be controlled at the point of origin by efficient general ventilation and by local exhaust ventilation. Isolation of the offending operation is helpful where the process does not yield readily to the above measures of control. Respiratory protective devices such as chemical filter respirators are justified as a last resort when all other measures of control have proved ineffective. These masks need periodical examination and proper maintenance. The education of the worker in the use of the respirator is of utmost importance.

### Alkalies

The alkalies used in industry are chiefly ammonia, potassium and sodium hydrates. The industrial hazard from ammonia is invariably due to the accidental escape of the liquid or gas. It is very irritating to the upper respiratory passages and may give rise to pulmonary oedema. Burns may follow the splashing of ammonia and other alkalies, especially in the eyes. Prevention is achieved by taking precautions to obviate the escape of ammonia and the use of goggles or eye shields. If splashing occurs, frequent irrigation of eyes by a 4 per cent solution of ammonium chloride should be ensured to reduce the fixed alkalies. Penicillin drops or ointment should follow irrigation.

### Acids

The common acids used in industry are sulphuric, nitric and hydrochloric acids. When splashed into the eyes they cause severe burns of the cornea and conjunctiva. Prevention of splashing by protective devices, training of workers in work methods and personal protection are important precautions. Tubs full of water, 'plunge baths' should be kept in the sections which involve the risk of chemical burns so that the affected individual can immediately plunge into it for washing the chemical without vigorous rubbing. In cold weather, the bath water should be kept at 38°C (about the body temperature) during working hours. A number of undines containing 3 per cent boric acid solution should be placed in strategic places and workmen should be taught how to irrigate the eyes immediately. Splashing clean water into the eyes is also helpful. Arrangements should be made for the mechanical transport of carboys containing acids covered with baskets and handled as little as possible.

## Physical Hazards

Physical hazards arise from poor-working conditions such as: -

(a) Extremes of temperature especially in hot working environments may lead to causation of heat effects, which have been discussed in another chapter.

(b) High humidity contributing to thermal discomfort.

(c) High or low barometric pressure.

(d) Radiant energy producing harmful effects (see next chapter).

(e) Noise and vibrations.

(f) Poor ventilation and lighting.

(g) Overcrowding of men, machine and equipment, which are important agents for causing accidents.

(h) Improper seating arrangements producing postural defects in the workers.

(j) Lifting heavy loads or incorrect technique of carrying loads.

(k) Industrial accidents arise from various causes. They are tabulated in Table -2

The effects of each of these hazards can either be eliminated or reduced by a careful study of working

conditions and planned action. A close collaboration of the factory engineer and supervisory staff is essential to guard against such health hazards.

### Welding Hazards

Welding is employed to join metal parts while the edges are in a molten state. There are mainly two methods of welding, oxyacetylene welding and electric welding. Excessive exposure will produce ultraviolet conjunctivitis, 'Arc-Eye' or 'Welder's Eye' which causes swelling of the eyelids, photophobia, a feeling of 'sand in the eyes' and conjunctival injection. Infrared radiation can also cause 'heat cataract'. The unprotected skin around the neck and face may receive burns from the ore or from the molten metal. Carbon monoxide, nitrous and metal fumes are produced which can be prevented from toxic effects by use of respirator. Screening by coloured glass in the form of very dark goggles, hand shields, or shields fixed on the working benches or helmets prevent exposure of the eyes to injuries. Good work method training is essential.

## Health Hazard in Foundry work

Founding consists of pouring molten metal into a mould which is made to the outside shape of a pattern of the article required and contains, in some case a core which will determine the dimensions of any internal cavity.

The basic principles of foundry work have hardly changed over the years though a lot of modernization has come, making plants more mechanized and automatic.

Molten metal is introduced into the mould. After cooling occurs, the mould is subjected to a 'shakeout' procedure which releases the casting and removes the core. The casting is then cleaned and any extraneous metal is removed from it. The basic process is as follows:

(a) Moulding and pattern making:

Hardwoods, metals or resins are used by pattern makers in this forming process. The moulding mix usually contains silica, sand, coal dust, and organic binders such as dextrine and carbon oil. The casting of non- ferrous metals often utilises graphite or metal dies in the moulding operation.

(b) Coremaking:

The processing of traditional cores involves oven curing that produces a choking odour. Several new binding systems contain various synthetic resins such as phenol formaldehyde and various amines. The curing of these resins is achieved by chemical reaction or heating. Gases may be used as catalysts for reactions. The mixing of sodium silicate with sand, and the passing of carbon dioxide through the mixed core, is also utilised. Silica gel and sodium carbonate are formed through this process which forms a rigid core.

(c) Melting and pouring:

Electrically powered induction furnaces are used to process higher grades of cast iron and steel. Large amounts of carbon monoxide are generated during cupola operations. Roasting ovens are used, in addition to furnaces, for refining copper and zinc. The molten metal is poured from the furnace by tilting or tapping the furnace, and the metal is then passed to the moulds.

(d) Shakeout (knockout):

The removal of the cooled casting from the mould is termed 'shakeout'. The moulding sand is dry and friable at this stage, and particles of metal, sand and core material can become airborne during this process. If coal dust is incorporated into a sand mould, carbon monoxide will be generated during cooling and shakeout.

(e) Dressing and cleaning:

In this process, the castings are mechanically tumbled with metallic abrasives in an enclosed drum. Abrasive blasting techniques are still utilised. A variety of non-metallic (corn husks, pecan shells, etc) and metallic (steel grit or shot) abrasives are used. A great deal of dust is generated by this blasting. Pneumatic grinding and chipping tools may be used for cleaning castings. Hydraulic blasting or vibration processes may be employed to remove cores from the castings.

### Health Hazards

The various processes outlined in the preceding section give rise to heat, molten metal splashes, dusts, noise, gases and vapours in the foundry environment. If these hazards are not controlled or contained, serious health effects in exposed workers can result. Foundry work also involves various manual operations which carry a risk of physical injury. The hazards are:

(a) Silicosis

**Silica dust presents a prominent hazard of silicosis.** This dust is generated during mixing, moulding, shakeout and dressing operations, and during sand conditioning for re-use. The dust arises from quartz in the sand, and the concentration of free silica in the air varies with the handling process, the efficiency of dust control, the chemical composition of the sand and the physical state of the sand, that is, whether the sand is screened or unscreened, wet or dry. Used sand is either dumped or re-milled, with water and binder added before it is re-used. The amount of respirable dust is increased by such re-use. Sand is dry at the mixing or 'mulling' stage prior to mould making, and at the shakeout stage; this dry sand is potentially more hazardous than wet sand. Screened sand does not produce as much silica dust as unscreened sand, and pure quartz sand is more hazardous than olivine sand. Abrasive blasting processes may involve the use of sand containing high concentrations of free silica.

(b) Irritation, allergy, asthma, metal fume fever, malignancy:

In addition to dusts, the air in foundries may contain the potential irritants like formaldehyde, various amines and phenol. These contaminants are generated primarily by the coremaking and moulding processes, and may irritate the eyes and the respiratory tract. Some hardwoods used in pattern making can release products which may cause asthma in exposed workers. Vapours from various resins can initiate severe allergic reactions. Carbon monoxide gas is produced in substantial amounts by a variety of furnaces. Exposure to concentrations of 500 to 1000 ppm for approximately 30 minutes may precipitate headache, accelerated breathing, nausea, dizziness and mental

confusion. Thus a possible secondary effect of exposure is an increased risk of accident and injury to the worker. Various metal fumes may be generated during founding processes, especially during melting and pouring operations. Lead, magnesium, zinc, copper, aluminium, cadmium, antimony, tin and beryllium fumes are commonly present in non-ferrous foundries. Iron oxide is the major fume generated in iron and steel operations. 'Metal fume fever' may result from exposure to these contaminants. This is an acute illness of short duration which commences some hours after inhalation of the metallic fumes. The initial symptoms are flu- like: nausea, headache, dry throat and coughing, and muscular pains. Chills and sweating may occur later. Recovery is usual within 24 hours after removal from exposure. The lead hazard in furnace cleaning, dross disposal and the fettling of lead alloys deserves particular attention. Besides dusts & fumes in foundries are known to have carcinogenic properties.

(c) Occupational dermatitis:

Formaldehyde, isocyanates, various resin products associated with pattern making and coremaking processes can irritate the skin and may precipitate allergic skin reactions.

(d) Noise induced hearing loss and related effects:

Some fettling workers have been shown to be exposed to levels of noise over 100 dB; shakeout and knockout processes are typically associated with readings of 90 - 110 dB. Mechanical sand mixing processes and forced draught furnaces may produce noise levels of 90 - 100 dB. Extraction fans, diecasting machines, core-making and shell-making equipment may also be sources of excessive noise.

(e) Vibration:

Pneumatic grinding and chipping tools used in dressing the cooled castings may cause vibration induced health effects in operators. Hazardous vibration equipment may also be utilized in shakeout and core removal operations.

(f) Heat and heat stress:

Radiant heat is the major contributor to the heat load imposed on the worker by the environment. Convective heat transfer adds to this radiant heat. Protective clothing is worn for protection against the heat radiating from the heat sources and against contact with molten metal. Such clothing greatly restricts the potential for body heat loss via evaporation. The effects of heat range from decreased concentration to painful cramps, fainting, heat exhaustion and heatstroke. Heat stress can also aggravate the effects of exposure to other agents such as noise and carbon monoxide.

(g) Accidents:

Serious burns may result from splashes of molten metal in the melting and pouring areas of foundries. Frequent, unprotected viewing of white-hot metals in furnaces and pouring areas may cause eye cataracts. Eye injuries from molten metal or fragments of metal may occur in pouring and dressing areas. During continuous casting processes, non-ferrous molten metals, such as copper and aluminium, may explode violently if they contact water. Injuries related to the manual handling of materials, and injuries due to falls, may occur. Grinding wheels used for dressing small articles may result in hand injuries.

**Preventive Measures**

Monitoring & Evaluation of exposure

Monitoring of the work environment, Personal monitoring, Biological monitoring should be undertaken. In some cases, biological monitoring may be required to supplement static or personal monitoring. When developing a monitoring program in foundries, due consideration should be given to the hazards in the foundry. In the control of health hazards due to a specific contaminant, where it has been demonstrated that the exposure of the employee to the contaminant is approaching the relevant exposure standard, or where biological monitoring indicates that an unacceptable exposure is occurring, immediate action must be taken to reduce the health hazard and intensive monitoring should continue. Worker exposure to dusts, gases and vapours should be kept as low as workable. Exposures should be well below the exposure standards recommended in the Factories Act 1948.

Engineering control measures:

(a) Elimination/substitution and process modification viz quartz sand can be substituted by olivine sand in 'sand blasting' as it is less hazardous. Silica-based polishing pastes should not be used in metal cleaning operations

(b) Engineering controls like local exhaust ventilation should be provided at the mixing or mulling stage as the sand is dry. It is a means of controlling carbon monoxide emissions at their source. Total enclosure of abrasive and cleaning operations should be provided. Potentially irritant vapours or fumes generated in coremaking or moulding processes should be collected by exhaust ventilation at the point of emission.

(c) The reduction of noise at the source or in the transmission path should be achieved wherever workable

Preventing physical injuries:

(a) Mechanically propelled vehicles or machinery should be inspected regularly.

(b) Contact between molten metal and water must be avoided. All ladles and other equipment used for handling metal should be completely dry before contacting molten metal.

(c) Good housekeeping practices are to be followed.

(d) Floors around furnaces should be of slip-resistant, non-combustible material, kept free of obstructions and cleaned regularly.

(e) Persons should be prohibited from entering furnace areas when the temperature exceeds 50°C.

(f) Foundries should be equipped with safety blankets, automatic emergency showers or hoses to

extinguish burning clothing.

(g) Self-contained breathing apparatus must be used in emergencies when high carbon monoxide concentrations are suspected.

Minimising the risk of heat illness:

People who have any history of heat intolerance or a circulatory disorder, anyone recovering from a fever, and any dehydrated worker must be regarded as being in a high-risk category for heat illness. Unacclimatised persons must be given time to acclimatise to work in the heat. Planned job rotation can assist in reducing exposure to heat. Cool water should always be available in close proximity to hot working areas and encouragement given for the use of these facilities. The exposure of workers to radiant heat can be reduced by the strategic positioning of shields between workstations and heat sources. Clothing should be carefully selected so that a balance between protection and facilitation of heat loss through evaporation is achieved.

Personal protective equipment:

Personal protective equipment such as goggles, padded gloves, ear muffs must be used by the workers. If the mechanical ventilation in the foundry is not adequate in removing the dust at all points of contamination, the wearing of personal respiratory protective equipment, such as a face mask/respirator, is a complementary preventive measure together with local exhaust ventilation. If operators are required to work inside the enclosure, a continuous- flow, air- line respirator must be worn.

Education and training:

All employees working with foundry hazards must be informed of the hazards and the precautions necessary to prevent damage to their health. Employees exposed to contamination hazards should be educated in the need for, and proper use of, facilities, clothing and equipment and thereby maintain a high standard of personal cleanliness.

Health assessment:

Preplacement examination and periodic medical examination of all workers should be done annually for early identification of health effects and for documentation for compensation claims. (28)

## Noise

It has already been realised that noise is a great hazard to human health. The whole world is getting increasingly conscious of noise pollution. Excessive and unwanted noise is always disliked by people and more so, it adversely affects the safety & working efficiency of workers in industries. Noise is a discordant sound resulting from non-periodic vibrations of air.

### Sources

The common sources of noise are military operations, aviation, submarines, automobiles and factories like boiler factories, steel mills, textile plants, can factories, ship yards, aeroplane factories and various other workshops. Domestic exposure occurs due to TV, radio, record players, tape recorders, VCR,VCD and so on.

### Effects

The loudness of sound depends on intensity and frequency. Human ear perceives, sounds of 20 to 20000 cycles per second (Hz). Sensitivity of ear changes at different frequencies. Most sensitive frequencies are from 500 to 5000 Hz. Prolonged exposure to sound levels of 90 decibels (dBs) and above cause permanent deafness. Very high intensity sounds (160 dBs and above) may produce damage in a single exposure. Noise can produce auditory effects and non-auditory effects (16, 29).

(a) Auditory Effects

**(i) Masking Effects**

Excessive noise leads to masking effect, which makes it impossible to hear normal speech.

**(ii) Acute Severe Exposure**

Sound above 160 dBs may rupture the tympanic membrane and may cause bleeding through ear. This leads to temporary deafness, which recovers after the healing occurs. This deafness is in all frequencies and is present only in the affected ear.

**(iii)Auditory Fatigue**

Sound level exposures above 90 dBs and 4000 Hz over prolonged period led to an auditory fatigue which is associated with whistling and ringing in ears.

**(iv) Occupational Deafness**

This is the most serious effect of noise and can be temporary or permanent.

- Temporary Deafness(Temporary Threshold shift)

This occurs due to an exposure of noise at 4000 6000 Hz in initial period and it may recover if the worker is withdrawn from exposure for sufficient length of time.

- Permanent Deafness (Permanent Threshold shift)

This occurs due to prolonged exposure to sound levels of 90 dBs and above. The victim is usually unaware of the damage initially. The extent of damage depends on intensity, frequency, and duration of exposure and individual susceptibility to noise levels. Audiogram shows hearing loss at frequencies above 2000 Hz but there is a typical dip (c5 dip) at 4000 Hz. Hearing loss is gradual and progressive. Worker is unaware of his deafness until it is severe. First symptom is inability to converse in which many people take part followed by tinnitus, buzzing and ringing & whistling sounds in ears. This is bilateral, periodic and transitory. Vertigo and ear pain is rare. There is repetition of sounds heard at work place during night when away from work (acoustic after-images). Audiogram shows bilateral hearing loss with typical c 5 dip (30 32).

(b) Non-auditory Effects

Excessive noise reduces general efficiency and increases fatigue. Sudden noise increases BP and intracranial pressure. It leads to giddiness, nausea, insomnia, tachycardia and tachypnoea. Irritation, annoyance and neurosis may ensue (33, 34).

### Prevention

(a) Control at Source
   (i) Monitor sound levels in work environments for frequencies and intensities and take action to reduce sound levels.
   (ii) Segregation of noisy machines.
   (iii) Apply sound mufflers to machines.
   (iv) Enclose noisy processes.
   (v) Change their designs suitably.

(b) Control of Transmission
   (i) Improve architectural designs of noisy buildings.
   (ii) Sound proofing of walls, ceiling and floors.

(c) Protection of Workers
   (i) Use of ear defenders e.g. ear plugs and ear muffs
   (ii) Rapid turn over of workers.
   (iii) Preplacement and periodic medical examination.
   (iv) Health education of the management, staff and workers.
   (v) Legal protection of workers against noise induced deafness (35, 36).

## Occupational Cancer

It has the following sequences: -

(a) Exposure to carcinogenic agent or factor;
(b) Long latent period during which continuous or interrupted application of the carcinogenic agent continues;
(c) Manifestation of precancerous conditions;
(d) Appearance of a state of malignancy;
(e) Appearance of invasive and metastatic carcinoma.

### Carcinogenic Agents

These include many chemical groups, various physical factors and diverse groups of viruses. Each of these groups manifests particular features and basic characteristics. Many of these agents occur together in combinations and present the problem of assessing the relative value of each component. At present the following groups are mentioned: -

(a) Carcinogens acting by surface contact on the skin such as coal tar derivatives;
(b) Carcinogens acting via the respiratory tract such as the industrial fumes,asbestos.
(c) Carcinogens entering the body the mouth and acting on the gastrointestinal tract such as food additives, contaminants, pesticides etc.
(d) Carcinogens entering the body by various routes and acting systemically on the liver, haemopoietic and lymphatic systems, bladder etc. like aniline dyes, benzene, naphtha etc.
(e) Carcinogens causing tumor developments by hormonal imbalance either by assimilation of hormones or toxic agents which disturb the hormonal balance in the body.
(f) Various forms of radiation causing skin tumours,

Table 6 : Prevention Of Occupational Cancer

| Technical | | Personal | Medical | Legal |
|---|---|---|---|---|
| Engineering | Process control | Personal protective equipment | Preplacement Medical Examination | Notification |
| Building | Substitution | Barrier creams | Periodic examination | Cancer registry |
| General ventilation | Isolation of harmful process | Bathing & washing | Mass screening of vulnerable group | Acts and Rules |
| Local exhaust system | Maintenance of plant equipment | Limitation of exposure | Analysis of medical records | Forbidding use of harmful chemicals |
| Plant equipment design | Dust control | Personal health habits | Knowledge of plant processes & materials | Periodic checks by factory inspectors |
| Mechanization | Environmental | Avoidance of repeated trauma & tar burns | Health education | Licencing Certifying surgeons |
| Monitoring physical and chemical waste disposal | Good house keeping | Protection against ionizing radiations | Early diagnosis and treatment | Compensation |
| | | | Special cancer clinics | |

bone sarcoma, lung cancer, leukaemia etc.

(g) Viruses capable of inducing tumours;

(h) Carcinogens acting on connective tissues e.g. Plastics;

(j) Mixed

**Sites**

The most common sites of the body affected are skin, lungs, bladder and blood forming organs. The characteristics of occupational cancer are: -

(a) Appear after prolonged exposure;

(b) Period between exposure and affection may be 10 to 20 years;

(c) May develop even after cessation of exposure;

(d) Average age incidence is earlier than other cancers.

(e) Localisation of the tumours is remarkably constant in any one occupation.

**Prevention**

This involves the elimination or substitution of any carcinogenic factor including promulgation of legislation, protection of those exposed to risk by suitable engineering measures and education and training.

Owing to the complexities of industrial carcinogenesis, however, there are difficulties in the application of all these methods. It is unusual to accept evidence of carcinogenicity in animals alone as justifying legislative action, which requires a long connected evidence of carcinogenicity in man. When there is epidemiological evidence that an industrial substance is carcinogenic, combined with experimental proof of its carcinogenicity in animals, the manufacturers should be advised of its hazards and forced to stop its manufacture, eliminate or substitute the process or material with a safe one or institute measures necessary to prevent contact of the worker. The manufacture of b-napthylamine a proven bladder carcinogen was stopped in many countries through voluntary action by the dye manufacturers. Where a risk of such substances has been proved beyond doubt, the law places a basis of claiming compensation of the hands of the worker and gives a warning to the employer, and finally prohibits the use of such material, process, or manufacture of the product. The industrial materials, proved to be highly carcinogenic both in animal experimentation and epidemiological studies in man, include b-naphthylamine benzidine, 3-3-dichlorobenzidine, 4- aminobiphenyl (xenylamine), polycyclic hydrocarbons, dimethylnitrosamine, nitrosomethy-lurethane, b-propiolactone, diazomethane, trinitrotoluene, beryllium salts, oxides, mineral oil, pitch, tar, 3:4 benzpyrene, radioactive substances, nickel, arsenic and asbestos.

Besides elimination, substitution and engineering devices of safety, the principles which protect workers exposed to risk from industrial carcinogens are the segregation of processes, mechanical handling, enclosure of processes, exhaust removal, chemical monitoring, dust control, use of protective clothing, provision of washing facilities, medical surveillance and education of the worker. Workers require a clear exposition of the risks to which they are exposed and of the reasons why protective measures and codes of hygiene are so important, of how these measures are to be carried out, combined with a warning of the possible consequences if they do not adhere to; and with advice to report any health abnormality, however trivial, to the factory doctor. The various preventive measures have been shown schematically in table 6 (37-42).

## Protection of the Worker

The worker is the most important component of the industrial set up. It is imperative that the worker remains in an optimal state of physical, mental and social health. To achieve this, it is of prime importance to fit the worker's skill to the job and the job to his skill. Therefore, from the medical point of view, a judicious preplacement medical examination should be carried out taking into consideration the hazards which the factory life will impose on the individual. It should, however, be realised that every factory job does not require the highest physical standard of health. Even a disabled person could be accepted in certain jobs where the partial disability of the individual will not in any way interfere with the efficient performance of his duties in that particular job. In other words, a disabled person should be viewed not as to how much he cannot do, but how much he really and safely can do. In addition to assessing his disability his residual ability should also be assessed. For instance, a few totally blind ex-soldiers have been employed in an optical factory and it has been found that their output has been more than that of normal men. They work through the sense of touch which evidently they have developed in themselves to an extraordinary degree of proficiency and also perhaps the blindness in their case has actually helped greater concentration on work by excluding visual distraction. Having ensured basic fitness it would be important to watch, through periodic medical examinations, the progress of the worker under the impact of his occupational environment. After selection and placement it is the duty of the management to provide adequate safeguards to protect him from accidents, toxic and other occupational hazards, not only to fulfil the employer's obligations under the Factory Act, but also ensure maximum individual and collective protection. It is then necessary to train him in work-methods and self-protection against all possible occupational hazards. If in spite of all these precautions the person does become a victim, the management should offer the remedial measures, social security, alternative placement and rehabilitation.

**Occupational Psychology**

Occupational psychology enables the study of psychological fitness for employment and investigation into the causes of a psychological breakdown due to stress and strain in certain occupations. This includes the investigations into aptitude for different kinds of work and into the causes of industrial fatigue. This wider aspect

Table 7 : Personal Protective Equipments

| S.No | Hazards | Part of body protected | PPE Recommended | I.S.No |
|---|---|---|---|---|
| 1. | Chemicals | Chest/Abdomen | Apron Rubber Acid & Alkali Proof 30" wide x 40 long | IS-4501-1981 |
| 2. | Chemicals | Full body | Acid Protective suit with Coat, Pant, Hood, PVC welded | - |

| 13. | Handling hot components | Hand | Asbestos hand gloves 16" long with cotton lining | - |
| 14. | Welding | Hand | Leather Gauntlets for welders 16" long | IS-2573 Type-I |
| 15. | Handling | Hand | Rubber Gauntlets Acid & Alkali proof 16" x 18" long (without internal lining) | - |
| 16. | Working on Electrical lines | Hand | Rubber gloves for Electrical purpose working voltage 4000V | IS-4770 Type-IV |
| 17. | Dust | Respiratory | Permacal face mask "Swasthya" | - |
| 18. | Fumes/Mist | Respiratory | Chemical Cartridge respirators | IS-18522 |
| 19. | Noise | Ear | Foam Ear plugs | IS-9167-1979 |
| 20. | Noise | Ear | Rubber Ear plugs | -do- |
| 21. | Fall from height | - | Safety belt | IS-3521 Type-2 |
| 22. | Toxic gas | Respiratory | Canister gas mask | IS-8523-1977 |
| 23. | Chemical | Foot | Industrial vulcanised rubber knee high boots | BS-5145 of 1984 |
| 24. | Fall of heavy objects | | Foot | Leather safety |
| shoes for heavy metal Industry | | | IS-1989 of 1978 | |
| | | | | |

of industrial psychology includes vocational guidance, personal supervision, management and the quality and nature of human relationship in industry. There are many psychological factors involved in occupational morbidity, work may be dull, monotonous, repetitive or otherwise un- suited to persons of certain temperament or character.

## Personal protective equipment (PPE)

Personal protective equipment generally provided in factories for protection against various hazards is given in table 7. The provision of PPEs does not enable an individual to take liberties against the hazard, as it is not foolproof. Hence, emphasis should be directed at prevention of hazards by making the system foolproof. At the same time, individuals who have been provided PPEs should use the same although there may be some difficulty and discomfort initially. Gradually the wearer shall get accustomed to the same and discomfort will vanish.

### Clothing

They should fit well; there should be no loose flap or string, even shoelaces should be tied tight. Persons exposed to inflammable, explosive or toxic dusts should not wear clothing having pockets, cuffs and turn-ups that might collect such dusts. Loose, torn or ragged garments, neckties, mufflers or head dresses and key or watch chains should not be worn near moving parts of a machine. Shirts with short sleeves should be worn in preference to rolled up sleeves, and pockets, if any, should be few and as small as practicable in all clothing. When the operation involves a danger of explosion or fire, wearing of articles such as, collars, eye shades, cap visors and spectacle frames made of celluloid or other inflammable materials should be prohibited during working hours. Sharp or pointed objects and explosive substances or Inflammable liquids should not be carried in pockets. The material and shape of special protective overalls should vary with the substances involved e.g. liquid proof or gas proof against corrosive and irritant liquids / gases; asbestos suits complete with a helmet, gloves and boots against risks of excessive heat and fire; against radio-active substances washable material so designed as to cover other clothing at the neck and wrists. Washing of working clothing is necessary at least once a week as prevention against contamination of other clothing.

### Head Gear

Well fitting helmets made of aluminium; fibreglass or steel should be worn as a protection against falling or flying objects and blow on the head. For protection of hair from overhead moving belt, well fitting caps of washable and non-inflammable material should be used.

### Eye and Ear Protection

Workers with errors of refraction should have the error corrected. Glasses or transparent plastic materials for goggles and windows of protectors should be free from striae and air bubbles. All goggles intended for mechanical protection should be splinter proof. Goggles and shields for workers engaged in welding, furnace work or any other operation where their eyes are exposed to glare should have filter lenses or windows of standard absorption value against ultraviolet and heat rays. Non-flammable, transparent visors, free of scratches should be provided for protection against glare and sparks. Goggles, when not in use should be kept in special closed containers protecting them from mechanical damage and should be inspected at regular intervals once a month and all defective parts should be replaced immediately. Earmuffs and earplugs should be used for protection against noise. These reduce the sound level exposure by about 20 dB each.

### Hand and Arm Protection

Gloves for workers handling sharp edged or abrasive objects should be made of tough material and where necessary provided with special reinforcements of leather pieces or even a metal piece over the palm. Gloves should also be made of steel mesh for use in cutting process. Gloves and sleeves for workers handling hot metals could be made of asbestos or other heat-resisting material. Gloves with sleeves made of rubber capable of withstanding voltage of 10000 or more should be used for electrical workers. Gauntlets made of natural synthetic rubber or pliable plastic material should be used when handling corrosive liquids. Close fitting gloves should be used for avoiding exposure to toxic fumes and infectious agents.

### Barrier Cream

It prevents penetration of irritant substance into the skin. Ideally a barrier cream should be non-irritating, non-sensitising, insoluble in substance against which being used, easily removable and cosmetically agreeable.

### Foot and Leg Protection

Leggings for workers handling molten metals should be made of asbestos or other suitable heat resisting material, extending to the knee. At the lower end they should also cover eyelets of footwear. Metal toe guards or safety boots or shoes should be worn in operations where heavy objects are handled. Footwear for workers handling corrosive liquids should be of rubber, specially treated leather, wood or other suitable corrosion resisting material. Footwear for electrical workers should have non-conductive soles.

### Respirators

The cardinal principles governing the choice of a respirator are the process and conditions that create the exposure; the chemical, physical, toxic or other hazardous properties of the substance from which protection is required; the nature of the duties performed by the persons wearing the equipment and the encumbrance or restriction of movement in the working area; and the facilities for maintenance, upkeep and supervision of use. Finally, all respiratory protective equipment should be capable of fitting various types of facial contours without leaking. The following are a few types of respirators used in various industrial processes and environments. These should all be inspected and

tested at regular intervals by responsible trained persons.

(a) Mechanical Filter Respirator

A mechanical filter respirator can only filter the suspended atmospheric impurities. A wide variety of impressive patterns and designs are available. None afford protection against solvent vapours, injurious gases or in atmospheres deficient in oxygen, and are essentially dust and fume filters in an otherwise healthy atmosphere. The simplest example of such type of respirator is the common surgical gauze mask. By introducing a thin layer of wet cotton wool in between the layers of gauze, it may be worn as a protection against coarse particles, such as fibres or sawdust. Their efficiency against fine particulate, such as those of silica dust, will depend upon the quality of the filtering medium. In course of time, these, filters become clogged and there is increased resistance to breathing. The filters should then be washed or changed. Everybody should be supplied with a personal mask.

(b) Chemical Cartridge Respirators and Canister Mask

Chemical cartridge respirators and canister masks ensure the purification of air, which passes through the canisters containing specific neutralisers against specific toxic gases. The canisters have a particular coloured design painted on them indicating the specific toxic gases against which they afford protection; e.g. an orange coloured canister indicates that it is meant to be used against nitrous fumes. The user has to depend upon the oxygen content of the atmosphere, therefore, such respirators should not be worn in confined or poorly ventilated places or where the concentration of the offending gases is high. The canister should be changed after each use, and if not in use, at an interval not exceeding one year or such other period as specified by the manufacturer. These should be properly maintained and all defective parts replaced.

(c) Breathing apparatus (supplied-air-respirators or hose masks)

The term 'supplied-air-respirators' means a respirator equipped with a hose line, through which fresh air is supplied under positive pressure whereas through hose masks the wearer can inhale air at atmospheric pressure. The length of hose in the former should not exceed 45 metres and in the latter it should not be more than 75 m. For hose mask the inside diameter of the hose should not be less than 2.5 cm and the hose should be of a non-collapsible type. These are also used when the canister for cartridge respirator cannot be used due to high concentration of dangerous gases or fumes. The body harness should be comfortable and should allow free movement of the wearer and also all component parts should withstand a pull of at least 115 kg.

(d) An oxygen breathing apparatus

An oxygen breathing apparatus consists of a face piece with a corrugated tube connecting it to an oxygen tank or cylinder. This is used by workers engaged in fire fighting, rescue or repair work in atmospheres containing high concentrations of gases or which is deficient in oxygen or sufficient pure air supply.

(e) A self-generated oxygen mask

A self-generated oxygen mask is a new type of oxygen breathing apparatus fitted with a small canister containing a chemical. Moisture from the inhaled air starts a chemical reaction, which liberates oxygen.

## Industrial Accidents

The most important industrial hazard due to machinery is the accidental injury. Accidents in industrial environments are due to various causes. Bad house keeping, faulty and unguarded machinery, faulty work methods, carelessness, ignorance, physical and mental illness, accident-proneness, and slackness in the maintenance of machinery or in the formation of an accident prevention organisation, are the important factors. The components of machinery are the main causes of accidents. Though the loss of productive capacity due to accidental disabilities major and minor, and even deaths cannot be measured definitely, it is obviously of same magnitude, as judged by the man-days or working time lost. Practical preventive measures are therefore essential to safeguard the workers against accidents. The safety officer must investigate all accidents with a view to ascertaining the cause, adopt safety measures against recurrence and to train personnel in accident prevention. Most of the accidents are preventable by the close collaboration of the factory engineer, safety officer, welfare officer, chemist, industrial hygienist and the medical officer. The worker plays an important role in the prevention of accidents. Some particular industries, occupations and processes cause particular types of injuries on particular parts of the body. Therefore, he must be educated and trained in various processes and handling of different type of machines. Tables 9(A) & 9(B) shows the general causes and give a broad outline of preventive measures against them.

The first step in any accident prevention programme is elimination of various hazards whilst designing the process. If this is not possible, the next best step would be to control the physical, mechanical and chemical hazards in work environment by suitable engineering design. But when this also is not possible or is not able to give full protection to workers the third line of defence has to be resorted i.e., the personal protective equipments. These protective equipments cannot eliminate hazard or stop an accident taking place. These equipments merely set up a barrier against the hazards thereby preventing or minimising an injury.

In selection of these equipments, the following points are to be borne in mind: -

(a) Type of hazard to be faced.

(b) Selection of right type of personal protective equipment.

(c) Availability of correct equipment in good condition at the work spot.

(d) Training of workers to use the equipment.

(e) Convincing the workers that the equipment if used will protect them from hazard.

(f) Making it a habit with the worker to use the equipment.

(g) Degree of protection needed.

(h) Ease & comfort with which it can be used and freedom of movement with equipment which should not hamper performance of the worker.

(j) Maintenance of these equipment.

(k) Periodical check up

(l) Good earthing

### Safety Audit

(a) Objectives of Safety Audit: -

(i) Critically evaluate the safety programme.

(ii) Evaluate the systems to identify and control hazards.

(iii) Check that the above system meets the statutory standards and codes of practice.

(b) Benefits of Safety Audit System: -

(i) Strengthening of the Organisation safety standard and programme.

(ii) Improve the skill and performance of employee and managers.

(iii) Helps to create group and self awareness and provides motivation.

(iv) Identifies specific deficiencies in the safety programme.

(v) Provides timely information before any injury producing incident occurs.

(c) Corporate Safety Audit System

Safety audit shall be carried out at three levels in the Ordnance Factories.

(i) Level-I

Internal Audit Inspection by Safety Officers from within the factory once in every three months.

(ii) Level-II

Audit Inspection by a group comprising of 3 officers of the factories in the concerned group, once in a period of six months.

(iii) Level-III

Annual Audit Inspection by the Regional Controller of Safety/O.F. Board.

Table - 9 (A) : Prevention of Industrial Accidents

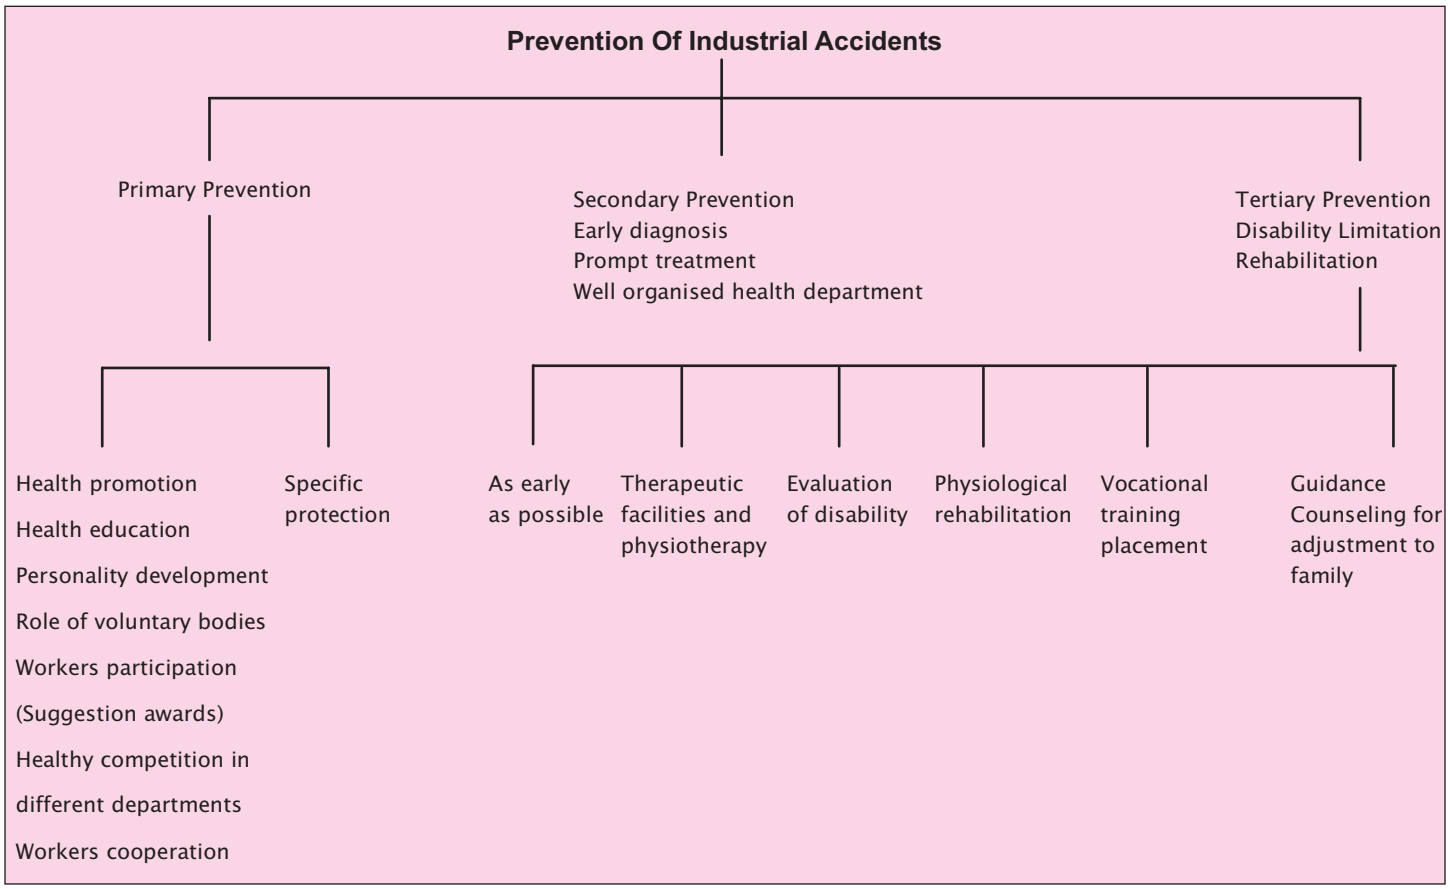

Table - 9 (B) : Prevention of Industrial Accidents

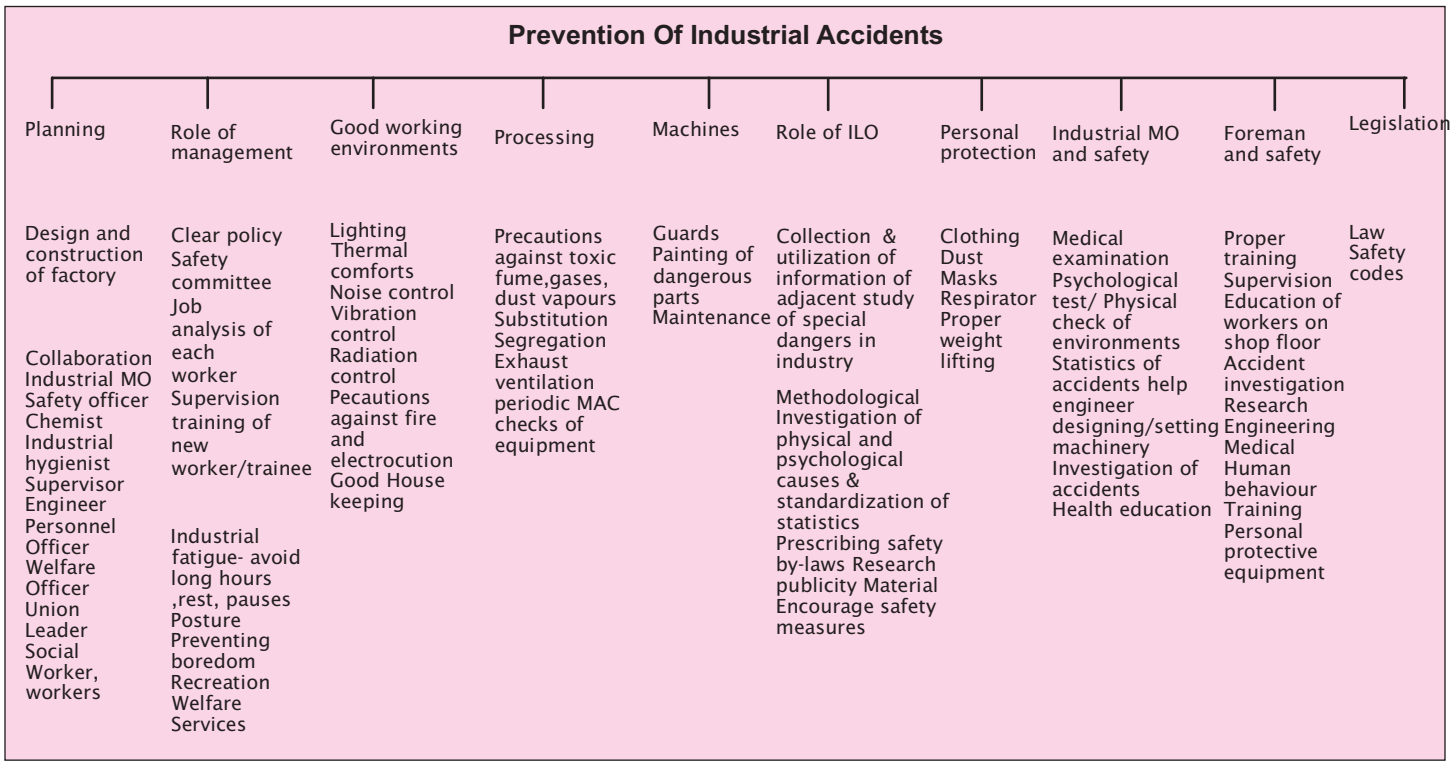


(d) Scope of Safety Audit: -

The Audit is necessarily very wide ranging in scope and covers all aspects of a company's operations. Some of the broad areas to be covered for Safety Audit are appended below: -

(i) Safety Policy - Involvement of Top Management, assignment of responsibility and accountability, workers participation through involvement.

(ii) Process Safety - Identification and control of hazards.

(iii) Fire Safety - Fire prevention and protection.

(iv) hazards and their control - Covering ventilation and exhaust system, work environment monitoring, personal protective equipment, emergency showers.

(v) Pollution control- Air, Water, Noise.

(vi) Review of Procedure - Operating, Maintenance, Start up & shut down, permits to workers etc.

(vii) Machine guarding.

(viii) Housekeeping.

(ix) Material Handling system.

(x) Safety.

(xi) Training of workers/Supervisory staff and Management personnel.

(xii) Accident reporting, investigation & Analysis.

(xiii) Emergency preparedness.

(xiv) Health, First Aid, Periodical Medical Examination.

### Accident Investigation

All accidents shall be investigated by the concerned Heads of Sections and an unambiguous report sent in Form No 14.Safety Section shall investigate selected accidents involving plants/ machineries/chemicals where accidents are due to unsafe conditions. In case of all serious accidents, a Board of Enquiry to investigate into the accident shall start investigation immediately on receipt of intimation by visiting the accident spot so that the evidence is not tampered. Photographs may be taken if necessary. The investigation should be towards fact finding and not fault finding. The concerned sections shall not disturb the site until it is cleared by the Board of Enquiry or Safety Officer.

### Accident Returns

The accident statistics indicating details of accidents, man-days lost, man-hours worked are compiled quarterly. A monthly report on the accidents taking place during the preceding month is also compiled.

### Accident Analysis

The accidents taking place in the factory shall be analysed by Safety Section, Department-wise and as per IS-3786-1983 as follows :-

(a) Unsafe mechanical or physical condition.

(b) Unsafe act

(c) Type of Accident.

(d) Agency of Injury.

(e) Nature of Injury.

(f) Location of Injury.

## Medical Examinations

### Preplacement Medical Examination

(a) All workers should undergo a medical examination before entering industrial employment for the first time (engagement or preplacement examination) or within I5 days of employment.

(b) Those under 14 years of age should not be employed except in technical schools, special training shops or apprenticeship courses.

(c) Section 34 of Factories Act states that: No woman or young person unaided by another person, lift, carry or move by hand or on the head, any material, article, tool or appliance exceeding the following limits :

Adult female -29. 5 kg.

Adolescent male -29. 5 kg.

Adolescent female -20 kg.

Male child -16 kg.

Female child -13. 5 kg.

(d) Medical services should collaborate closely with the technical services of industrial establishments to ensure as perfect a selection of workers as possible from the standpoint of physical, physiological and psychological suitability and also from that of the worker's skill.

(e) The pre-placement medical examination should consist of a general clinical examination and special investigation, where indicated. Diagnosis made on these medical examinations should be strictly confidential. Persons suffering from unsafe traits, such as, 'accident-proneness' should not be employed.

(f) Proper job analysis should be done for all the jobs and each person should be placed in such a way that he fits in the job and the job fits him.

### Periodical Medical Examination

(a) Periodical medical examination should be carried out at regular intervals (monthly, quarterly, yearly) depending upon the hazard to which a worker is exposed.

(b) In addition medical examination of workers should be carried out on their returning from sick leave and those seeking change of employment.

(c) The clinical examination should be supplemented by special investigations where indicated.

(d) Date and results of such examination should be recorded in special registers maintained for this purpose.

**Medical Records**

Meticulous attention should be paid to the maintenance of all statistical records/documents. These should be carefully studied and analysed for correct evaluation. These records will help in planning, development and efficient operation of the occupational health service. Graphs should represent ratios per 1000 and not actual figures. The latter are fallacious and of no comparative

| | |
|---|---|
| Average days lost per worker | $\frac{\text{Total Number of days lost in a period}}{\text{Total Number of effective full time employees (EFT)}}$ |

value. Amongst other documents/ records, and 'Absentee register' is of special importance and gives an indication for taking appropriate measures for the improvement of industrial safety and hygiene in the factories.

**(a) Analysis of sickness or morbidity**

Total sickness absence expressed as the average number of days lost per worker employed during the period and is calculated as: -

NOTE : With a view to obtain more accuracy with regard to low figures of small factories, cases of 'sickness absence' may be divided into 'long term' and 'short term' absence (over or under 7 days respectively).

(b) Analysis of Accidents

The higher risk of accidents is greater in certain occupations than in others. In order to compare the frequency and the severity of accidents in a given period, the International Labour office has standardised the following ratios for each million man-hours worked: -

(i) Frequency rate : $\frac{E \times 1{,}000{,}000}{C}$

(ii) Severity rate : $\frac{F \times 1{,}000{,}000}{C}$

NOTE : E = Number of accidents causing loss of working time in the given period.

C = Total man-hours worked in the given period.

F = Total hours loss through accidents occurring in the given period.

## Air Pollution

In recent years, air pollution by smoke and noxious gases, dusts and fumes has become an important public health problem. Turbulence in the air usually ensures that the pollutants put into it are rapidly removed. This process, however, may not be adequate to deal with the exorbitant amount of pollutants. Moreover, due to temperature inversion in still weather, cold air near the ground comes to underlie the warm air, and the pollutants accumulate near the earth's surface. The most important air pollutant is smoke resulting from incomplete combustion of solid, liquid and gaseous fuels. Use of fuel is associated with all aspects of our life but industrial uses are the most important sources of smoke in the atmosphere. Besides industry, the shipyards, rail and road transport, thermal power stations and household activities also pollute the atmosphere with smoke. Smoke is often mixed with dense fog, which has come to be termed as 'smog'.

Most coals, cokes and heavier oils contain sulphur compounds, which on burning emit sulphur dioxide. Combustion of gasoline yields carbon monoxide and the irritating hydrocarbon known as olefin. Other volatile organic compounds present in polluted air in big cities are cresol, phenol, toluene, xylene, 3:4 benzpyrene, aldehydes, soot and tar compounds. Industrial contaminants specific to some industries are, sulphur dioxide from smelting operations, chemical plants and oil refineries; sulphuric acid mist from acid producing plants; fluoride compounds emitted by aluminium plants, phosphate from fertilizer plants and refinery processes; radio-active wastes from atomic reactors; suspended matter from pulp and paper mills, steel plants and tanneries, and so on. Dust is a special hazard from industries like Portland cement manufacturing (43 46).

**Ill Effects on Health**

Air polluted with sulphur dioxide and sulphuric acid can produce acute respiratory irritation and distress. This may prove to be a final burden for the persons suffering from respiratory or/and cardiac disease and allergic disorders of the respiratory tracts, the aged, and for premature infants. The other ill effect attributed to air pollution is the increased incidence of lung cancer. Unpleasant odours of polluted air may cause perpetual anorexia and gastric troubles. Interference with visibility may be a contributory factor towards increasing the frequency of road accidents. Eye troubles also increase in a smoky atmosphere. In any case it is very depressing to work and move in smoky and smogy environments. Silicosis and pneumoconiosis occur due to pollution with dusts.

## Trade Effluents

Indiscriminate discharge of untreated liquid wastes into a stream makes the water unpotable, destroys fish and renders it unfit for bathing and recreation purposes. Livestock and dairy cattle may get poisoned by drinking water contaminated with industrial wastes like insecticides and mineral oil etc., or give an unpleasant flavour to milk. Anthrax is known to be transmitted by using water polluted with slaughterhouse or tanneries wastes. Wastewater from chemical and ammunition factories contain untreated compounds like arsenic, cyanides etc., which are toxic to plant, animal and human life. Untreated trade effluents discharged into a sewer make the final disposal of sewage unsatisfactory. Trade effluents from gas works give an offensive taste and smell to water. The indiscriminate discharge of wastewater on land may cause water logging, infertility of soil and even destruction of standing crops.

**Control Measures**

(a) Effective legal provisions for control of water and

soil pollution by proper disposal of trade effluents should be provided. A technical organisation to assess nature and magnitude of water pollution is required. Water (prevention and control of pollution) Act, 1974 & Environmental Protection Act 1986 refers.

(b) Similarly, legislative procedures for the control of smoke nuisance coupled with regular monitoring of air pollutants, and rigid enforcement of these provisions are the chief measures for controlling smoke pollution of the atmosphere. Standards for the sulphur content of coal and smoke in the air must be laid down. Air pollution control Act 1981& Environmental Protection Act 1986 refers.

(c) A technical organisation to monitor the water, soil and air pollution, and advice on methods of treatment and to determine suitable standards for disposal should be established.

(d) Administrative machinery to enforce legal provisions with representatives from the state health department, factory inspectorate and public health engineering should ensure that these essential requirements are fulfilled.

(e) The proper siting of residential and industrial areas by sound town planning is important to reduce the hazards from air pollution.

(f) Smoke nuisance from railway locomotives, ships and also the industry can be eliminated by a change over to diesel fuel or electric power.

(g) The active cooperation of industrialists who must recognise their responsibility in this matter plays a vital role in control of air pollution and disposal of effluents.

(h) The education of legislators, industrialist and workmen is important to make them appreciate the problem and their respective role in minimising the hazards.

## Social security and welfare of industrial worker

### The Factories Act 1948

#### Introduction

Society has an obligation to protect the health of the workers engaged in diverse occupations. Factory laws have thus been framed in every country to govern the conditions in industry and to safeguard the health and welfare of the workers. The factories Act was enacted by the parliament of India in 1948, and since then it has been revised and amended from time to time (47), the latest being the Factories (Amendment) Act, 1987. The amendment in 1987 was elaborate following the Bhopal Gas Tragedy. Prior to 1987, the owner of the Factory could wash his hands off the responsibility for Safety and Health aspects by entrusting the day to day affairs to a managing agent. However, after the Bhopal Gas Tragedy the Government realised how hollow the definition of "occupier" under the Factories Act was. Accordingly, the Factories (Amendment) Act was passed in 1987 to amend the definition of "occupier". This landmark amendment in the Factories Act, 1948 in effect means that the affair of the Company cannot be entrusted to a managing agent, and the owners or directors of the factories will be deemed to be the 'occupier' of the factory. This makes the factory owners directly responsible for ensuring Safe and Healthy working conditions in their factory.

#### Scope of the Act

The Act defines "factory" as an establishment employing 10 or more workers where power is used, and 20 or more workers where power is not used. The term "Worker" includes within its meaning contract labour employed in the manufacturing process. The Act applies to the whole of India except the State of Jammu and Kashmir. Under the provisions of the Act, the State Governments are authorised to appoint besides the Chief Inspector of Factories as many Additional Chief Inspector of Factories, Joint Chief Inspectors, Deputy Chief Inspectors and Inspectors as they think fit to enforce the provisions of the law. The system of enforcement of Factories Act, 1948 is established on two tier basis. At the Central level, the Director General Factory Advisory Services & Labour Institutes (DGFASLI) has an advisory role. It coordinates the activities of the Factory Inspectorates and provides training and advisory services to the Inspectors. In addition it also assists the Ministry in drafting amendments to the Act and the Model Rules. The latter are recommended to the State Governments for adoption with necessary modifications to suit local conditions. The Factory Inspectorates under the State Governments and Union Territories carry out the enforcement functions (48).

#### General Duties of Employer

The Act specifically directs the employer to ensure the Health, Safety and Welfare of all workers while they are at work in the factory. His duties include ensuring:

(a) Proper maintenance of plant and systems of work in the factory

(b) Ensuring safety in connection with the use, handling, storage and transport of articles and substances

(c) Provision of information, instruction, training and supervision necessary to ensure the health and safety of all workers at work

(d) Provision and maintenance of risk free and safe means of access, and egress from, all places in the factory

(e) Provision, maintenance and monitoring of working environment in the factory so that the same is risk free and safe

In addition, the Act casts a duty on the manufacturers who design articles and substances for use in factories to ensure the following:

(a) Ensure that the article is so designed and constructed as to be safe and without risks to the health of the workers

(b) Carry out such tests and examination and provide information necessary for effective

implementation of Safety and Health provisions

**The Inspecting Staff**

The State Government is empowered to appoint Inspectors/ Additional Chief Inspector of Factories and as many officers, it thinks fit to ensure that provisions of the Act are complied with (49). These Inspectors are empowered to:

Enter any factory or any place which he believes is being used as a factory, make examination of the premises, plant, machinery, article or substance, inquire into any accident or dangerous occurrence, inspect registers or any other document relating to the factory, seize, any register, or other document, in respect of any offence under this Act, direct the occupier to leave undisturbed any part of the factory for the purpose of an enquiry into violation of the Factories Act, take measurements and photographs necessary for inquiry into violations of the Factories Act.

**Certifying Surgeons**

The State Government is empowered to appoint qualified medical practitioners to be certifying surgeons for the purposes of the Factories Act. The duties of the Certifying Surgeon are:

(a) The examination and certification of young persons under this Act,

(b) The examination of persons engaged in dangerous occupations or processes,

(c) The exercising of medical supervision for any factory where-

  (i) Cases of illness have occurred due to the nature of the manufacturing process carried on, or other conditions of work prevailing therein

  (ii) By reason of any change in the manufacturing process carried on (or in the substances used therein), there is likelihood of injury to the health of workers employed

  (iii) Young persons are employed in any work which is likely to cause injury to their health

**Health and Safety**

Elaborate provisions have been made in the Act under Chapter III, IV and IV A with regard to health and safety of workers. These chapters deal with laws pertaining to such matters as cleanliness, lighting, ventilation, treatment of workers, effluents and their disposal, elimination of dusts and fumes in the workplace, provision of spittoons, control of temperature, supply of cool drinking water and for the employment of cleaner to keep the water closets clean. A minimum of 350 cu feet of space for each worker for factories installed before 1948 and 500 cu feet for factories installed after 1948 has been prescribed by the govt not taking into account space more than 14 feet above ground level. The Act also prescribes in detail provisions relating to the safety of workers. Section 40B provides for the appointment of "Safety Officers" in every factory wherein 1000 or more workers are ordinarily employed. The State Government is empowered to prescribe maximum weights, which may be lifted or carried by men, women and children. Some of the other safety provisions relate to caring of machinery, devices for cutting off power, hoists and lifts, protections of eyes and precautions against dangerous fumes, explosive and inflammable materials.

**Welfare**

Chapter V of the Act relates to welfare measures for the worker. The Act specifies that wherein more than 250 workers are ordinarily employed, a canteen shall be provided. In every factory, wherein 30 or more women workers are ordinarily employed, a creche should be provided. Provisions have been made under the Act to ensure adequate washing facilities, facilities for storing and drying clothes, sitting, first aid appliances, shelters, rest rooms and lunchrooms. There should be a welfare officer for every factory employing more than 500 workers.

**Employment in Hazardous Processes**

Chapter IV A, incorporated by the Factories (Amendment) Act, 1987 relates to hazardous processes. A Site Appraisal Committee consisting of Chief Inspector and other members, not more than 14 in number, is to be constituted to submit recommendations on the siting of factories using hazardous processes. Provisions have been made for workers, participation in safety management in industries involving hazardous processes.

**Hours of Work**

The Act has prescribed a maximum of 56 hrs of work (60 hrs including overtime) per week with maximum spread over of work upto 12 hrs per day (including rest interval of 1/2 hr after every 5 hrs of work). For adolescents, the maximum hours of work per day have been restricted to 4 1/2 hours.

**Employment of Young Persons and Women**

The Act prohibits employment of children below 14 years of age. Persons between the ages of 15 and 18 years are to be duly certified as adolescents by "Certifying Surgeons" and also deemed thus fit to work. Adolescent employees and women are restricted from employment in certain dangerous occupations and hazardous processes and are allowed to work between 6 A.M. and 7 P.M.

**Leave with Wages**

The Act lays down that besides weekly holidays, every worker will be entitled to leave with wages after 12 months of continuous work at the rate of one day for every 20 days of work for adults and one day for every 15 days of work for adolescents.

**Notifiable Occupational Diseases**

The Act gives a schedule of Notifiable diseases (see 3rd schedule of the Act). It is obligatory on the part of the factory management to give information regarding specified accidents, which cause death or serious bodily

**Social security schemes in India**

- Central Government Health Scheme (CGHS)
- Central Maternity Benefit Act 1961
- Workmen's Compensation Act 1923
- Employees State Insurance Act 1948
- The Family Pension Scheme 1971
- Employees Provident Fund Organisation
- Various Insurance Schemes of LIC, private insurers
- Armed Forces Personnel Provident Fund (AFPP Fund)
- Defence Services Officers Provident Fund (DSOP Fund)

injury and regarding occupational disease. Provisions have also been made for safety and occupational health surveys in the factories.

### Social Security Schemes

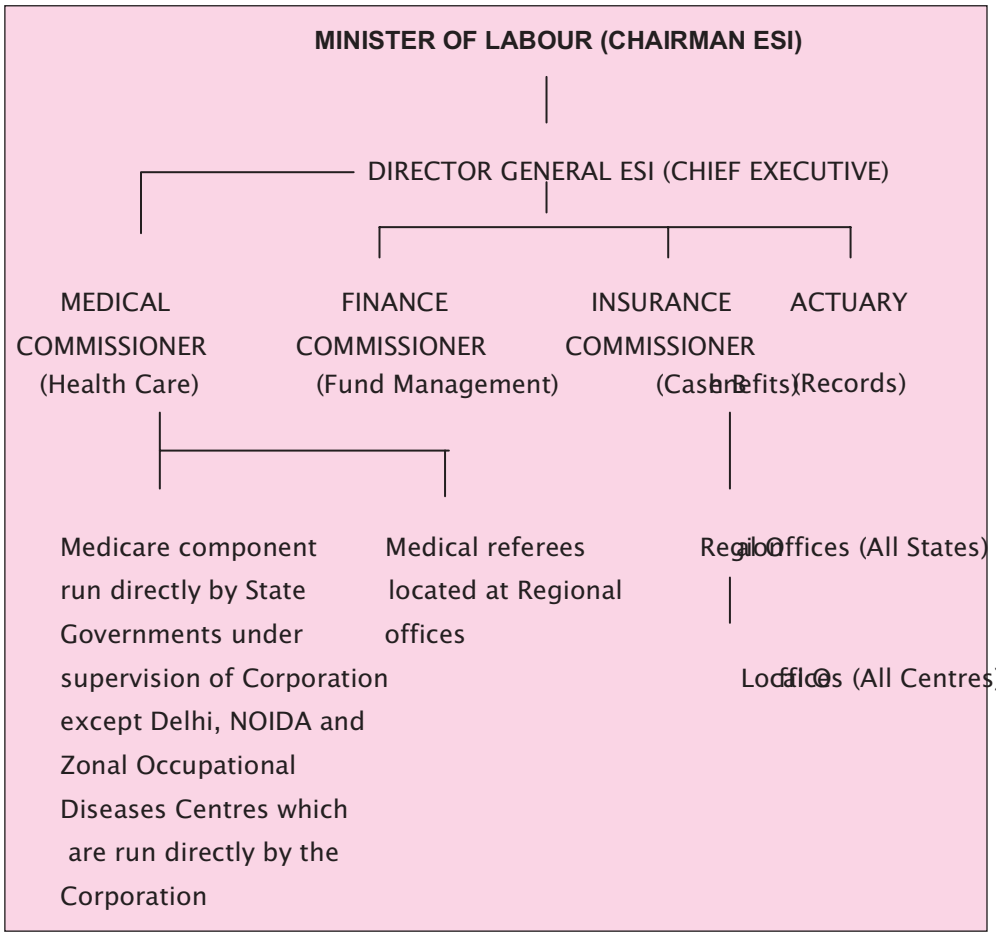
Social Security is a wide term and it is difficult to have a standard uniform definition of the term. The International Labour Organization (ILO) defines it as "the security that society furnishes through appropriate organization against certain risks to which its members are exposed". It is Social because it represents a collective effort by society. The security is provided in an organized form and therefore is not haphazard. However this definition does not identify the risks against which social security protects an individual. Beveridge has tried to identify some of the risks against which this security provides protection. He states "Social Security is an attack on five giants - Want, Disease, Ignorance, Squalor and Idleness". Friedlander defines it as "a programme provided by society against those contingencies of modern life, like sickness, unemployment, old age, dependency, industrial accidents and invalidism against which the individual cannot be expected to protect himself and his family by his own ability or foresight". The Social Security legislation is a part of Social Welfare legislation, which emerged and was evolved during the world wide depression of 1929 when laissez faire did not work well. Due to the late industrialization of the country such legislation also came into being very late in India.

### The Employees State Insurance Act 1948

The ESI Scheme is hailed as the largest Social Security Scheme of its kind in Asia. The ESI Act 1948 was enacted to "provide for certain benefits to employees in case of sickness and employment injury and to make provision for certain other matters in relation thereto". It has undergone amendments several times. The ESI Act, at present, applies in the first instance to non- seasonal factories using power in the manufacturing process and employing 10 or more persons and non power using factories employing 20 or more persons for wages. A factory or an establishment to which this Act applies shall continue to be governed by this Act notwithstanding that the number of persons employed therein at any time falls below the limit specified by or under this Act or the manufacturing process therein ceases to be carried on with the aid of power.

The Act contains an enabling provision under which the "appropriate government" is empowered to extend the provisions of the Act to other classes of establishments. Under these provisions most of the State Governments have extended provisions of the Act to the following classes of establishments: (50)

Table 10 : National setup of The ESI Corporation



(a) Shops, hotels, restaurants, cinemas including preview theatres, road motor transport agencies, newspaper establishments, employing 20 or more persons;

(b) Beedi manufacturing establishments employing 10 or more persons in the implemented area;

(c) State pencil manufacturing establishments employing one or more persons.

All factories or establishments to which the Act applies are required to register themselves in the Local Office of the ESI Corporation. The Act empowers the Central Government, the State Government and the Corporation to frame rules for the running of the Scheme. For carrying out its functions a statutory body called the ESI Corporation has been set up with the Minister of Labour as its Chairman. It has representatives of the Central and State Governments, employers, employees, medical professionals and members of Parliament. The Chief Executive of the Corporation is the Director General ESI who is assisted by an Insurance Commissioner, a Medical Commissioner, a Finance Commissioner and an Actuary. The DGESI and the Finance Commissioner are appointed by the Central Government. The other executives get promoted through ESI departmental channels. The Corporation has one Regional office each, in all the States who have Local offices under them in all areas covered by the Act (Table 10). There is a Medical Benefit Council, which decides medical care policies, headed by the DGHS who is assisted by the Medical Commissioner.

The other members of the Medical Benefit Council include Dy DGHS, State ESI medical heads, and representatives of employers, employees and medical professionals. The latter are nominated by the Indian Medical Association. The duties of Medical Benefit Council are:

(a) Advise the Corporation and the Standing Committee on matters relating to the administration of medical benefit, the certification for purposes of the grant of benefits and other connected matters;

(b) Have such powers and duties of investigation as may be prescribed in relation to complaints against medical practitioners in connection with medical treatment and attendance; and

(c) Perform such other duties in connection with medical treatment and attendance as may be specified in the regulations.

The Medical Care component called the Kingpin of the scheme is to provide full preventive, curative and occupational health services to its beneficiaries (51,52,53). Through it the Scheme provides:

(a) Out-patient treatment

(b) Domiciliary treatment

(c) Specialist Consultation

(d) In-patient treatment

(e) Free supply of drugs, dressings, artificial limbs, aids and appliances

(f) X-ray and laboratory investigations

(g) Vaccination and preventive inoculations

(h) Antenatal care, confinement and postnatal care

(j) Ambulance service or conveyance charges for going to hospitals, diagnostic Centres, etc. where admissible

(k) Family welfare services and other national health programme services

(l) Medical certification

(m) Special provisions including super-specialist services

(n) Early detection and diagnosis of occupational diseases (50)

Initially the medical care was provided only to workers in active employment. It has subsequently been extended to families of workers. In 1989, the Act was amended to include provision of medical care to an IP who ceases to be in insurable employment on account of permanent disablement, subject to payment of contribution, till the date on which he would have been superannuated had he not sustained such permanent disablement. It also brought under the 'medical care umbrella' retired workers and their spouses subject to payment of nominal contribution of Rs 10 only by a subsequent amendment. This Scheme is run by the State Governments under the guidance of the Corporation except in Delhi and NOIDA where it is run directly by the Corporation (50). The State Government bears 1/8th of the cost of medical care and the balance is met by the Corporation. For budgetary calculations the ceiling for the total cost on medical care benefit has been fixed at Rs 500 per IP annually. These benefits are provided free of cost including hospitalization in case of sickness, employment injury and maternity related causes. Medical Care is provided either directly through the exclusive ESI Hospitals and Dispensaries or indirectly through a panel of private medical practitioners (Panel System). All industrial Centres having large concentration of Insured Persons have the direct pattern of medical care, and the indirect pattern is restricted to areas having less concentration of Insured Persons where providing exclusive ESI services is not considered cost effective. It has its own referral chain and patients requiring super specialty treatment can be referred to the Zonal level ESI hospitals cum occupational Centres. In addition patients can be sent to specialised non ESI hospitals also at the expense of the ESI Corporation.

Besides, the ESI Scheme provides the following major benefits (50):

Sickness Benefit

This consists of periodical cash payment to an insured person if his sickness is duly certified by an ESI / Insurance Medical Practitioner. The benefit is payable for a variable period of time depending on the type of illness and

subject to the individual remaining under medical treatment provided under the Act. The insured person is protected from dismissal or discharge from service by the employer during the period of sickness.

### Maternity Benefit

The benefit is payable in cash to an insured Woman for confinement/ miscarriage or sickness arising out of pregnancy/confinement or premature birth of child or miscarriage. For confinement the duration of benefit is 12 weeks, for miscarriage 6 weeks and for sickness arising out of confinement 30 days. The Benefit is allowed at about full wages.

### Disablement Benefit

The Act provides for periodic cash payment, besides free medical treatment, in the event of a temporary or permanent disablement as a result of employment injury as well as occupational diseases.

### Dependent benefit

In case of death, as a result of employment injury, the dependents of an insured person are eligible for periodical payments.

### Funeral benefit

Funeral expenses are in the nature of lump sum payment upto a maximum of Rs 1500 made to defray the expenditure on the funeral of a deceased insured person. This payment is to be made to the eldest surviving member of the family of the deceased.

### Unemployment Allowance

This benefit has been introduced from 01 Apr 2005 & provides for an unemployment allowance to an individual for a maximum period of 6 months on account of closure of a factory or establishment, retrenchment or permanent invalidity arising out of non employment injury, after being in insurable employment for five or more years.

## General Prevention and Control Measures

The fields of preventive medicine and public health share the goals of promoting general health, preventing specific diseases, and applying the concepts and techniques of epidemiology to attain these goals. Preventive medicine seeks to enhance the lives of individuals by helping them improve their own health, whereas public health attempts to promote health in populations through the application of organized community efforts.

### Classification of Diseases

Diseases can broadly be classified as communicable and non-communicable as under :

(a) Communicable Diseases

These are illnesses caused due to invasion by specific microorganisms or their toxic products. The transmission of the agent or its products occurs from a source reservoir by direct or indirect means.

(b) Non-communicable Diseases

These are diseases, which are not caused by specific microorganisms and are not spread from one person to the other. These diseases may be metabolic, degenerative, neoplastic, mental, allergic, constitutional or accidental.

### Principles of Prevention and Control

The practical application and aim of epidemiological investigation and intelligence are to prevent and control the entry and spread of diseases in communities. The amenability of a disease to prevention and control depends upon the knowledge of its aetiology, epidemiology, mode of contraction, route and mode of transmission of the aetiological agent, the natural history or course of the disease and the incubation period. The better the knowledge of these factors, the greater is the amenability of the disease to prevention and control. The principles of prevention and control are applicable to non-communicable diseases as well as communicable diseases. However, a better knowledge of the specific aetiological agent and epidemiology makes it easier to apply the principles of prevention and control to most communicable diseases. The ever increasing knowledge of the aetiological and epidemiological factors involved in the causation of non communicable diseases has now made the control and prevention of many non communicable diseases possible as well.

### Natural History of Disease

The disease process is a dynamic one and is initiated by a disturbance of the balance between man and environment. The term 'natural history of disease' is applied to its course in man. Disease as seen in the hospital is but an episode in the natural history. The natural history of disease can be seen as having three stages: the pre disease stage, the latent (asymptomatic) disease stage, and the symptomatic disease stage. Another classification of the natural history is the pre pathogenesis phase (pre disease phase), the pathogenesis phase (the latent and symptomatic disease stage) and the post pathogenesis phase. In the pre disease stage the individual possess various factors that promote or resist disease, these include genetic make up, demographic characteristics (especially age), environmental exposures, nutritional history, social environment, immunologic capability and behavioral patterns. Over time, these and other factors may cause a disease process to begin. Thus potentially man is always in the midst of disease but only when the agent, host and environmental factors, the three components of the epidemiological triad, interact that the disease process is initiated. The pathogenic period begins with the entry of disease agent in the human host as a result of the disease provoking stimuli. If the disease producing process is underway but no symptoms of disease are apparent, the disease is said to be in the latent stage. This stage represents a window of opportunity during which detection followed by treatment provides a better chance of cure or at least of effective treatment. Once the agent becomes established and multiplies, there are tissues or physiologic changes in the host and the disease process is advanced enough to produce clinical manifestations, it is said to be in the symptomatic stage. The end result of the disease process may be complete recovery, chronicity, disability or death. (1 – 3).

### Levels of Prevention and Control

The modern concept of health as 'the state of complete physical, mental and social well being and not merely the absence of disease or infirmity' warrants the application of preventive and control measures in the three phases in the natural history of disease discussed above. Prevention of disease means barring or preventing its initial entry into man or a community while 'control' means arresting the further progress and propagation after its entry in an individual host or a community at large. Prevention entails anticipatory action to remove the possibility that a disease will ever occur. Control entails action to prevent invasion of the non-affected but exposed individuals in the affected community. As far as the non-communicable diseases are concerned, some are amenable to simple means of protection e. g. ill effects of cold and heat, while others require more intricate and elaborate preventive and control measures. The natural history and epidemiology of the non-communicable diseases such as cancer, cardiovascular diseases, accidental injuries and occupational diseases, have to be studied in detail to detect vulnerable points or links where preventive or control measures can be applied (1 - 3).

The objective in the pre-pathogenic phase is to achieve primary prevention, firstly through health promotion by socio-economic improvement and providing healthful housing, adequate nutrition, clothing, healthy living & working environments, and secondly by giving specific protection through immunization, environmental sanitation, use of specific nutrients, protection against occupational hazards, accidents, protection from carcinogens or allergens and so on.

In the pathogenic phase, secondary prevention aims at early case detection & treatment as well as uncovering the vulnerable community in the submerged part of the iceberg. It limits dissemination of infection and prevents occurrence of secondary cases in the community by reducing the infectious pool. The methods employed in early case detection are

(a) Case finding measures-individual or mass or by contact tracing.
(b) Screening surveys.
(c) Surveillance techniques and
(d) Selective examination of high risk groups.

In the post-pathogenic phase, disability limitation helps early rehabilitation of the patients. The objective is to halt the further progress of the disease process by instituting adequate therapy to limit the disability, prevent further complications through physiotherapy and other techniques of physical medicine. A rapid rehabilitation prevents the recovered individual from lapsing back into ill health, both physical and mental and protects the community from social disruption and diseases. Rehabilitation aims at restoring and retraining a patient to live and work within the limits of his disability but to the maximum of his residual capacity. This is termed as the tertiary prevention.

The various levels and stages of prevention in relation to the periods in the natural history of disease are shown in Table - 1.

Communicable diseases can be classified according to the aetiological agent or as per the route and mode of transmission. Usually both methods are employed. However, as they have a definite chain of transmission from the reservoir or source through a route upto the susceptible host or recipient, it is more convenient from the point of view of prevention and control, to classify them according to their mode of transmission. The latter, which also indicates the portal of entry & venue of exit of the infecting organism is as follows :

(a) Contact transmission - direct and indirect.
(b) Vehicle transmission - water, food, milk etc.
(c) Vector transmission - by arthropods.
(d) Air-borne transmission - droplet, droplet nuclei andinfected dust.
(e) Animal-borne transmission - zoonoses
(f) Trans placental transmission

**Control Measures**

These aim at exterminating the causative agent in its reservoir at the source of its production, its destruction soon after exit and before it starts its spread by interrupting its path of transmission. Action at these levels requires knowledge of the multifarious factors concerned with the inanimate or animate reservoir or source, various links in the chain of transmission and different approaches to the recipient susceptible host.

The practical measure of control broadly fall under three main heads. One or all of these measures may be applied according to the circumstances of the case (1, 4 - 6)

(a) Control of Reservoir and Source of Infection

The first link in the chain of causation is the existence of infected persons, cases (clinical or subclinical) or carriers, who constitute the primary source of infection. The general measures of control of the reservoir of infection are :

(i) Early detection of cases.
(ii) Notification
(iii) Isolation
(iv) Treatment.
(v) Quarantine.
(vi) Surveillance.
(vii) Disinfection.

(b) Block the channels of Transmission

This may be achieved by general environmental control, specific control measures such as safe water supply, sanitary disposal of sewage & other waste products, high standard of food hygiene, vector control, personal hygiene, proper ventilation, prevention of overcrowding and dust control.

Table -1 : Levels of prevention

| Levels of prevention | Appropriate response | Period in the natural history where applied |
|---|---|---|
| Primary prevention | ✎ Health promotion (eg. Encourage healthy lifestyle changes, balanced nutrition and clean environment)<br>✎ Specific Protection (eg., immunizations Occupational and automobile safety measures) | Pre-pathogenesis |
| Secondary prevention | ✎ Early Diagnosis & treatment | Pathogenesis |
| Tertiary prevention | ✎ Disability limitation (i.e., institute medical or surgical treatment to limit damage from the disease)<br>✎ Rehabilitation (i.e. identify and teach Methods to reduce physical and social disability) | Pathogenesis and Post-pathogenesis |

(c) Protection of Susceptible Population

This is carried out by immunization, chemoprophylaxis, good nutrition, health education and personal protection.

**Control Measures on the Occurrence of an Infectious Disease**

In public health practice, the action to control the communicable diseases has to be crystallized into the form of a 'drill' which should involve no elaborate thought or preparation because the aetiological agents travel fast and gain momentum and invasive force as they proceed from person to person. The usual sequence of action to control the spread of an infectious disease is as follows :

(a) Early detection of case.
(b) Isolation of the case for the entire period of infectivity.
(c) Prompt and effective treatment of case.
(d) Disinfection of discharges and fomites.
(e) Notification.
(f) Surveillance of contacts.
(g) Mass immunization of the vulnerable community.
(h) Investigation of the current outbreak.
(j) Survey to assess endemicity.

**Legislative Control**

Statutory legislation have been made at the central, state and district levels or at the municipal cantonment / peripheral rural levels for imposing legal obligations on people to facilitate control actions. In the Armed Forces, notification to higher authorities and other actions in connection with communicable diseases are to be carried out in accordance with RMSAF Chapter XIII and under the provisions of the Cantonment Act, 1924, in so far as it pertains to the civil population in the cantonments. Similar action has been evolved and enforced by statutes to prevent and control occupational diseases, effects of ionizing radiations, use of agricultural fertilizers or insecticides. More and more are being included in national and international surveillance procedures with a view to prevent and control them. The list of notifiable communicable diseases in the Armed forces is given here under. The notification form (AFMSF-73) is used for reporting the infectious case.

Notifiable Diseases

Diseases which are notifiable in the Armed Forces are arranged in groups according to the procedures to be adopted. These are shown in Table - 2.

Table - 2 : Notifiable diseases in the armed forces

| | |
|---|---|
| Group 'A'<br>Cholera, Yellow Fever | By telegram/signal to ADMS, reported to DDMS and DGMS (and equivalent officers in the case of IN and IAF) and Director of Health services of the state. In addition, the notification form AFMSF-73 will be forwarded to MO in charge unit, and ADMS, with a copy to DDMS (and equivalent officers in the case of IN and IAF). The following information will be given in the telegram/signal :-<br>(a) Disease<br>(b) Date of occurrence<br>(c) Rank/Rating and unit/ ship of patient.<br>(d) Probable source of infection<br>(e) Preventable precautions taken.<br>(f) No. of death since last report<br>(g) Whether the disease is prevalent in local civil population, town or district. (The code laid down in RMSAF will be used). |
| Group 'B'<br>Acute poliomyelitis<br>Anthrax<br>Cerebrospinal fever<br>Diphtheria<br>Encephalitis<br>Enteric gp of fevers<br>Epidemic influenza<br>Epidemic pneumonia<br>Outbreak of food poisoning<br>Plague<br>Relapsing fever<br>Typhus and other rickettsial diseases | On the notification form in quadruplicate; one copy each to MO in charge unit, ADMS, DDMS and DGMS (and equivalent Officers in the case of IN and IAF. |
| Group 'C'<br>Chickenpox<br>Dysentery<br>Malaria<br>Measles<br>Mumps<br>Pulmonary tuberculosis<br>Scarlet fever | On the notification form in triplicate; one copy each to MO in charge unit, ADMS, SMO or administrative authority in the case of IN; and in the case of IAF, DGMS(Air) and PMO concerned (where applicable) DDMS if made notifiable by DDMS and DGMS (Navy) for IN personnel |

Notification Procedure

Copies of the notification form should be prepared in respect of all ranks including families and civilians by the medical officer in charge of the case in consultation with the medical officer in charge of the unit and submitted to the OC hospital who should distribute them as above and retain one copy for record. When a case has been received as a transfer from another station, a note should be made in the general remarks column stating the station from which the case was transferred. Only information of

interest or practical value regarding the source of infection, preventive measures etc. will be entered on the form. It is always desirable to inform the medical officer in charge of the unit by telephone as soon as a case of notifiable disease is diagnosed. In the event of an outbreak of any of the above diseases attaining epidemic proportions, it will suffice if the number of cases by units or sub-units is submitted, whereas names of individuals may be omitted. A detailed special report of the outbreak should be submitted by the ADMS/ SMO/ PMO to the DDMS for onward transmission to the DGMS. The occurrence of the following diseases amongst personnel of the armed forces should be notified by the officer commanding service hospital without delay to the local civil health authority concerned e. g. district or municipal officer of health.

(a) Anthrax
(b) Plague
(c) Cholera
(d) Relapsing Fever
(e) Diphtheria
(f) Fevers of the typhus gp
(g) Typhoid fever only)
(h) Influenza (if epidemic

**Note:** Details of rank, name and number etc, such as are required for notification form, need not be given in the reports, to be submitted to local Civil health authority.

Alteration in Diagnosis

In the event of an alteration of diagnosis becoming necessary, all those originally notified should be informed accordingly. A new notification form should be rendered if the new diagnosis is that of a notifiable disease.

Other Infectious Diseases

Infectious diseases other than those enumerated above should, if occurring in epidemic form, be reported in manuscript to the ADMS/ SMO/ administrative authority in case of IN and in case of IAF, DGMS (Air) and PMO concerned where applicable by the ADMS/ SMO (IN)/ PMO (IAF)). The ADMS should keep the DDMS Command and through him the DGMS informed of the progress of such epidemics. Should the above mentioned infectious diseases or other infectious diseases occur in epidemic form among the civil population in localities adjacent to those occupied by the troops and be considered likely to spread to the troops, manuscript reports should be made to the ADMS/ SMO (IN)/ PMO (IAF)/ DGMS.

## Disinfection

### General consideration (4)

Definitions

**(a) Disinfection**

This means destruction outside the body, of specific microorganisms, which cause communicable diseases.

**(b) Disinfectants**

These are the agents used for disinfection.

**(c) Antiseptics**

These are the chemical agents, which inhibit the growth and multiplication of microorganisms, but are not strong enough to destroy them completely. A sufficiently diluted or weakened disinfectant becomes an antiseptic.

**(d) Disinfestation**

This means destruction of undesirable animal forms, especially arthropod ectoparasites present upon the persons or on domestic animals. The term also includes destruction or avoidance of endoparasites like helminths, and rodent destruction. However, in practice this term mainly refers to the destruction of ectoparasites like lice, sarcoptes, bugs and fleas and their ova and eggs.

**(e) Disinfestants**

These are the agents used for disinfestation. Disinfestants which are specially used against arthopods are called 'insecticides' and 'acaricides' depending on their special values in practice. A number of disinfectants are disinfestants if used in adequate strength, but all disinfestants or insecticides are not disinfectants.

**(f) Detergents**

These are surface cleansers and degreasers. They dissolve grease and oily matter and thereby help removal of dirt etc. , from any material when rinsed or washed with water consequently removing the micro-organisms sheltered by grease and dirt.

**(g) Deodorants**

These are substances, which mask the unpleasant odours without having disinfecting or antiseptic powers. Many disinfectants and antiseptics mask putrefactive odours also.

Objective

The object of these processes is to cut the links in the chain of the spread of communicable diseases and reduce nuisance. They can, therefore, be considered as supplementary to environmental sanitation. The main objective can be achieved with minimum effort and maximum success if the aetiology and mode of transmission of each disease is clearly understood, ecology and bionomics of their agents are known, procedures are rational and specifically directed against the paths of its spread and not employed merely as placebos to appease the ignorant mind. Much time, energy and money are wasted on disinfection of places which only require ventilation and cleansing. Some situations may need only the disinfection and other may need only disinfestation while a few may need both. Agents and procedures adopted will, therefore, depend upon the situation as well as nature of the problem. Disinfection is discussed hereunder.

### Disinfection Procedures

(a) Concurrent Disinfection

It means the disinfection of the patient himself, of his excreta and discharges and of all articles used by him or likely to have been contaminated during the course of his illness, including the hands and clothing of attendants.

(b) Terminal Disinfection

It means the disinfection of the room or premises and their contents after the patient has recovered, died or has been removed elsewhere. This includes the vehicle or

ambulance, the wheel chairs and stretcher used by the patient. This is either 'local or 'complete'.

(i) **Local** : It is the disinfection of the bedding and the bedsheet occupied by the patient, the walls, floor, furniture including the kit box, shelf, lockers and their contents and all other surfaces or articles within 2 meters all round the bed.

(ii) **Complete** : It is the disinfection of the whole room and all its contents.

Prophylactic Disinfection

It means chemical treatment or boiling of water, pasteurization of milk, washing of hands and so on.

Concurrent disinfection destroys maximum number of pathogenic organisms while their virulence and infectivity are maximum. Terminal disinfection exterminates the residual infection likely to have been left behind by the patient. Although the virulence of the pathogenic organisms is at its height just when they leave the host, some organisms retain it at a high level for a long time after their exit from the host, under favourable conditions. Thus all spores and some bacteria, like tuberculosis, survive and retain their virulence for a long time outside the host; some intestinal pathogens have a long saprophytic life; and some viruses are markedly tenacious extra corporeally. Therefore, while greater reduction in dissemination of infection is achieved by immediate concurrent disinfection, terminal disinfection is definitely complementary. However, as the infective propensity for non-sporing bacteria rapidly diminishes in their extra corporeal existence, properly carried out concurrent disinfection should relegate terminal disinfection to a subordinate position.

### Classification of Disinfecting Agents

Disinfecting agents can be classified as follows :

**(a) Natural Agents**

(i) Fresh air

(ii) Sunlight

**(b) Physical Agents**

(i) Dry Heat

- Burning
- Hot dry air
- Contact heat-ironing

(ii) Moist Heat

- Boiling (with or without chemical agent).
- Steaming-current steam and steam under
- Pressure.

(iii) Radiation

- Lonising radiation
- Ultraviolet rays.

**(c) Chemical Agents**

(i) Solids.

(ii) Liquids.

(iii) Gases.

(iv) Aerosols.

It will not, however, be correct to suppose that the action of any agent is circumscribed in or confined to its particular group only. Many disinfectants act both by physical action and chemical action e. g. soap acts by physically removing the grease and dirt which shelter the organisms as well as by its chemical action. Often, in practice, disinfection by chemical agents can be complemented or supplemented by physical agents. Thus clothing can first be soaked in a chemical agent, then steamed and finally washed, dried in the sun and ironed. Similarly disinfection by boiling can be accelerated or aided by the addition of a chemical or soap.

Natural Agents

Fresh air dilutes the bacterial content in enclosed places and desiccates micro-organisms by dehumidification. Sunlight disinfects due to the desiccating effect of its heat rays and the action of its ultraviolet rays. Indeed, this disinfecting power of the sun has made life possible in the insanitary tropical and subtropical environments. Although these agents are slow in action and frequently unreliable owing to the resistance of certain organisms, they are valuable adjuncts to artificial methods. In their absence the saprophytic life of all germs is prolonged. Thus, during epidemics, cinema theatres act as foci for the dissemination of infection since they usually admit no direct sunlight and little fresh air, whilst respiratory moisture delays desiccation.

Physical Agents

Heat kills ectoparasites and micro-organisms by coagulating their protoplasm. It may be employed in a dry or moist form. To ensure perfect sterility, the former demands a higher temperature and / or longer exposure than the latter. Heat, especially in the moist form, is the only physical agent that is reliably used for artificial disinfection and disinfestation in preventive medical practice.

**(a) Dry Heat**

Burning is a certain and rapid method of disinfecting and disinfestation but has only a limited scope. It may, however, be the only available method on active service. For example, clothing contaminated by excreta of cholera patients may be burnt, or the ground which has been contaminated by an anthrax carcass may be disinfected by burning straw or oil on the top of it. Contact heat applied by pressing irons over clothing may be used to disinfest louse and mites. Hot air ovens are used to disinfect glass ware such as petridishes, sharp instruments, swabs, dressing, chalk, Vaseline etc. The temperature of the air in the oven should be maintained at 160°C for at least one hour.

**(b) Moist Heat**

Boiling is quite effective in killing all non-sporing organisms, Spores being very resistant require boiling for an hour and a half. Boiling is largely used for sterilizing instruments and is useful for disinfecting bed clothing, underwear and similar articles. Blood stains become fixed by boiling owing to the coagulation of protein; these

should, therefore, be first removed by soaking in cold soapy water. Another disadvantage of boiling is that it is unsuitable for thick bedding of woolens. The effect of boiling can be enhanced by adding soap or washing soda to water. Steaming is the most efficient procedure of disinfection and disinfestation. The usual method is to expose the infected articles to 'saturated steam' in 'current steam' or 'under pressure'.

**(c) Radiation**

(i) **Ionizing Radiation** : Gamma radiation or electron beams have the advantage of combining great penetrative power with little or no effect on the object to be sterilized. Bandages, catgut, dressing and surgical instruments may be sterilized by ionizing radiation. These methods are used commercially. The isotope used is Cobalt 60.

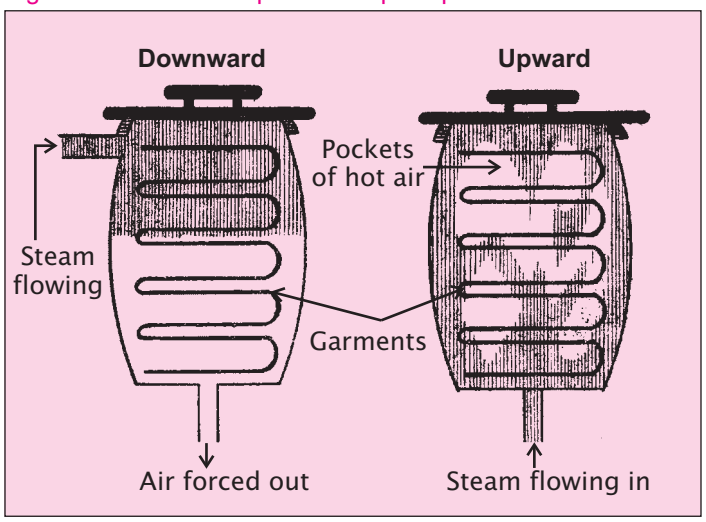
(ii) **Ultraviolet Rays** : Ultraviolet rays delivered from an apparatus hung in the ceiling at the entrance of special purpose rooms like the one in which premature infants are kept or in operation theatres, temporarily disinfect the objects and air entering inside.

**Steam Disinfection**

Steam in contact with boiling water from which it is generated has the temperature of 100°C and is called as 'saturated steam'. When it comes in contact with colder objects it immediately condenses and every gramme of it transfers a latent heat of 537 calories to that object and it contracts to about 0. 0015th of its volume and creates a partial vacuum. To fill the empty space more steam immediately rushes, condenses, releases the latent heat and again creates a partial vacuum. Continued repetition of this process achieves penetration of steam throughout the mass of, the fabric. Heat is thus transferred to the exposed articles until its temperature is raised to 100°C. Intimate contact with saturated steam is instantly fatal to all non-sporing organisms. Steam, however, gets mixed with the air contained in the clothing. Air absorbs heat, impedes intimate contact of steam with the fabric and being a bad conductor of heat, insulates clothing and reduces penetration, and thus disinfects much less efficiently than pure steam. This difficulty can be overcome by extracting air from the disinfection chamber before introducing steam into it, or by a downward displacement of air by steam introduced at the top of the chamber.

Steam being lighter than air when introduced from below into a chamber, it naturally ascends taking the line of least resistance between the layers of the clothing instead of through their texture, without displacing the air contained in it. If admitted at the top of the container it forms a supernatant layer, and if it cannot escape from above, descends gradually layer by layer through the fabric. If steam continues to enter from the top, all the air is pressed out of the fabric and the container through an escape hole provided at the bottom of the chamber. Finally, the steam completely penetrating throughout the mass of textiles rapidly raises the temperature of

Fig - 1 : Downward displacement principle



everything in the container to 100°C. The 'Serbian barrel' shown in Fig – 1 demonstrates this 'downward displacement of air' principle with clarity and simplicity.

Steam introduced at atmospheric pressure is known as 'current' or 'unconfined' steam; and at pressure in excess of that is called 'pressure' or 'confined steam'. The penetration of the pressure steam is no better than the current steam unless the chamber is vacuumised. By increasing pressure after creating vacuum much higher temperatures can be attained than the 100°C obtained with current steam. This renders 'pressure steam' disinfection more effective. This temperature of steam with a 0. 33 kg per square cm rise of pressure above the atmosphere is 109°C, at 0. 66 kg it is 115°C, at 1 kg 121°C, at 1. 33 kg 126°C, and at 2.66 kg per square cm it goes upto 141°C and so on.

Pressure Steam Disinfectors

A typical pressure steam disinfector consists of a double-jacketed wrought-iron cylinder, loaded at one end and unloaded at the other, each end having a hinged iron door. The clothing is placed in a cradle which is run on rails in the cylinder and the doors are clamped. Steam is first admitted in the outer jacket for heating the cylinder. The cylinder is then vacuumised and steam is introduced in it at 133 kg/ cm2 pressure for 10 min. After this, it is revacuumised and recharged with steam at the same pressure for further ten minutes, followed by aspiration of hot air through the clothing. Finally the clothing is taken out in a dry state from the other end. The whole operation takes about 35 min. Pressure-steam disinfectors of various types, but operated on the same principle are seen in large military hospitals.

Current-steam Disinfector

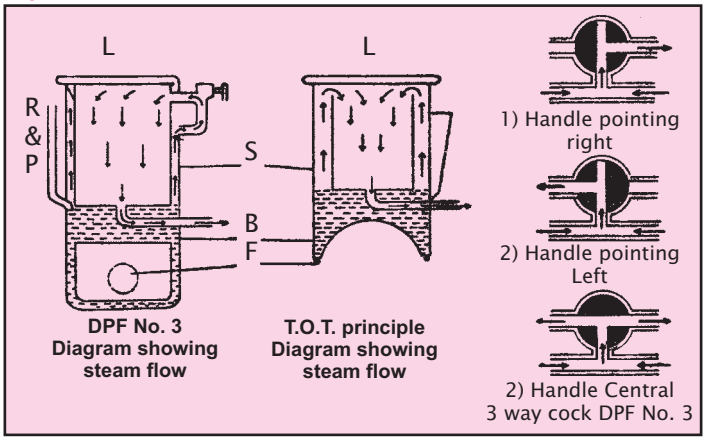
Pressure-steam requires apparatus with considerable extra strength and weight. Therefore, its use is practicable only in garrison stations and large hospitals. The current-steam apparatus, operated on the 'principle of downward displacement of air' being lighter and portable, is ideal for use on active service and in temporary camps. The

current-steam disinfectors at present in use are the TOT Disinfector (Fig -2) and Disinfector portable field (Fig - 3)

**The 'TOT' Disinfector**

This is a portable 'downward-air-displacement' current-steam disinfector named after its designer, T. O. Thompson. It is a rectangular metal box, the bottom of which has the fire chamber (F) with a built in 20 l capacity boiler (B) over it, and the upper part is a double jacketted steam chamber (S). The lid (L) is well fitting, air tight and asbestos/ hemp or felt lined. Heating is done by a burner, firewood or coal, for which a simple trench-fire-place (T) is required. Clothing is placed in the steam chamber and the lid is clamped so as to fit firmly. Steam generated in the boiler travels up between the two jackets of the steam chamber and, being stopped by the clamped lid, is forced down into it. It can not escape until all air is displaced downwards and forced out of the spaces between the interstices of the fabrics. It finally reaches the escape pipe through the hole (H) in the bottom of the container. This entire process takes about 10 min when steam will be seen spurting from the steam escape pipe (P) with a whistling noise. A definite continuous spout, and not the intermittent wisps of steam, indicates that the chamber is filled with steam without any air left in it. Steam is allowed to spout for 5 min and then the lid is opened, clothing is taken out and aired for drying. The process is repeated until all clothing is disinfected. At each loading about 9 to10 blankets or one man's full kit can be treated, provided the blankets are not brand new and are neatly folded and pressed well down into the chamber, corners up most to allow easy removal. About 5 1 of water should be added at each reloading.

Fig - 2 : TOT Disinfector

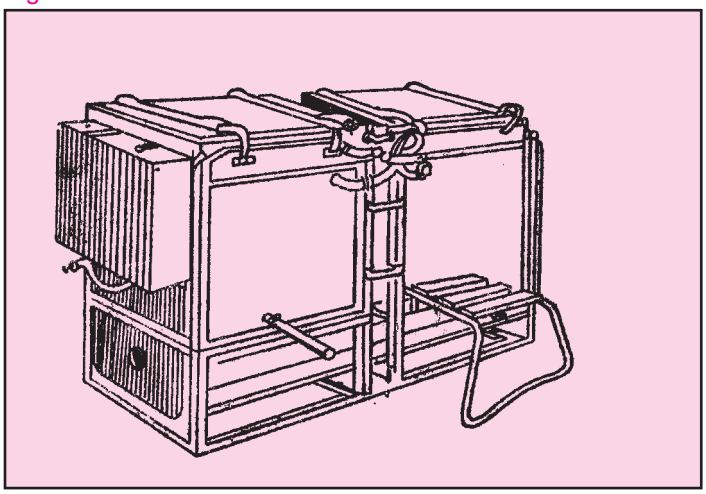


**Disinfector Portable Field**

The disinfector is also of the 'downward air displacement' type. It has two halves of identical construction bolted together (Fig - 3).

The front burner half carries a detachable 180 l capacity water reservoir with a water level gauge. The back flue-box half carries the detachable flue box and a pipe which is immersed in boiler water and is open to atmosphere, and therefore serves as low water alarm and also as a pressure limiting device. Through the detachable boiler section at the bottom, runs the fire tube with 5 cm space

Fig - 3 : Disinfector Portable field



around it. The boiler holds 80 l of water. The top chamber section carries the disinfecting chamber. Between this and the outer sheet is a 3 cm steam space surrounding the chamber. The front and back halves are interconnected by a loose fire tube connector, a water-pipe assembly which equalizes the water level and drains the water space, and steam pipe assembly which collects the steam generated in both halves and passes it to either of the disinfecting chambers separately or to both simultaneously. The water and steam pipe assemblies are joined to the disinfector body by unions with ground faces. When union nuts are taken off, the entire assembly comes away. Procedure of its working is briefly as follows :

(a) The boiler is filled via the water reservoir till the gauge shows 1. 5 cm and then the water reservoir itself is filled. There will then be about 260 l of water in the boiler and the reservoir, enough for two hours steaming. The burner is started and pushed into the opening of the fire tube with the burner plate abutting against its porch way. The flame should be kept steady.

(b) Articles for disinfection are collected on a ground sheet on the 'dirty side'. These may be tied in blankets to make bundles of the size of the chamber or loaded directly in layers. Blankets are folded to make neat bundles on the slings supplied. Steam from the boiler rises up in the steam space from where it is drawn off by tubes and admitted at the top of the disinfection chambers, at a pressure slightly above the atmosphere. Steam continuously entering from the top displaces all the air in the chamber and fabrics downwards and finally, completely filling the chamber, escapes through the bottom exhaust pipe in a continuous 'full bore' steam of vapour.

(c) To start with, the first chamber is loaded while the steam is diverted by the three-way valve to the other chamber. After loading, the lid is clamped down and the three-way valve is turned over to admit all steam into it. The second chamber is then loaded and the three-way valve is turned midway

to admit steam to both chambers simultaneously. After12 min, steam will issue forth 'full bore' from the exhaust pipe of the first chamber. After 5 min of the 'full bore' exhaust, disinfection of that chamber is complete and the three way valve is set to pass all steam to the second chamber, while the first is emptied and reloaded. By this time the second chamber may have completed its 5 min of 'full bore' exhaust and all steam is passed to the new load in the first chamber while the second is recharged. These cycles are repeated till all clothes are disinfected. The water level is always maintained showing 1. 5 cm up in the gauge-glass by replenishing at short intervals.

(d) Operating and working party as follows will be needed. 3 men to hand over the dirty clothing; 3 men to take over the disinfected clothing; and 3 men to operate the disinfector, No. 1 to attend to the boiler and burner, No. 2 to load the disinfector on the dirty side, and No. 3 on the clean side to operate the three way valve, unload the disinfector and pass the disinfected clothing to men who air them and hand them over to the loading party. There should be no passage of persons between dirty and clean sides, and the only passage of articles should be via the disinfection chambers. The output is about 200 blankets per hour. After the work is over the water should be drained out of the disinfector.

(e) The 'Disinfection centre' should have two apartments, the 'infected' or 'dirty' apartment and the 'disinfected' or 'clean' apartment. The disinfector should be built in between the two rooms, without communication between the two sides except through the disinfector, so that the receiving end opens into the 'infected' side and the other into the 'disinfected' side. After the work is over the water should be drained out of the disinfector.

### Chemical Agents

Chemical disinfectants and disinfectants may be solid, liquids, gases or aerosols. Solids act as disinfectants only in solution. A few disinfectants as powders, act better when dissolved. Gases like sulphur dioxide and formaldehyde also act as better disinfectants in the presence of adequate moisture. The disinfecting power of a chemical depends upon its basic toxicity, concentration, penetrating power, the medium in which it is to act, the resistance of organism required to be killed, the extent to which the organism is protected by organic matter like pus or faeces, and the period of contact allowed. The ideal chemical disinfectant should be capable of destroying all micro-organisms in all probable media within half an hour; it should be harmless to man and higher animals; it should not spoil metals, clothing and other household goods in the concentration usually employed; for convenience of transportation it should be obtainable in a highly concentrated form; it should be capable of forming a solution or stable emulsion in water (even in hard water); and finally it should be cheap. The main problem with any disinfectant, however, is the ability of its particles to gain contact with bacteriae. Capsulated organisms resist penetration to a marked degree; the organisms locked up even in microscopic masses of pus, mucus, faeces etc. are protected against most disinfectants unless the time of contact is long and the concentration high. Disinfection by chemicals is thus a complex process and the estimation of the true disinfecting power of any chemical agent is difficult (7, 8).

#### Estimation of Germicidal Power

The best known test for assessing germicidal power is the 'Rideal- Walker phenol coefficient test' (R. W. ). In this test the bactericidal power of any chemical is compared with that of phenol under identical conditions. This is done by observing the comparative sterilizing effects of a series of dilutions of the particular chemical and those of phenol against a standard dose of a standard culture of the Lister strain of B. typhosum, in a standard time, at a standard temperature. The RW coefficient is obtained by dividing the highest sterilizing dilution of the agent under test by the highest dilution of phenol sterilizing in the same time. For example, if cresol diluted 1:1200 and phenol diluted 1:100 both produce sterility, say, in 15 min, the RW coefficient of cresol would be 12 i. e. cresol has 12 times the disinfecting power of phenol. The test, however, does not indicate the disinfecting powers of disinfectants under natural conditions. For example, the mercurial salts show a high RW coefficient but their disinfecting action is arrested by albuminous materials. Chlorine and potassium permanganate lose a great deal of potency in the presence of organic matter, while others like cresol are only slightly handicapped. Various modified tests, like Chick-Martins test, take into account the effects of extraneous material. However, the unmodified Rideal-Walker test is useful for comparing the germicidal power of different batches of the same disinfectant.

#### Solids

**(a) Quicklime**

It is used in the burial of animals dead of anthrax; for disinfecting byres and stables after the occurrence of a case of anthrax; and as 25 per cent lime wash for walls, ceiling and floors of barns, sheds, stables, kitchen, stores and so on. Slaked lime is used as a deodorant in and around urinals, soakage pits, greases traps; to promote bacterial growth by retarding acidity in deep trench latrines; and as a final spread over shallow trenches.

**(b) Chlorine Compounds**

Bleaching powder, water sterilizing powder, sodium hypochlorite and many other kindred substances containing chlorine are used to sterilize water and vegetables. Bleaching powder in combination with boric acid has been used as eusol in surgery. The practice of sprinkling bleaching powder in drains, gutters, latrine pails etc. is wasteful and useless.

#### Liquids

**(a) Coal Tar Derivatives**

These are obtained by its fractional distillation and are most widely used of all the liquid disinfectants. This group includes the aniline dyes, the phenols and the cresols.

(i) **Cresol** : It is a dark brown, oily, readily emulsifiable liquid. Liquor cresoli fortis, known in the Armed Forces as 'disinfecting fluid black' or simply as cresol, is the most convenient and the most useful general disinfectant. It turns white on dilution with water and is extremely stable. Liquor cresoli fortis has a RW coefficient of 12, but cresol commercially supplied may have a 10 RW. All containers are marked with the RW of the contained cresol so that, by increasing or decreasing the amount of dilution with water a final disinfectant liquid of known strength can be made. For general use, like scrubbing bedsteads the dilution of 1 per cent of RW 10 cresol is enough. In this dilution it is not dangerously toxic if swallowed, is only mildly irritating to the skin, and possesses high germicidal power. For disinfecting bedpans, sputum or excreta a dilution of 2. 5% of RW 10 cresol is needed. Even in this dilution cresol does not destroy fabrics. Although it is rapidly fatal to micro-organisms when it comes in contact with them, its penetration into a mass of sputum or faeces is not good. Therefore, as a measure of greater safety, a 5 per cent emulsion is used for disinfecting sputum of tuberculosis cases and faeces of some excremental disease cases. Cresol is of great value in the disinfection of the receptacle after the contained infective material has been disposed of.

(ii) **Izal** : This is saponified cresol, officially known as 'disinfecting fluid white (Izal)'. This correct nomenclature should always be used. It is used in 3 per cent strength for disinfecting mouthpieces of telephones and microphones, of RT sets and PA sets and the face pieces of respirators. It should not be used for any other purpose.

**(b) Dettol**

This is chloroxylenol. It is non-irritating but inactivated by organic matter. It is active against streptococci but has no effect on some gram-negative bacteria.

**(c) Commercial Formalin**

This is a 40 percent aqueous solution of formaldehyde. It is a powerful disinfectant, but since it is very irritating to the hands, eyes and respiratory passages, it is not used as a general disinfectant. It can be used in a 5 per cent dilution for disinfecting rooms, tents, huts, or vehicles and for spraying fur-coats, leather, rubber, metal and similar articles which are destroyed by steam. It is used for disinfecting valuable like jewellery, gold and ornaments and watches. It is used for preserving tissues required to be sent to the laboratory for examination.

Gases

**(a) Sulphur Dioxide**

This gas has been used for fumigation against rats in ships and warehouses by the Clayton apparatus in which a forced draft from a blower ensures complete combustion of sulphur. By means of pipes led from the generator, a concentration of 15 per cent sulphur dioxide is attained in the air in enclosed places. Sulphur dioxide is not dangerous to human life, but tarnishes metals, discolours paints, destroys pictures, spoils grain and entails a risk of fire.

**(b) Formaldehyde**

The gas is generated popularly by pouring liquid formalin over crystals of potassium permanganate placed in a deep pan. About 300 ml of formalin and 150 gm of potassium permanganate are required for 1000 cft of space. The room is to be kept closed for 6 to 12 hours to allow disinfection.

Aerosols

Aerosols are mists released into the air by a special atomizer to disinfect the air in enclosed places. Their action is believed to be either due to collision with and absorption by organisms or condensation of vapour on bacteria-carrying particles, quickly destroying their bacterial content. The ideal aerosol should be non-irritating to the mucosa, non-toxic even after prolonged exposure, invisible, inodorous, non-corrosive, non-inflammable, highly bactericidal in low concentrations, and capable of penetrating organisms in dried secretions such as saliva. The most effective and irritating particles have a diameter of less than 1 micron and act at dilution ranging 1 in 100 million to 500 million volume of air. Aerosol has an advantage over ultra violet rays in the disinfection of air in enclosed places due to their penetration to the remote corners of rooms. Aerosols so far tried for killing bacteriae suspended in the air, fall into three groups viz. hypochlorites, resorcinols and glycols. Insecticide aerosols are effective against insects only. They contain Freon gas, Pyrethrum and DDT in solutions.

**Practice in the Armed Forces**

On the occurrence of a case of communicable disease in the Armed Forces barracks, and married quarters or treatment of a case in hospital, both concurrent and terminal disinfection are required to be carried out vide RMSAF paras 710 to 714. Concurrent disinfection of the patient himself, of his infective body-discharges immediately on voidance, of all articles used by him, nursing appliances immediately after use and clothing and linen when soiled or change is carried out during the course of an infectious illness. Terminal disinfection is carried out after the patient is dead or discharged or transferred. While only the 'local' terminal disinfection is necessary in all cases of infections, 'complete' disinfection is carried out for cholera, pulmonary tuberculosis, puerperal sepsis and pneumonic plague after the diagnosis. Chemical disinfectants like cresol and formalin are usually used for treating walls, floors, bedstead, furniture, fixtures, nursing appliances and articles of personal use. Blankets used by all patients and

complete clothing used by infectious patient are disinfected by steam and then washed, dried in the sun and ironed. If a steam disinfector is not available they are soaked in 2. 5 per cent cresol for half an hour. To summarize, disinfection of the following must always be considered in all cases of infectious illness :

(a) The patient's excreta and discharges, linen, utensils and other articles used by the patient.

(b) The quarters occupied by the patient before removal to hospital and their contents.

(c) The vehicle in which the patient is conveyed to hospital.

(d) On recovery of the patient, the ward/ room in which the patient was treated and its contents.

(e) In the case of carriers or contacts disinfection should be carried out at the discretion of the officer in medical charge.

In the Armed Forces, as practically all cases of infectious diseases are treated in hospitals, the disinfection is always carried out by trained persons. Occasionally when an infectious case has to be treated in quarters, full instructions in writing should be given. Disinfection and disinfestation should be carried out under the direction of medical authorities. Working parties are to be provided by the COs of units. In the Army, the scale of authorized disinfectants are given in SRS; in the Navy and Air Force these are to be drawn as per scales authorized from time to time through administrative orders/ instructions.

Details of Procedures to be followed

**(a) Concurrent Disinfection**

It should always be considered as extremely important. Concurrent disinfection of various infective materials in appropriate cases should be carried out as follows :

(i) Sputum should be received directly into sputum cups containing 2. 5 per cent cresol and afterwards burnt.

(ii) Nasal, aural and eye discharges should be received directly into small pieces of linen, cotton or cotton wool, and immediately burnt. Vaginal or urethral discharges and those from open sores should also be similarly received on pads left in situ under dressings and burnt after removal at frequent intervals. Handkerchiefs should be soaked in 2. 5 percent cresol solution before washing with soap and ironing.

(iii) Contents of bed pans and urine bottles used by patients suffering from gastro-intestinal diseases as well as their vomits should be thoroughly mixed with an equal quantity of 2. 5 per cent cresol and allowed to stand for 2 hours before throwing down the sluice or water closet or incinerated. Bed pans and bottles should subsequently be steeped in 2. 5 per cent cresol for15 min to half an hour and then washed.

(iv) Bed linen, blankets etc. which have been soiled with infectious discharges, exudates or excreta should be steeped in 2. 5 percent cresol for half an hour before removal from the ward. Special bedding and clothing marked with 'I' are reserved for use of patients suffering from infectious diseases.

**(b) Terminal Disinfection**

It is complementary to the concurrent disinfection. All clothing, mattresses, bedding, linen, personal wear and similar articles within the specified areas for local or complete disinfection as indicated are packed in sacks, or sheets soaked in 2. 5 per cent cresol and removed to the disinfection center for steam disinfection. After disinfecting, the articles of clothing and linen are washed with soap, dried in the sun and ironed. The floor, the walls, the tent-walls and wall-skirting, bedsteads, shelves, kit boxes and any other metal or wooden article, other than those which are removed for steam disinfection, are disinfected in situ by scrubbing or spraying with 2. 5 per cent cresol. After a suitable period of contact with the disinfectant, these may be washed.

**(c) Some Special Disinfections**

(i) **Vehicle or Aircraft** : Spray or swab with 5 per cent formalin or 2. 5 per cent cresol followed by washing in hot water with soda.

(ii) **Crockery and Cutlery** : Steep for half an hour in 2. 5 per cent cresol followed by washing in hot water with soda.

(iii) **Toys, Book and Papers** : If of small value, they may be burnt. If valuable, spray or swab with 5 per cent formalin followed by exposure to the air for two to three days.

(iv) **Shaving Brushes** : Thoroughly wash in 5 per cent soap solution containing one per cent soda ash at 50˚C. Allow to stand in one per cent soda ash at 50˚C for half an hour. Soak for half an hour in 10 percent formalin solution at 50˚C. Allow to dry in the shade, bristles downwards.

(v) **Latrine Seats** : Scrub with 2. 5 per cent cresol, which should then be allowed to dry on the seat.

Routine Disinfection of Personal Clothing

Disinfection / disinfestation of personal clothing in units obviates the possibility of any inadvertent transmission of contagious infection or louse infestation or bed bugs from person to person. Formerly routine steam disinfection of winter clothing used to be carried out after the clothing was withdrawn at the termination of the winter season, before stowing away for the summer. The present practice is to wash such clothing with soap and hot water at 60˚C, and afterwards expose them to the sun for 24 hours. After drying and ironing, it is stowed away in rat proof boxes or racks, after interposing naphthalene mothballs in between layers. Coloured clothing is fumigated with carbon tetrachloride by laundry units. Cotton clothing is boiled in soap solution, dried and ironed.

The common disinfectant in use and their dosage is shown in Table - 3 and Table - 4

Table - 3 : Recommended dilution of Chlorine releasing compounds

| Available Chlorine | "Clean" condition | "Dirty" Condition |
|---|---|---|
| Required chlorine | 0.1% 1gm/litre | 0.5%, 5 gm/litre |
| Sodium hypochlorite solution 5% available chlorine | 20 ml/litre | 100 ml/litre |
| Calcium hypochlorite 70% available chlorine | 1.4 gm/litre | 7.0 gm/litre |
| (NaOCl Powder) Sodium dischlorosocyanurate | 1.7 gm/litre | 8.5 gm/litre |
| (NaOCl Tablets Sodium dischlorosocyanurate | 1 tablet/litre | 4 tablets/litre |
| Chloramine (25% available chlorine) | 20 gm/litre | 20 gm/litre |

Table - 4 : Non-chlorine releasing compounds (used for disinfection of items which are adversely affected upon by chlorine).

| Name of Disinfectant | Required concentration | Contact period | Used for disinfection of |
|---|---|---|---|
| Ethanol | 70% | 3-5 min | Smooth metal surfaces, table tops, incubators, thermometers |
| Alkaline Glutaraldehyde | 2% | 30 min | Ambu bags, suction tubes/bottles, laryngoscopes, endotracheal tubes, catheters etc. |
| Formaldehyde / Formalin | 3 - 4% | 30 min | Furniture, rooms, walls, blankets, beds, books etc. |
| Savlon | 1% | 30 min | Cheatle forceps. |
| Dettol (chloroxylenol) | 5% | 15 min | Instruments & plastic equipment |

# Immunization

## Introduction

The concept of immunity has intrigued mankind for thousands of years. The prehistoric view of disease was that it was caused by supernatural forces, and that illness was a form of theurgic punishment for "bad deeds" or "evil thoughts" visited upon the soul by the gods or by one's enemies(1). The first written descriptions of the concept of immunity may have been made by the Athenian Thucydides who, in 430 BC, described that when the plague hit Athens "the sick and the dying were tended by the pitying care of those who had recovered, because they knew the course of the disease and were themselves free from apprehensions. For no one was ever attacked a second time, or not with a fatal result(2) The term "immunes", is also found in the epic poem "Pharsalia" written around 60 B. C. by the poet Marcus Annaeus Lucanus to describe a North African tribe's resistance to snake venom (3). The first clinical description of immunity which arose from a specific disease causing organism is probably *Kitab fi al-jadari wa-al-hasbah* (4) written by the physician in the 9th century. However, it was with Louis Pasteur's Germ theory of disease that the fledgling science of immunology began to explain how bacteria caused disease, and how, following infection, the human body gained the ability to resist further insults (3).

Burnet and Medawar, Nobel Prize winners in 1960 put forth the concept that Man had learnt to tolerate his own tissues (self) and was intolerant to foreign tissues (i. e. not self). The concept of 'self' and 'not self', therefore, means that under normal conditions the body tolerates its own tissues (immunological tolerance), and recognizes and destroys foreign tissues. In the modern sense, therefore, immunity has been defined as the ability of the body to recognize, destroy and eliminate antigenic material foreign to its own. It is imperative to have updated knowledge regarding the immunologic basis of diseases and immunization, when dealing with the issue of immunization (5, 6).

## Basics of Immunology

The immune system is a collection of mechanisms within an organism that protects against infection by identifying and killing pathogens and tumor cells.

### Structure and function of Immune system

Tissues and Organs Important for Immune function include :

(a) Cells derived from stem cells: liver, bone marrow

(b) Cells that are stored, multiply, interact, and mature in: thymus, spleen, lymph nodes, blood

(c) Transport: lymphatic vessels

(d) Accessory Organs : Appendix, tonsils, intestines

The immune system detects a wide variety of pathogens, such as viruses and parasitic worms and distinguishes them from the organism's normal cells and tissues. The immune system protects organisms from infection with layered defenses of increasing specificity. Most simply, physical barriers prevent pathogens such as bacteria and viruses from entering the body. If a pathogen breaches these barriers, the innate immune system provides an immediate, but non-specific response. Innate immune systems are found in all plants and animals. However, if pathogens successfully evade the innate response, vertebrates possess a third layer of protection, the adaptive immune system. Here, the immune system adapts its response during an infection to improve its recognition of the pathogen. This improved response is then retained after the pathogen has been eliminated, in the form of an immunological memory, and allows the adaptive immune system to mount faster and stronger attacks each time this pathogen is encountered (7,8).

### Antigens

An antigen is defined as a substance which when introduced into the tissues stimulates the production of specific antibodies and combines specifically with the antibody so produced(3). By far the best antigens are proteins (eg diphtheria toxin, tetanus toxin); others are poly-saccharides (eg. blood group antigens), lipids and nucleic acids. There are also incomplete antigens called 'haptens' which by themselves are not antigenic but can provoke an immune response by combining with one of the body's proteins in such a way that the protein becomes 'foreign' to the body. Penicillin is an example of 'hapten'. On contact with an antigen the host can respond in three different ways :

(a) Circulating antibody is formed.

(b) A delayed-type cell mediated hypersensitivity reaction may result on second contact with the antigen.

(c) Tolerance, which means that on second contact with the same antigen no response will be provoked.

The type of response in a particular case will depend largely on the antigen itself, the dosage, and the route of application and possibly on other lesser-known factors (9).

### Antibodies

An antibody is a protein substance that appears in the body as a result of invasion by an antigen. It is capable of reacting specifically with the same antigen, which provokes its production. The sites of maximum antibody formation are the lymph nodes and spleen. Smaller collections of antibody producing cells are widely scattered in various tissues throughout the body. Plasma cells also produce antibodies. Antibodies may be antitoxic such as diphtheria and tetanus, antibacterial like typhoid or antiviral such as polio.

### Immunoglobulins

These comprise of families of closely related globulin molecules, which are synthesized by cells of reticulo-endothelial system. The human immunoglobulin system is divided into five major classes IgG, IgA, IgM, IgD and

IgE. The molecule of each immunoglobulin is understood to consist of K (Kappa) and L (Lambda) polypeptide chain. It is still an open question whether all immunoglobulins are antibodies that have arisen as a result of antigenic stimulation(10)).

**(a) IgG**

Repeated exposure to antigen leads to its accumulation in serum and it comprises about 80 per cent of serum antibodies in an adult. Antibodies to gram positive pyogenic bacteria, antiviral and antitoxic antibodies are found exclusively among IgG globulins. Further, this is the immunoglobulin, which is transported across the placenta. Maternally derived IgG is slowly replaced by actively synthesized IgG which appears at 1-3 months of age and then rapidly rises. Adult levels are reached by the age of one to two years. Normal adult serum level of IgG is 600-1800 mg/100 ml.

**(b) IgA**

This fraction has been found to contain isohaemagglutinins, antibrucella, antidiphtheria antibodies and comprises about 10 per cent of the serum antibodies. Saliva, colostrum and tears are relatively rich in this fraction. Nasal and bronchial secretions, bile, intestinal juices and prostatic fluid also contain IgA. It seems to play a decisive role in local immunity. IgA synthesis begins two weeks after birth. Normal adult serum level is 70-380 mg/100 ml.

**(c) IgM**

This fraction is found to have high agglutinating and complement fixation ability. Wasserman antibodies and bactericidal antibodies against Gram negative organisms (endotoxins) are almost exclusively found in IgM. It accounts for 5 to 10 per cent of serum antibodies. It cannot pass through placenta. Normal adult serum level is 20-130 mg/100 ml.

**(d) IgD**

Normal adult serum level is 4-40 mg/100 ml.

**(e) IgE**

The antibodies in this fraction have the ability to fix themselves firmly to tissues and remain so fixed. They are likely to play an important role in allergic reactions.

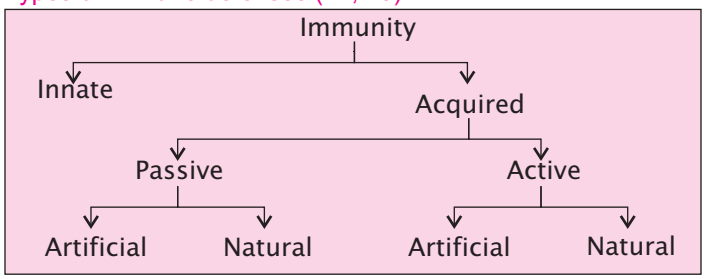
Immunity

Table - 1

| Nonspecific defense mechanisms | | Specific defense mechanisms (immune system) |
|---|---|---|
| **First line of defense** | **Second line of defense** | **Third line of defense** |
| Skin<br>Mucous membranes<br>Secretions of skin & mucous membranes | Phagocytic White blood cells<br>Antimicrobial proteins<br>The | Lymphocytes<br>Antibodies |

The modern word "immunity" derives from the latin *immunis*, meaning exemption from military service, tax payments or other public services and is defined as

Types of immune defenses (12, 13)



"Ability of an organism to recognize and defend itself against specific pathogens or antigens" (11).

**Innate and Adaptive Immunity**

The normal individual has two levels of defence against foreign agents. The first type is present in neonatal animals and in invertebrates namely natural or innate immunity. This type of immunity is sometimes referred to as non-specific but broadly specific would be a better description. The second type of immunity is adaptive or acquired immunity and is confined to vertebrates.

**Innate (or natural) immunity**

This is made up of several components.

(a) Physical barriers are the first line of defense against infection. The skin and mucous membranes provide a continuous surface which must be breached and back this up with mechanical protection through cilia and mucous.

(b) Physiological factors such as pH, temperature and oxygen tension limit microbial growth. The acid environment of the stomach combined with microbial competition from the commensal flora inhibits gut infection.

(c) Protein secretions into external body fluids such as lysozyme also help resist invasion. Soluble factors within the body such as complement, interferons and collectins and other "broadly specific" molecules such as C-reactive protein are of considerable importance in protection against infection.

(c) Phagocytic cells are critical in the defense against bacterial and simple eukaryotic pathogens. Macrophages and Polymorphonuclear leucocytes (PMN) can recognise bacterial and yeast cell walls through broadly specific receptors (usually for carbohydrate structures) and this recognition is greatly enhanced by activated complement (opsonin) (7).

**Acquired immunity**

Acquired immunity is also called adaptive immunity and develops only after exposure to inducing agents such as microbes, toxins, or other foreign substances.

Table - 2 : Comparison between active & passive immunity

| Active Immunity | Passive Immunity |
|---|---|
| 1. Usually produced in response to bacteria viruses, . toxins or toxoids | 1. Produced by serum containing already prepared antibodies |
| 2. Body cells take an active part in the production of immunity | 2. Cells of body do not take part in the production of antibodies. |
| 3. It takes sometime to develop the antibody in the system. | 3. No time is lapsed in getting the antibodies circulating in the system. |
| 4. Immunity lasts long | 4. Immunity lasts for a short period, usually 10-14 days. |
| 5. Used for prepathogenic prophylaxis and treatment of subacute or chronic infections in order to increase resistance of the body | 5. Used for treatment of acute infection and for tiding over the crisis or incubation period |

**Active immunity**

(a) Naturally acquired active immunity occurs when a person is exposed to a live pathogen, and develops a primary immune response, which leads to immunological memory. This type of immunity is "natural" because it is not induced by man.

(b) Artificially acquired active immunity can be induced by a vaccine, a substance that contains antigen. A vaccine stimulates a primary response against the antigen without causing symptoms of the disease.

**Passive immunity**

Passive immunity is the transfer of active immunity, in the form of readymade antibodies, from one individual to another.

**Naturally acquired passive immunity**

Passive immunity can occur naturally, when maternal antibodies are transferred to the fetus through the placenta or through breast milk(14, 15).

**Artificially acquired passive immunity**

Artificially acquired passive immunity is a short-term immunization induced by the transfer of antibodies, which can be administered in several forms; as human or animal Plasma or serum or pooled human immunoglobulin (16).

**Active versus Passive Immunity**

Some differentiating points between active and passive immunity are given in Table -2.

Host defenses

There are two different types of Host defenses that the body exhibits as a result of exposure to antigen. They are:

(a) The humoral immune response involves the activation and clonal selection of B cells, resulting in the production of antibodies.

(b) The cell-mediated immune response involves the activation and clonal selection of cytotoxic T cells.

Humoral immunity is active when the organism generates its own antibodies, and passive when antibodies are transferred between individuals. Similarly, cell mediated immunity is active when the organisms' own T-cells are stimulated and passive when T cells come from another organism (17).

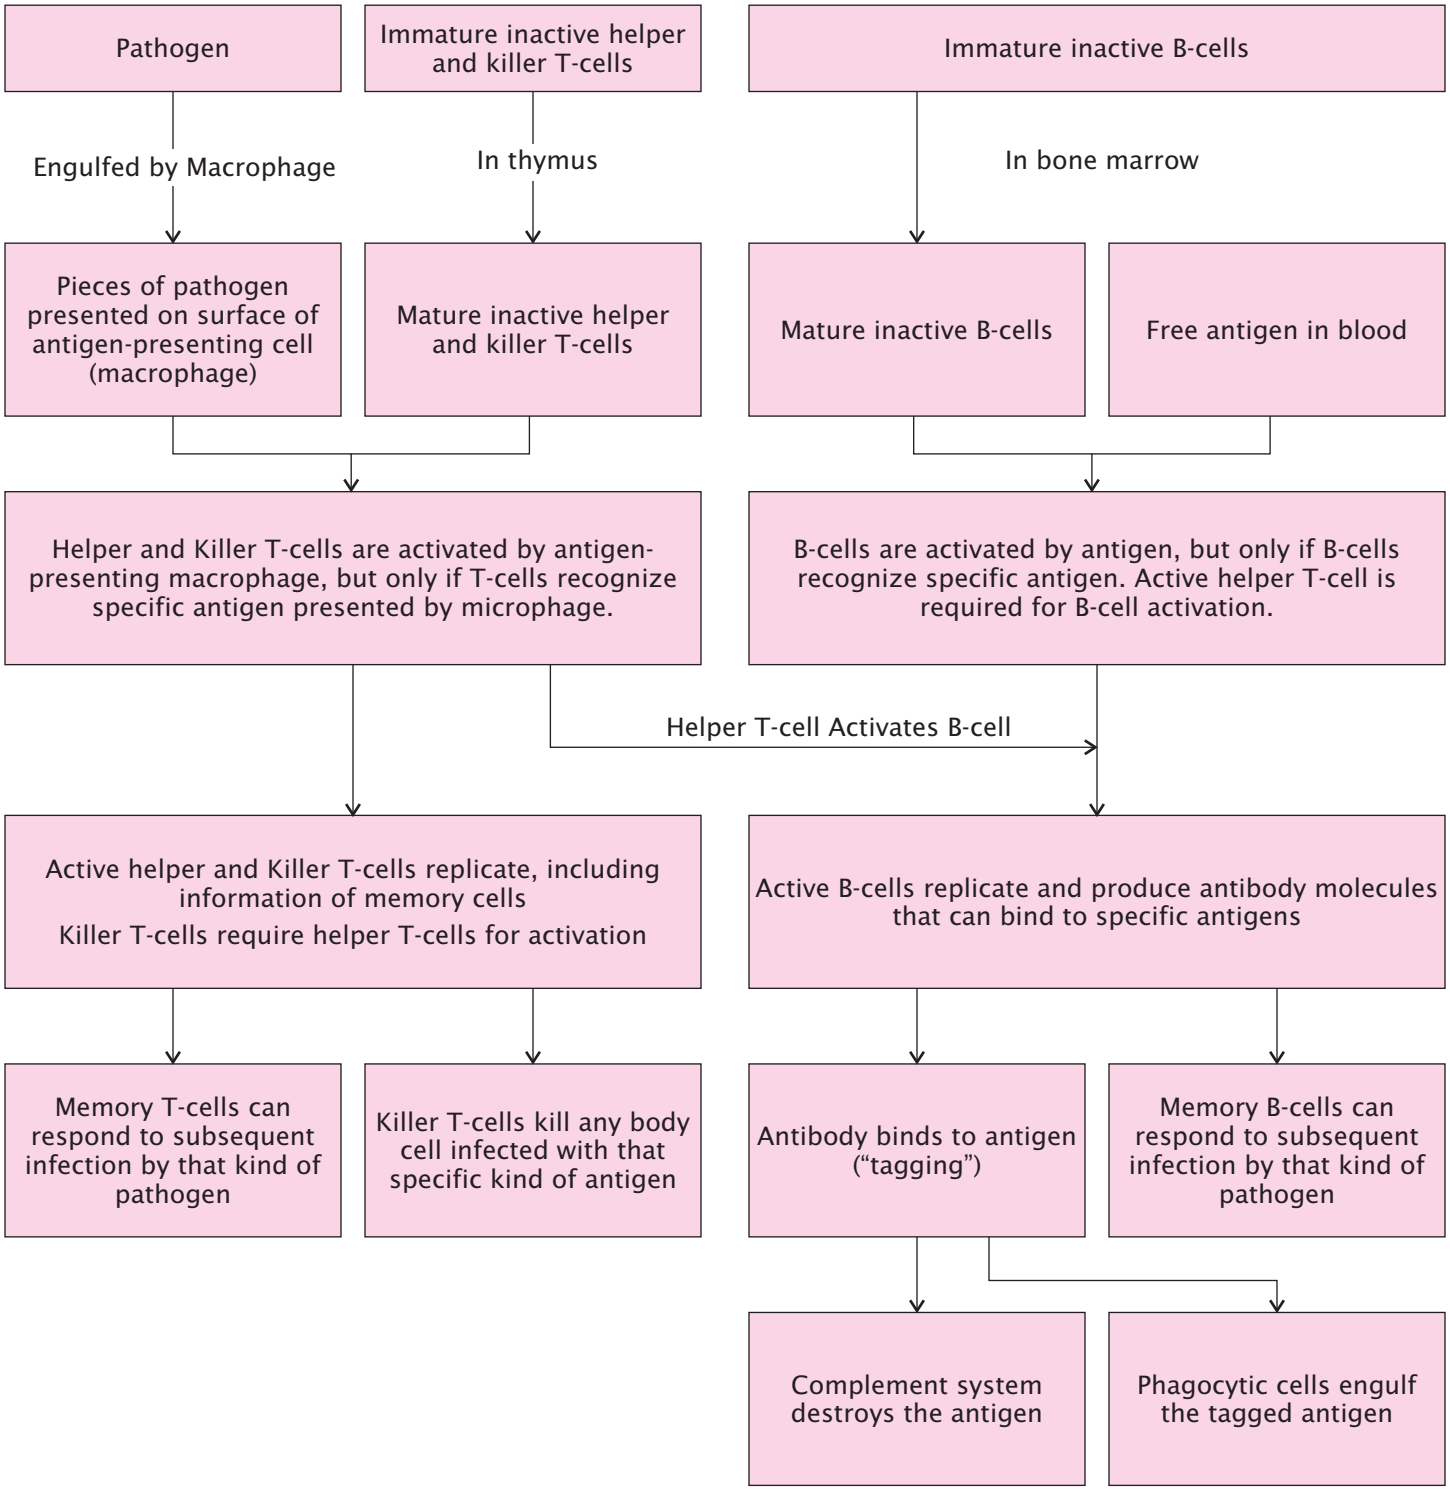
**Humoral immunity**

An immunocompetent but as yet immature B-lymphocyte is stimulated to maturity when an antigen binds to its surface receptors and there is a T helper cell nearby (to release a cytokine). This sensitizes or primes the B cell and it undergoes clonal selection, which means it reproduces asexually by mitosis. Most of the family of clones become plasma cells. These cells, after an initial lag, produce highly specific antibodies at a rate of as many as 2000 molecules per second for four to five days. The other B cells become long-lived memory(18).

**Cell-mediated immunity**

Macrophages engulf antigens and process them internally. This sensitizes the T cells to recognize these antigens. T cells are primed in the thymus, where they undergo two selection processes. The first positive selection process weeds out only those T cells with the correct set of receptors that can recognize the MHC molecules responsible for self-recognition. Then a negative selection process begins whereby T cells that can recognize MHC molecules complexed with foreign peptides are allowed to pass out of the thymus. Cytotoxic or killer T cells (CD8+) do their work by releasing lymphotoxins, which cause cell lysis. Helper T cells (CD4+) serve as managers, directing the immune response. They secrete chemicals called lymphokines that stimulate cytotoxic T cells and B cells to grow and divide, attract neutrophils, and enhance the ability of macrophages to engulf and destroy microbes. The process by which T cells and B cells interact with antigens is summarized in the diagram (Fig - 1)

Fig - 1



Pathogen
Immature inactive helper and killer T-cells
Immature inactive B-cells
Engulfed by Macrophage
In thymus
In bone marrow
Pieces of pathogen presented on surface of antigen-presenting cell (macrophage)
Mature inactive helper and killer T-cells
Mature inactive B-cells
Free antigen in blood
Helper and Killer T-cells are activated by antigen-presenting macrophage, but only if T-cells recognize specific antigen presented by microphage.
B-cells are activated by antigen, but only if B-cells recognize specific antigen. Active helper T-cell is required for B-cell activation.
Helper T-cell Activates B-cell
Active helper and Killer T-cells replicate, including information of memory cells
Killer T-cells require helper T-cells for activation
Active B-cells replicate and produce antibody molecules that can bind to specific antigens
Memory T-cells can respond to subsequent infection by that kind of pathogen
Killer T-cells kill any body cell infected with that specific kind of antigen
Antibody binds to antigen ("tagging")
Memory B-cells can respond to subsequent infection by that kind of pathogen
Complement system destroys the antigen
Phagocytic cells engulf the tagged antigen

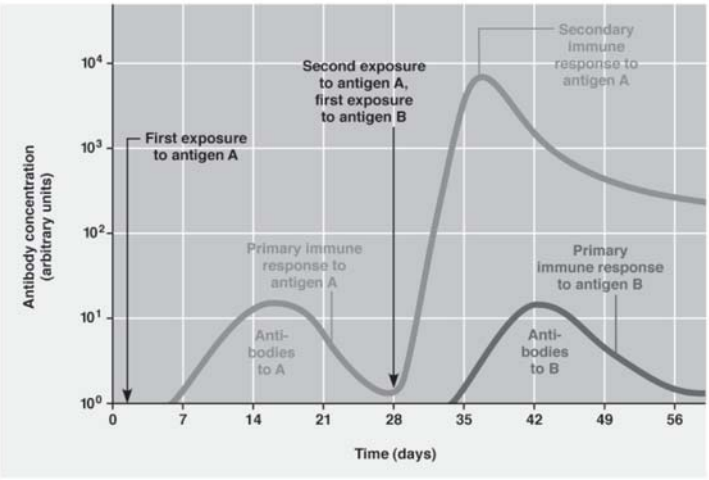
Local Immunity

The cells of the tissue attacked are as much concerned in offering resistance to the infecting agent as the antibodies or phagocytes; this is the local immunity. Besredka, who first evolved the primary importance of local immunity in prophylaxis against diseases, suggested that if the particular tissues attacked by a particular infective agent (e. g. in typhoid and dysentery the intestines and in anthrax the skin) are previously unsusceptible, the person would behave as if completely immune. Local immunity is believed to be produced by fixation of various specific humoral antibodies in tissues, cells; or it may be nonspecific response of local tissues, induced by a local application of antigen, against a subsequent infection threatening systemic disease. This principle is now employed for producing immunity against poliomyelitis by giving Sabin's oral poliomyelitis vaccine.

Herd Immunity

Herd Immunity is the immunity of a group of people or a community taken as a whole. In the epidemiology of infectious diseases, consideration of herd immunity is of greater importance than that of individual immunity. Epidemics disappear from a community long before 100 per cent of its members become immune, either naturally through epidemics or artificially through mass immunization. Epidemiological immunity is usually established even when, say only 80 to 85 % people in the community become immune. The other 20 % people enjoy freedom from infection by virtue of their belonging to the 'herd'. Herd immunity can also develop through the process of natural selection by weeding out of the susceptible successive generations due to death from disease. The level of herd immunity at a given time depends on the herd structure which is constantly changing. Influx of susceptible people and occurrence of new births lower the herd immunity. The herd structure includes the hosts (population) belonging to the herd species, and also the presence and distribution of alternative animal hosts and possible insect vectors as well as those environmental and social factors that favour or inhibit the spread of infection from host to host. The herd structure plays a decisive role in the immunity status of the herd (19) .

Fig - 2 : Immune response



**Types of Immune Response**

The first encounter with an antigen is known as the primary response. Re-encounter with the same antigen causes a secondary response that is more rapid and powerful (20) .

**Immune responses depends on**

(a) Nature and dose of antigen
(b) Route of administration
(c) Type of adjuvants used
(d) Nutritional status of the recipient

## Immunisation

Immunisation is the process by which an individual is exposed to an agent that is designed to fortify his or her immune system against that agent. The material is known as an immunogen. Immunization is the same as inoculation and vaccination in that inoculation and vaccination use a viable infecting agent like immunization does.

**History of immunization**

While Dr. Jenner (1749-1823) has been recognized as the first doctor to give sophisticated immunization, it was British dairy farmer Benjamin Jestey who noticed that "milkmaids" did not become infected with small pox or displayed a milder form. Jestey took the pus from an infected cow's udder and inoculated his wife and children with cowpox, thereby making them immune to smallpox. By injecting a human with the cowpox virus (which was harmless to humans) , Jenner swiftly found that the immunized human was then also immune to smallpox. The process spread quickly, and the use of cowpox immunization has led to the eradication of smallpox in modern human society. After successful vaccination campaigns throughout the 19th and 20th centuries, the

Table - 3 : Milestones in vaccination

| | |
|---|---|
| 1798 | Smallpox |
| 1885 | Rabies |
| 1897 | Plague |
| 1923 | Diphtheria |
| 1926 | Pertussis |
| 1927 | Tuberculosis (BCG) |
| 1927 | Tetanus |
| 1935 | Yellow Fever |
| **After World War II** | |
| 1955 | Injectable Polio Vaccine (IPV) |
| 1962 | Oral Polio Vaccine (OPV) |
| 1964 | Measles |
| 1967 | Mumps |
| 1970 | Rubella |
| 1981 | Hepatitis B |

World Health Organization (WHO) certified the eradication of smallpox in 1979.

### Vaccines

These are immunobiological substances designed to produce specific protection against diseases by stimulating production of protective anti body or other immune mechanisms. A number of agents can be used to provide protection against diseases. This protection can be active where antibodies are produced by our own bodies in response to vaccines or passive where antibodies are received in ready made form of Immunoglobulins or Non Human Antisera

### Immune response to vaccination

The Vaccine mimics the infection with the respective pathogen, but without risk of the disease. The consequent immune response may be manifested through antibody (humoral immunity) or cell mediated immunity (CMI) , or both. If the antigen stimulates Th1 series of T helper lymphocytes, then stronger cytotoxic lymphocytic response is obtained; if Th2 series is stimulated, the ultimate expression of immunity is predominantly humoral. Carbohydrate antigens are T cell independent; hence they stimulate B cells directly without T helper cell modulation. The result is predominantly IgM response without IgG production or induction of immunological memory. BCG elicit CMI.

Maternal CMI is not transferred to the foetus. Therefore BCG can be given at birth. OPV is given by mouth; it establishes local infection in a proportion of children. Maternal antibody in the infant's circulation is a very weak inhibitory factor; hence OPV also can be given at birth. Hepatitis B surface antigen is an excellent immunogen, overcoming, to a large extent, the inhibiting effect of maternal antibody; hence that too can be given at birth. On the other hand, live Measles vaccine may be completely inhibited in the presence of detectable maternal antibody in the infant's circulation. Therefore Measles vaccine is given after a delay of 9 months from birth and MMR only after 12 months (8) .

The goal of all vaccines is to promote a primary immune reaction so that when the organism is again exposed to the antigen, a much stronger secondary immune response will be elicited. Any subsequent immune response to an antigen is called a secondary response and it has

(a) A shorter lag time,
(b) More rapid buildup,
(c) A higher overall level of response,
(d) A more specific or better "fit" to the invading antigen,
(e) Utilizes IgG instead of the large multipurpose antibody IgM.

### There are four types of traditional vaccines

(a) Live (attenuated)
(b) Inactivated (killed)
(c) Toxoids
(d) Subunit and recombinant

### Live Vaccines

Are prepared from live attenuated organisms. They are very potent immunizing agents because:

(a) Live organisms multiply in the host
(b) All major and minor antigenic components are present
(c) Target organs may be colonized
(d) May replace wild strains in the community

However, live vaccines also suffer from some drawbacks. Safety is an issue because mutation may take place resulting in disease. Live vaccines can not be used for immunodeficient patients and they can not be used during pregnancy.

Two important precautions have to be observed while using live vaccines. Two live vaccines are usually not used together. They are to be given at different sites or three weeks apart. The other important aspect that must be kept in mind is that live vaccines have exacting storage requirements.

Live vaccines have been developed for all kinds of organisms. Examples off live vaccines for different kinds of organisms include

Bacterial

(a) BCG
(b) Typhoid oral

Viral

(a) Measles, Mumps, Rubella
(b) Oral Polio
(c) Yellow fever, influenza

Rickettsial

(a) Epidemic typhus

### Inactivated (Killed) Vaccines

These are prepared from organisms killed by heat or chemicals.

Killed vaccines are very safe but less efficacious than live vaccines. They require multiple doses which may be administered as a series of primary doses followed by regular booster doses. The only absolute contraindication is hypersensitivity

Examples of inactivated vaccines of different kinds of organisms include

**Bacterial**

(a) Typhoid
(b) Pertusis
(c) Cholera

Viral

(a) Rabies
(b) Hepatitis B
(c) Japanese encephalitis

### Toxoids

These are produced from detoxicated toxins. The body produces antibodies against the toxin in response to

toxoids. They offer no protection against infection. Toxoids are very safe and highly effective

**Examples:** Diphtheria, Tetanus

**Passive Immunisation**

Passive immunization may be administered using human or animal products. Conventionally human products are called immunoglobulins and animal products are called anti sera. Animal products are cheaper but suffer from the disadvantage of greater chances of immediate or delayed hypersensitivity.

Human Immunoglobulins

Non specific or generalized protection is offered by normal immunoglobulins while protection against specific diseases is given by using hyperimmune immunoglobulins

**Normal immunoglobulins**

Normal immunoglobulins provide non specific immediate ready made protection for upto three weeks. No live vaccine should be given for 12 weeks following administration of immunoglobulins. They should be administered at least two weeks after a live vaccine

**Examples:** Measles, Hepatitis A

**Specific hyperimmune immunoglobulins**

Specific hyperimmune immunoglobulins are made from plasma of recently recovered patients. They are to be given immediately after exposure. Peak blood levels are usually achieved in two days. They have a half life of three to five weeks

**Examples:** HBIG, VZIG, Rabies, Tetanus

Animal Anti-sera or anti toxin

Animal anti-sera are generally equine in origin. Their biggest draw back is that they may cause anaphylactic reactions or serum sickness

**Examples:** Diphtheria, Tetanus, Rabies, Botulism, Gas gangrene, Snake Bite.

Table - 4 : Immunizing agents

## National Immunization Schedule

Any immunization schedule is drawn up keeping two important factors in mind. Firstly the vaccines need to be administered in doses and schedules which produce an adequate immunological response in the recipient. Secondly the schedule should be administratively the most convenient and one which is likely to be most acceptable to the target population.

The National Immunization schedule drawn up for India factors in both these aspects (21). Only a quarter of all deliveries in India take place in some kind of a health care facility. Therefore, most infants are not available at birth for immunization. The schedule aims at minimizing the number of visits required to be made by the mother and child. The schedule also aims at minimizing the number of injections required to be given keeping in mind the risks that each injections poses for the infants. The schedule also keeps the time gap between visits as easy to remember as possible so that illiterate women also do not

Table - 5 : National immunisation schedule

| | |
|---|---|
| **Infants** | |
| At Birth | BCG, OPV – 0 (Institutional delivery) |
| 6 weeks | BCG (If not given at birth) |
| | DPT – 1, OPV – 1 |
| 10 Weeks | DPT – 2, OPV – 2 |
| 14 Weeks | DPT – 3, OPV – 3 |
| 09 months | Measles |
| **Children** | |
| 16 – 24 mths | DPT and OPV |
| 5 – 6 yrs | DT* |
| 10 yrs | TT* |
| 16 yrs | TT * |
| (If there is no clear evidence of previous immunization two doses one month apart to be given) | |
| **Pregnant Women** | |
| Early pregnancy | TT – 1 |
| One month later | TT – 2 |
| (In case of clear evidence of primary immunization or two doses during previous pregnancy, only single dose to be given) | |

have any problem in following the schedule. At the same time care has been taken to ensure that the schedule does not compromise the immunological efficacy of the vaccines.

## Immunization in Armed Forces

Immunization of troops against the enteric group of fevers and tetanus has proved efficacious to reduce the incidence of this disease and prevent outbreak in units, though stationed amidst epidemic or endemic localities. All ranks and their families and civilian employees, including private servants are therefore immunized. Those who refuse or neglect to be immunised run a personal risk and endanger the health of the community as a whole. The immunization against quarantinable disease under the International Health Regulations, 1971 viz, yellow fever, is carried out in the designated centers. Immunizations specially offered for infants and children are DPT, DT, polio, measles and BCG.

Commanders are responsible for maintaining the immunization state of units under their command at 100 % level at all times against the diseases notified, provide facilities for carrying out immunization recommended, maintain a unit vaccination register, ensure that personnel proceeding on leave or temporary duty or permanent transfer to another unit are fully protected prior to their departure and will not fall due for immunization during transit or soon after arrival at their destination, and ensure that all the families in the unit/station are fully protected. All personnel whose families are residing in places where there are no military establishments should be advised to get themselves protected from civil health authorities. Medical Officers are responsible for maintaining facilities for carrying out immunization and administering the same to all individuals who present themselves. They are also required to keep necessary records in the personal book (AB-64) of the individuals immunised and render such returns as may be called for by higher authorities after checking the unit immunization state. Medical officers should periodically check the protection state of the units under their medical care and ensure 100 per cent protection level at all times.

### Immunization Records

A register in which the details of immunizations are recorded for all ranks of the units is maintained by every unit/sub-unit commander as shown in Table - 6. The date of administration of Typhoid and TT should be recorded immediately in ink. The column which shows the 'date next due' should always be filled in pencil. Three or four lines should be allotted to each individual in these registers. A similar register should be maintained for families of all ranks living in the station. The unit administrative officer should ensure that the registers are maintained up-to-date, checked on the first day of every month and a list of individuals who are due for immunization sent to the MI Room/RAP. Personnel should then be sent in batches once a week, usually on a Saturday before the actual date on which due with a nominal roll and their personal books (AB-64) and Health Record Card. Entries in respect of officers and JCOs should be made in the Health Record Card and unit copy of the medical history AFMSF-1. The medical officer should ensure that all immunization carried out are at the same time entered in AB-64/AFMSF-1 and Health Record Card, dated and signed and the MO's name is entered in block capitals below his signature. From this nominal roll, the unit immunization register is brought upto-date.

The immunization schedule recommended for families and children of the Armed Forces personnel is as under :

(a) Schedule of routine immunization for children will be as per Table-5

(b) Schedule of Immunization for Women.

Table - 6 : Register of vaccination and inoculation

| Personal No. | Rank/Rate | Name | Typhoid Inolculation | | Antitetanus (TT) | | Special Immunisatio, If any | |
|---|---|---|---|---|---|---|---|---|
| | | | Date done | Date next due ( in pencil | Date done | Date next due ( in pencil | Date done | Date next due ( in pencil |

(i) It is desirable that women are also immunised against Tetanus with Tetanus toxoid. The procedure to be followed is the same as that for service personnel.

(ii) For protection of the neonates against Tetanus, the pregnant women should be adequately protected with Tetanus toxoid. Booster dose should be given to the women every time she becomes pregnant. The last dose of Tetanus toxoid should be given at least eight weeks before the expected date of delivery.

(iii) In case of pregnant women not protected against Tetanus earlier, the following schedule of Tetanus toxoid will be followed :

16 - 20 weeks - 1st dose

20 - 24 weeks - 2nd dose

**Immunization against Typhoid**

A typhoid vaccine is used for the pre-exposure active immunization. The vaccine used in the Armed Forces is a heat killed and phenol-preserved vaccine containing 1000 million S typhi. Routine immunization of all categories of entrants to the Armed Forces is to be carried out as soon as they join their training centers by giving vaccine as mentioned in Table 7. Families of service personnel are immunised under the same schedule. The dose will be reduced for the elderly and physically weak persons.

Reactions due to this vaccination vary in intensity from individual to individual but an overwhelming majority do not suffer for more than 48 hours, most of them showing only malaise after 24 hours. The most commonly occurring manifestation of reactions are local pain, swelling and redness, fever up to 39ºC, headache and body ache. Very few persons, particularly those in whom the interval after the previous injection had been much longer than one year or those in indifferent health, suffer from a severe reaction, which can be ameliorated by 0. 5 g of aspirin. The immunization does not abort the disease if the person is already incubating the infection, but it will do him no harm and probably reduces the severity and cut short the course of clinical illness.

**Immunization Against Tetanus**

This is an obligatory immunization in the Armed Forces. Pre-exposure active immunization is carried out by tetanus toxoid (TT) . For post-exposure passive immunization antitetanus serum may be administered.

Active Immunization

Tetanus Toxoid (TT) is used in the Armed Forces for pre-exposure immunization against Tetanus. It confers long lasting, active immunity. All ranks are immunised as soon as they enter the Armed forces and subsequently reimmunised with the procedure described below. The RMO should scrutinize the records of all newly posted personnel for this requirement and always ensure that the Immunization State of the personnel under his medical care is at 100 percent level. On recruitment, Armed Forces personnel should be immunized as per Table 8. A high degree of immunity is conferred only when the third dose of toxoid is administered. Therefore, it should be considered as part of the basic course of immunization. A 'booster' dose of 0. 5 ml given every five years maintains the immunity at a high level. The booster dose should be annually repeated when a greater liability to injuries is expected e.g. when a greater risk of contamination of wounds is expected e.g. while working in proximity with animals in AT Coy or dairy farms. In the event of a wound or injury with high risk of tetanus in a person who is adequately immunized, a booster dose of 0. 5 ml of TT should be given provided the last dose was given more than a year back. Injections are given deep intramuscularly. Rarely individuals with a history of asthma or hay fever may develop an allergic reaction, otherwise in normal individuals there is no particular reaction. Children who have received the full course of

Table - 7 : Dosage of typhoid vaccine

| Category | Initial Vaccination | | Re-vaccination | |
|---|---|---|---|---|
| | First dose (ml) | Interval | Second dose (ml) | Booster dose (ml) |
| Adult males/ Women/ | 0.5 | 4-6 weeks | 0.5 | 0.5 after 3 years |
| Children above 10 years | | | | |
| Children below 10 years | 0.25 | 4-6 weeks | 0.25 | 0.25 after 3 years |

Table - 8 : Dosage of tetanus immunisation

| Categories | Initial vaccination | | | Revaccination |
|---|---|---|---|---|
| | Ist dose | 2nd dose after 4-6 weeks | 3rd dose after 6 -12 months | every 5 yrs |
| Adult male/female/ children above 10 yrs | 0.5ml | 0.5ml | 0.5ml | 0.5ml |

triple antigen should get 5 yearly booster doses of TT.

**Col n**

All es are sensitive to heat to some extent, but some are sensitive than others. The commonly used EPI vac may be ranked according to their sensitivity to hea llows:

**M itive**

OPV
Measles
DTP, Yellow Fever
BCG
Hib, DT
Td, TT, Hepatitis B

**Least Sensitive**

(Note however, that all freeze-dried vaccines become much more heat-sensitive after they have been reconstituted, and it is then even more important that they are not exposed to heat.

**Sensitivity to cold**

Some vaccines are also sensitive to being too cold. For these vaccines, freezing or exposure to temperatures below zero degrees centigrade (0°C) can also cause loss of potency, and again, the ine will become useless. For these vac it is therefore essential to protect them not from heat, but also from freezing. The vac sensitive to freezing (as well as to heat) are

**Mo sitive**

Hep B
Hib (Liquid)
DTP
DT
Td
TT

**Least Sensitive**

**Sensitivity to light**

Some vaccines are also very sensitive to strong light. For these vaccines, exposure to ultraviolet light will also cause loss of potency, so they must always be protected against sunlight or fluorescent (neon) light. BCG, measles, MR, MMR and rubella vaccines are sensitive to light (as well as to heat) . Normally, these vaccines are supplied in vials made from dark brown glass, which gives them some protection against light damage, but care must still be taken to keep them covered and protected from strong light at all times (22, 23) .

**Recommended storage temperatures for vaccines**

The recommended conditions for storing vaccines are shown in Fig - 3. This diagram indicates the maximum times and temperatures in each case. At the higher levels of the cold chain, i. e. , at national (central) , and regional or province level, OPV must be kept frozen between minus 15 and minus 25 degrees centigrade (-15°C to -25°C) . Freeze-dried vaccines (i.e., BCG, measles, MMR and yellow fever) may also be kept frozen at –15°C to –25°C if cold chain space permits, but this is neither essential nor recommended. At other levels of the cold chain, these vaccines should be stored between plus 2 and plus 8 degrees centigrade (+2°C and +8°C) . All other EPI vaccines should be stored at between +2°C and +8°C at all levels of the cold chain (24) .

If a vaccine is damaged by heat and loses some of its potency, this loss can never be restored, and the damage is permanent. Each time heat damage occurs, the loss of potency accumulates, and eventually, if the cold chain is not correctly maintained, all potency will be lost, and the vaccine becomes useless.

Where space permits, diluents supplied separately from the vaccine may safely be stored in the cold chain at between +2°C to +8°C<br>Note a. 6 months is the maximum recommended storage time at primary level. This includes the period required to obtain clearance from the National Regulatory Authority.</td></tr>
</table>

**Expiry date**

Even when stored at the correct temperature, vaccines do not retain their potency for ever, and all vaccines have an expiry date. This is the date by which the vaccine must be used, and will be printed on all vials and packets during

manufacture. The expiry date shown on each vaccine vial and on each packet assumes the vaccine has been properly stored and transported at all times, in accordance with the guidelines shown in the above Figure. If the vaccine has been damaged by heat or other causes however, its potency will be reduced even before the expiry date shown on the vial or packet is reached.

Only vaccine stocks which are fit for use should be kept in the vaccine cold chain. Any expired vials, heat damaged vials or vials with VVMs beyond the discard point should not be kept in the cold store, refrigerator or freezer, as they may be confused with good quality vaccines. If unusable vaccines need to be kept for a period before disposal, for example, until accounting or auditing procedures have been completed, such vials should be kept outside the cold chain, separated from all usable stocks and carefully labeled to avoid mistaken use (24) .

**Correct conditions for storing diluents for vaccines**

Diluents for vaccines are less sensitive to storage temperatures than the vaccines with which they are used, but may be kept in the cold chain between +2°C to +8°C if space permits. When vaccines are reconstituted, the diluent should be at same temperature as the vaccine, so sufficient diluent for daily needs should be kept in the cold chain at the point of vaccine use (health centre or vaccination post) . At other levels of the cold chain (central, provincial or district stores) it is not necessary to keep any diluent in the cold chain unless it is planned to use it for reconstituting vaccine within the next 24 hours. However, diluent vials must never be frozen. This will risk cracking the glass and allowing contamination of the contents, so diluent vials must never be kept in a freezer, or allowed to be in contact with any frozen surface (25) .

Freeze-dried vaccines and their diluents should always be distributed together in matching quantities. The vaccines must be kept in the cold chain between +2°C and +8°C at all times, or optionally, at –15°C to –25°C if cold chain space permits. For each distribution link, the cold chain will normally comprise cold boxes or vaccine carriers with ice packs. The diluents do not need to be kept in the cold chain unless they will be used for within the next 24 hours. However, diluents must travel with the vaccine at all times, and the diluent must always be of the correct type, and from the same manufacturer as the vaccine which it is accompanying. This is essential to ensure that the health worker always has equal numbers of vaccine vials and diluent vials for reconstituting them, and that he/she has the correct type of diluent for the vaccine being used.

Diluents may appear to be simple water, but in fact usually contain a variety of salts, chemicals and additives required to stabilize a specific vaccine after reconstitution. Each vaccine requires a specific diluent and therefore, diluents are not interchangeable. Therefore, diluent made for measles vaccine, for example, must not be used for reconstituting BCG, yellow fever or any other type of vaccine. Likewise, diluent made by one manufacturer for use with a certain vaccine cannot be used for reconstituting the same type of vaccine produced by another manufacturer. This means that diluent for measles vaccine made by company 'A' cannot be used for reconstituting measles vaccine made by company 'B'.

Some combination vaccines comprise a freeze-dried component (such as Hib) which is designed to be reconstituted by a liquid vaccine (such as DTP or DTP-HepB liquid vaccine) instead of a normal diluent. For such combination vaccines, it is again vital that ONLY vaccines manufactured and licensed for this purpose are combined. Note also that for combination vaccines where the diluent is itself a vaccine, ALL components must now be kept in the cold chain between +2°C and +8°C at all times. As for all other freeze dried vaccines, it is also essential that the 'diluent' travels with the vaccine at all times.

**Cold Chain**

Cold chain is a system of transporting and storing vaccines at recommended temperature from manufacturer to the point of use. All the vaccines can be stored at temperatures between +2 °C to +8°C. However for long term storage of OPV and Measles call be stored at sub zero temperatures in deep freezers. DPT, DT and TT should never be frozen. BCG and diluent ampoules should not be frozen, as ampoules are likely to crack. Diluents required for measles and BCG should be stored at +2 °C to +8 °C in the refrigerator.

**Cold Chain includes**

(a) Walk in cold rooms (WICs)
(b) Deep freezers
(c) Ice - lined refrigerators (ILRs)
(d) Refrigerators
(e) Cold box
(f) Vaccine carrier
(g) Day carrier
(h) Ice packs

Walk in cold rooms

These are used for the storage of large quantities of vaccines. They require constant electric supply. Vaccines can be stored up to 3 months. They serve a region of 4-5 districts.

Deep freezers and ILRs

These are provided at the district and CHC level and can store upto 1 month supply of vaccines. Capacity is 300/240 L. they can be used for storing OPV and measles. Ice packs are also prepared.

Small Deep Freezers and ILRs

These are provided at the PHC and can store upto 1 month supply of vaccines. Capacity is 140 L. They do not have a freezer compartment.

Refrigerators

While using a refrigerator for the purpose of keeping vaccines, certain Do's and Don'ts to be followed are given in Table - 9.

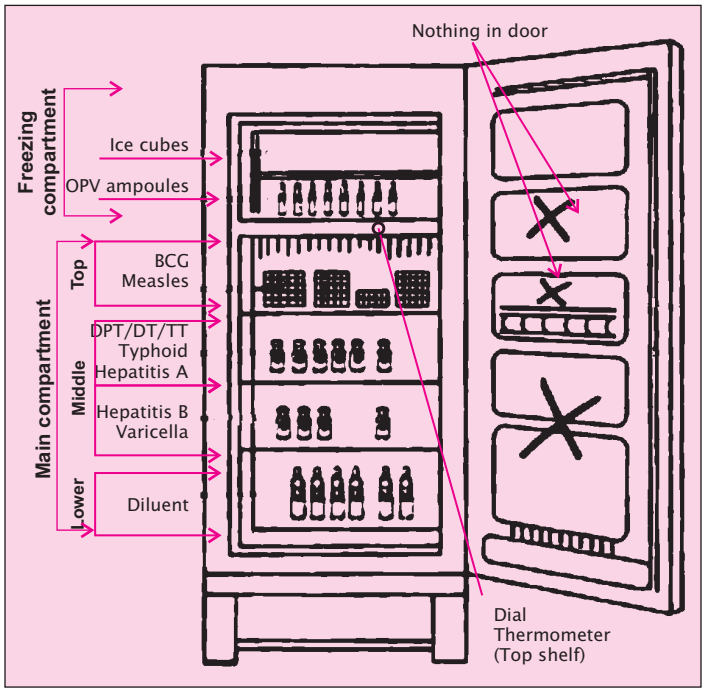
Vaccine Carriers

Used for transporting small quantity of vaccines to sub center. These are made of insulating material. Each carries

Table - 9

| Do's |
|---|
| Keep in cool room away from sunlight |
| At least 10 cm away from the wall |
| Keep ice pack in freezer |
| Defrost periodically |
| Check temp. and maintain record |
| **Dont's** |
| Open unless necessary |
| Keep vaccine in the door |
| Keep food inside |
| Keep more than one month's requirement |
| Keep expired vaccines |

Fig - 4 : Refrigerator showing vaccines stored correctly in clinic setup



four ice packs. The vaccines should be used on the same day. They should be kept away from direct sunlight.

Day Carriers

These are also made of insulating material and carry two ice packs. They can keep few vials for 6 to 8 hrs at a time.

Ice Packs

These are flat plastic water bottles filled with water. They are available in three capacities: 400ml, 500ml and 600ml. they are prepared by keeping in freezer. Water is filled upto the mark on the bottle. They should be kept frozen and ready for use. Cracked bottles should be discarded.

Quality of Cold Chain

The quality of the cold chain is monitored by the National Quality Control Lab. Located at Kasauli. The quality check is done before release of the vaccines. Reverse Cold Chain is also maintained to check vaccines for their potency.

### Vaccine stock management

**Vaccine stock management is done at three points**

(a) When vaccine consignments arrive at the storage point
(b) While vaccines and diluents remain in storage
(c) When vaccine and diluent stocks leave a storage point

When vaccine consignments arrive at the storage point

**The information to be recorded is**

(a) The type of vaccine
(b) The quantity received (in doses)
(c) The vaccine manufacturer
(d) The manufacturing batch or lot number (s) - (note there may be more than one batch or lot in a consignment)
(e) The expiry date (s) for each batch or lot
(f) The status of the Vaccine Vial Monitors (VVMs) on arrival of the consignment
(g) The status of the Cold Chain Monitor card (CCM) on arrival of the consignment

While vaccines and diluents remain in storage it is necessary to note the following details:

(a) All stocks must be distributed well before their expiry date
(b) Regularly check the expiry dates of the stock
(c) The principle of "earliest expiry first out (EEFO) " should be followed

When vaccine and diluent stocks leave a storage point, that is, at the time of distribution the information to be recoreded is:

(a) The quantity distributed (in doses)
(b) Batch numbers and expiry dates
(c) The destination for the consignment (i. e. , name of the region, province, district, etc)
(d) The balance remaining (in doses) of that batch or lot number after subtracting the amount distributed (26).

## UIP Vaccines

### BCG Vaccine

The BCG vaccine was first used to immunize humans in 1921. Following its introduction into the WHO Expanded Programme on Immunization in 1974, the vaccine soon reached global coverage rates exceeding 80% in countries endemic for TB. At present, about 100 million children receive BCG vaccine each year. Although the oldest of currently used vaccines, BCG is still controversial in that there are conflicting data on its protective efficacy. Most high-burden countries practice BCG vaccination of infants as part of the national childhood immunization

programme, but in industrialized countries, where the disease has become rare, vaccination of defined high-risk groups is increasingly becoming the preferred strategy(27).

A number of BCG vaccine strains are available, although the French Pasteur strain 1173 P2, the Danish strain 1331, the Glaxo strain 1077 and the Tokyo strain 172 account for about 90% of BCG vaccinations worldwide. In terms of efficacy, no BCG strain is demonstrably better than another, and there is no global consensus as to which strain of BCG is optimal for general use.

Administration of the vaccine

WHO recommends intradermal application of the vaccine, preferably on the deltoid region of the arm using special syringe as early as possible after birth. Newborn accines should receive half the dose given to older children. Within a few months of vaccination, the local reaction is replaced by a small scar. Presence of a typical scar is used as a marker of previous BCG vaccination but is not a marker of protection against TB. In the absence of a scar in children in endemic countries, BCG vaccination should be repeated.

Vaccine efficacy

Vaccine efficacy ranges from 0 to 80 percent. The Copenhagen vaccine strain showed 77% protection following vaccination of schoolchildren in England and 0% protection when used in the general population of southern India. BCG vaccine has protective effect against meningitis and disseminated TB in children Meta-analysis of 10 randomized and controlled studies showed that the average protection against TB meningitis and disseminated disease was 86%; the corresponding result of case-control studies was 75%(28,29,30)..

Duration of protection

The duration of protection after neonatal BCG vaccination is not well known but commonly believed to decline gradually to non-significant levels after 10-20 years. BCG vaccination does not prevent reactivation of latent TB, the main source of bacillary dissemination in the community. Hence, BCG vaccination has essentially no impact on TB transmission.

Adverse events

Complications following BCG vaccination are rare: Significant local reactions, such as extensive local ulceration and regional lymphadenitis occur in <1:1000 persons(31).

Indications and Contraindications as recommended by WHO

**Indications**

(a) For all infants living in areas where TB is highly endemic

(b) For infants and children at particular risk of TB exposure in otherwise low-endemic areas

(c) For persons exposed to multidrug-resistant MTB

**contraindications**

(a) For persons with impaired immunity (symptomatic HIV infection, known or suspected congenital immunodeficiency, leukaemia, lymphoma or generalized malignant disease);

(b) For patients under immunosupressive treatment (corticosteroids, alkylating agents, antimetabolites, radiation)

(c) In pregnancy.

New vaccines against TB

In recent years, there has been a dramatic increase in the number of candidate TB vaccines evaluated in research laboratories. Better understanding of the immunological deficits of BCG and impressive progress in knowledge of mycobacterial genomics have paved the way for promising new products. The main vaccine targets are prevention of infection in naive individuals, prevention of reactivation of latent infection and therapeutic vaccines to prevent relapses in TB patients. Currently, the most favoured research strategies include recombinant modified BCG vaccines, attenuated strains of MTB, subunit vaccines and DNA vaccines.

**Summary : BCG Vaccine**

- Attenuated M. tuberculosis var bovis developed in 1921.
- Protects against TB Meningitis, Miliary TB especially in Children
- Maternal antibodies do not interfere with BCG vaccine as CMI is not transferred transplacentally, hence should be given as early as possible after birth
- Vaccine efficacy ranges from 0 to 80 percent. Neonatal immunization induces long term protection
- Supplied freeze dried, store frozen or refrigerated
- Use reconstituted BCG within 4-6 hours
- Inject intradermally over left shoulder at the insertion of Deltoid.
- Local lesion due to bacterial multiplication; Heals leaving scars; If no scar, repeat BCG

**Polio Vaccine**

Poliomyelitis is an acute communicable disease caused by poliovirus types 1, 2 and 3, transmitted through person-to person contact. In the pre-vaccine era, virtually all children were exposed to poliovirus, and on average 1 out of 200 susceptible children infected by poliovirus developed paralytic poliomyelitis.

An effective IPV(Salk vaccine), comprising all three serotypes, was licensed after large-scale field trials in 1955. Extensive use of this vaccine decreased poliomyelitis incidence in many industrialized countries and interrupted wild poliovirus transmission. Starting in 1963, trivalent OPV (Sabin vaccine) replaced IPV as the primary means of prevention of poliomyelitis in most countries, because of the ease of administration, enhanced mucosal immunity providing a more effective barrier to transmission and community wide circulation of wild poliovirus, secondary spread of Sabin-derived

vaccine virus from vaccinees to close contacts thus immunizing some unvaccinated contacts and lower cost(32).

Oral Polio Vaccine

The oral polio vaccine is a suspension of over 1 million particles of polioviruses type 1, 2 and 3 together. It is supplied with a stabilizing agent, namely magnesium chloride. Therefore the potency is quite stable under refrigeration or freezing. The virus survives the acidity of the stomach and confers local immunity. However, for reasons not clearly understood, the 'take' rate is relatively low in our children. For the above reason, multiple doses of OPV are necessary before 90 – 95% of children develop immune responses to all 3 poliovirus types. In addition to the "Routine OPV doses", "Pulse OPV doses every year on National Immunization days (NID's) till the age of 5 years are also mandatory. The risks due to OPV comprise cases of vaccine-associated paralytic poliomyelitis (VAPP), outbreaks of circulating vaccine-derived polioviruses (cVDPVs) and long-term carriers of VDPVs identified among immunodeficient persons (iVDPVs)(33).

Eradication is defined as no case of paralytic poliomyelitis by wild polio virus in last 3 calendar years along with absence of wild polio virus in the community, where excellent clinical and virological surveillance exists and the coverage of routine OPV is more than 80%.

Polio elimination is defined as Zero cases of paralytic poliomyelitis by the wild polio virus in one calendar year with other criteria same as in eradication.

(a) Adequate immunization is the method of eradication

(b) Clinical surveillance is the method to identify AFP status

(c) Virological investigations are necessary to document confirmation of polio virus.

**Summary: Oral Polio Vaccine**

- Live attenuated Poliovirus types 1, 2 and 3 developed by SABIN, 1961
- Temperature sensitive, store frozen or refrigerated
- Can be given simultaneously with any other vaccine
- Multiple doses necessary to ensure vaccine virus take and antibody response to all 3 types of polioviruses
- First dose is recommended in the newborn period or as early as possible
- IAP recommends additional doses of OPV as a part of Pulse Polio programme every year till the age of 5 years.

**Summary: Injectable (Killed) Oral Polio Vaccine**

- Formaldehyde Killed Polio Virus grown in monkey kidney / human Diploid cell
- Contains 20, 8 and 32 D antigen units against type 1, 2 and 3 Polio Viruses respectively
- Seroconversion 90-95% after 2 doses and 99% after 3 doses
- Thermostable and is indicated in Immuniocompromised individuals, HIV infection and

Pulse Polio Immunization

On National Immunization Days (NID's), pulse doses of oral polio vaccine has to be administered, simultaneously to all susceptible infants and children, would produce immunity to all and prevent wild poliovirus to multiply in the gut.

Injectable Killed Polio Vaccine (IPV)

IPV is formaldehyde killed poliovirus grown in monkey kidney cell/human diploid cells containing 20, 8 & 32 D antigen against type 1, 2 and 3 poliovirus respectively. It is highly immunogenic. Seroconversion is 90-95%, after 2 doses and 99% after 3 doses. It produces excellent humoral immunity as well as local pharyngeal and possible intestinal immunity. The vaccine is very safe. However, it is not available at present in the Indian market for routine use and is licensed only for use in immunocompromised children.

**DPT Vaccine**

Diphtheria is a potentially acute disease caused by exotoxin producing Corynebacterium diphtheriae.

The combination of diphtheria toxoid, whole cell killed pertussis vaccine and tetanus toxoid is popularly known as the triple antigen. While the two toxoids are highly immunogenic and antibodies to them are almost completely protective, the pertussis vaccine, given in 3 doses, has a protective efficacy of about 70-80% only.

Administration of the vaccine

The DPT must be injected intramuscularly and the preferred site is the anterolateral aspect of the thigh. The immunization should begin by six weeks of life and completed before the ninth month at the latest, although it can be given at any period before 5 years of age. Initially three doses at monthly intervals are injected intramuscularly. Booster doses are given during the second year and just before the child starts going to school(34).

Adverse events and Contraindications

**Summary: DPT Vaccine**

- Diphtheria toxoid (Ramon & Glenny, 1923)
- Killed Bordetella pertussis (Madsen, 1923)
- Tetanus toxoid (Ramon & Zoeller, 1927)
- Toxoids adjuvanted (Aluminium hydroxide/phosphate)
- DPT vaccine supplied as liquid, store refrigerated
- Aluminium adjuvanted vaccines should not be frozen
- Inject intramuscularly, anterolateral thigh
- Alert parents about local reaction and fever; Paracetamol to be given to reduce pain/fever
- Progressive neurological disease or serious adverse reaction to earlier dose are contraindications for DPT; replace with DT Vaccine

Local pain and redness and fever after DPT are almost entirely due to the pertussis component. Convulsions following DPT vaccine are rare, and when occur, they may be the earliest signs of some incipient neurological disease in the infant. For these reasons, progressive neurological diseases are the only contraindication to first dose of DPT immunization. Severe adverse reactions in the form of anaphylaxis and encephalopathy occurring within 7 days to the earlier dose are contraindications for subsequent doses of DPT(35-39).

### Tetanus Toxoid

Indian Academy of pediatrics recommend TT at 10 and 16 years. After completing the full course of 7 doses, there is no need for additional doses during pregnancy, at least for the next 10 years. Thereafter a single booster would be sufficient to extend immunity for another 10 years. For pregnant women who have not had previous immunization, at least 2 doses should be given during pregnancy so that protective antibody would be transferred to the infant in order to prevent neonatal tetanus. Td is the preferred preparation for active tetanus immunization in wound management of patients greater than or equal to 7 years of age. Because a large proportion of adults are susceptible, this plan enhances diphtheria protection. For inadequately vaccinated patients of all ages, complete primary vaccination should be ensured

### Tetanus Immunoglobulin (TIG)

It is a liquid or freeze-dried preparation containing immunoglobulins, mainly IgG obtained from plasma or serum containing specific antibodies against the toxin of Clostridium tetani.

#### Indications

Burns, injuries, open and compound fractures. Unimmunised or inadequately immunised mothers.

#### Contraindications

Subjects already sensitized with serums of animal origin, existence of prior or present allergic manifestations (asthma, eczema, etc).

#### Adverse Effects

Local pain, fever, flushing, headache and chills may occur.

#### Dosage

Prophylaxis 250 – 500 I.U. Intramuscular.

Therapeutic : Tetanus neonatorum 500 – 1000 I.U. intramuscular or 250 I.U. intrathecal.

In adults and children 500 – 1000 I.U. intramuscular and / or 250 – 500 I.U. intrathecally.

### Measles Vaccine

Measles is an extremely contagious viral disease that, before the widespread use of measles vaccine, affected almost every child in the world. High-risk groups for measles complications include infants and persons suffering from chronic diseases and impaired immunity, or from severe malnutrition, including vitamin A deficiency.

The Measles vaccine consists of live attenuated Measles virus, developed by Enders, in 1960. The original virus strain was isolated from a child by the name Edmonston; therefore the virus strain was also named Edmonston. In liquid suspension the vaccine virus is very heat-labile; in the freeze-dried state the shelf life of the vaccine is one to two years. The vaccine may be stored frozen or refrigerated. But, after reconstitution, the vaccine should be injected within 4-6 hours. During such interval the liquid vaccine should be kept cold, either in the refrigerator or vaccine carrier.

#### Administration of the vaccine

The vaccine should be injected subcutaneously. The preferred site is right upper arm; this is only for uniformity. It can also be injected over the anterolateral thigh, but subcutaneously. The vaccine induces both humoral and cellular immune responses comparable to those following natural infection.

#### Vaccination schedule and vaccine efficacy

The optimum age for measles vaccination depends on the local epidemiological situation and on programmatic considerations. Given the immaturity of the immune system as well as the presence of neutralizing maternal antibodies, vaccination of infants before or at 6 months of age may often fail to induce immunity. In most developing countries, children are vaccinated against measles at 9 months of age, when seroconversion rates of 80–85% may be expected. In case of an outbreak (or impending outbreak) infants completed 180 days (6 months) may be given the vaccine, provided such infants (given vaccine below 9 months) are revaccinated after at least 3 months of interval. A single dose of live, attenuated measles vaccine is generally felt to provide lifelong protection(40,41).

#### Adverse reactions

Adverse reactions following measles vaccination, alone or in fixed combinations, are generally mild and transient. Slight pain and tenderness at the site of injection may occur within 24 hours, sometimes followed by mild fever and local Lymphadenopathy. Thrombocytopenia purpura occurs in approximately 1 in 30 000 vaccinated

**Summary: Measles Vaccine**

- Live attenuated Measles virus vaccine developed by Enders, 1960
- Vaccine further attenuated (Eg. Schwarz, Edmonston-Zagreb)
- MV supplied freeze dried, Store frozen or refrigerated
- Use reconstituted vaccine within 4-6 hours (Refrigerate, do not freeze)
- Inject subcutaneously, preferably right upper arm
- Recommended age 9 months (270 days ) plus
- During Measles outbreak, may be given at 6 months Plus
- If given at < 9 months, repeat dose after interval of at least 3 months
- Alert parents of fever 5-10 days later; Paracetamol may be given

individuals

## NON UIP VACCINES

### Mumps Vaccine

Mumps (or parotitis epidemica) is a viral infection primarily affecting the salivary glands mostly causing a mild childhood disease but it may also affect adults, among whom complications such as meningitis and orchitis are relatively common.

Mumps Vaccine can be prevented by vaccination given either as a monovalent vaccine or as part of MMR vaccine. A live attenuated monovalent Mumps vaccine was first developed by Hilleman in 1966. The mumps component in MMR vaccine contains live attenuated Mumps virus. Mumps vaccines are recommended for use in a 1-dose schedule, given at age 12-18 months(42)

Adverse reactions

In general, adverse reactions to mumps vaccination are rare and mild. The most common adverse reactions following mumps vaccination are parotitis and low-grade fever.

### Rubella Vaccine

Rubella occurs worldwide and is normally a mild childhood disease. However, infection during early pregnancy may cause fetal death or congenital rubella syndrome characterized by multiple defects, particularly to the brain, heart, eyes and ears(43,44).

A live attenuated Rubella vaccine was developed by Waller in 1962. The current rubella vaccine available commercially is derived from RA 27/3 vaccine strain grown in human diploid cell cultures. It is available either as a monovalent vaccine or as a part of combination vaccine – MMR. It contains live attenuated virus not less than 1000 TCID50. It is a highly immunogenic vaccine with positive antibody response in 95% of susceptible vaccinees. It provides long term and probably life long protection(45,46).

The primary purpose of rubella vaccination is to prevent the occurrence of congenital rubella infection including CRS. Two approaches are recommended by WHO:

(a) Prevention of CRS only, through immunization of adolescent girls and/or women of childbearing age

(b) Elimination of rubella as well as CRS through universal vaccination of infants and young children (with/ without mass campaigns), surveillance, and assuring immunity in women of childbearing age.

### MMR Vaccine

MMR Vaccine is available as single as well as multidose (5 dose) vial. The diluent for injection is available separately. The dose of the reconstituted vaccine is 0.5 ml per dose, to be administered subcutaneously in the upper arm. The vaccine should be stored between +2 to +8°C in the ordinary compartment of the fridge. Reconstituted vaccine should be used within 6 hours.

IAP recommends a dose of MMR vaccine to all children. For infants given Measles vaccine at 9 months, MMR vaccine may be given between 12-15 months of age. If Measles vaccine is given later, a 3 months gap is advisable. If Measles vaccine was missed altogether, one MMR dose should be given at or after 12 months. The vaccine can be given along with any other vaccine like DPT, OPV but at different sites using different syringes and needles(47).

### Hepatitis B Vaccine

The main objective of hepatitis B immunization strategies is to prevent chronic hepatitis B virus (HBV) infection and its serious consequences, including liver cirrhosis and hepatocellular cancer (HCC) (49).. Routine vaccination of all infants against HBV infection should become an integral part of national immunization schedules worldwide

In India, 3-7% of individuals, from school age upwards, are found to be chronic carriers of Hepatitis B Virus (HBV). The younger the age of infection, the higher the chance of becoming chronically infected as carrier. The World Health Organization recommends universal Hepatitis B Vaccination.

Administration of the vaccine

Two types of hepatitis B vaccines are available: plasma derived vaccines and recombinant vaccines. The two vaccines show no differences in terms of reactogenicity, efficacy or duration of protection. The complete vaccine series induces protective antibody levels in >95% of infants, children and young adults.

Hepatitis B vaccine should be given IM at antero-lateral thigh in infants. In older children/adults it should be administered at deltoid region. The minimum recommended interval between the doses is four weeks. Longer dose intervals may increase the final anti-HBs titres but not the seroconversion rates(49).

Using the principles described, the IAP recommends the commencement of HB immunization at birth. Two alternate schedules are available:-

(a) Infants
  (i) Birth, 6 and 14 weeks
  (ii) 6, 10 and 14 weeks. (Combined DTPw/Hepatitis B vaccine can be preferred)

(b) For older children, adolescents and adults the recommended schedule is elected date, 1 month and 6 months Booster dose is not recommended as of date.

As an adjuvanated vaccine, it should not be frozen. If frozen accidentally, the vaccine should be discarded.

Adverse Events

In placebo-controlled studies, with the exception of local pain, reported events such as myalgia and transient fever have not been more frequent than in the placebo group. Reports of severe anaphylactic reactions are also very rare.

Contraindications and Precautions

Hepatitis B vaccination is contraindicated for persons with a history of hypersensitivity to yeast or to any vaccine component. Pregnancy is not a contraindication to vaccination. Limited data indicate no apparent risk for adverse events to developing fetuses when hepatitis B vaccine is administered to pregnant women (50).

Passive immunization against hepatitis B

Temporary immunity may be obtained using hepatitis B immune globulin (HBIG) for post-exposure prophylaxis.

HBIG prophylaxis may be indicated

(a) For newborn infants whose mothers are HBsAg-positive

(b) Following percutaneous or mucous membrane exposure to HBsAg-positive blood or body fluids

(c) Following sexual exposure to an HBsAg-positive person

(d) To protect patients from recurrent HBV infection following liver transplantation.

HBIG does not interfere with generation of antibody response to hepatitis B vaccine. As a rule, HBIG should be used as an adjunct to hepatitis B vaccine. However, in full-term newborns, the protection against perinatally acquired infection achieved by immediate (<24 hours) hepatitis B vaccination is not significantly improved by the addition of HBIG.

**Summary HB Vaccine - *Development of Vaccines***

- Safe, immunogenic, effective HB vaccine available since 1982
- Highly purified preparation of HBsAg
- HBsAg is a glycoprotein that makes up outer envelope of HBV
- Two type of vaccine : plasma derived and Recombinant DNA
- To be shipped and stored at 2° C - 8° C
- IM Injection at deltoid in adult, adolescent and children and anterolateral thigh in neonates and infants upto 2 years
- Immunogenicity is > 95% in a variety of vaccination schedules
- No booster dose recommended

**Dosage:** Following exposure to HBsAg.

**Adults:** 1000 – 2000 I.U., I.M.

**Children:** 32-48 I.U.,/kg body wt. This should be administered within 7 days (preferably within 48 hrs) after exposure to HBsAg.

**Neonates:** Initial dose is 100 – 200 I.U. The first dose should be administered within 5 days after birth. The booster dose should be 32 – 48 I.U./kg of body wt., between 2 & 3 months after initial dose.

### Typhoid Vaccine

Typhoid fever is a serious systemic infection caused by the enteric pathogen Salmonella typhi. The infection is spread by the faecal-oral route and closely associated with poor food hygiene and inadequate sanitation. Typhoid fever is widely prevalent in India and three different types of vaccines are available. The choice of vaccine depends upon the age of commencement of the vaccine and the availability.

The Whole Cell Typhoid Vaccine

The heat-killed, phenol-preserved, and the acetone killed lyophilized whole cell Salmonella typhi vaccine was developed one century ago. This typhoid vaccine is extremely safe from serious reactions and is reasonably effective .

Primary course include 2 doses, 4 or more weeks apart and a single booster dose is recommended every 3 years. In field trials the vaccine has been associated with fever and systemic reactions in 9%-34% of the recipients, and with short absences from work or school in 2%-17% of cases This vaccine is extremely cheap and well suited for giving to children of families who cannot afford more expensive vaccines(51).

The Vi Polysaccharide Vaccine:

The Vi polysaccharide, purified and adjuvanted is another satisfactory typhoid vaccine with reasonable efficacy & low reactogenicity. As polysaccharide antigens are T cell independent, this vaccine is

(a) Non-immunogenic below 2 years of age

(b) Induces IgM response without IgG response

(c) Not able to induce immunological memory; hence not able to induce booster effect.

When a dose is repeated 3-5 years later, it induces response similar to the first dose. Adverse reactions seem limited to fever (0%-1%), headache (1.5%-3%) and erythema or induration >1 cm at the site of injection (7%)(52).

Oral Ty21a Vaccine:

This is a live attenuated strain of S. typhi Ty21a that was developed in the early 1970s by chemical mutagenesis. This live attenuated strain of S.typhi, namely Ty21a, is genetically stable, and does not revert to virulence. Indeed it does not induce a true "infection" as only very limited multiplication occurs in the gastrointestinal tract after oral feeding. It is not excreted in large numbers and is non-transmissible under natural conditions. Very large number of bacteria are necessary as oral doses in order to achieve sufficient degree of local immunity, which is the main basis of protection afforded by this vaccine. The bacteria are acid-labile. Hence the stomach acidity has to be either neutralised or bypassed when Ty21a is fed orally. The vaccine is administrated orally as enteric coated capsules and is registered for use from 6 years of age. The vaccine is to be given in three sittings, on alternate days. The protective efficacy is as good as other available typhoid vaccines. Immunization needs to be repeated every 3-5 years(53,54).

### Hib Conjugate Vaccine

Haemophilus influenzae type b (Hib) is estimated to cause at least 3 million cases of serious disease every year and 3,86,000 deaths. Although cases occur worldwide, the

**Summary: Typhoid Vaccine**

**1. Whole Cell**

- Killed S. typhi, often with S. paratyphi A (TA)
- Developed by Wright, 1896
- Liquid, store refrigerated, inject subcutaneously
- Primary course: 2 doses 4 weeks
- Boosters: Once in 3-5 years
- Dose: 0.5 ml SC

**2. Vi polysaccharide**

- Vi polysaccharide, developed by Robbins, 1984
- Liquid, adjuvanted, store refrigerated
- Inject IM; give at or after 2 years of age
- Dose 0.5 ml
- To be repeated 3 years later

**3. Oral**

- Live attenuated S.typhi, developed by Germanier, 1975
- Strain name: Ty 21 a
- Enteric coated capsules: store refrigerated administrative orally on alternate days, 3 doses
- To be repeated 3-5 years later

burden of Hib disease is most significant in developing countries.

Haemophilus influenzae type b vaccine is a very effective and safe vaccine. Both PRP-T and PRP - CRM 197 conjugate Hib vaccine are now available in India. All Hib-containing vaccines should be stored at between +2 ˚C and +8 ˚C. Liquid Hib vaccine should never be frozen (55).

Vaccine Administration

As Hib disease is age dependant and Hib immunization

**Summary: HIB Vaccine**

- H. influenzae b capsular polysaccharide
- Conjugated to protein antigens to improve immunogenicity
- Monovalent or DPT / Hib conjugate
- 3 doses 1-2 months apart
- Booster at 15-18 months
- Beyond 18 month a single dose up to 5 years

involves boosting of natural immunity, 3 doses when initiated below 6 months, 2 doses between 6 to 12 months and 1 dose between 12 to 15 months should be given. A booster is recommended at 15 to 18 months. Beyond 18 month a single dose is recommended upto 5 years of age and above 5 years Hib vaccination is not recommended (56,57).

Hib vaccine has not been associated with any serious adverse effects. However, redness, swelling and pain at the site of injection may occur in as many as 25% of those who have been vaccinated(58).

### Japanese B Encephalitis Vaccine

Japanese encephalitis (JE) is the most important form of viral encephalitis in Asia. It is estimated that the JE virus causes at least 50 000 cases of clinical disease each year, mostly among children aged <10 years, resulting in about 10 000 deaths and 15 000 cases of long-term, neuro-psychiatric sequelae.

Currently, the three types of JE vaccines in large scale use are (59)

(a) The mouse brain-derived, purified and inactivated vaccine, which is based on either the Nakayama or Beijing strains of the JE virus and produced in several Asian countries

(b) The cell culture-derived, inactivated JE vaccine based on the Beijing P-3 strain

(c) The cell culture-derived, live attenuated vaccine based on the SA 14-14-2 strain of the JE virus.

Both the mouse-brain derived and the cell culture-based vaccines are considered efficacious and to have an acceptable safety profile for use in children. However, with the mouse-brain derived vaccine, rare cases of potentially fatal acute disseminated encephalomyelitis and hypersensitivity reactions have been reported among vaccinated children in endemic regions and in travellers from non endemic locations(60-62).

Many Asian countries have adopted a schedule of 2 primary doses preferably 4 weeks apart, followed by a booster after 1 year. In some countries, subsequent boosters are recommended, usually at about 3-year intervals up to the age of 10–15 years(59).

This vaccine is based on the genetically stable, neuro attenuated SA 14-14-2 strain of the JE virus, which elicits broad immunity against heterologous JE viruses. Case control studies and numerous large-scale field trials in China have consistently shown an efficacy of at least 95% following 2 doses administered at an interval of 1 year(63).

The Indian strain of the Japanese B Encephalitis vaccine produced by Central Research Insititute, Kasauli, Shimla, is available through central and state health authorities for use in endemic areas during epidemic situation in the specific regions of the country where the infection is prevalent.

### Meningococcal Vaccine

Meningococcal meningitis and septicaemia are caused by various sero groups of Neisseria meningitidis. Endemic disease occurs worldwide and is mostly caused by meningococci of serogroups A, B, or C. The group A meningococcus is the predominant cause of large epidemics.

Vaccines are available against four serogroups of meningococci A, C, W-135 and Y. No effective serogroup B vaccine is presently available. The vaccines are either

monovalent i.e. A, C, etc. or polyvalent i.e. A-C, A-C-Y, A-C-Y-W135, etc. The efficacy rate of a single dose of serogroup A or serogroup C vaccine is 90% in adults and children over 2 years of age. The four polysaccharide antigens ( A, C, Y and W135 ) have been combined into a tetravalent vaccine. It is available in single-dose and multi-dose vials distributed as lyophilized powder that contains 50 micrograms of each component per dose. The vaccine should be stored at -20oC(64,65).

Dosage and Route of Administration

For both adults and children, vaccine when reconstituted is administered subcutaneously as a 0.5 ml dose. Protective levels of antibody can be expected after 7-10 days.

Indications (64)

(a) Routine immunisation of recruits may be considered. This practice has eliminated nearly all diseases among military personnel in the United States(66).

(b) In household contacts, as an adjunct to chemoprophylaxis.

(c) Routine immunization for asplenic people and those with previously described immunodeficiencies.

(d) Vaccination is recommended for outbreak control for disease caused by any of the serotypes carried by the vaccine.

(e) Travellers to hyperendemic or endemic areas .

Precautions and Contra-indications

Adverse reactions are mild and consist of pain and tenderness at the site of injection for 1-2 days. Mild to moderate local reactions range from infrequent to more than 40%, among vaccine recipients(67,68). No adverse effects have been documented among women vaccinated during pregnancy or their newborns. There are no known contraindications. The vaccine is not recommended for use in children under 2 years of age(69,70).

Revaccination

The need for revaccination of older children and adults has not been determined, antibody levels decline rapidly over 2 to 3 years and if indications still exist for immunisation, revaccination may be considered within 3 to 5 years (71).

Varicella Vaccine

**Summary: Varicella Vaccine**

- Developed by Takahashi in 1971 in Japan
- Live attenuated Oka Strain
- Vaccine available as Lyophilized powder
- Dissolve in 0.5 ml diluent
- SC Injection
- Single dose 12 months – 12 years
- Two doses beyond 13 years; 1 month apart
- Efficacy 95- 99%
- No booster dose recommended

Varicella (chickenpox) is an acute, highly contagious viral disease with worldwide distribution. While mostly a mild disorder in childhood, varicella tends to be more severe in adults. It may be fatal, especially in neonates and in immunocompromised persons.

Takahashi et al developed the live attenuated vaccine from Oka strain in Japan.. The recommended dose is 0.5 ml which provides at least 1350 plaque forming units of the virus. The vaccine is administered subcutaneously in the upper arm/thigh region. The vaccine is recommended after the age of 1 year. Upto the age of 12 years, one dose is required and if given after 12 years, 2 doses are needed at an interval of 1 month. Both humoral and cell mediated immunity develops in more than 95% cases after a single dose between 1-12 years and 99% after 2 doses in children 13 years and above(72-74).

**Hepatitis A Vaccine**

Hepatitis A is a relatively benign infection in children. About 85% of HAV infection in children 1-2 years old, 50% between 3-5 years and 20% above the age of 5 years.

Several inactivated or live attenuated vaccines against hepatitis A have been developed, but only 4 inactivated hepatitis A vaccines are currently available internationally. All 4 vaccines are similar in terms of efficacy and side-effect profile. The vaccines are given parenterally, as a 2-dose series, 6-18 months apart. The dose of vaccine, vaccination schedule, ages for which the vaccine is licensed, and whether there is a paediatric and adult formulation varies from manufacturer to manufacturer. No vaccine is licensed for children aged < 1 year(75,76).

**Summary: Hepatitis A Vaccine**

- Inactivated vaccine containing HM 175 strain grown in MRC5 cell line
- 2-dose series, 6-18 months apart.
- Efficacy – 94-100%
- No booster dose

The vaccine efficacy is 94-100% and the duration of protection is long lasting, hence no booster dose is recommended at present. The current vaccines are well tolerated and no serious adverse events have been statistically linked to their use. Contraindications to hepatitis A vaccination include a known allergy to any of the vaccine components(77).

**Pneumococcal Vaccine**

Diseases caused by Streptococcus pneumoniae (the pneumococcus) are a major public health problem worldwide. Serious pneumococcal infections include pneumonia, meningitis and febrile bacteraemia; otitis media, sinusitis and bronchitis are more common but less serious manifestations.

Two types of vaccine are currently available – a 23 valent polysaccharide vaccine (available in India) and a 7 valent conjugate polysaccharide vaccine in some countries of the world(78).

23-valent polysaccharide vaccine is capable of prevention of 85% of meningitis and bacteremia caused by pneumococcus. Each dose is 0.5 ml containing 25 ug of individual serotype polysaccharide. A single intramuscular injection is recommended after the age of 2 years with booster every 3-5 years till the age of 10 years(79,80).

The 7 valent conjugate polysaccharide vaccine manufacturer recommends three intramuscular injections in infants aged under 6 months, the first dose usually given at 2 months of age, with an interval of at least 1 month between doses.

### Influenza Vaccine

Influenza virus types A and B are both common causes of acute respiratory illnesses, although influenza A viruses are the principal cause of large epidemics, as well as pandemics(81). Both inactivated and live, attenuated influenza vaccines are available. There are 3 types of inactivated influenza vaccine, namely whole virus vaccines, split virus vaccines and subunit vaccines. In most countries, whole virus vaccines have been replaced by less reactogenic split virus and subunit vaccines. The inactivated influenza vaccine produced in embryonated eggs are immunogenic and associated with minimal side effects. These multivalent vaccine usually contain 3 virus strains (usually 2 type A and 1 type B) with composition changed periodically in anticipation of the prevalent influenza strains expected to circulate in the country(82).

The vaccine is given in 2 doses in children 6 months to 9 years of age and one dose above 9 years of age. The dose is 0.25 ml between 6 months to 3 years IM and 0.5 ml after the age of 3 years. The vaccine is not routinely recommended in India since the prevalent antigenic types are not known. However, in some high risk children and adolescents, the vaccine may be helpful. The vaccine is effective for only short period(83).

#### Live, attenuated influenza vaccines

For several years, live, attenuated influenza vaccines for nasal application have been used successfully in the Russian Federation. The temperature-sensitive vaccine virus will replicate well in the relatively cool environment of the nasopharynx, but poorly in the lower respiratory tract. This vaccine is reported to be safe and highly efficacious following 1 single dose in adults and children >3 years of age(84-86).

Based on data from industrialized countries, and listed in order of priority, the following groups of individuals may be targeted for vaccination in order to reduce the incidence of severe illness and premature death.

(a) Residents of institutions for elderly people and the disabled.

(b) Elderly, non-institutionalized individuals with chronic heart or lung diseases, metabolic or renal disease, or immunodeficiencies.

(c) All individuals >6 months of age with any of the conditions listed above.

(d) Elderly individuals above a nationally defined age limit, irrespective of other risk factors.

### Rabies Vaccine

Rabies is the most dreaded disease known to mankind, once the disease occurs, it invariably leads to death. Rabies virus is a RNA virus classified as Rhabdovirus family. Rabies occurs due to the bite of rabid animals. In India almost all the rabies cases occur due to the bites of dog. The incubation period averages 4-6 weeks but ranges from 5 days to more than 1 year.

There are 2 types of vaccines available in India

(a) Nerve tissue vaccine

(b) Tissue culture vaccines

  (i) Human diploid cell vaccine

  (ii) Purified chick embryo cell vaccine

  (iii) Vero cell vaccine

Nerve tissue vaccine is no longer recommended because of its poor efficacy and life threatening adverse reactions in the form of neuroparalytic conditions of 1:2000 to 1: 8000 doses(87,88).

#### Tissue culture vaccines

All tissue culture vaccines are having almost equal efficacy and any one of them can be used.

#### Post exposure prophylaxis

After thoroughly cleaning the wound with soap and water and appropriate tetanus prophylaxis, rabies immunoglobulin either human or equine in the dose of 20 I.U. and 40 I.U./kg body weight respectively is infiltrated around the wound in case of severe bite or bites in the upper extremities, trunk, head and face. Currently IM injection of RIG is not recommended (89,90).

#### Pre-exposure prophylaxis

1 ml of any of the tissue culture vaccine is given intramuscularly over the deltoid region on day 0, 7 and 28 for the high risk group

In order to reduce the cost of post-exposure treatment, intradermal multisite regimens using a fraction of the intramuscular volume per intradermal inoculation site have been developed (91).

**Summary: Rabies Vaccine**

**Post exposure Prophylaxis**

**Tissue Culture Vaccine**

- 1 ml per dose irrespective of age in deltoid region in infants >2 years; and in anterolateral aspect of thigh in infants< 2 years.
- Schedule Day 0, 3, 7, 14 and 28
- Re-exposure within 5 years - 2 doses - day 0 and 7 ; after 5 years full course. Earlier if anti rabies antibody titre falls below 0.5 IU / ml

**Pre exposure Prophylaxis**

- 1 ml per dose, any Tissue Culture Vaccine, IM,
- Schedule Day 0, 7 and 28
- Indicated for High Risk Group
  - Laboratory staff working with Rabies Virus
  - Veterinarians
  - Wild life staff

Rabies Immunoglobulin

It is a liquid or freeze dried preparation containing immunoglobulins mainly IgG obtained from plasma or serum of donors immunised against rabies and contains specific antibodies that neutralise the rabies virus. It provides passive protection when given immediately to individuals exposed to rabies virus with minimum interference of active immunization with human diploid – cell vaccine(92).

**Adverse Effects :** Local tenderness, muscle soreness or stiffness at the injection site, low grade fever, sensitization to repeated injections of human globulin in immunoglobulin deficient patients.

**Indications :** All injuries, even licks, on mucous membranes by wild animals (or even pet animals) suspected to be suffering from rabies.

### Immunization against Cholera

Throughout history, devastating outbreaks of cholera have resulted in millions of cases and hundreds of thousands of deaths. Until recently, the only available cholera vaccines was phenol-killed whole cell killed vaccine, administered in 2 doses, 2 weeks apart. Unfortunately, the protective efficacy of vaccine is only about 50%, duration of protection hardly exceeds 6 months.

The live, attenuated CVD 103-HgR vaccine

A live, attenuated oral cholera vaccine containing the genetically manipulated classical V. cholerae strain CVD 103-HgR has been available since 1994 which confer a high level of protection (> 90%) against moderate and severe cholera.

Universal mass immunization in the civil population or in the Armed Forces is not practiced. Both the whole cell killed and the CVD 103-HgR vaccines may be recommended for travellers to high-risk regions(93).

### International Vaccination Requirement

Immunization Against Yellow Fever

Yellow fever (YF) is a mosquito-borne, viral haemorrhagic fever that is endemic in tropical regions of Africa and South America.

Vaccination against yellow fever is the most effective method for the prevention of spread of the disease by international travel(94). Two types of vaccines are available(95).

**(a) 17 D Vaccine**

This is the approved vaccine for international travel. It is a live, attenuated chick embryo grown 17D-strain freeze-dried vaccine. For storage at WHO approved centres, the vaccine can be kept for 3 months at +4˚C. If the storage is for a longer duration, a temperature of -25˚C is to be maintained. After reconstitution, it should be used within half an hour.

**(b) Dakar Vaccine**

It is also called French Neurotoxic Virus at the Pasteur Institute Dakar. It is thermostable and can be easily transported. However, it has produced post-vaccinial encephalitis in children. WHO has not approved use of this vaccine for international travel.

Table - 10 : Validity of international certificate of vaccination

| Type of vaccination | Certificate | |
|---|---|---|
| | Valid for | Valid from |
| Yellow fever-primary vaccination | 10 years | 10 days after vaccination |
| Yellow fever-re-vaccination | 10 years | at once after revaccination |

**Administration of vaccine**

17-D vaccine is given subcutaneously at the insertion of deltoid in a single dose of 0.5 ml. The immunity begins within 10-12 days and lasts for at least 10 years however the Persistence of neutralizing antibody 30--35 years after immunization with 17D yellow fever vaccine has been observed (96). Yellow fever vaccination is available at designated centres certified by the Government of India, Armed Forces Clinic New Delhi is one of such centres.

International certificate of vaccination is required only for one disease i.e. Yellow fever. The period of validity of the certificate is shown in Table 10.

Protection is recommended against certain other diseases for international travellers although the international certificate is not required. These diseases are as under: -

(a) Cholera

Cholera vaccine may be taken by all travellers proceeding to endemic areas. It offers partial protection against the disease.

(b) Enteric Infections

Vaccination and revaccination against typhoid is strongly advised for all travellers proceeding to endemic areas.

(c) Hepatitis A

A single intramuscular injection of human normal Immunoglobulin 500 mg or 1.2 mg/kg body weight is effective almost immediately and its efficacy lasts for six months. Active immunisation with HAVRIX is available in our country.

(d) Tetanus

A booster dose of Tetanus toxoid should be taken if 5 years or more have elapsed since the last injection of a complete course or booster.

### Immunization in Special Circumstances (97)

(a) Immunization in preterm infants

All vaccines should be administered as per schedule irrespective of birth weight or period of gestation except Hepatitis B. If the weight of the baby is less than 2 kg and mother is HBsAg negative, then Hepatitis B vaccine is postponed till the baby attains a weight of 2 kg or 2 months of age. However, if the mother is HBsAg positive, then both Hepatitis B vaccine and Hepatitis B

immunoglobulin is administered within 12 hours of birth followed by 3 more doses at 1, 2 and 6-12 months.

(b) Children receiving corticosteroids:

Children receiving corticosteroids at the dose of 2 mg/kg/day for more than 14 days should not receive live virus vaccines until steroid has been discontinued for at least 1 month.

(c) Vaccination in HIV/AIDS

Table - 11 summarizes the recommendation of WHO and Advisory Committee on Immunization Practices and American Academy of Paediatrics.

(d) Vaccination schedule for children not immunized in time

Table -12 depicts the schedule which should be followed in case of unimmunized child.

(e) Lapsed immunization

A lapse in the immunization schedule does not require reinstitution of the entire series. Immunizations should be given at the next visit as if the usual interval had elapsed and the immunization schedule should be completed at the next available opportunity. In case of r uncertain immunization status, it is appropriate to start the schedule of unimmunized child.

(f) Immunization of Adolescents

Reasons for adolescent immunization fall into the following three broad categories:

(a) To boost the waning immunity by giving booster doses.

(b) To counter a specific risk e.g. due to travel, life style etc.

**International Certificate of Vaccination**

These are individual certificates and should not be used collectively. Certificates are printed in English and French;

Table - 11 : Vaccination reommendations in HIV infected symptomatic and asymptomatic children

| Vaccine | Known Asymptomatic | | Known Symptomatic | |
|---|---|---|---|---|
| | WHO | ACIP/AAP | W H O | ACIP/AAP |
| BCG | Yes* | No | No | No |
| DPT/DtaP | Yes | Yes | Yes | Yes |
| OPV | Yes | No | No | No |
| Measles/MMR | Yes | Yes | Yes | Yes |
| IPV | - | Yes | - | Yes |
| Hepatitis B | Yes | Yes | Yes | Yes |
| Hib | - | Yes | - | Yes |
| Pneumococcal | - | Yes | - | Yes |
| Invluenza | - | Yes | - | Yes |
| Varicella | - | Consider | - | Consider |
| Hepatitis | - | Yes | - | Yes |
| * For regions where risk of TB is high | | | | |

Table - 12 : Vaccination schedule of an unimmunised child

| Age | Less than 5 years | More than 5 years |
|---|---|---|
| 1st visit | BCG, OPV, DPT, HB | TT/Td, HB |
| 2nd visit (1 month later) | OPV, DPT, HB | TT/Td, HB |
| 3rd visit (1 month later) | OPV, DPT, MMR, Typhoid | MMR, Typhoid |
| 1 Year later | OPV, DPT, HB | HB |
| Every 3 Years | Typhoid Booster | Typhoid Booster |

Table - 13 : Vaccination Schedule in Adolescents

| Vaccine | Age |
|---|---|
| Tetanus Toxoid | Booster at 10 and 16 years |
| Rubella vaccine | As part of MMR vaccine or (Monovalent) 1 dose to girls at 12-13 years of age, if not given earlier |
| MMR Vaccine | 1 dose at 12-13 years of age. (if not given earlier) |
| Hepatitis B. Vaccine | 3 Doses (0, 1 and 6 m) if not given earlier |
| Typhoid Vaccine | TA, Vi or Oral typhoid vaccine every 3 years |
| Varicella Vaccine* | 1 dose upto 12-13 years, and 2 doses after 13 years of age. (if not given earlier) |
| Hepatitis A Vaccine* | 2 doses (0 and 6 months) if not given earlier |
| Varicella* and Hepatitis A* vaccine are additional vaccines. These vaccines are recommended depending upon the epidemiology of these diseases especially in the adolescent age group where fatal complications are likely | |

# Collection of Specimens for Laboratory Investigations

## Guidelines for sample collection, transport and dispatch

The proper collection and transport to the laboratory of a specimen for examination is a critically important step in the ultimate confirmation that a microorganism is responsible for the infectious disease process. A poorly collected specimen not only may result in failure to recover important agents, but also lead to incorrect or harmful therapy if treatment is directed towards a commensal or a contaminant organism.

Specimens collected and submitted for laboratory investigations are utilized for microbiology, biochemical estimations, immunological tests, histopathological studies, and even molecular diagnosis and electron microscopy studies. High quality specimens should be optimally timed, of adequate quantity, correctly sampled with minimum contamination from resident flora and accompanied with relevant history and clinical details of the individual. Information which is of value for the investigation, such as, identity of the source and of the sender and precise nature of the examination required, should be provided legibly.

Specimens must be preserved in such a way that the delay in transit will not materially reduce the chances of successful examination. All precautions must be taken so that the specimen is not contaminated or damaged during transit.

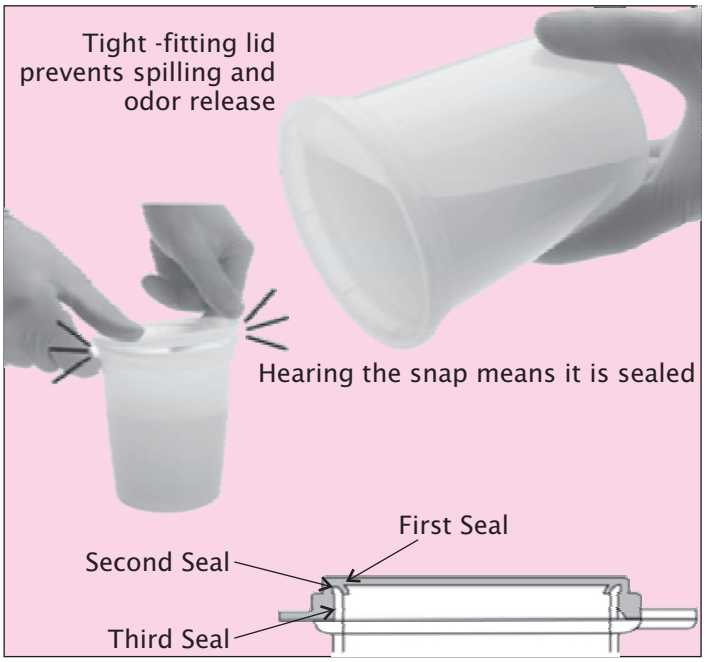
In the subsequent paragraphs only basic methods for collection and dispatch are outlined. These must be supplemented and modified in accordance with instructions issued from time to time and by liaison with the laboratory undertaking the work. All medical officers should be familiar with new methods that may be introduced or modifications made in the established methods.

Medical Officers will be required to collect and ensure proper transport of various specimens for laboratory testing, not only for individual cases in clinical settings but also in mass occurrence of cases in outbreak / epidemic situations. During such settings it would also be wise to dwell upon the "syndromic approach" to decide which specimens would need to be collected as well as to work out the methods of proper collection and transport of such specimen, as mentioned in detail in standard publications of WHO (1,2).

### Routine safety precautions

Specimens should be collected in sturdy containers with adequate closure to prevent spillage or leakage. Spill-proof containers are essential for transport of specimen to distant tertiary laboratories to ensure that the specimen does not leak, get contaminated or pose any kind of hazard to the specimen handler / transporter or laboratory personnel at destination. Such spill-proof containers are commercially available. The lid may be a snap-close or a screw cap one (Fig - 1).

Fig - 1 : An ideal Universal container showing the triple mechanism of sealing.



Specimen transport bags may be used to transport specimens by hand especially over long distances. This specimen bag could be improvised with a large zip lock bag containing a smaller size zip lock bag for samples and another separate bag firmly taped to the outside used for holding the requisition slip and other relevant documents. This 3 pocket design prevents soiling of the requisition slip should accidental spillage occur and helps contain the spillage within a closed space. They may also be printed with red-and-black biohazard warning and handling instructions (Fig - 2).

(a) Open the Zip lock bag, insert specimen in the inner bag and seal.

(b) Seal the outer bag to prevent leakage of specimen.

(c) Insert requisition papers in another bag taped to the outside.

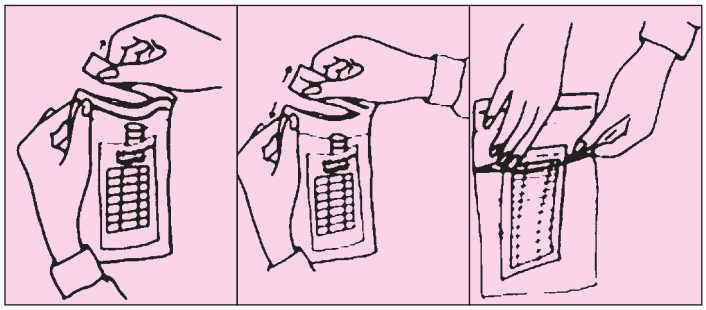
Alternately, sturdy plastic bags, one inside another may be used and sealed using a simple electric sealer or by using the flame.

### Safety while collecting specimens: Universal Safety Precautions (USP)

Universal safety precautions advise that blood, body fluids and tissue material from all patients should be considered as potentially infectious.

USP is intended to protect the Health Care Worker (HCW) and the patients from infections with blood borne agents in health care settings. USP is not intended to prevent

Fig - 2 : Method of using ziplock bags for sample transport



transmission of all pathogens; additional precautions are necessary to prevent transmission of other infectious agents. The fluids to which USP apply include blood, semen, vaginal fluid, amniotic fluid, peritoneal fluid, pleural fluid, synovial fluid, breast milk (only in case of situations like breast milk banking), and saliva (mainly in respect to practice of dental surgery, since saliva in such practice is often contaminated with blood). USP does not apply to following fluids unless they contain visible blood: feces, nasal secretions, sputum, sweat, tears, urine and vomit.

USP have the two main elements which need to be remembered while handling specimens. These include hand-washing and use of gloves.

(a) Hand-washing

This is the single most important measure for preventing the spread of infection. Hands should be washed between patient contact, after contact with blood, bloody fluids and secretions and after removal of gloves. Washing hands with plain soap is adequate and is likely to prevent as much as 70% of transmissible infections. However recent studies state that an alcohol based hand scrub may also be used

(b) Use of gloves

All specimens must be considered a potential health hazard. Use of gloves is necessary and cuts and abrasions on hands should be adequately covered with adhesive bandages if individual is handling specimens. Gloves should be used when touching blood, body fluids, mucous membranes and non-intact skin and also when performing procedures in which contact with blood/ bloody fluids is likely, e.g., suturing lacerations, venepuncture, catheterization, endoscopy, cleaning a spill etc. Gloves should be changed when contaminated, damaged and between successive patient contact. It may be noted that using gloves does not replace the need for washing hands. Both vinyl and latex gloves are equally effective. Utility gloves can be decontaminated and reused 3 to 4 times (after proper sterilization each time), but they should be discarded if there is any evidence of deterioration or tear. The use of gloves should be limited to the particular task and removed as soon as it is complete. Hands should always be washed after removal of gloves as micropores or inevident damage may allow infectious material inside

**Disposal of Sharp objects**

Used disposable syringes and sharps such as broken glass should be placed in a puncture-resistant container located as close to the working area as possible. Used needles should never be recapped or manipulated with both hands, or by any other technique that involves directing the point of a needle towards any part of the body. Used needles from disposable syringes should not be removed by hand, nor should they be bent, broken or other wise manipulated by hand. Once these 'sharps' have been placed in a puncture resistant container, the container should be sealed properly. The exterior of the container should be wiped with Sodium Hypochlorite solution having 0.1% available chlorine (1000 parts per million of available chlorine).

**Cleaning spills of infectious material**

Don appropriate protective equipment i.e. at a minimum one must wear gloves and eye protection during spill clean-up to protect oneself from exposure. Large fragments of glass should be removed individually using paper towels, after having poured the disinfectant and given the contact time specified. Smaller pieces of glass are best removed by using moistened absorbent cotton after adequate contact with the disinfectant.

**Procedure to clean up spills:**

(a) Pour 1% freshly prepared Sodium hypochlorite solution over the spill in sufficient quantity to completely cover the area starting from outer edge inward.

(b) Cover the spill with paper towel or absorbent material such as absorbent cotton

(c) Leave for 30 min

(d) Clean the spill using gloved hands and dispose all material into 1% Sodium hypochlorite

(e) Wipe up the whole spill area again with fresh absorbent material using gloved hands and dispose of the absorbent material into Sodium hypochlorite

(f) Wipe the surface with soap and water

(g) Remove gloves and discard into Sodium hypochlorite

(h) Wash hands in running water

(j) Decontaminate all equipment that have been used in the cleaning such as mug, bucket, mops etc. in Sodium hypochlorite

If blood or other body fluids spill on work surfaces, recommendations from the Centers for Disease Control (CDC) advises cleaning the contaminated area with either a high-level disinfectant or a bleach solution. The CDC recommends a solution of one part bleach to 10 parts water (1:10) for heavy spills and a solution of one part bleach to 100 parts water (1:100) for lighter spills.

**Caution**: (1:10) bleach solution is caustic. Avoid direct contact with skin and eyes. Prepare the bleach solution in a well-ventilated area.

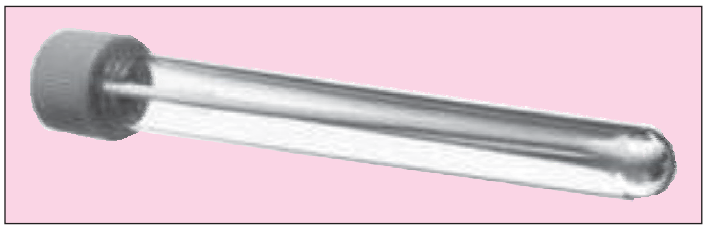
## Specimen collection for infections of various sites

The specimen to be collected is largely determined by the type of infection. The kind of specimens is as outlined in Table - 1.

### Swabs

These are used for obtaining specimens, from sites easily approachable from the outside such as nasal, naso-pharyngeal, laryngeal, conjunctival, cervical, vaginal, rectal swabs and so on. They are made by wrapping a piece of cotton wool round one end of a wooden swab stick. This is placed in a clean test tube, the mouth of which is closed with a cotton plug, and sterilized in the Hot air oven. Such swabs are also available commercially (Fig - 3)

Fig - 3 : A commercially available cotton tip applicator



For collection of specimen the following procedure should be followed:

(a) Two swabs should be taken. These should be thoroughly soaked in the pus or the exudate and put back in the sterile test tube and sent to the laboratory immediately. If some delay is anticipated one of the swabs should be put in a sterile transport medium like Stuart's medium and both these stored at 4°C in the refrigerator.

(b) When specimens are collected involving minimal or no exudate as in case of a diphtheritic membrane, the swabs should be moistened before collection in a sterile medium such as nutrient broth or sterile normal saline. After collection the

Table - 1 : Specimen collection of various infections

| S no | Site of infection | Specimen to be collected |
|---|---|---|
| 1 | Blood stream / Systemic | Blood / bone-marrow aspirate/ IV catheter tip |
| 2 | Respiratory tract | Sputum/ Bronchoalveolar lavage/ Trans Tracheal Aspirate / Lung aspirate |
| 3 | Gastrointestinal tract | Duodenal aspirate/ fecal sample/ rectal swab |
| 4 | Urinary tract | Mid-stream urine/ catheter urine/ cystoscopic sample of urine/ suprapubic aspiration |
| 5 | CNS | CSF/ ventricular tap |
| 6 | Eye, ear, nose, sinus & throat | Swabs/ antral puncture material |
| 7 | Wound infections & infections of fascial planes | Swab from under scab/ aspiration from deep planes. For tissues & biopsies for culture, send in saline not in formalin!<br>For anaerobic culture, send aspirate in a syringe where the needle is impaled into a sterile rubber bung or send material on swab/ bits of tissue in Stuart's transport medium. Alternately, material can be sent in Thioglycollate or Robertson's cooked meat medium. Liaise with the laboratory. |
| 8 | Genital tract (Female) | High vaginal swab / intracervical swab/ aspiration from pouch of Douglas/ aspiration from uterine cavity |
| 9 | Genital tract (Male) | Material from urethral discharge on slide for staining and also on swab (transported in Stuart's transport medium). Urine after prostatic massage |
| 10 | Dentistry- gingivocrevicial fluid in periodontitis/ abscess | Aspirated material in syringe in which needle is impaled into a sterile rubber bung; paper points & material using microcurette (capillary) can be sent in Stuart's transport medium. |

swabs should be sent to the laboratory immediately. If any delay is anticipated the swabs should be preserved at 4°C in the refrigerator, upright on a stand.

(c) For obtaining laryngeal swabs care must be taken that the swab does not touch the tongue.

(d) The throat swab is guided to the posterior pharynx under illumination of the oral cavity. The patient is instructed to tilt the head back and breathe deeply. The tongue is gently depressed with a tongue depressor to visualize the tonsillar fossae and posterior pharynx. If not available, a gloved finger or an icecream stick may be used for the same. Having the patient to phonate "ah", the tonsillar areas and the posterior pharynx are firmly rubbed with the swab which is then placed back in the glass tube to prevent drying. Care should be taken not to touch the tongue or oral cavity. Any purulent exudate should be sampled separately and correctly labeled. In all circumstances the individual obtaining a sample of throat swab from suspected diphtheria infection should wear gloves, goggles and mask as the organism is highly infectious.

(e) On no account should a swab reach the laboratory dry, as organisms are often killed by dessication and valuable information may therefore be lost.

**Collection of Blood for culture**

Blood culture is carried out for the diagnosis of bacteremia which may be present in the Enteric group of fevers, Brucellosis, Subacute bacterial endocarditis and other bacterial causes of PUO. Ten ml of blood is collected in 50 - 100 ml of medium. This prevents clotting of blood by dilution and a large volume of blood ensures a better chance of isolation of organisms. Blood should be collected before starting antibiotics. Ideally three and at least two samples must be taken from different sites within a half to one hour interval. Alternatively, in patients requiring early institution of antibiotics, three samples of blood 10 ml each should be taken from three different sites using three separate syringes and needles. In children 1-5 ml blood may be drawn in place of 10 ml in adults.

Strict aseptic precautions should be observed while collecting the blood sample and the phlebotomist should wear sterile gloves. A tourniquet is applied above the site of collection. The site of venepuncture is disinfected in a circle of about 6 cm diameter with 70% alcohol on a sterile swab. The alcohol is allowed to dry. This is followed by application of tincture iodine or 10% povidone iodine starting from the centre of the circle. The iodine is allowed to dry and then 70% alcohol swabbing is repeated as before. After allowing the skin to dry the blood is collected in a sterile autoclaved syringe and immediately transferred to the culture media in blood culture bottles. The screw cap of the blood culture bottle should be opened over the flame of a spirit lamp and after the blood is delivered in the bottle, the screw cap and the mouth of the bottle is flamed and then closed tightly. When the bottle has a rubber cap, the top of the cap is sterilized using 70% alcohol, allowed to dry and the blood inoculated through the rubber cap. The collected blood should be thoroughly mixed with the medium and the bottles sent to the laboratory.

The following culture media are used for culturing blood:-

(a) Brain heart infusion (BHI) broth with 0.5% agar or Glucose broth- supports growth of most organisms

(b) Taurocholate broth- enrichment medium for enteric group of organisms especially for Salmonellae.

(c) Castaneda biphasic medium- this medium need not be opened repeatedly for subculture as an agar slant is incorporated. It is preferred where incubation is likely to be more than two weeks as in suspected brucellosis.

(d) Thioglycollate broth- for anaerobic organisms.

When leptospirosis is suspected, blood is collected in 1% sodium oxalate in phosphate buffer (pH 7.5), 1% Liquoid (sodium polyanethol sulphonate) in sterile saline or in EDTA and sent across to a surveillance centre that uses special semisolid and liquid media (Fletcher's, Korthof, Ellinghausen- McCullough) to grow the organism.

**Cerebrospinal fluid**

(a) The lumbar puncture set is made up of one or more lumbar puncture needles, glass syringe, hypodermic needles and a piece of folded lint to serve as a towel. All these articles are wrapped in two pieces of lint so that the outer piece maintains the remainder of the packet in a sterile state at all times. This packet is packed into a stainless steel drum, autoclaved and kept ready by 'Central Sterile Store Department (CSSD)". After use the instruments are cleaned, repacked and autoclaved so that a sterile set is always ready for use.

(b) Lumbar puncture is carried out with the patient lying along the edge of the bed, with the head and spine well flexed. The spine should be in a horizontal plane. Tincture of iodine / povidone iodine should be used to clean the skin. Scrubbing up and sterilisation of the hands must be carried out as thoroughly as for any surgical operation. A local anaesthetic may be used. The puncture is made in the midline in the interspace between either the third and fourth or fourth and fifth lumbar spines.

(c) The first few drops are allowed to flow into a sterile bottle and then the samples required for culture and serological tests collected in another sterile bottle. It is advisable to collect the sample in screw capped flat bottom sterile plastic vials so that spillage and contamination are avoided. If suitable media are available, these can be inoculated by allowing the fluid to pour direct onto the media plate/ tube. If suitable culture media are not available by the bed-side, the sample of CSF that is collected should be dispatched immediately to the nearest laboratory ensuring that the fluid is kept warm at body temperature during transit. Any admixture with blood will render the fluid

unsuitable for biochemical examination. For a cytological examination, the fluid may be collected in a bottle containing Wintrobe's anticoagulant. A cytological examination must be carried out as soon as possible, preferably within 1/2 hour as otherwise the cells undergo degeneration rendering correct reporting impossible.

CSF specimens for culture must never be refrigerated as most of the incriminating organisms are sensitive to cold. When transporting CSF to another laboratory for bacterial culture, send at ambient temperature and not in ice but if being sent for serology, ice can be used around the sample. CSF samples do not need a transport medium.

**Urine for Bacteriological Examination**

The sample required is a midstream specimen of urine (MSU) after thorough local toilet using running water. Other samples that may be sent for bacteriological culture, in special situations, are suprapubic aspirate (SPA), catheter sample, sample through cystoscope and, for acid fast bacilli (AFB) Early Morning Specimen of Urine (EMSU) X 3 consecutive days. Unlike earlier belief, there is no role of 24 h collection of urine for mycobacterial culture. The kind of sample should be clearly stated on the requisition form. A proper history of the case in terms of intake of antibiotics, past infection, use of diuretics and if the sample is of an antenatal case should be clearly outlined.

The urine collected must be labeled with the name and examination required and sent to laboratory as fresh as possible, preferably within 2 hours of collection. The best method is to use sterile screw-capped wide mouth bottles with a flat bottom (universal container). Such containers are available commercially. Penicillin vials should not to be used under any circumstances. Urine specimens should be collected before administration of antibiotics and after a bladder holding of at least 2 hrs.

**Pus**

Although pus is usually sampled with a swab, it is more satisfactory whenever possible, to take a liquid sample with a syringe or pipette. When the lesion is deep-seated and opens through a sinus, the whole of the inner dressing should be sent in a sterile container. Swabs should be placed in Stuart's Transport Medium for the preservation of anaerobes and microbes sensitive to drying. There must be no delay in submitting swabs in transport medium because some species will grow in it at room temperature and may obliterate the true pathogens. In suspected anaerobic infections (foul smell, deep abscess etc.) aspirated material is mandatory. If collected in a syringe the entire syringe along with the material should be sent to the laboratory with the tip of the needle plunged into sterile rubber bung.

**Exudates and Other Pathological Fluids**

Pleural, cystic and ascitic fluids are collected direct from the cannula or aspirator into sterile test tubes for general examination. For bacteriological examination, collect 5 ml directly in a sterile test tube and forward to the laboratory as soon as possible. If the fluid tends to clot, a small crystal of potassium oxalate may be added. In order to avoid contamination due to spillage, screw capped universal containers should be used instead of test tubes. If tuberculosis is suspected, as much of the material as possible should be collected and forwarded.

**Eye infections**

Suppurative material from the conjunctiva should be taken from the inner canthus with a swab which is moistened previously with sterile saline. Sample swabs from the eye should be put into Stuarts transport medium as these specimens may have organisms which may not survive any delay in transportation. Alternatively, a bed-side inoculation is done on Blood agar, MacConkey agar and Sabouraud's agar.

**Ear and nose infections**

Antral puncture material from ENT cases should be taken for aerobic & anaerobic culture. In diabetics with swelling over maxillary region, suspect a mycotic etiology & take a punch biopsy for fungal culture. Forward this in sterile saline in a sterile capped container.

Samples for diagnosis of Upper respiratory Infections

Throat swab, nasopharyngeal swab and naso-pharyngeal (NP) washings can be assessed for pathogens.

Samples For Diagnosis Of lower Respiratory Infections

Sputum and broncho-alveolar lavage (BAL), Trans-tracheal aspirate (TTA)-in debilitated cases, failure of routine sputum culture and when anaerobes are implicated and Trans-cutaneous lung aspirate is used in selected areas.

**Collection of Sputum**

Only the early morning sputum obtained from the lower respiratory passages should be sent for examination. Saliva or nasopharyngeal secretions are useless. Suitable postural drainage (physiotherapy assisted) or nebulisation may have to be arranged before a representative sample can be obtained. The sputum should be coughed up and directly collected in a wide mouth screw capped sterile container. If the laboratory is near, the bedside spittoon without a disinfectant in it should be sent. For cytology of the sputum, two thin smears fixed for half an hour in a mixture of equal parts of ethyl alcohol and ether, and air-dried should also be forwarded. These slides may be wrapped in foil after fixing and dispatched to the nearest centre for reporting. For culture of tubercle bacillus, specimens of sputum collected in screw-capped container early in the morning for three consecutive days may be used. Alternatively sputum may be collected directly into McCartney bottles containing 5 ml of Tri-sodium phosphate (TSP) medium and sent to the laboratory for making slides for ZN stain and for culture of tubercle bacillus.

**Collection of Pleural Fluid**

This is collected under aseptic precautions in sterile containers like any other body fluid and sent at the earliest to the laboratory.

Preparation for Microscopy

Using a wire loop a purulent portion of the sputum is placed on the slide and spread evenly to give a smear of approximately 3 x 2 cm. The smear is allowed to air-dry

Table - 2 : Interpretation of Microscopy for Acid fast bacilli (WHO)

| Examination | Grading | No. of fields to be examined |
|---|---|---|
| More than 10 AFB per one oil immersion field | 3+ | 20 |
| 1-10 AFB per one oil immersion field | 2+ | 50 |
| 10-99 AFB per 100 oil immersion fields | 1+ | 100 |
| 1-9 AFB per 100 oil immersion fields | Record exact no. seen | 100 |
| | | 100 |

**Stool collection procedure for Ova, Cyst and Culture**

Stool for ova/cyst of parasites may be collected in a clean, dry, disposable container, plastic wrap stretched under the toilet seat, or into a waxed cardboard container. It must be a dry specimen i. e. not contaminated with water or urine, with an acceptable specimen being: faeces. For collection of material for demonstration of ova of pinworm, a cellotape can be used over the perianal area, removed and attached to a clean dry microscope slide. The slide is wrapped in paper and sent to the laboratory with the requisition form.

For culture, portion of stool which contains pus, mucus or blood should be transferred to a dry sterile container, preferably screw capped. The specimen should be delivered to the laboratory as soon as possible preferably within two hours of collection. If delay is anticipated, store specimen at 4°C. It is sometimes useful, in cases of chronic dysentery, to obtain a rectal swab through the proctoscope. Dispatch the rectal swab as quickly as possible to the laboratory to avoid drying.

Preservation of Helminths for examination later:

Cestodes should be washed in water and trematodes in saline; they should be killed and preserved in 4 % formalin and not in spirit. Nematodes should be washed in saline, killed by hot water at 70°C and preserved in 70 per cent alcohol.

**Stool samples for Enteropathogens**

(a) Dysentery Group of Organisms :

(i) When the laboratory is near, send the fecal sample to the laboratory, as soon as it is passed in a bedpan. The sample must not contain any antiseptic, and the urine must be passed separately and not in the pan.

(ii) When the laboratory is some distance away or it is not practicable to get the specimen to the laboratory quickly, take about one ml of sample with mucus flake and put it into a bottle containing neutral glycerin - saline solution (Cary Blair medium). This medium should be pink in color; yellow solution is acidic and should not be used. The selection of the sample is important and must be carefully done by the medical officer himself.

(iii) In cases of suspected amoebic infection, finding of vegetative form of *E. histolytica* is diagnostic. This is possible only by examination of a fresh specimen of stool.

(b) Cholera

The isolation of *Vibrio cholerae* from a suspected case of cholera is made from a specimen of freshly passed stool or the rectal swab obtained from beyond the anal sphincter. A hanging-drop preparation of the sample will show *Vibrio cholerae* exhibiting "darting motility". If facilities for bacteriological examination are available locally, the material should be placed directly on a suitable solid medium - MacConkey's agar and Thiosulphate citrate bile salt sucrose agar (TCBSA). If however, a delay of some hours is anticipated, the specimen of faeces should be placed in a bottle containing 10 ml of an alkaline transport/ preserving medium such as Alkaline peptone water (pH 8. 4) obtained from the nearest laboratory. In the case of the examination of convalescents or contacts, about I-3 g of stool should be sent in Alkaline peptone water.

(c) Other Enteric group of organisms

Similar to that outlined in para (i) & (ii) above.

(d) Helminths

Sample of faeces may be preserved for subsequent examination for presence of helminthic eggs by mixing a specimen of faeces, the size of a pea, in 30 ml of 1 per cent solution of common salt or 2 % antiformin in water.

(e) Coccidian parasites

Fresh stool may be sent in a clean dry screw capped container for detection of cyst of Isospora, Cryptosporidium and Microsporidium. The cold ZN stain (Kinyoun stain) is used to detect this group of parasites. Coccidian parasites are often the cause of intractable diarrhea in the HIV affected but may also, at times, affect an immunocompetent host.

**Preparation of Blood Slides**

(a) Cleaning of Slides

(i) New Slides

The new slides are placed in dichromate cleaning-fluid for 48 hours and then washed in running tap water. This is followed by rinse in distilled water and thereafter stored in 95% ethyl alcohol. The slides are wiped dry with clean muslin cloth before use.

(ii) Used dirty Slides

After use, slides are put into 2% chlorosol, washed in tap water and boiled in washing soda solution for 20 minutes. A tap-water wash follows and then

a rinse in 5% hydrochloric acid. This is followed by wash in tap water and then distilled water. Thereafter, they are wiped using soft muslin and air-dried.

(b) Thin Blood films

The sides of the finger are pressed so as to raise the pulp of the finger. Ideally, commercially available pricking lancet is used. Otherwise, a bayonet pointed disposable needle serves well for the purpose of pricking. Pins, injection needles, and sewing needles should be avoided. The prick should be bold and about 3 mm deep. Light pressure on the sides of this finger in an outward direction helps the flow of blood by opening the wound. Squeezing is to be discouraged as it leads to dilution of capillary blood with tissue fluid and thus to erroneous results. The first drop of blood from a skin puncture is wiped dry with cotton wool and subsequent drops of blood are utilized for tests. A drop of blood is placed ½ inch from the edge of the slide. Take two or three polished slides and select one with a smooth and even end as a "spreader". Place the slide with drop of blood on a table so that the end with the blood drop is towards the right, while holding the other end by the edges with the forefinger and thumb of left hand, place the spreader somewhere about the middle of the slide at an angle of about 45˚ and draw it to the right till it touches the drop of blood which then runs and spreads along the edge of the spreader. Before the blood has reached the margins, push spreader with a firm steady motion but without unnecessary pressure, to obtain a tongue - shaped smear. An ideal film should be about 1½" long and ¾ " wide. It should be slightly thick at its beginning but reasonably thin near its tail, where red cells when seen under a microscope should be seen, just touching one another but not overlapping. When held against light, the thin portion of the films should show a play of colors. Films which are too long or too wide, which show bands due to irregular thickness, vacuoles due to grease, or streakiness due to an irregular edge to the spreader should be rejected.

(c) Thick Blood Films

These smears are better suited for the detailed examination of blood for haemoparasites such as malaria and microfilaria. Thick films are preferable when a large number of examinations have to be made. As a large volume of blood is examined, the thick film method increases the number of positive findings. Three to five drops of blood, each of the size of a drop for the thin film, are collected on a clean and polished slide, pooled together and spread with a needle into an even thick film about 10 mm square. The thickness of the film should be such as to allow newsprint to be read through it. The slide is then placed on a flat surface to dry in the air, but not in the sun, and covered with a saucer or petri dish. When dry, the slide is wrapped in a piece of paper on which the date and patient's name are written. When examination for microfilaria is needed, the slide is fixed in methanol for a few minutes before wrapping it up in paper for dispatch to the laboratory.

**Specimens for molecular diagnosis**

It is important to liaise with the laboratory before sending the sample. The sample (biopsy/ autopsy tissue, aspirate, body fluids) sent should be representative, adequate & fresh. No sample should be sent in formalin or heparin. If blood is sent, collect whole blood in EDTA with the cold-chain being maintained especially when specimens are being sent over long distance. Body fluids should be sent in cold chain, without any preservative added. A detailed history of the case and the suspected bacteria/ virus for which PCR is required should be entered on the form. It is also necessary that whatever results are available, should be correlated with clinical & other findings.

## Diagnosis of viral infections

With the demand for viral identification having markedly increased, refinements in viral identification are seeing the light of day.

The lab diagnosis of viral infections rests upon these predominant approaches:

(a) Isolation/cultivation of viruses on cell lines
(b) Direct detection of the viral antigen by Immunofluorescence or ELISA
(c) Detection of the specific antibody by Indirect Immunofluorescence or ELISA
(d) Detection of the specific genetic sequence by molecular method such as PCR

The procedure followed in collecting specimens for virological investigations is as given below:

**General Principles**

The choice of specimen to be collected for viral diagnosis depends on the nature and symptoms of the patient and the pathogenesis of the suspected agent. Specimens should be taken as early as possible in the acute phase of the illness. All samples including blood samples for serology should be taken aseptically. For virus isolation, swabs and other specimens that may dry in transit should be placed in Viral transport medium (VTM) such as Hank's Balanced salt solution (BSS). Samples for isolation of virus should never be frozen but held at 4 - 6 ˚C in an ordinary refrigerator. This can preserve the sample for upto ten days. For composition of VTM, see Appendix E.

**Throat swab**

A throat swab should be obtained as described earlier. The swab should be put in VTM in a sterile screw capped bottle, the swab stick being broken off at the mouth of the bottle and the screw cap closed after flaming the rim of the bottle. The specimen should be sent to the laboratory surrounded by ice in an insulated container and send in ice in an insulated container.

**Throat washings**

Let the patient gargle with about 5 ml of sterile physiological saline/ VTM and collect the washings in a clean disposable paper cup. Transfer this to a sterile screw capped container and send it in ice in a insulated container.

**Nasopharyngeal swab**

A nasopharyngeal swab should be obtained by carefully

inserting a dry sterile cotton wool swab through a nasal speculum parallel to the floor of the nose. The swab is then rotated on the nasopharyngeal membranes for a few seconds and then put into VTM in a sterile screw capped bottle, the swab stick being broken off at the mouth of the bottle and the screw cap closed after flaming the rim of the bottle. The specimen should be sent to the laboratory surrounded by ice in an insulated container.

**Nasopharyngeal washings**

1- 1. 5 ml of normal saline is instilled into one nostril with a sterile syringe with the head of the patient slightly tilted back. Aspirate the normal saline from the nostril with a sterile plastic catheter inserted into the nostril parallel to the palate. Repeat with other nostril. Aspirate nasopharyngeal secretions collecting 1-2ml in VTM. Send in ice in an insulated container.

**Blood and serum**

Blood should be obtained by aseptic venepuncture. For virus isolation, the sample of blood should be prevented from clotting by adding 1 IU of heparin per ml of blood. For serology, sample of blood should be allowed to clot in a sterile container and serum separated aseptically. Blood is allowed to clot at 4°C. Whole blood should not be frozen before serum preparation since blood may get hemolysed. To show rise in antibody titre two samples of blood for serum should be taken as follows :

(a) First sample for detection of IgM to be drawn as early in the disease as possible but not later than 5 days after onset.

(b) Second specimen for IgG detection 10-14 days after onset of symptoms.

**Faeces**

A piece of faeces weighing approximately 4-8 g is collected and dispatched to the laboratory in ice. Liquid stool is dispatched as it is in a sterile screw capped container maintaining cold chain.

**Cerebrospinal Fluid (CSF)**

About 1-1. 5 ml is collected aseptically in a sterile screw capped container without adding VTM and dispatched to the laboratory in wet ice.

**Biopsy and Postmortem Specimen**

The biopsy and postmortem specimens of tissue for virus isolation should be collected aseptically using several sets of sterile instruments. The specimens should be cut into 1cm$^3$ size and placed in VTM in sterile screw capped containers.

Apart from the above mentioned specimens, vesicular lesion smears and nasopharyngeal smears as well as smears from cell sediments after centrifugation may be sent for **Immunofluorescence** (for detection of viral

Table - 3 : Type of specimen for viral studies by principal body system infected

| System/ Organ | Specimen Required For Isolation | Serological Examination |
|---|---|---|
| Central nervous | blood, CSF, brain biopsy, throat swab | Faeces, Paired sera |
| Cardio-vascular | Faeces | Paired sera |
| Skin | Macular/papular scraping, vesicular/pustular fluid, crusts, throat swabs | Paired sera |
| Eye | Conjunctival scrapings or swabs | Paired sera |
| Liver | Blood, serum | Paired sera |
| Fever | Heparinised blood, | |

Table - 4 : Method of collection of samples for viral studies

| Type of specimens | Method of collection |
|---|---|
| Rectal swab | Insert swab 4-6 cm into rectum- VTM |
| Stool | Collect 2-4 gm in VTM |
| Genito-urinary | Collect in VTM |
| Dermal swab | Disrupt vesicle & collect fluid with swab - VTM |
| Mucosal swab | Swab back and forth over lesion & place swab into VTM |
| Conjunctival swab | Swab lower conjunctiva with flexible fine-shafted swab premoistened with saline - VTM |
| Respiratory | Nasal, naso-pharyngeal, throat swabs and fluids - VTM |
| Blood | Collect 8-10ml in Na Citrate or EDTA |
| Bone marrow | Collect 2ml in Na Citrate or EDTA |
| CSF | 2-5ml in sterile container - No VTM |
| Urine | Collect 10-20ml mid stream sample - No VTM |
| Tissues | Place tissue bits ( lung, brain etc.) in VTM |

Table - 5 : Optimal specimen for viral studies

| Specimens | Transport media if required (VTM) | Purpose/ Lab investigation |
|---|---|---|
| Throat swab PCR | Yes | Isolation of virus, IF, |
| Nasopharyngeal swab /aspirate | Yes | Isolation of virus, IF, PCR |
| CSF | No | Serology, Isolation of virus, PCR |
| Faeces | No | Isolation of virus |
| Urine | No | Isolation of virus |
| Blood(clotted), serum | No | Serology, Isolation of virus |

antigen). Many viruses can be detected at tertiary centers by this technique or the Shell-vial technique.

Important information about specimens required for different viral infections is shown In Table - 3, Table - 4 & Table - 5.

Note:

(a) The storage condition for serum separated for viral serology, pending immediate testing, is 20°C and during transport and prior to immediate testing, is 2-8° C. This however does not apply to clotted blood or whole blood in EDTA which should not be frozen as haemolysis occurs. Urine collected for virus isolation should be preserved at 2-6°C and not frozen. This temperature can preserve the sample for 7-10 days.

(b) For serology, paired sera are indicated, spaced 2-3 weeks apart. No preservatives should be added to serum separated for serology.

(c) Fluid specimens (body fluids, CSF, urine) do not require any transport media and should not be diluted.

(d) If viral isolation is contemplated, do not freeze specimens at minus 20°C Celsius, as infectivity of many viruses is rapidly lost at this temperature. Storing for such specimens, for periods up-to 10 days can be at 2-8°C and for longer periods, at -70°C.

(e) Any type of swab may be used for collection of specimen except calcium alginate fibre-tip which may inactivate Herpes simplex virus (HSV).

## Transport media for bacteriological tests

When the patient is not close to the bacteriological laboratory there is a risk that the pathogen in a bacteriological specimen may not survive or may be overgrown by non-pathogens during the time it takes to transport the specimen to the laboratory. A swab can be inserted into the medium and the extra stem nipped off after which the rubber cap is put. The medium maintains anaerobic conditions within and thus, prevents multiplication of organisms. The nutrients are limited hence it does not allow overgrowth by commensals.

### (a) Stuart's transport medium

An opaque white gel. The medium contains leuco-methylene blue that becomes blue on oxidation. Do not use if the medium is blue in color. The medium contains sod thioglycollate, sod glycerophosphate, calcium chloride, agar, Methylene blue and DW at pH 7. 4. It is distributed in small bijou bottles almost till brim and is autoclaved at 121°C X 15 min.

### (b) Amies transport medium

This has Sodium thioglycollate, sodium chloride, Potassium chloride, Calcium chloride, Magnesium chloride, disodium hydrogen phosphate, Potassium dihydrogen phosphate along with agar 0. 4%, finely powdered charcoal and distilled water at pH 7. 2. It is dispensed in the same way as Stuart's transport medium.

### (c) Pike's medium

This medium is used to preserve *Streptococcus pyogenes, pneumococci* and *Haemophilus influenzae* in nose and throat swabs. It is blood agar containing crystal violet 1 in 1, 000, 000 and sodium azide 1 in 16, 000 distributed as stab cultures in tubes/ bottles.

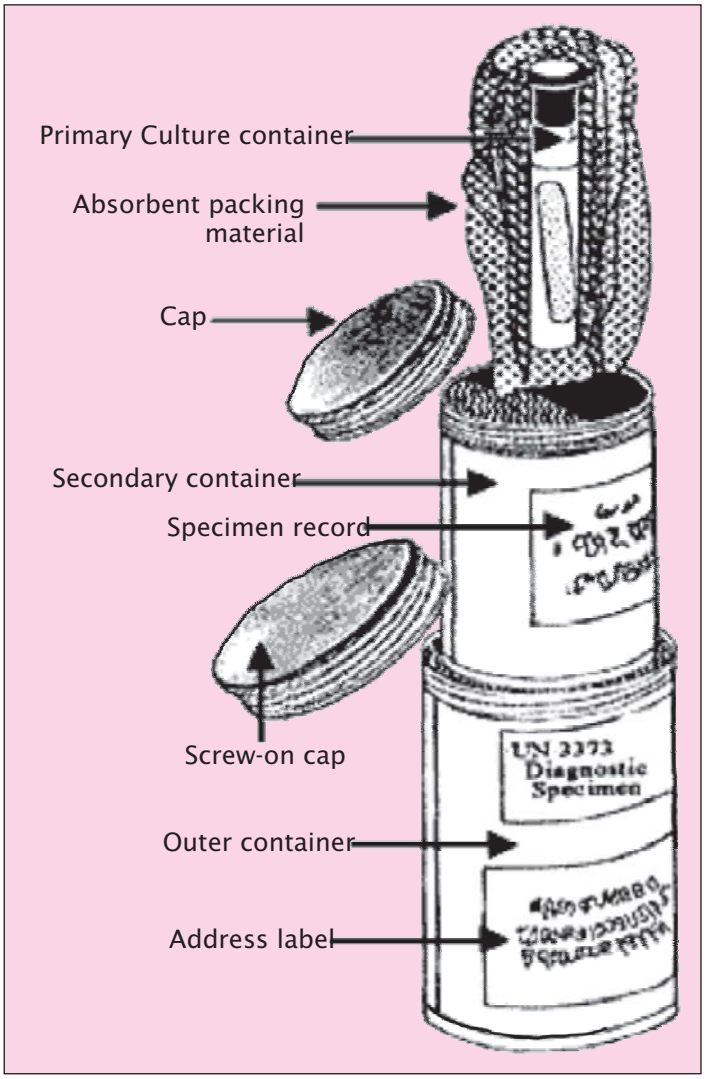
### (d) Glycerol saline transport medium for Typhoid bacilli (Cary-Blair medium)

Prevents overgrowth of other intestinal organisms and preserves typhoid bacilli. It contains Glycerol, NaCl, disodium hydrogen phosphate, phenol red and water and is a purple-pink colour. It is dispensed in 6 ml volume in universal containers. The fluid should not be used if it becomes acidic indicated by a change in colour to yellow.

### The Three-tier packaging method for transport of diagnostic specimens (Fig. 4)

The packaging comprises a diagnostic specimen within a cryovial (a specimen carrier), a secondary container and an outer transport container. The specimen in the labeled primary container must be water tight, air tight and wrapped in absorbent material such as cotton wool to

Fig - 4 : The three tier packaging method for transporting samples



absorb any leakage. After tightening the cap, sealing tape may be applied e. g. Parafilm or a waterproof plastic tape over the cap and the top of the specimen container. The sealed cryovial is in turn placed in a suitably sized plastic bag together with a small amount of absorbent material. The bag must be sealed either using a sealer or a flame. Alternatively, zip lock bags may be used.

The secondary container is sealed with a screw capped lid, labeled, packed with absorbent packing material and placed within an outer transport container. The outer container protects the contents from physical damage and water while in transit. It should therefore be made of metal, wood or fibreboard with a shock absorbent padding within and a tight fitting lid. Two or more sealed specimens from the same patient may be placed in a larger plastic bag and sealed.

Specimens from different patients should never be sealed in the same plastic bag but may be double bagged and thereafter proper labeling put into the same secondary container. In daily practice, coolant packs that have been frozen in the deep freezer are used to keep the temperature at 4-8$^{o}$C which is maintained for a period of 2-3 days. These ice packs can be reused after disinfection of the surface. A good substitute is sealed plastic bags containing ice cubes. Dry ice may also be used wherever available. A vaccine carrier if used instead of a transport carrier needs to be thoroughly disinfected before reuse but must never be reused for vaccine carriage again. A Biohazard symbol is to be fixed outside the secondary as well as the outer container.

**Processing of Tissue for Histopathological Examination**

Specimens for histopathological examination or gross preservation must be placed immediately after removal in a fixing fluid consisting of one part of commercial formalin to nine parts of normal saline. This should be up-to 50 times (but not less than 10 times) the volume of the specimen. Normal saline without the addition of formalin is not a preservative. If a properly equipped laboratory is available, the whole specimen should be sent without delay to the pathologist; otherwise proceed to treat the specimen as follows before its dispatch to the laboratory :

(a) Biopsies and small operative specimens up-to bean-size should be placed in a bottle with fixing fluid and forwarded without delay.

(b) Medium size and bulky operative specimens should be adequately incised to ensure quick penetration of the fixation fluid in to all parts of the tissue and prevent autolysis, and then placed in a large container with an excess of fixing fluid. This specially applies to lymph glands. The direction of incisions should be such that surfaces useful for demonstration remain intact.

(c) Large solid organs should be cut into representative slices about 2 cm thick.

(d) Hollow organs should be filled with fixing fluid and tied.

(e) Postmortem material should be obtained soon after death.

(f) Cover the floor of the container with cotton wool or suspend the specimen in the fixing fluid without it touching the sides of the container.

(g) All specimens should be accompanied by a properly completed laboratory examination request form. In case of postmortem material a copy of clinical history and postmortem report should be included.

(h) Endometrial Specimens

Since the endometrium is exceedingly soft and undergoes rapid autolysis, it should be carefully handled and properly fixed. Before fixation, however, it is best to remove clots of blood and mucus. These may be separated either by rinsing the fragments of tissue gently in physiological saline or by spreading them on a fine-meshed sieve or fabric, from which they may be transferred into the fixing solution with one arm of a blunt forceps, exercising care to avoid squeezing or pinching them. Endometrial curettings are never to be wrapped in fabric. The ideal fixative for endometrium is 10% neutral formalin. Tissue may be left in the fixative for weeks without harm.

(j) Tissue for Electron Microscopy

The biopsy specimen is cut into small pieces of 1 mm size and immediately transferred into buffered glutaraldehyde fixative (3% phosphate buffered cold glutaraldehyde solution of pH 7. 2 to 7. 4). Fix the tissue in this fixative for 2 hours. The specimen may be washed with the same buffer which was used to prepare the buffered glutaraldehyde. Seal the container properly and dispatch to EM Laboratory, AFMC, Pune.

## When called to Investigate an outbreak

The investigation of an outbreak needs a syndromic approach. The case definition needs to be adhered to. The case details are an extremely important part of the investigation. A laboratory investigation form is shown in Appendix “A”. The laboratory should be ready to move at short notice and an “Outbreak Investigation Kit” as shown in Appendix “B” needs to be kept ready and periodically checked. Samples to be collected must be planned in advance and all prerequisites should be methodically packed. Proper planning, sampling and transport will pay good dividends and go a long way in providing a scientific answer.

**Selective commonly-encountered conditions: Parasitic**

Malaria

**Microscopy**

The gold standard for the diagnosis of malaria is microscopy. The sample is a thick and thin blood film made on the same slide or on different slides. In experienced hands, microscopy on dehaemoglobinised thick film can detect as low as 5-10 parasites/µl of blood. Dehaemoglobinization is done by either of the following two ways: a) With glacial acetic acid & tartaric acid mixture

(4 parts of 2% glacial acetic acid and 1 part of 2% crystalline tartaric acid) : The film is flooded with the mixture and as soon as the dehaemoglobinization is complete (evidenced by a grey-white color of the film) the fluid is drained off by tilting. It is then fixed with methyl alcohol for 3-5 min. Next the slide is washed with neutral/slightly alkaline distilled water so that every trace of acid is rid of b) Using distilled water by placing the slide with blood film in a vertical position in a glass cylinder for 5-10 min. When the film is colorless, it is taken out and dried in an upright position. Then staining with Leishman, Wright stain or Leishman-Giemsa is done as usual. A "Parasite index" must always be provided to quantify the infection (100 oil immersion fields of a thick dehaemoglobinised blood smear are scanned using X 7 ocular and X100 of oil immersion lens; this scans roughly 0. 25 ml blood; the final result is expressed in parasites/ml blood) This may also be done on a stained dehaemoglobinised thick blood smear by counting the number of parasites alongside 200 WBC and multiplying the result by 40 (the TLC count is presumed normal at 8000/mm$^3$). Despite inaccuracies due to variation in WBC count among individuals it provides reasonable information. Alternately, total number of parasitized RBC is counted against 10, 000 RBC in a thin stained film that has roughly 20 RBC per oil immersion field. Parasitized RBC more than 5% is labeled as hyperparasitaemia.

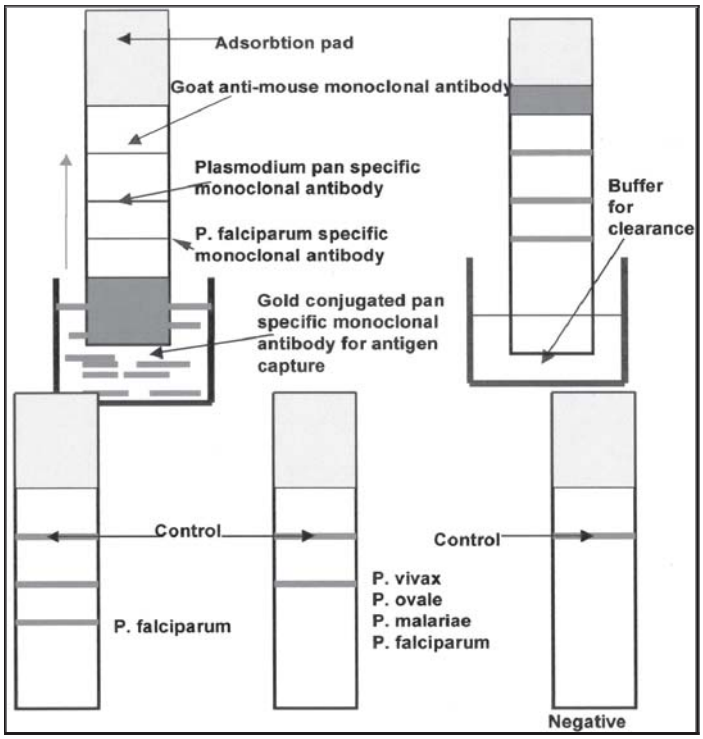
**Immunological test**

The target for immunological tests is the use of monoclonal antibody against one of the antigens associated with malaria. The tests for malarial antigen are grouped as **Rapid Diagnostic Tests (RDT)**. These tests use finger-stick or whole blood in EDTA, take only 10-15 min to perform and can be done in field conditions. Two types of rapid tests are available: one that identifies Histidine-rich-protein-2 (HRP-2) of *Plasmodium falciparum* (Pf) and others based on detection of isomers of parasite lactic dehydrogenase (pLDH) of falciparum malaria as well as a common pLDH for all four malarial species (Fig. 5). The HRP-2 antigen is synthesized and released by trophozoites and immature gametocyte stage and persist in peripheral blood up-to 2 weeks after chemotherapy and parasite clearance as confirmed by microscopy. These tests have a low sensitivity for detection of infection with low-level parasitemia (<100 parasites/ul) and mature gametocytes. Parasite LDH is produced by both asexual and sexual stages of the malaria parasite. Test kits currently available can distinguish *P falciparum* from non-falciparum infections but cannot distinguish among the three other species. Tests that detect pLDH do not generate persistent positive results following chemotherapy. Use of RDT does not eliminate need for malaria microscopy and all RDTs must ideally be followed by microscopy as low level infections are often not possible to detect. Immunological test for detection of antibody is an ELISA based assay and does not necessarily detect a current infection.

**QBC (Quantitative buffy coat from Necton-Dickinson, USA)**

This is based on microscopy using capillary tubes coated on the inside with fluorochromes such as acridine orange

Fig - 5 : RDT for Malaria



that stain any parasite present. These tubes are evaluated after centrifugation of the blood using fluorescence based microscopy of the RBC layer. The method is expensive but specific and requires special equipment and supplies (centrifuge and centrifuge tubes, special light sources and filters) besides individual expertise.

**Molecular method**

Polymerase chain reaction using a Multiplex PCR for all four species is possible but needs special equipment and expertise.

Kalazar (visceral Leishmaniasis)

**Microscopy**

The protozoan parasite *Leishmania donovani* causing visceral Leishmaniasis may be detected in a thick blood film stained by Leishman, Leishman-Giemsa or Wright stain. The amastigote forms may be seen within circulating monocytes. These look pinkish oval in outline with dark purple kinetoplast and nucleus. However, they are best detected by examination of an aspirate from spleen or bone marrow where the amastigote forms are seen within the macrophages. Cutaneous and Mucocutaneous leishmaniasis is confirmed by histopathology of the lesion for amastigote stage of the parasite.

**Demonstration of antibody: by ELISA**

**Non-specific serological tests**

These tests are based on the detection of increased gamma globulins in the blood. In Napier's aldehyde test, a drop of 40% formalin is added to 1 ml of serum. A positive test shows rapid and complete coagulation of serum. In Chopra's Antimony test a 4% urea stibamine solution is

mixed with serum. A positive test is indicated by the formation of a profuse flocculent precipitate.

**Culture**

Culture of the parasite is possible in a well equipped laboratory undertaking such procedures regularly. The medium used is NNN (Novy-McNeal-Nicolle) medium. Specimens are inoculated into the water of condensation and incubated at 22˚C for 1-4 weeks. At the end of every week, a drop of condensation fluid is examined for Promastigote forms of *L. donovani.*

**Molecular technique (PCR)**

This is very specific but needs expertise and sophisticated apparatus.

**Selective commonly-encountered conditions: Bacterial**

Leptospirosis

Leptospirosis is a bacterial infection that affects humans and animals. It is caused by bacteria of the genus Leptospira. In humans it causes a wide range of symptoms. Some infected persons may be asymptomatic. Others develop high fever, severe headache, chills, muscle aches, vomiting and diarrhea. They usually have jaundice, conjunctival congestion or a rash. If the disease is not treated, the patient can develop encephalitis, hepatic or renal failure and respiratory distress. In rare cases death occurs. Many of these symptoms mimic Dengue fever, Malaria and Chikungunya.

Screening test is available based on latex agglutination technique with serum for detection of the Leptospira Group specific IgM antibody. Confirmation requires culture and detection of specific Leptospira antibody by a sensitive test such as ELISA followed by Microscopic Agglutination Test (MAT) to determine the serotype. The MAT is only possible in a reference laboratory. For culture, blood is collected in EDTA and sent in ice to an appropriately equipped lab for culture. Specially devised media have to be used. The same sample can also be used for examination of the organism using dark ground illumination (DGI). A fresh sample of urine, alkalinized by adding Sodium bicarbonate so as to have a pH around 9. 0, can be sent to an appropriately equipped lab for DGI. A sample of 5 ml blood must be taken in a sterile screw cap vial for serum for carrying out

a) Screening test for group specific antibody by latex agglutination
b) ELISA test for specific IgM antibody and, if indicated
c) MAT (Microscopic agglutination test)

The samples consisting of blood in EDTA, blood in sterile container for serum and alkalinized fresh urine may be sent to the lab with prior intimation, with clinical and investigation details of the case.

Leprosy

**(a) Skin Biopsy**

It is taken from a lesion situated in a richly innervated area e. g. forearm. The biopsy should be reasonably large and taken from the progressive edge of the lesion including normal skin. It should be wedge shaped reaching deep into the subcutaneous tissue. The base of the wedge in the subcutaneous tissue should be broader than the skin surface. The longitudinal axis of the wedge should be parallel to the general course of the subcutaneous nerve bundle in the area chosen. The biopsy material obtained is immediately fixed in 10 percent normal saline and forwarded for histological examination. In the lepromatous type of leprosy, material is collected for demonstration of *Mycobacterium leprae* by Ziehl-Neelsen (ZN) stain. In the neural type, clinical examination suffices for diagnosis and bacteriological methods are of little use.

**(b) Skin and Nasal Scrapings**

Thickened area of skin is selected. The site is cleaned with alcohol and ether, pinched up between thumb and index finger and a linear cut is made up to the dermis at the apex of the fold by means of a sharp scalpel point. The base and the sides of the incision are thoroughly scraped and the material collected is smeared on the slide and fixed with heat. For nasal scrapings the nose is cleaned with moist swabs and a cut is made in the mucus membrane of the septum if no obviously ulcerated areas are present. The site is scraped gently to obtain the material for smears.

Polymerase chain reaction (PCR) is a sensitive and specific molecular diagnostic test for Leprosy, but needs infrastructure and expertise. It is however, of limited utility for paucibacillary or borderline cases. Tissue biopsy or aspirate from lesion in sterile saline may be subjected to PCR. All results should be correlated with other clinical and laboratory findings.

Bacterial STD

Syphilis

The Spirochaete Treponema pallidum is highly infectious. Therefore, while collecting serous exudate from lesions, such as chancre, mucous patch etc. rubber gloves and eye-protection should be worn. Thoroughly cleanse the sore and its surroundings with a swab of cotton wool, which has been soaked in 2 per cent saline. If an antiseptic has been applied to the sore, a wet dressing of saline solution is applied carefully to the sore for three days prior to taking the specimen. Scrape the margin of the sore lightly with a blunt instrument to remove the superficial epithelium. Squeeze the base of the ulcer so as to promote oozing of serous fluid. Slight bleeding will probably occur but will soon cease and in a minute or two, clear serum will exude from the scarified area. Transfer a portion of the serum to a slide, cover it with a cover-slip and ring with Vaseline to prevent currents occurring due to evaporation. The preparation should be examined by DGI immediately. Darkfield examination for T. pallidum, of material aspirated from enlarged lymph glands is of particular diagnostic value in intra-urethral chancres, lesions obscured by phimosis or paraphimosis, old involuted chancres upon which the local darkfield examinations are repeatedly negative, dirty, painful and secondarily infected chancres, all chancres or secondary lesions within the oral cavity (specially chancres of tonsils), secondary syphilitic lesions with moderate lymhadenopathy and in the differential diagnosis of

syphilis and lymphogranuloma venereum. A positive finding is diagnostic as non- pathogenic spirochetes do not occur in lymph nodes. The material aspirated can also be submitted after fixing in alcohol for silver impregnation such as Fontana stain. The technique of aspiration is simple. After swabbing tincture of iodine on the skin over the enlarged gland, take about 0. 5 ml sterile saline into a 5 ml syringe. Fix the gland with the fingers, insert the needle in it, inject the saline, rotate the needle for 30 to 40 seconds and gently move the gland from side by moving the needle. Withdraw the slightly blood-tinged serum and carry out a thorough darkfield examination.

When facilitiy for immediate microscopic examination does not exist, touch the drop of serum with a sterile 15 cm long capillary tube with both its ends opened and hold in a horizontal position. The exudate from the sore or gland will then rapidly enter the tube. When about 2 to 3 cm of the exudate has entered, the tube is sealed at one end by heating; and when the serum retracts on cooling of the sealed end, seal the other end while holding the tube horizontally. Pack carefully and send to the nearest laboratory.

Simultaneously, sample of 5 ml blood has to be collected for serological tests (VDRL or RPR, TPHA).

Gonorrhoea

(a) The sample for Neisseria gonorrhoeae is the purulent urethral discharge. The meatus is cleaned with gauze soaked in saline, the purulent material is collected on a sterile charcoal impregnated swab, put in Stuart transport medium and sent for culture. Culture is done on chocolate agar and Mueller-Hinton medium in an atmosphere of carbon dioxide. Thayer Martin medium is employed as a selective medium in chronic cases. The material is also taken on-to a clean slide, air-dried and sent to the laboratory, wrapped in paper for Gram stain. The organisms are seen as Gram negative intracellular diplococci. In appropriately equipped laboratories, Fluorescent antibody technique can be used on the smears to demonstrate the gonococcal antigen.

(b) In women, besides the urethral discharge, cervical swabs should also be collected using a speculum. As the organism is extremely delicate and fastidious, it is preferable to carry out a bedside inoculation of media.

(c) In chronic infections there may not be any urethral discharge. The "morning drop" of secretion may be examined or some exudates may be obtained in males after prostatic massage. It may be possible to demonstrate gonococci in centrifuged deposits of urine.

Chancroid (soft sore)

Because a clinical diagnosis of chancroid is often inaccurate, laboratory confirmation of the diagnosis should be sought.

(a) Gram stain of a swab of the ulcer may reveal a predominance of Gram negative coccobacilli but is often difficult to interpret.

(b) Isolation of Haemophilus ducreyi from a swab of the lesion or from the aspirate of suppurative lymph nodes confirms the diagnosis. Selective and supplemented media and use of a $CO_2$ jar are required.

(c) A multiplex PCR based assay is available commercially and is more promising.

**Selected viral conditions**

Dengue fever and Dengue haemorrhagic fever (DHF)

Dengue fever, caused by a flavivirus is a mosquito-borne infection which in recent years has become a major international public health concern. There are four distinct, but closely related serotypes of dengue virus (serotypes 1-4) that cause dengue. Most dengue virus infections are subclinical. Self-limited dengue fever is the usual outcome. Recovery from infection by one provides lifelong immunity against that serotype but confers only partial and transient protection against subsequent infection by the other three. There is good evidence that sequential infection increases the risk of more serious disease resulting in Dengue Hemorrhagic Fever (DHF).

The case definition of Dengue fever is an acute febrile illness of 2-7 days duration with 2 or more of the following: headache, retro-orbital pain, rash, haemorrhagic manifestations and leucopenia. A probable or confirmed case of dengue fever with haemorrhagic tendencies is evidenced by one or more of the following: positive tourniquet test, petechiae, ecchymoses or purpura, bleeding from buccal mucosa, GI tract, injection site and signs of plasma leakage (pleural effusion, ascitis, hypoproteinemia). The haematological criteria are thrombocytopenia (platelets 1, 00, 000/$mm^3$ or less) and haemoconcentration (>20% rise of PCV for age & sex).

**Samples that need to be collected for diagnosis are as follows:**

**For serology**

(a) A blood sample for serum as soon as possible after the onset of illness (acute serum)

(b) A second sample after 10 days (convalescent serum)

(c) A third sample may be drawn 21 days after first sample (late convalescent serum).

The tests required to be done are Dengue IgM and IgG ELISA test and, in field conditions, Dengue IgM & IgG Rapid strip test (Immunochromatographic test). Early dengue is characterized by the presence of detectable IgM antibodies 3-5 days after the onset of infection. Later in the disease there is elevation of specific IgG antibodies. In case clinical suspicion is high and initial IgM test is negative, repeat the test after 2-3 days for confirmation. In neurological involvement CSF can also be used for serology using appropriate kits.

**For virus isolation**

This has to be an early sample. Virus can be isolated

provided the sample is taken in the first few days of illness and processed without delay. Suitable specimens are acute phase serum, plasma, washed buffy coat from the patient, autopsy tissues from fatal cases especially liver, spleen, lymph nodes and thymus as well as mosquitoes collected from the area under surveillance. Samples for virus isolation should be immediately transported within 48 h to referral centre in an ice-box.

**Molecular method**

A PCR can be undertaken in a tertiary laboratory to detect the genetic sequence for a particular strain or all four strains in a Multiplex format.

### Japanese encephalitis (JE)

Japanese encephalitis is a zoonotic viral disease by a Group B arbovirus (flavivirus) that involves the central nervous system. In nature the virus is maintained in animals especially pigs and in birds particularly in cattle egrets, pond herons etc. The case definition for JE is a case of high grade fever of acute onset with at least two of the following: decrease in level of consciousness independent of convulsions, significant change in mental status/ behavior and convulsions.

**Laboratory diagnosis of JE**

Laboratory diagnosis of JE is done by following methods:

(a) Demonstration of viral antigen in the autopsied brain tissue by the fluorescent antibody test

(b) Isolation and identification of the virus from CSF, occasionally from peripheral blood (within 3-4 days after onset of symptoms) or in autopsied brain tissue.

(c) Detection of antibodies to JE virus detected by haemagglutination inhibition test and IgM capture ELISA test. The antigen and reagents for both tests are available from National Institute of Virology at Pune.

The tests mentioned are not available in peripheral hospital laboratories. The samples (separated serum, whole blood in EDTA, autopsied brain in saline) should therefore be preserved at refrigerator temperature of 2-8°C and transported to referral laboratory for further processing. The laboratories that are undertaking work on JE in India are: National Institute of Virology, Ambedkar Road Pune, National Institute of Communicable Disease, 22, Shyam Nath Marg, Delhi, Sanjay Gandhi Post Graduate Institute of Medical Research, Rae Bareilley Road, Lucknow, King George Medical College, Lucknow, School of Tropical Medicine, 110, Chittaranjan Avenue, Kolkata, Veterinary Biological Institute, Hyderabad and King Institure of Preventive Medicine, Chennai. Armed Forces Medical College liaises with NIV Pune for the samples received.

### Kyasanur forest disease (KFD)

This condition came to the fore with an outbreak of monkey deaths and haemorrhagic fever with jaundice in 1957 in the Kyasanur forest of Mysore (now Karnataka) State. The virus, a flavivirus, was isolated from the dead langur monkeys and *Haemophysalis* ticks. Outbreaks have occurred among the human population within Karnataka and serologic evidence of infection exists in North Western States and even the Andaman islands. The illness begins abruptly with fever, headache, chills, vomiting, myalgia, photophobia and conjunctival suffusion. There is hepatosplenomegaly and lymphadenopathy. Petechiae may be present. At this stage clinically it can be mistaken for dengue fever, chikungunya or malaria. Acute haemorrhagic manifestations may occur and renal failure is known. After defervescence, a second phase starts with neurological symptoms. Laboratory findings are similar to that for DHF with leucopenia, thrombocytopenia, rise of haematocrit and elevated hepatic transaminases. Patients have detectable viremia upto 12 days after onset of illness. Laboratory diagnosis consists of serologic demonstration of IgM antibody, isolation of the virus and molecular detection of the viral genomic sequences. These tests are undertaken by a reference laboratory such as NIV at Pune. For virus isolation and molecular methods, blood should be collected in EDTA and serum should be preserved for serological studies.

### Chikungunya

The chikungunya fever is caused by chukungunya virus (CHIKV) of genus Alphavirus of Togaviraedia family and spread by culicine mosquitoes (*Aedes aegypti* and *Aedes albopictus*). Chikungunya was first reported in 1952 from Makonde plateaus between Tanzania and Mozambique and virus isolated by Ross in 1953. It is a Makonde word meaning "the one which bends up". This refers to the position of the affected patient acquired due to excruciating pain in joints. The arthropod vector remains infected for life. In India there have been several outbreaks as far East as Kolkata and also in Kerala, Tamil Nadu and Karnataka. The case definition is an acute febrile illness with several of the following symptoms: headache, incapacitating joint pains, backache, photophobia and itchy rashes. Usual presentation is a triad of "fever, rashes and arthralgia". The routine laboratory parameters may be similar to dengue fever with leucopenia, thrombocytopenia, rise of haematocrit. It may rarely be complicated with meningoencephalitis, hepatitis and myocarditis.

The diagnosis is confirmed by

(a) Serum positive for specific IgM antibodies by IgM capture ELISA (Immunochromatographic tests are available and a combined strip test with dengue fever IgM is also available)

(b) A four-fold increase of titer in paired sera by Haemagglutination Inhibition (HAI) test

(c) RT-PCR of the viral RNA

(d) Virus isolation from serum.

### Hepatitis A

Hepatitis A, a picornavirus, is acquired by the faeco-oral route with the initial source being contaminated water supply. Contacts of patients are often affected and need to be protected using the Hepatitis A vaccine or the specific Immunoglobulin preferably within 2 weeks of contact.

Laboratory diagnosis consists of demonstration of Anti HAV IgM antibody in serum along with biochemical parameters. Anti HAV IgG develops in an affected patient and is known to persist for prolonged period of months.

Hepatitis E

Hepatitis E, as yet an unclassified virus, is acquired by the faeco-oral route and often causes outbreaks of jaundice in the community. It is particularly common among the developing countries of SE Asia. The source is contaminated water. This condition may often take a serious turn in pregnant women in the third trimester of pregnancy. Laboratory diagnosis consists of demonstration of IgM antibody to Hepatitis E by ELISA. Molecular methods are possible with whole blood in EDTA or with serum.

Rabies

**Antemortem diagnosis**

Specimens that can help in antemortem diagnosis in an affected individual are skin biopsy with dermis from the nape of the neck, antemortem saliva, CSF and corneal smears (in 2ml PBS or phosphate buffered saline with 0. 75% bovine albumin) for detection of the rabies antigen using direct Immunofluorescence (FAT). The titer of rabies specific antibody by Rapid Fluorescence Focus Inhibition Test (RFFIT) has to be ascertained in both the CSF and the serum at the same time. A sample of 5 ml blood should therefore be collected at the same sitting. Presence of antibody in CSF is pathognomonic for rabies irrespective of immunization status. RFFIT is done in a reference laboratory such as NIMHANS Bangalore.

**Post-mortem examination:**

The diagnosis of rabies, post-mortem, is carried out by examining the brain tissue for the presence of the virus. This is done by

(a) Demonstration of Negri bodies in the wet impression smears of the hippocampus or cerebellum stained with Seller's Stain. Seller's stain is made up of two components: Seller's A is 1% basic fuchsin in methyl alcohol and Seller's B is 1% methylene blue in methyl alcohol. For use 1 part of A is mixed with 2 parts of B and used immediately on a wet preparation of “imprint smear”.

(b) Isolation of the virus by intra-cerebral inoculation into suckling mice.

(c) Direct Fluorescent Antibody Test (FAT) for rabies virus antigen. Of these, demonstration of the Negri bodies can be carried out in the peripheral laboratory. However, as the Negri bodies may be absent in an animal suffering from rabies, it is essential that the brain tissue should be sent to AFMC for other tests. The following is the systematic procedure for the removal of the brain of the deceased individual or the animal suspected to be rabid:

The removal of the brain must be undertaken with all precautions for personal protection. Apron, goggles, face masks and gloves must be worn. If during removal there is accidental contact with the infective material, an appropriate dose of human rabies immunoglobulin (HRIG) 20 IU/KG and simultaneous course of antirabies vaccine has to be taken as per laid-down guidelines of post-exposure immunisation.

For the removal of the brain, incise the skin along the mid - coronal line. Reflect the skin along with underlying muscles on either side and remove the skullcap by sawing all around. In absence of a saw, the skull can be opened by a chisel with a sharp tap from the hammer. The dura is incised and the brain is removed by dividing the spinal cord at the foramen. The brain is divided into two halves along the median sagittal plane. One half is fixed in ten percent formal-saline or in Zenker's fixative for histopathology. Prepare impression smears from the cerebellum, hippocampus and cortex before putting in 50% glycerol-saline. This tissue in 50% Glycerol-saline will be used for virology studies (demonstration of Negri bodies by Seller's stain, virus isolation, fluorescent antibody test). Five millimeter thick sections are taken from the hippocampus, cerebellum and cortex and put in 10 times their volume of 50 per cent glycerol in sterile isotonic saline for dispatch by fastest means to AFMC. While removing the brain from an animal, the salivary glands should also be removed and sent to AFMC in a sterile container surrounded by wet ice.

To expose the hippocampus, a longitudinal incision about 2. 5 cm long is made in the posterior third of the cerebral hemisphere, about ½ cm away from the midline. The incision is continued down through the grey matter and then completely through the white matter until the lateral ventricle is reached. Hippocampus major is a glistening white and semi-cylindrical body which on section presents a characteristic rolled surface extending laterally on each side forming the bases of lateral ventricles. One or two millimeter thick smooth cut slices are made in the middle of each hippocampus for making impression smears. These slices are placed on a smooth board and scrupulously cleaned slides are then pressed down upon them. Thin films of cells which will adhere to the slides (“imprint smear”) are fixed for 2 to 3 min in methyl alcohol and then stained by Giemsa, Mann or Seller's method of staining.

HIV infection

An arsenal of laboratory methods is available to screen blood for HIV infection, diagnose HIV infection, and monitor disease progression in individuals infected by HIV. These tests can be classified into those that:

(a) Detect antibody

(b) Identify antigen

(c) Detect or monitor viral nucleic acids

(d) Provide an estimate of T lymphocyte numbers and cell phenotype.

Antibody detection is, however, the most widely used and most effective way to identify HIV infection. Tests to detect antibody to HIV can be further classified as:

**(a) Screening tests**

Screening tests which are designed to detect all infected

individuals or samples.

**(b) Supplemental assays**

Supplemental assays which are designed to identify individuals who are not infected but who have reactive screening test results.

Accordingly, screening tests possess a high degree of sensitivity, whereas confirmatory assays have a high specificity. Tests with high sensitivity produce few false-negative results, whereas tests with high specificity produce few false-positive results. Regardless of the results, because laboratory tests have their limitations, they are meant to be used ideally in conjunction with clinical diagnosis.

**Screening tests**

These tests which are basically rapid and relatively cheap include

(a) Enzyme Linked Immunosorbent Assay (ELISA)
(b) Rapid tests
(c) Simple tests

**(a) ELISA**

This is the most commonly used test to screen for HIV infection because of its relatively simple methodology, inherent high sensitivity, and suitability for testing large numbers of samples, particularly in blood testing centers. More than 40 different ELISA test kits are currently available, but only about 10 are licensed. A common feature of all varieties of ELISA is the use of enzyme conjugates that bind to specific HIV antibody, and substrates / chromogens that produce color in a reaction catalyzed by the bound enzyme conjugate. The most popular **ELISA** involves an **indirect method** in which HIV antigen is attached to a well of a 96-well microtiter plate, or to a macroscopic bead that subsequently is placed in a well of a plate. Antibody in the sample is allowed to react with the antigen-coated solid support, usually for 30 minutes at 37˚C or 40˚C. After a wash step to remove unbound serum components, addition of a conjugate (an anti-human immunoglobulin with a bound enzyme) binds to the specific antibody that is attached to the antigens on the solid phase. Another wash later, addition of an appropriate substrate results in color development that is detected by a spectrophotometer. The color is proportional to specific HIV antibody concentration in the sample and is expressed as Optical density values (OD).

**An addition to ELISA** technology is the **antigen sandwich method** in which an enzyme (alkaline phosphatase or horseradish-peroxidase) is conjugated to an HIV antigen (similar to the immobilized antigen on the solid phase). The antibody in the sample is "sandwiched" between two antigen molecules, one immobilized on the solid phase and one containing the enzyme. Subsequently, the addition of substrate results in color development in proportion to antibody concentration. The antigen sandwich ELISA is considered the most sensitive screening method, given its ability to detect all isotypes of antibody (including IgM). Although ELISA tests require an initial investment of expensive instruments like plate washer, spectrophotometers etc. , the running cost is rather low as compared to the supplemental tests.

**(b) Rapid tests**

These tests have a total reaction time of less than 30 minutes. They are more expensive per test than ELISA, though they do not require complex equipment. Importantly, these rapid assays are easy to perform and have utility in developing countries where facilities may not be optimal, stable electricity may be unavailable, and formally trained laboratory workers are not always available.

**There are two types of rapid tests :** Latex agglutination and Dot-blot assays. In Latex agglutination test a colloidal suspension of latex beads is coated with synthetic peptide antigen e. g. env polypeptide. Reaction with HIV antibody produces cross-linking of the latex antigen, which results in agglutination. In Dot-blot assay microscopic particles are coated with a synthetic peptide and then immobilized on a nitrocellulose membrane. Patient's serum containing antibodies, conjugate, developer and stop solutions are then added in sequence with usual incubation and washing steps. Color then develops which is in proportion to the amount of HIV antibody bound to the peptide coated microparticles. Most of these rapid assays now incorporate a built-in control that indicates that the test was performed correctly. In addition, several varieties are available that include two "dots, " which allow the differentiation of HIV-1 and HIV-2 infection. Other rapid test formats include dipsticks, in which antigen is attached on the "teeth" of comb-like devices; several of these rapid tests have the ability to differentiate HIV-1 and HIV-2.

**(c) Simple tests**

This type of HIV test requires greater than 30 minutes but has procedures that can be performed easily without instrumentation. Within this class of tests are agglutination assays in which antigen-coated particles (RBC, latex particles, gelatin particles) are allowed to react with serum antibodies to form visible clumping (agglutination). If RBC is used, the technique is termed passive hemagglutination (PHA); with the use of latex particles, it is known as latex agglutination (LA).

**Supplemental tests**

These tests are also serological tests for detection of antibodies against HIV. These tests are recommended for validation of the positive results of the screening assays. The primary purpose of supplemental tests is to ensure that uninfected individuals who test reactive by screening assays are not incorrectly identified as being HIV infected.

There are two types of supplemental tests that are commonly used: Western blot assay and Immunofluorescence test

**(a) Western Blot Test**

The Western blot is probably the most widely accepted supplemental assay for the detection of antibodies to the retroviruses; most authorities consider it the "gold standard" for validation of HIV results. It is based on using an electrophoretic technique to separate HIV antigens derived from a lysate of virus grown in culture. This

technique denatures the viral components, imparts a negative charge to the antigens, and separates them based primarily according to their molecular weights. The separation of antigens in the technique allows for the identification of specific antibodies to each of the viral antigens in a subsequent set of steps similar to the ELISA methodology.

Depending on the particular antibodies in the sample, reactivity with the separated antigenic components results in band profiles. The classification of Western blot results is determined by certain criteria. Most institutions now follow the CDC guidelines, which require reactivity to at least two of the following antigens: p24, gp41, gp120/160 for a positive classification. It is now universally accepted that a negative result is the absence of all bands.

**(b) Indirect Immunofluorescent Antibody Assay (IFA)**

In this technique, cells (usually lymphocytes) are infected with HIV and are fixed to a microscope slide. Serum containing HIV antibodies is added and reacts with the intracellular HIV. The slide is washed and then allowed to react with anti-immunoglobulin antibodies with a covalently bound fluorescence label attached. The reaction is visualized using a fluorescent microscope.

**Line Immunoassay for HIV**

Another alternative to the classic Western blot and IFA confirmatory tests is the line immunoassay (LIA). In this assay, recombinant or synthetic peptide antigens are applied on a nitrocellulose strip, rather than electrophoresed as in the Western blot. This use of "artificial" antigens decreases the presence of contaminating substances derived from cell culture that can cause interference and sometimes - false reactions.

**HIV-2 infection**

As with HIV-1 screening tests, a variety of test formats are available to detect antibodies to HIV-2, including ELISA beads, ELISA microtiter, and rapid/simple assays.

Diagnostically, HIV-2 infections can present problems. Screening tests designed to detect infection by HIV-1 do not always detect infection by HIV-2 and vice-versa. To address this issue, commercially available HIV-1/2 "combination tests, " which incorporate antigens from both viruses, can be used to screen sera in an attempt to identify either infection.

**Detection of HIV-Specific circulating antigen (p-24):**

The antigen test detects HIV free antigen (p-24) in the serum. HIV antigenemia occurs during "window period" and during late disease when the patient is usually symptomatic. HIV antigenemia is also seen in a newborn. Therefore, an antigen test may be useful, (a) during "window period", (b) during late disease when the patient is symptomatic, (c) to detect HIV infection in a newborn because diagnosis is difficult due to the presence of maternal antibodies. (d) When HIV dementia and encephalopathy is suspected and the test is performed with the cerebro spinal fluid. Only 30% patients during window period, 50-60% of AIDS patients, 30-40% of patients with AIDS related complex (ARC) and 10% of asymptomatic patients are antigen positive.

This test employs indirect ELISA technology.

**Polymerase Chain Reaction (PCR) for HIV:**

In this technique, the target HIV RNA or proviral DNA is amplified enzymatically in vitro by chemical reaction. It is an extremely sensitive assay because a single copy of proviral DNA can be amplified and then be detected by the probe. This technique allows detection of HIV prior to the detection by antibody assays. PCR can probably detect infection even before viral culture becomes positive. Presently, it is the most sensitive known method for identification of HIV infection. However, at present, the PCR technique is not suitable for use in routine laboratories.

**Quantification of HIV-1 plasma viral RNA**

Quantitative measurement of HIV-1 RNA (viral load) has been invaluable in studies of HIV-1 replication dynamics, individual prognosis, and treatment response to antiretroviral medications. In clinical practice, HIV-1 plasma viral load measurement has become the standard of care for decisions regarding initiation and monitoring of antiretroviral therapy. Three different techniques namely RT-PCR (Reverse transcriptase PCR), NASBA (nucleic acid sequence based amplification) and branched-DNA (b-DNA) assay have been employed to develop kits by commercial companies. RT-PCR and NASBA reactions are template (plasma RNA) amplification assays, whereas b-DNA assay amplifies the signal from the RNA-DNA hybridization reaction. As of now, only the RT-PCR method marketed by M/S Roche (Amplicor HIV-1 Monitor version, 1. 5) is FDA approved. It is important to get the CD4 and HIV-1 plasma Viral loads to be measured by the same laboratory every time for follow-up.

## Water for Chemical and Bacteriological Examination

**(I) Collection of samples**

These should be collected under the supervision of the MO. A fair average sample of the supply should be collected and submitted. Samples from any individual source should be taken at the same point and at the same time for chemical and bacteriological examination.

(a) Samples for chemical examination should measure at least 5 L and should be forwarded in Winchester bottles. Samples should be taken without disturbing any sediment and while the bottles are fully submerged.

(b) For bacteriological examination, 180 ml are required. If circumstances allow, the media should be inoculated with water on the spot; a delay of 24 h in inoculation does not, however, affect the results. Samples must be collected and forwarded in sterile bottles obtained from the laboratory. If chlorinated water is being tested a crystal of sodium thiosulphate should be sterilized with the bottle, so that the bacteriological picture at the time of sampling is obtained; otherwise sterilization will continue during transit.

(c) In piped supplies samples should be taken direct from the mains and from delivery taps to the

houses. Before a sample is taken, water should be allowed to run freely so that the impurities in the pipes lumen may be washed out. Flame the tap for a minute before taking the sample, ensuring against leakage from the washer at the top of the tap into the samples. Before reopening the sterilized bottle, flame its neck and stopper for half a minute by means of Spirit-lamp. Remove the stopper and hold it with a sterilized pair of forceps. The stopper is flamed again before it is replaced in the bottle, which in the meanwhile has been completely filled in, so that no bubble of air is retained.

(d) In the case of streams, rivers and lakes, collect water from the middle as well as from near the banks. The bottle is filled by dipping the bottle (with a stopper in position attached to the neck with a piece of string) below the surface and then removing the stopper under water with forceps. This avoids the collection of surface water with scum.

(e) Samples from a well are obtained with bottles weighted with lead or stone having two cords attached, one to the neck and the other to the stopper. The bottle is lowered to the required depth and is filled by jerking out the stopper by means of the attached cord. The bottle should be quickly raised after it is filled and then re-stoppered.

All bottled samples of water must be sealed before dispatch to the laboratory and should be accompanied by the filled requisition form.

**(II) Transportation of water for testing**

Each sample should be labeled giving full particulars of its source, date of collection and examination requested. Samples should be forwarded by the most expeditious route. Those for bacteriological examination should reach the laboratory within three hours of collection. Where a delay of more than three hours is unavoidable the bottle must be kept on ice; and where the specimen has to be transported some distance, it must be packed with saw dust and ice and dispatched by courier escort. Full information on the form at Appendix " C" at the end of this chapter must be dispatched separately at the same time mentioning the identity of the sample referred to. Report on the water sample must be as per form shown in Appendix "D". Microbiology result is usually given separately in terms of coliform count per ml of water submitted.

**Food and Beverages**

Samples of fresh milk, water and aerated waters for chemical and bacteriological examination are sent to the nearest laboratory. Samples of tinned food, grains and beverages are sent to the composite food laboratories (ASC) located at Delhi, Mumbai and Jammu. These laboratories deal with examination of such samples for their storage life and fitness for human consumption. Samples must be taken under the supervision of an officer who should ensure that the following directions are carried out :

(a) A fair average sample should be taken e. g. both the crust and core of bread and cheese should be included; the milk should be well mixed by stirring before taking the sample and so on. The use of paper or other packing inside the receptacle, in which any of the samples except grains is forwarded, is prohibited, unless the sample is contained in its original wrapper.

(b) Canned articles should be sent in unopened containers. If this is impracticable, at least send the original container with the sample.

(c) Articles not packed in original containers should be packed in clean glass stoppered bottles of such a size that the sample completely fills the bottles; solids should be packed in clean tins; and semisolids should be packed either in bottles or tins, whichever is more suitable, or in clean glazed earthenware jars fitted with clean bungs.

| | |
|---|---|
| Milk | 180 ml |
| Condensed milk | 1 tin |
| Dried milk, milk food etc | 60 g |
| Butter, margarine, ghee etc | 120 g |
| Cheese | 120 g |
| Bread | 1 complete loaf |
| Biscuits | 240 g |
| Flour | 120 g |
| Oatmeal. | 60 g |
| Atta | 120 g |
| Rice. | 120 g |
| Tea. | 60 g |
| Coffee | 120 g |
| Cocoa | 60 g |
| Tinned meat, fish etc. | 1 tin |
| Sausages | 1 full tin |
| Dried or smoked meat or fish | 240 g |
| Lard or its manufacture substitutes | 120 g |
| Tinned or bottled fruits, vegetables etc | 1 tin or bottle |
| Sugar | 120 g |
| Jams/syrups | 1 tin/jar |
| Confectionery, sweets etc. | 120 g |
| Pepper, mustard, spices etc. | 60 g |
| Vinegar, sauces etc. | 150 g |
| Lime juice and other similar preparations | 150 g |
| Beer or stout. | 1 bottle |
| Spirits (whisky, gin, brandy, rum) | 1 bottle |
| Aerated water. | 1 bottle |

(d) Samples for bacteriological examination should be packed with aseptic precautions in sterile glass-stopper bottles. The material should be dispatched to reach the laboratory within three hours of collection, otherwise bacterial multiplication may alter initial picture. If delay is

inevitable the material should be preserved in a refrigerator or ice and then forwarded.

**Minimum Quantities**

The minimum quantities which should be sent for examination are as follows :

**Dispatching Particulars of Samples**

Each sample must be securely packed, labeled, and sealed by the officer taking the sample and forwarded so as to reach the laboratory expeditiously. The request should be signed by the officer taking the samples and may be countersigned by the officer at whose request the sample was taken. Full details of each sample sent should be dispatched separately by registered post on laboratory request. For more details, the nearest supply depot should be contacted. This information should include the nature and quantity of the sample, the source of the sample and the date of procuring it, the exact nature of the examination required, and the reasons for examination. In suspected poisoning, a clinical summary of the case must be sent. This summary should state the length of the time which elapsed between the consumption of the article and the onset of the symptoms observed in the order of their occurrence, the present condition of the patient or patients and the condition of other persons who have consumed the articles or similar articles from the same consignment as the sample. Reports of analysis carried out at the military food laboratory are sent to the unit sending the sample.

## Poisoning Specimens for Chemical Examination

**(a) Procedure**

Poisoning is sometimes obvious from the start but when it is uncertain or obscure or being considered because of lack of positive findings the alimentary tract and the organs of elimination deserve prime consideration. However, it must be remembered that except in corrosive poisons, the pathological findings are rarely conclusive, and appropriate viscera will have to be submitted for chemical analysis. It is therefore vital to collect and preserve the right material in the right way, quickly enough to avert failure and preferably in cold storage. The selection of viscera and materials to be preserved for chemical analysis is based on the course the poison takes in the body and its distribution in various organs and tissues. There is a common misconception that it is necessary to preserve only gastric contents in order to establish if poisoning has occurred in a given case. It should be pointed out that the gastrointestinal tract is not the only route of entry of poison into the body. Further more, if any significant period (4 to 6 hours) elapses from the time of ingestion until death or treatment, the poison will have passed out of the stomach. Poison could also have been introduced in the stomach after death to mask a homicidal act. The detection and distribution of a toxic agent in different body fluids and tissues is therefore of vital importance.

**(b) Specimens**

In non-fatal cases vomit, faeces, urine, blood, remnants of food consumed and any other article suspected to be the source of the poison should be sent. In fatal cases, kidney, liver, stomach contents, intestines and bladder should be sent in addition. At the time of postmortem, care must be taken that the contents of the hollow organs do not contaminate the solid organs. Details of material to be sent for chemical examination are given in Table - 6.

Table - 6 : Details of viscera to be sent for chemical Examination in fatal cases

| Material | Quantity |
|---|---|
| Stomach | Whole |
| Stomach contents | 300 ml. If less available, whole quantity |
| Small intestine | 90 cm in adults, 180 cm in children and whole in infants |
| Small intestine contents | 100 ml. If less available, whole quantity |
| Liver, preferably the portion containing gall | 500 gm. of liver in adults and whole in bladder along with its contents* children |
| Spleen + | Half in adults and whole in children |
| Kidneys | Half from each kidney in adults and both kidneys in children |
| Urine | 100-200 ml. If less available, whole quantity |

* The gall bladder and bile should be routinely preserved because examination of bile or, if the gall bladder was empty at postmortem, the gall bladder itself will show the presence of a large number of drugs including morphine (free and conjugated), cocaine, methadone and its metabolites, glutathione, many antibiotics and major tranquilizers or their metabolites.

\+ If septicaemia is suspected and the cause of it is not obvious, spleen tissue should be cultured. It may reveal an unsuspected terminal

**(c) Packing**

Specimens must be packed separately. Clean bottles or jars made of good quality glass with well fitting, clean and sound corks, or glass stoppers, and large enough to contain one and a half times the volume of the specimen should be used. In case of suspected poisoning by substances other than alcohol, all perishable material should be sent immersed in good quality rectified spirit or saturated solution of sodium chloride sufficient in quantity to cover the material in whatever position the vessel containing it may be held; a sample of spirit/preservative used should be sent for ready reference. In case of suspected alcohol poisoning the contents of the stomach and its washings in water are placed in a bottle with a sufficient quantity of salt to saturate the solution and leave a little salt undissolved.

The stomach itself and other materials are placed in rectified spirit as above. The stopper should be carefully tied down with a piece of cloth or leather and carefully sealed. A ring of beeswax or candle wax should be placed round the lip of the bottle so as to cover the shoulder of the bottle and sealed with the office seal of the officer in charge of the case. Each packing should be labeled giving name of the case, nature of the contents, preservative used and date of packing. The containers should be placed in a wooden or tin box, large enough to allow a layer of raw cotton (at least 2 cm thick) between the vessels as well as between the vessels and the box. The box itself is encased in cloth, which should be securely stitched and sealed. The seal should be at intervals not exceeding 7. 5 cm along each line of sewing.

**(d) Dispatch**

The specimens are sent with as little delay as possible to the nearest Government Chemical Examiner by registered post or courier together with all details, which will give him a clue. The forwarding letter should enumerate the specimens sent giving the exact date and means of dispatch. A specimen of the seal should also be enclosed.

## Appendix A

Laboratory Investigation form during Epidemics

Date:_____

(To be filled by the clinician / epidemiologist)

Patient's name : _____ Patient's ID number : _____

Father's / Husband's name : _____ Age / Sex : _____

Address: _____

_____

Date of onset of illness : _____

_____

Date of hospitalization/ reporting to the MI Room : _____

_____

Clinical signs, symptoms (with duration) : _____

_____

Treatment history: _____

Results of previous investigations (if any) : _____

_____

Any other relevant information : _____

_____

Specimen details :

| Nature of specimen | Date of collection | Investigation required |
|---|---|---|
| | | |
| | | |
| | | |

**Details of sender:**

Name of sender: _____

Unit / Address : _____

Fax : _____ Mobile : _____

E-mail : _____

Signature

(All information has to be complete. Always send the sample in cold chain unless specified otherwise)

# Appendix B

**Outbreak investigation kit**

(To be kept ready in the laboratory. The lab should check the kit fortnightly)

- Disposable storage vials (5 ml, 3 ml) & holders
- Disposable sample collection vials
- Stool culture bottles (plastic screw capped)
- Throat swabs
- Blood culture bottles (to be placed fresh)
- Viral transport medium as required
- Cary Blair medium / Stuart medium (place fresh)
- Vacutainers (plain, EDTA) with needles & holder
- Disposable syringes with needle (5ml, 10 ml)
- Tourniquet
- Gloves assorted sizes
- Triple layer surgical mask
- Disposable gowns
- Autopipette 10 µl, 50 µl, sterile pipette tips in holder boxes
- Puncture proof discarding bags
- Vaccine carrier with ice-pack
- Spirit lamp / gas lighter
- Match box
- Test tube rack
- Centrifuge tubes
- Cleaned slides & cover slips in plenty
- A small portable centrifuge, if available
- Vaccine carrier
- Ice-box / Thermocol box
- Torch, cells
- Mosquito repellant cream
- Rubber bands
- Ziploc plastic bags (Assorted sizes)
- Absorbent material (Newspaper, tissue paper, absorbent cotton)
- Sterile Absorbent cotton-wool balls, packed
- Labels, self-sticking including Bio-hazard labels
- Glass marking pens
- Adhesive tape, cellotape
- Scissors
- Scalpel / sterile blades
- Spatula (wrapped in paper)
- Forceps
- Loop holder
- Pasteur pipettes (sterilized)
- Rapid diagnostic kits eg. $H_2S$ strip for water testing, latex agglutination for meningitis, card test for dengue, chikungunya, malaria
- Band-aid
- Sod hypochlorite concentrate (4%)
- Hand disinfectant
- Lab request forms
- Stationery (paper, pencil, eraser, calculator, sketch pens, ball pens)
- Lancets (packed)
- Coolant packs
- Cardboard containers (assorted sizes)

## Appendix C

**Form for submitting Sample of Water**

1. Sample of water collected from _____ (identity number mentioned on the label).
2. The reason for and exact nature of the examination required _____.
3. Date and hour of sampling _____.
4. Nature and location of source of water, the site of sampling _____.
5. Nature and distance of any source from which an inflow of pollution appears probable _____.
6. Geological strata likely to affect the water constituents _____.
7. If the source be a well: -
   i. Depth of the water surface
   ii. Depth of the water
   iii. Staining
   iv. Coping
   v. Covering
   vi. Strata penetrated
   vii. Method of raising water
8. If stored surface water, nature of collecting surface and conditions of storage
9. Meteorological conditions; heavy rainfall or drought
10. Any treatment the water has received: -
    (i) Clarification
    (ii) Chlorination
    (iii) Softening
    (iv) Boiling

Station:-

Date:-

Name, appointment and address
of Officer requesting analysis
(IN BLOCK LETTERS)

## Appendix D

Report on Water Sample

Received from _____

On _____

The sample was labeled _____

The results of the chemical analysis in parts per 100,000 were as follows: -

Colour in 60 cm tube _____

Odour _____

Insoluble matter _____

Reaction, pH value _____

Ammonia, free and saline _____

Ammonia, albuminoid _____

Oxygen absorbed from : ¼ hour _____ 4 hour _____

Permanganate _____

Nitrogen present as nitrites _____

Nitrogen present as nitrates _____

Chlorine present as chlorides _____

Hardness Total _____

Temporary _____

Permanent _____

Total solids _____

The result of bacteriological examinations is as follows :

_____

_____

_____

_____

Conclusions :

_____

_____

_____

_____

Date : _____

Place : _____ Signature of OIC Lab

## Appendix E

Constituents for preparation of VTM (Hanks Balanced Salt Solution)

| **10X Hank's A Solution** | |
|---|---|
| NaCl = 80 g; KCl = 4 g<br><br>Dissolve this in 1 Litre of Double Distilled water | |
| **10X Hank's B Solution**: | |
| $Na_2HPO_4$ | = 0.6 g |
| $KH_2PO_4$ | = 0.6 g |
| Glucose | = 10.0 g |
| Phenol red (1%) | = 16.0 ml |
| Dissolve this in 1 Litre of Double Distilled water. This is dispensed in 6 ml volume in 10 ml screw capped vials and autoclaved at 15 lb/in² X 15 min | |
| **Preparation of working solution 100ml VTM (Hank's)** | |
| Solution A | = 10.0 ml |
| Solution B | = 10.0 ml |
| Bovine serum albumin (BSA) | = 7.5 ml |
| Antibiotic solution (100X)<br>[contains streptopenicillin, Gentamicin & Mycostatin] | = 1.0 ml |
| Glutamine | = 1.0 ml |
| Double Distilled water | = 70.5 ml |

## Medical Entomology

**Author**
**Dr (Mrs) Rina Tilak**

Dr (Mrs) Rina Tilak

# Introduction to Entomology

The word 'Entomology' is derived from the Greek words 'ENTOMON' meaning an insect and 'LOGOS' meaning science, thus making Entomology 'the branch of science which deals with the study of insects'. However, the scope of the subject has been broadened to include study of all Arthropods. The phylum has many important classes of which class Insecta is the largest. The other important classes are Arachnida, Crustacea and Myriapoda.

Arthropod borne diseases are one of the leading causes of morbidity and mortality the world over and pose a major public health challenge especially to the third world or developing countries. The Armed Forces personnel are at special risk due to their enhanced susceptibility to exposure to vectors due to exigencies of service. For this reason, Armed Forces Medical Officers should have a good working knowledge as regards arthropods of medical importance. An overview of the same is being presented in this chapter. Interested personnel are advised to refer to standard textbooks on Medical entomology and references cited at the end of the chapter for detailed information on vector biology and control (1,2,3,4).

## Modes of Disease Transmission

Arthropods transmit diseases to man through mechanical or biological (which includes propogative, cyclo-propogative and cyclo-developmental) modes of transmission the details of which have been already discussed in the section on Principles of Epidemiology. In addition, there are some **other specialized modes of disease transmission, often encountered** in ticks and mites, which are as follows:

### Trans-ovarian

The disease organism is transmitted to eggs through ovary of infected female, e.g. *Orientia tsutsugamushi*, the agent for Scrub typhus is transmitted by trombiculid mite-*Leptotrombidium deliense*.

### Trans-stadial

The disease causing organism is transmitted from one stage to another e.g. Tick typhus organism *Rickettsia conorii* is transmitted from infected larva to nymph to adult.

### Arthropod Borne Diseases

The important arthropod borne diseases are listed in Table 1 along with their vectors, causative organisms and their reservoir hosts.

Table - 1 : Important arthropod borne diseases

| | Disease | Vector | Causal organism | Reservoir |
|---|---|---|---|---|
| I | **Mosquito borne diseases** | | | |
| | Malaria | Anopheles species | Plasmodium species | Man |
| | Filariasis | Culex quinquefasciatus | W bancrofti (nocturnal, periodic) | Man |
| | | Aedes niveus group | W. bancrofti (diurnal sub-periodic) | Man |
| | | Mansonoides species | Brugia malayi infection | Man, Primate |
| | Chikungunya | Aedes species | Arbovirus group A | Man |
| | Dengue fever & DHF | Aedes species | Arbovirus group B | Man |
| | Yellow fever | *Aedes* species | Arbovirus group B | Man / Monkeys |
| | Japanese Encephalitis | Culex vishnui group (C tritaeniorhynchus) | Arbovirus group B | Mammals/ Birds |
| II | **Sandfly borne diseases** | | | |
| | Leishmaniasis | | | |
| | a) Visceral (Kala azar) | Phlebotomus argentipes | Leishmania donovani | Man/Man made |
| | b) Cutaneous (Oriental sore) | | P. papatasi | L. tropicaMan/Man made |
| | c) Espundia | P. sergenti | Virus | Man/Man made |
| | d) Sandfly fever | P. sergenti / P. papatasi | Virus | Man |
| | **Disease** | **Vector** | **Causal organism** | **Reservoir** |

| | | | | |
|---|---|---|---|---|
| III | **Fly borne diseases** | | | |
| | Bacillary dysentery | *M. domestica* | *Shigella* | Man |
| | Amoebic dysentery | M. domestica | E. histolytica | Man |
| | Gastroenteritis | M. domestica | Specific/Non specific organisms | Man /animals |
| | Typhoid | M. domestica | Salmonella typhi | Man |
| | Paratyphoid | M. domestica | Paratyphi A & B | Man |
| | Cholera | M. domestica | Vibrio cholera | Man |
| | Poliomyelitis | | Virus | Man |
| | Viral hepatitis (Type A) | M. domestica | HAV | Man |
| | Trachoma | M. domestica | C trachomatis | Man |
| | Yaws | *M. domestica* | *T pertenue* | Man |
| IV | **Flea borne diseases** | | | |
| | Plague (Bubonic) | Xenopsylla species | Yersinia pestis | Rodents |
| | Endemic/Murine Typhus | Xenopsylla species | R. typhi | Rodents / Domestic animal |
| | Chiggerosis (Jigger) | Tunga penetrans (chigoe) | -- | -- |
| | Dipylidium caninum | Ctenocephalides felis / canis | | Dipylidium caninum Dogs, cats, wild Carnivores |
| | Hymenolepis diminuta | X. cheopis / N. fasciatus | Hymenolepis diminuta | Carnivores |
| | H nana | X. cheopis / C. canis / Pulex irritans | H nana | Rats, mice |
| V | **Louse borne diseases** | | | |
| | Epidemic typhus | Pediculus humanus | R. prowazeki | Man |
| | Epidemic relapsing fever | Pediculus humanus | Borrelia recurrentis | Man |
| | Trench fever | Pediculus humanus | B quintana | Man/animals |
| | Dermatitis | Pediculus humanus / capitis | | Secondary organisms Man |
| VI | **Tick borne diseases** | | | |
| | Kyasanur Forest Disease (KFD) | Hard ticks species | Arbovirus group B | Monkeys/Birds |
| | Tularaemia | Hard ticks species | P tularensis | Rabbits/Rodents / cattle |
| | Indian Tick Typhus | Hard ticks species | *R. Conorii* | Dogs |
| | Relapsing fever | Soft Tick | B duttoni | Rats |
| VII | **Mite borne diseases** | | | |
| | Scrub typhus | L. deliense | Orientia tsutsugamushi | Rodents |
| | Rickettsial pox | - | R. akari | Rodents |
| | Scabies | S. scabei | - | Man |
| VIII | **Cyclops transmitted diseases** | | | |
| | Dracontiasis | Cyclops species | D. medinensis | Man |
| | Fish tape worm | Cyclops species | D. latum | Fish |
| IX | **Reduviid bugs** | | | |
| | Chagas disease | Reduviid/Cone-nosed | T. cruzi | Domestic animals / man |
| X | **Tsetse flies** | | | |
| | Trypanosomiasis | Glossina species | T. gambiense & T. rhodesiense | Wild animals / cattle / man |

Dr (Mrs) Rina Tilak

# Principles of Vector Control

Control of arthropods is one of the key strategies in the management of Vector borne diseases. We should have sound knowledge of the bionomics, distribution, seasonal prevalence, vectorial capacity, insecticide susceptibility status and role of arthropods in disease transmission coupled with the knowledge of identification features of the vectors incriminated for formulating effective control strategies. The various control options available are as follows:

(a) Environmental Control
(b) Biological Control
(c) Chemical Control
(d) Personal Protective measures
(e) Mechanical control
(f) Physical control
(g) Genetic control
(h) Legislative control

## Environmental Control

The important environmental control measures which are increasingly being used in the developed countries are described below (5, 6, 7) :

### Environmental Management

This has been defined as "The planning, organization, carrying out and monitoring of activities for the modification and/or manipulation of environmental factors or their interaction with man with a view to preventing or minimizing vector propagation and reducing man-vector-pathogen contact." This is a naturalistic approach which attempts to extend and intensify natural factors which limit vector breeding, survival and contact with man.

Environmental Modification

It is defined as "A form of environmental management consisting of any physical transformation that is permanent or long-lasting of land, water and vegetation, aimed at preventing, eliminating or reducing the habitats of vectors without causing unduly adverse effects on the quality of the human environment". Environmental modification includes drainage, filling, velocity alteration, land leveling and transformation of impoundment margins.

Environmental Manipulation

It is defined as "A form of environmental management consisting in any planned recurrent activity aimed at producing temporary conditions unfavourable to the breeding of vectors in their habitats". Examples of environmental manipulation activities are water salinity changes, stream flushing and regulation of the water level in reservoirs, vegetation removal, shading and exposure to sunlight.

Modification or Manipulation of Human Habitation or Behaviour

This means "A form of environmental management that reduces man - vector - pathogen contact". Examples of this approach are siting of settlements away from vector sources, mosquito/rodent proofing, personal protection and hygienic measures against vectors and provision of mechanical barriers, providing facilities for water supply, disposal of waste water and excreta, laundry, bathing and recreation to prevent or discourage human contact with infested water.

## Chemical control

The new era of control of vector borne disease began with the discovery of the insecticidal value of Dichlorodiphenytrichloroethane (DDT). DDT was first synthesized by Othmar Zeidler in 1874 at Strasbourg, Germany. In 1939, Paul Muller of the Geigy Company in Basle, Switzerland, discovered its remarkably long residual insecticidal property, earning him the Noble Prize in Medicine. The availability of several effective, safe and low cost pesticides, coupled with improvements in the techniques of their application, made it possible to embark upon extensive countrywide programmes for the control or eradication of such major vector borne diseases. However, development of resistance amongst vectors to insecticides as well as the growing concern about environmental contamination resulting from the use of persistent insecticides has become issues of concern. In view of this, research on newer and safer insecticides and promotion of their widespread use as well as better methods of application is being intensified throughout the world (8 -15).

### Classification if Insecticides

The most common classification used is based on chemical composition, as presented in Fig - 1.

### Natural Insecticides

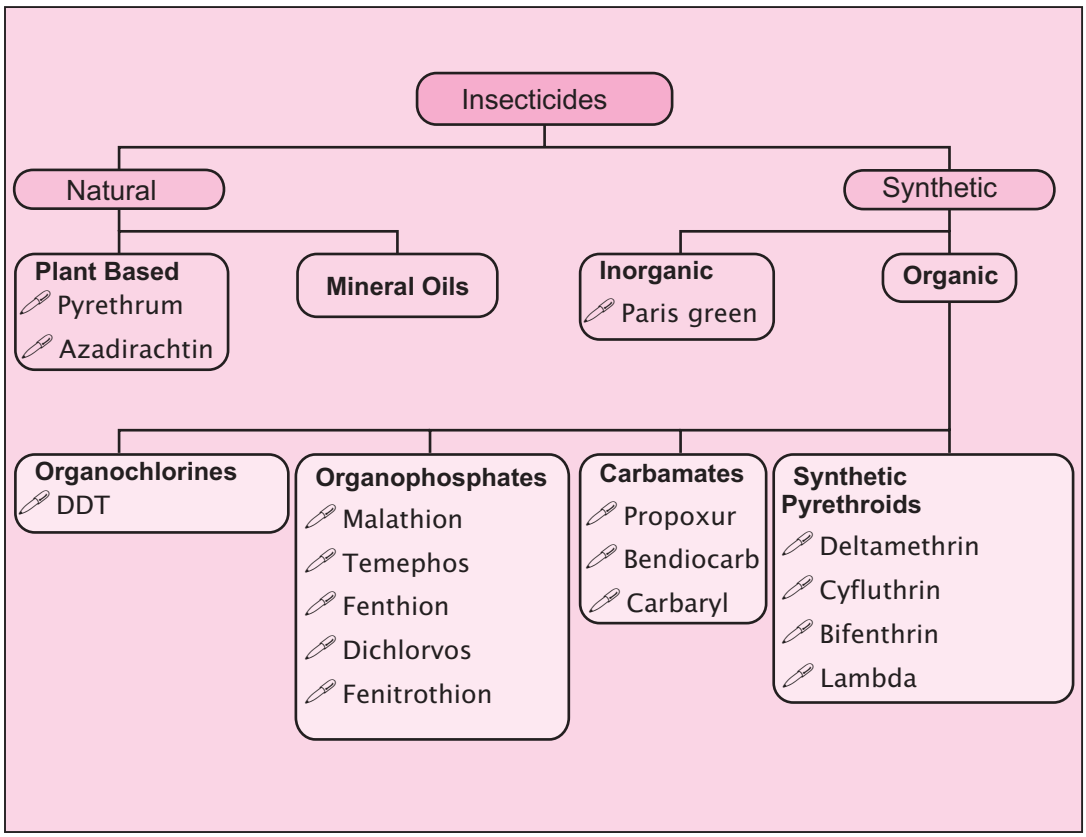
Plant based

### Pyrethrum

Pyrethrum extract is obtained from the dried heads of the flower *Chrysanthemum cinerariafolium* and contains the active ingredients pyrethrins I and II, constituting 1 to 2 percent of the total weight of the raw pyrethrum. Pyrethrum is characterized by rapid knockdown action on arthropods even when used in very low dilution. It has practically no residual effect, which makes repeated applications necessary. Pyrethrum is available as 2 percent extract. 1 litre of this extract is mixed with 19 litres of kerosene to get 0.1% solution. Using a 0.4 mm or lower calibre nozzle, 50 to 100 ml of pyrethrum solution in kerosene oil is sprayed per 100 $m^3$ of space. It is one of the main insecticidal constituents in aerosol dispensers

and also an insecticide of choice for ULV sprays. Synthetic pyrethroids.

Fig. 1: Classification of insecticides as per chemical composition



Pyrethrum is perhaps the most acceptable insecticide for use in cook houses, dining halls and other food preparation areas.

**Azadirachtin**

This is obtained from the seed kernels of Neem plant. It may have some insecticidal & fungicidal, including insect growth regulating qualities. It has been variously formulated for mosquito larval and adult control in the form of liquid and cream formulations. Neem products contain up to 3% Azadiractin. At present, its use is not fully evidence based.

**Mineral Oils**

Kerosene oil, diesel oil, petrol and crude engine oil have been successfully used as mosquito larvicides. The oil film cuts off the air supply, enters and blocks the trachea, may act as a stomach poison, and also lowers surface tension which prevents larvae from floating. Malariol is the best and easiest larvicidal oil to use for Anopheline and Culicine larvae. Malariol oil is used @ 10 litres per 500 linear mts.

**Synthetic insecticides**

These can be organic and inorganic. The only inorganic compound which was used as mosquito larvicide was Paris green (Copper-aceto-arsenite). It acted as stomach poison when ingested by mosquito larvae. However, it is not used any more for mosquito control.

The organic insecticides fall into four major groups, viz. Organochlorines, Organophosphates, Carbamates and

Organochlorine Compounds

These compounds are contact poisons and act on the nervous system. These or their degradation products are stored in body fat and may be excreted in milk, urine or sweat. They all have variable residual action for variable periods and are toxic to man and animals. The most important and the only member of this group used in Public Health is DDT (Dichlorodiphenyltrichloroethane). Currently DDT is being used for Indoor residual spray in North Eastern states only. A deposit of 1 g of DDT/$m^2$ of surface area of walls and ceiling up to a height of 3.5 m in all dwellings applied at 8 weeks' interval effectively controls majority of the mosquitoes and also other arthropods resting on the treated wall (Refer to Chapter on Mosquitoes for further details on use). As per Govt. of India Gazette notification number S.O. 378(E) dt. 26th May 1989, the use of DDT in Agriculture has been withdrawn and restricted to 10000 MT/ annum for Public Health programme except in case of North East as Insecticidal Residual Spray (IRS).

Organophosphorus Compounds

These insecticides are derivatives of phosphoric acid and act by inhibiting the activity of cholinesterase. Many of the insects, which have become resistant to Organochlorines are still susceptible to the members of this group. However, due to their extensive use in agricultural as well as public health field, more and more insects are developing resistance to Organophos-phorus compounds. Some of the common compounds are Malathion, Temephos, Fenthion, Dichlorovos (DDVP) and Fenitrothion and so on.

**Malathion**

It is one of the least toxic Organophosphorus compounds. It is available as Malathion Technical (95%) for use as space spray, 50 percent Water Dispersible Powder (WDP) and Emulsifiable Concentrate (EC) for residual control and 90% dust for use against fleas and lice. Malathion under the National Vector Borne Diseases Control Programme is being used as Indoor Residual Spray against mosquitoes in areas where the vectors have become resistant to DDT. The dosage of its application is 2 g/$m^2$ (Refer to Chapter on Mosquitoes for details). As ULV spray it has been very

widely used during outbreaks of DHF and JE as an anti adult mosquito measure. Development of resistance has been reported in a large number of vectors to Malathion.

**Temephos (Abate)**

It is available as 50% EC. It is the only insecticide approved for use in potable water. Because of its low toxicity, it has been successfully used for the control of *A. stephensi* breeding in wells and domestic containers at a dosage of 1ppm (Refer to Chapter on Mosquitoes for details). It has proved to be very successful in Guinea worm eradication programme in India.

**Fenthion (Baytex)**

It is formulated as 50 percent EC and as granules containing 2 percent toxicant. It is a good mosquito larvicide but can not be used in potable water bodies. It is highly effective as a larvicide against *C quinquefasciatus* or any other vector found breeding in non potable water bodies at a dosage of 1 ppm (Refer Chapter on Mosquitoes for further details). It can also be used for housefly control as a larvicide (Refer to Chapter on Houseflies for details).

**Pirimiphos methyl**

This insecticide is being considered as an alternative insecticide for Indoor residual spray. It is available as 25% WP; 2 kg is mixed in 10 litres of water and sprayed @ 10 litres/ 250 sq m area to give a deposit of 2g/sqm. Three rounds of spray are recommended as is followed in case of Malathion.

**Dichloro-dimethyl-dichlorvinyl-phosphate (DDVP or Dichlorvos)**

It differs from other Organophosphorus compounds in that it possesses a much greater vapour pressure at ordinary temperature which produces fatal insecticidal vapour. It is available as 72.6% EC and in aerosol formulations. It can be combined with solid substances like wax and used as tablets or bricks thus allowing it to evaporate slowly. It is one of the common insecticides used for disinsecting aircraft. It is an effective housefly larvicide.

**Fenitrothion**

It is available as Fenitrothion 40 percent water dispersible powder (WDP). The insecticide has shown promise as an effective insecticide for control of bedbugs; however toxicity constraints have limited its widespread use.

Carbamates

These compounds are derivatives of carbamic acid and resemble Organophosphorus compounds in their mode of action. Some of the preparations produce a rapid knockdown effect like that of pyrethrum. The inhibition is reversible with the Carbamates and hence these compounds are less toxic. Some of the compounds in common use are Propoxur (Baygon), Carbaryl and Bendiocarb.

**Propoxur (Baygon/Blattenex)**

It is formulated as WDP as well as EC. It is considered as the least toxic Carbamate compound for man and domestic animals. It has a flushing out effect and therefore is commonly used for cockroach and bedbug control. It is also used in bait formulations against houseflies and cockroaches.

**Bendiocarb**

Bendiocarb is an alternative insecticide for indoor residual spraying. It is available as 80% WP. For indoor residual spraying, it is recommended @ 200 mg/sq m. Two rounds of spray are recommended for effective control against Malaria.

Synthetic Pyrethroids

These are synthetic derivatives of natural Pyrethrum. These are highly potent with quick knock down action and long residual life. Synthetic pyrethroids are many times more effective than the previously available insecticides. Their relative safety to man and higher animals and efficient biodegradability makes them very attractive materials for integrated vector control. The commonly available products are Permethrin, Allethrin, Phenothrin, Cypermethrin, Cyfluthrin, Deltamethrin and Bifenthrin. The Synthetic pyrethroids are formulated as WDP, EC, SC, Flow, EW and ULV formulations. Being broad spectrum, these insecticides are being used as residual spray, space spray and topical applications as well as for treatment of clothing.

**Deltamethrin**

It is one of the most widely used Synthetic Pyrethroid molecule in the field of vector control. It is available in many formulations for various vector control strategies viz. SC 2.5% (Flow) formulation for treatment of bed net and routine household pest control activity; 2.5% WP formulation for indoor residual spray in Malathion resistant areas and 1.25 ULV for space spraying.

**Cyfluthrin**

Besides Deltamethrin, this is the next most widely used molecule. It is available as 05 EW formulation for treatment of bed nets; 5% EC for household use and 10% WP for use as indoor residual spray in Malathion resistant areas.

**Permethrin**

Widely used for control of lice, scabies and for treatment of clothing and bed nets. The product is formulated as Shampoo formulation for use as anti-lice treatment and 5% cream for use in scabies treatment. Bed nets treated with Permethrin at the manufacturing stage itself are available as Pretreated or Long Lasting Nets (LLN's).

**Newer group of insecticides**

Phenyl pyrazoles

Fipronil is the only member of this class of insecticide. Fipronil acts by antagonizing the effect of GABA. It is available as 0.3% Gel for use against cockroaches as a crack and crevice treatment. It has a unique action called 'cascade effect' which is possible due to coprophagy seen in cockroaches. When cockroaches consume the insecticide bait, they are killed. These dead cockroaches when consumed by other cockroaches, it results in their death and this goes on for about two months or so, thus

obviating the need to retreat the area at lesser intervals.

Neo Nicotinoids

Imidacloprid is the sole member from this class. It acts on the Central Nervous System of insects, causing irreversible blockage of Postsynaptic nicotinergic acetylcholine receptors. Imidacloprid is a systemic insecticide, having notable contact and stomach action. Imidacloprid is available as 2.15 % Gel for use against cockroaches and as Bait for use against Houseflies, where it is formulated with housefly pheromone Muscalure.

Biorational Insecticides

'Biorational' means any substance of natural origin that has a detrimental or lethal effect on specific target pest, e.g. insects. Possess a unique mode of action. These insecticides are non-toxic to man, plants and animals, and have little or no adverse effects on the environment. The biorational insecticides are presented in Fig - 2 :

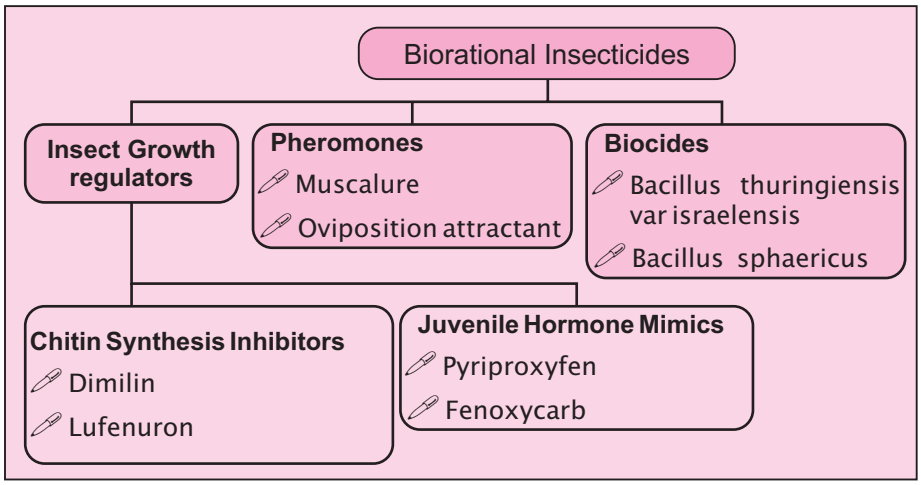
**Insect Growth Regulators**

A new approach to vector control is the use of substances that adversely affect insect growth and development. The enzymes and hormones that regulate developmental processes within an insect's body, often known as insect growth regulators (IGRs), can be used to stimulate development at inappropriate times or inhibit it at other times. They are quite selective in their mode of action and potentially act only on target species. The major groups of IGR compounds include:

**Chitin Synthesis Inhibitors**

They are most effective when used against the immature stages of a vector. Diflubenzuron, currently registered under the trade name Dimilin, is used for controlling mosquitoes, houseflies etc. Lufenuron is especially effective in flea and tick infestation control on animals. Novaluron is a recent addition to the list, which has been found effective against the mosquitoes. Dimilin is available as 25% EC, WP & 0.5% Granules and is used @ 1.0 g/ acre of surface water as mosquito larvicide. Novaluron is a contact larvicide and is available as 10% EC; it is used @ 20 µg a.i./ l and the efficacy lasts up to 3 months.

Fig - 2 : Biorational Insecticides used in Vector Control



**Juvenile Hormone Analogues or Mimics (JHMs)**

Juvenile Hormone Analogues or Mimics (JHMs) act by inhibiting the developmental changes associated with embryogenesis, morphogenesis, and reproduction. Several compounds (e.g., Pyriproxyfen, Fenoxycarb, Lufenuron, Triflumuron) have been successfully incorporated into vector management programmes especially Dengue and Malaria and in products used for controlling ants, fleas, and other household pests. Pyriproxyfen has a residual effect up to 3 to 6 month indoors and 30 days outdoors. It is widely used against mosquitoes @ 2gm a.i./ sq m.

Biocides

The two biocides used in the field of vector control are *Bacillus thuringiensis* var *israelensis* and *Bacillus sphaericus.* Both these products are widely used as larvicides in Mosquito control programmes and act as stomach poison (16-18).

***Bacillus thuringiensis var israelensis* (Bti)**

It has been found to be effective as Mosquito larvicide. It is a gram positive spore forming bacteria. The product is available as WP, Granules, AS & Briquette. Bti 12 AS is used @ 20ml/m³ and has been found to be effective up to 15 days (for details refer chapter on mosquito). Bti however, suffers from the disadvantage that it can not be used in polluted waters or where particulate matter is more; it also cannot recycle in nature. It is used in non potable water bodies.

***Bacillus sphaericus***

A naturally occurring bacterium used against mosquito larvae. It is more effective in polluted water and can recycle in nature. It is available in various formulations like Bti viz. pellets, briquettes, granules & WP. It is used @ 20ml/m³ and has been found to be effective up to three weeks.

**Fumigants**

Some of the fumigants used as pesticides are Carbon tetrachloride, Methyl bromide, Ethylene dibromide, Chloropicrin, Carbon disulphide and Dichlorvos (DDVP).

## Application Techniques

Control of arthropods in different habitats necessitates the use of different types of spraying equipment as well as a variety of formulations such as liquids, granules and dusts. For example, control may involve treatment of small domestic or peridomestic water collections which are ideal breeding places for *Aedes* mosquitoes; applications to stagnant waters in cesspools, ditches and drains where *Culex* mosquitoes breed, large bodies of standing water where certain *Anopheles* mosquito species may be breeding; or aerosol spraying of extensive areas to halt epidemics. To meet with diverse situations, significant progress has been made in improving the spraying

equipment. The ultra low volume (ULV) equipment for ground and aerial spray to control mosquitoes and other haematophagous arthropods has resulted in not only the elimination of several impediments like frequent mixing and reloading but helped in increasing the speed of application and reducing the dosages and costs. It is specially recommended for control of an outbreak of vector borne disease (19, 20).

### Types of formulations

Formulations essentially are of three types: Solid or dry, liquid and gaseous formulations.

Solid or dry formulations

#### Dusts

Dusts are normally ready-to-use formulations with a low percentage of active ingredient (usually 1 - 10%) plus a very fine inert carrier such as talc, chalk, diatomaceous earth, clay or volcanic ash. Dusts are always used dry and can easily drift into non-target areas if they are not applied carefully. For this reason, they are only used for outdoor applications when the wind is calm. A common use for dusts is in crack and crevice or spot treatments indoors in out-of-sight areas (behind equipment, in wall voids, and so on) which remain dry. The residual pesticidal activity of dust is normally fairly long, provided the dust stays dry. Dusts are used on people during mass delousing operations to control outbreaks of lice. Dusts are also used for flea control during Plague outbreak. Dusts aren't generally absorbed through the skin, but may be dangerous if inhaled into the respiratory tract.

#### Granules

These are basically the same as dust formulation, except the carrier particles are larger. Granules are also available in timed-release formulations that release a dosage of the pesticide over an extended period of time. Granules have the advantage of providing longer lasting effects and less drift than generally occurs with liquids or dusts.

The percentage of insecticide in granules and pellets varies from 1 to 5 percent. These can be used in irrigation channels, irrigated or flooded lands, paddy fields, and particularly where there is vegetation on the water surface. These can be effectively used also in small water collections such as ornamental tanks and earthen pots, tree holes and other domestic or peridomestic breeding places of *Aedes* mosquitoes.

#### Wettable powder

This formulation consists of the technical grade pesticide, an inert carrier and a wetting agent (usually a synthetic detergent) that helps it mix with water. These usually contain 50 to 75 percent of the toxicant. Most of these can be put directly into water and require only slight agitation to make suspension while others may require mixing with a small amount of water to form a paste or slurry. The required volume of water is then added to paste or slurry followed by thorough agitation of the mixture, to make a suspension. A great advantage of a suspension is that the pesticide stays on porous surfaces like concrete, plaster or unpainted wood. Water penetrates these surfaces, leaving the carrier and the maximum amount of the pesticide on the surface available to kill pests. Suspensions have other advantages, too. They have no solvent odor, and they don't tend to irritate or penetrate skin. However, they generally need agitation to keep pesticidal particles from settling down. Also, they tend to clog sprayer nozzles and strainers, especially when the wettable powder is stored for long periods in humid areas.

Liquid formulations

#### Emulsifiable concentrates

Emulsifiable concentrates consist of the technical grade pesticide (typically 45% to 75%), a solvent, and an emulsifying agent, usually a synthetic detergent. This agent allows the concentrate to be diluted in water, resulting in an emulsion.

Emulsifiable concentrates are usually clear but emulsions look similar to milk. Finished sprays are emulsions or solutions diluted to field strength. Unlike solutions, most emulsions need a little periodic agitation to keep the concentrate from separating out of the water. Emulsions are used for residual treatments. Pests that contact these surfaces are killed by the pesticidal residue. Emulsions may damage aluminum, varnish, and painted surfaces, due to the action of solvents such as xylene. Emulsions may also be corrosive to metal sprayers and their fittings.

#### Oil solutions

These formulations consist of a technical grade pesticide dissolved in a solvent such as kerosene or diesel oil. Solutions are available as ready-to-use formulations (for example ordinary household fly and mosquito sprays with a low percentage of pesticide) and as solution concentrates. These concentrates should be diluted in oil or another suitable solvent. Some concentrates are used without dilution in Ultra low volume (ULV) applications. Oil solutions applied as finished sprays often kill insects on contact, since the oil helps the pesticide penetrate the insect's waxy body wall.

Gaseous formulations

Gases are primarily used in fumigation operations. They may be prepared as liquefied gases and packaged in pressure containers or in a material form that reacts with the moisture in the air to form a gas. Gases are the most dangerous pesticides used and hence special safety equipment and training are necessary when using gases. One of the common gaseous formulations viz. Calcium cyanide (powder) and Aluminium phosphide (tablet) are used for rodent control.

Special formulations

#### Resin strips

Pesticide-impregnated resin strips release vapor when they are heated or exposed to normal room temperatures. The use of resin strips in rooms occupied by the young, the elderly or in food preparation and food serving areas should be prohibited.

#### Baits

Baits are commonly used to manage scavenging pests such as rodents, ants, flies, and cockroaches, which are

particularly difficult to manage with standard techniques. Baits consist of the toxicant mixed with a food attractive to the target pest or with water. Thus, baits made with local foods are normally more effective than premixed formulations. Recent development is the use of pheromone Muscalure with Imidacloprid as bait for houseflies.

**Gel**

Gels comprise of some food attractant mixed with the toxicant and some stabilizing agents. Examples are Fipronil and Imidacloprid Gels marketed for use against cockroaches.

**Shampoo**

It is used against head lice infestation. Permethrin is available as Shampoo formulation under the trade name "Mediker".

**Beads/ Pellets/ Briquettes**

Small, floating beads, pellets or briquettes incorporating biocides-Bti and *B. sphaericus* are sometimes used against Anopheline larvae. These formulations can be made into controlled release formulations as well.

**Paints and Lacquers**

These can be used for incorporation of insecticides for certain situations like control of pests on ships. They are effective for long periods. The new insecticide, Imidacloprid is also available as a paint formulation against houseflies.

**Mats/ Coils**

These are special formulations which have been developed as controlled release formulation for indoor use against mosquitoes. These have Synthetic pyrethroids, usually Allethrin, as the toxicant which knocks down the mosquitoes when used indoors.

**Aerosols**

Aerosols are pressurized cans containing a small amount of pesticide driven through a small nozzle. They are commonly used as space sprays for flying insects viz. Mosquitoes and Houseflies and as residual sprays (Mites / ticks) depending on the formulation. Care should be taken since they can explode if punctured or overheated, even after the pesticide has been dispensed. Common insecticides used are Pyrethroids, Malathion, DDVP and repellents like DEET and DEPA. These are used for disinsecting aircrafts, tents, rooms, other small enclosures, uniforms and for topical application. An emission of nearly 15 seconds is enough for a 100 $m^3$ space.

**Equipment**

Equipment used for vector control can be broadly classified as ground equipment and equipment used for aerial applications (19, 21).

The Ground Equipment

Includes sprayers for production of fine or coarse spray which may be either manually operated or power operated; or, sprayers for the production of mist which may be either with gaseous energy nozzles (manual operated or power operated) or with centrifugal nozzles. These also include devices for the production of aerosols which may be mechanical, thermal or gaseous energy aerosol generators. Other type of ground equipment includes dusting equipment which may be manually operated or power operated, and applicators for granules and pellets, manually or power operated.

The Aerial Equipment

Includes equipment for aerial sprays (boom and nozzle system).

The equipment commonly used for spraying various insecticidal formulations are the hand operated sprayers, power operated sprayers, aerosol dispensers, fog generators and dusters.

Hand Operated Equipment

These are hand sprayers, knapsack sprayer and compression sprayer.

**Hand Sprayer**

The hand sprayer is used for space spraying of small apartments. It is provided with a small can for holding ½ - 1½ L of spray fluid and a cylindrical plunger type air pump. The nozzle size is less than 0.4 mm, in order to produce a fine spray. The simplest form is the familiar 'flit gun' producing intermittent spray. A number of other light hand sprayers have been designed which can be pressurized in the manner of compression sprayers and are used to produce a mist or fine droplet spray.

**Knapsack Sprayer**

This is designed to fit on to the back of the operator and usually has a capacity of 15 to 20 L. It incorporates a light but powerful diaphragm pump actuated by a lever carried forward to the operator's hand where it is worked by an up-and-down movement. These sprayers are used both for larviciding and residual spraying. The nozzle size used for residual spraying varies between 0.78 to 1.0 mm so as to produce a coarse spray.

**Compression Pneumatic Sprayer**

This is the commonest type of equipment used in National Vector Borne Diseases Control Programme (NVBDCP) and in the Armed Forces for the application of insecticides. It has a hand operated pump incorporated to build up adequate pressure. When the pressure is released by a trigger on the lance, the liquid is forced out from the tank to the nozzle by the compressed air and continuous spray of the insecticide formulation is produced. It is slung over the shoulder with one strap or may be carried on the back with two straps. It is operated by one person.

Power Operated Sprayers

These are useful for application of insecticides over large areas. These are hydraulic sprayers in which the spray liquid is expelled to the nozzle by positive displacement by the plunger pump. Insecticide tanks built into a truck or mounted over a hand trolley are connected directly to a power operated compressor.

**Insecticidal Fog Generators**

Several types are now available for the production of

insecticidal fogs in the open on a large scale. In these fogging machines the oily solution of the insecticide is finely atomized by the powerful blast of hot exhaust gases from a petrol engine.

Aerosol Dispensers

These are used for disinsectisation of aircrafts, tents, rooms and similar small enclosures. It contains insecticide and a propellant. Common aerosols contain Synthetic pyrethroids, often used for mosquito and fly control.

Dust Gun

Insecticidal dusts are applied against lice, fleas in rat burrows or on water surfaces as dry powders diluted with inert dusts. Small light weight guns are used for mass delousing of infested people.

**Residual Spraying**

This is the application of insecticides to surfaces so that the insecticide particles remain on the surface in the form, size and quantity suitable for insects to pick up on contact and sufficient to exert a lethal effect over a long period. Organochlorine, Organophosphorus, Synthetic pyrethroids and Carbamate compounds can thus be applied on the inside walls of houses and also on thick bushes in forests. The type of surface to which an insecticide is applied influences its toxicity against insects and its persistence. Solutions and emulsions quickly get soaked in the absorbent surfaces of soft bricks and mud walls which take in a large portion of insecticidal material deposited on them; but when suspended in water it remains over the surface after the water evaporates or gets absorbed. The nozzles of sprayers used for residual spraying must conform to the need of having a droplet size which is neither too large nor too small. Similarly, safety precautions should be observed, as follows, while spraying (22):

(a) Do not eat, drink or smoke while working.

(b) Wash your hands and face with soap and water after spraying and before eating, smoking or drinking.

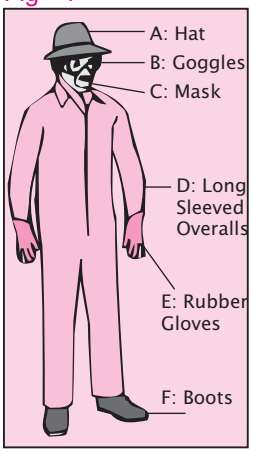
(c) Shower or bathe at the end of every day's work and change into clean clothes.

(d) Wash your overalls and other protective clothing at the end of each working day in soap and water and keep them separate from the rest of the family's clothes.

(e) If the insecticide gets on your skin, wash off immediately with soap and water.

(f) Change your clothes immediately if they become contaminated with insecticides.

Fig - 4



(g) Inform your supervisor immediately, if you do not feel well. Wear protective clothing as shown in Fig - 4

(i) Broad rim hat (protects head, face and neck from spray droplets)

(ii) Goggles or face shield (protects face and eyes against spray fall-out.)

(iii) Face mask (protects nose and mouth from airborne particles of the spray fall-out.)

(iv) Long sleeved overalls. (Keep overalls outside of boots.)

(v) Rubber gloves.

(vi) Boots.

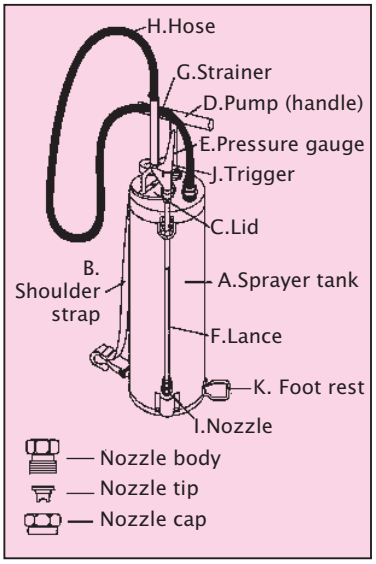
**Preparations**

**The household** - Inform the householder of the spraying schedule and the purpose of spraying, giving them time to prepare and vacate the house. Occupants, including pet animals, MUST leave houses before spraying. Rooms occupied by sick people who cannot be moved must NOT be sprayed. Remove all household items, including water, food, cooking utensils and toys from the house. Move and cover, or take out the furniture to allow easy access for spraying walls. Items that can not be removed should be well covered.

**Equipment**

Indoor residual spraying of insecticides is normally done using hand-operated compression sprayers. Before starting a spray operation, the equipment must be checked. Faulty sprayers may result in poor control or over-treatment. Examine the sprayer visually to ensure that all parts are present, assembled correctly and are in good condition (Fig - 5).

Fig - 5

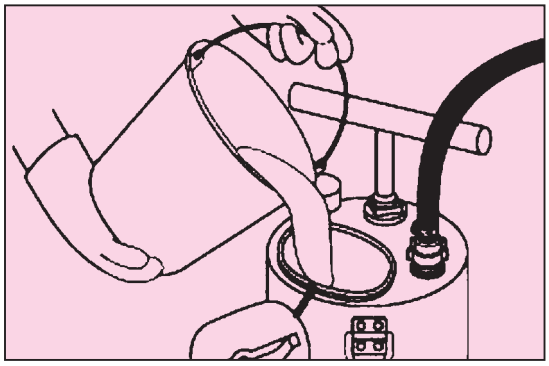


A. Sprayer tank
B. Shoulder strap
C. Lid
D. Pump (handle)
E. Pressure gauge
F. Lance
G. Strainer
H. Hose

I. Nozzle - check correct type of nozzle is fitted and is not damaged or worn (flat fan nozzle with 55 to 60º swath and 0.75 l/min flow rate at 700 g/ sq cm).

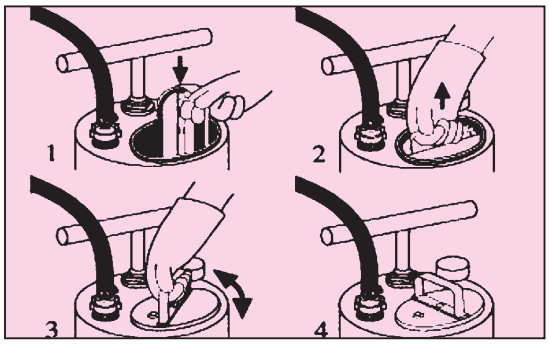
J. Trigger on/off valve. Is the strainer inside valve handle clean?

Fig - 6



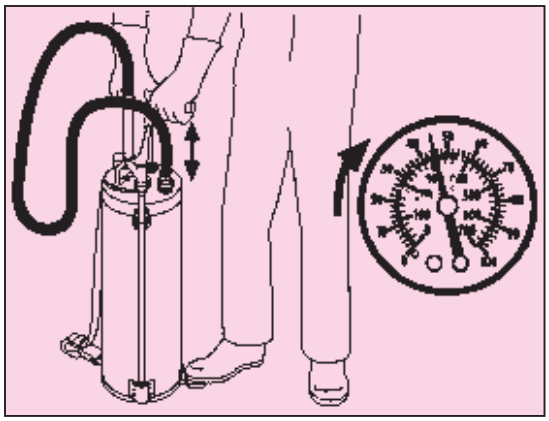
K Foot rest

Fig - 7



Before using an insecticide use clean water to ensure that the equipment operates properly and does not leak. Wear protective clothing. To check, follow the steps below:

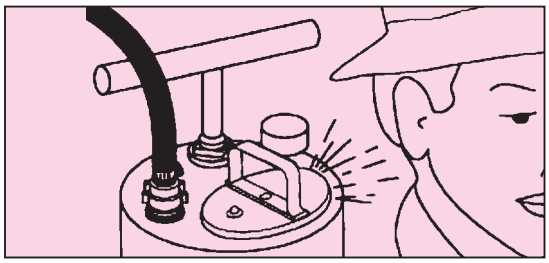
Fig - 8



(a) Pour clean water into the tank (never fill tank more than 3/4 full) (Fig - 6).

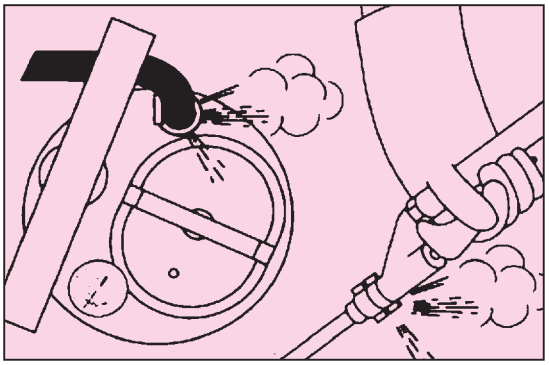
(b) Fit the lid. Turn the handle to lock the lid in position (Fig - 7).

Fig - 9



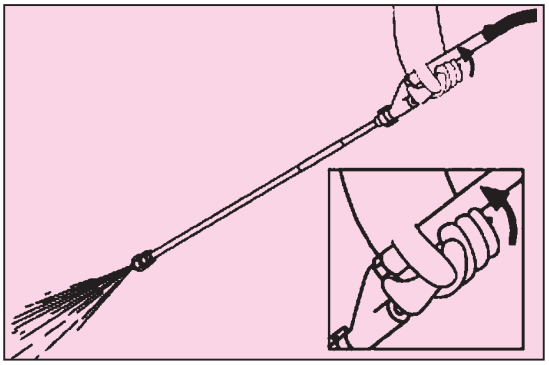
(c) Operate the pump using both hands and with foot on the footrest. Pump to the working pressure 55 psi (Fig - 8).

Fig - 10



(d) Check tank is holding pressure. Listen for hissing sound of escaping air (Fig - 9).

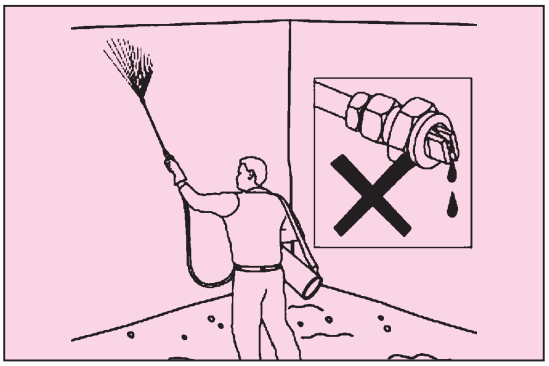
Fig - 11



(e) Check to make sure there are no leaks along lance and hose, especially where hose joins tank and trigger on/off valve (Fig - 10).

(f) Operate trigger on/off valve to make sure that spray is emitted from the nozzle (Fig - 11).

Fig - 12



(g) Check the spray pattern from the nozzle by spraying a dry wall surface. Look to see that the pattern is even and without streaks. Ensure nozzle does not drip when trigger on-off valve is released (Fig - 12).

(h) Calibrate the nozzle with water in the tank. Pump to 55 psi (700 g / sq cm). Open the trigger on-off valve for one minute, collect the discharge and measure the

amount in a measuring jug. Empty the jug. Discharge for a further one minute and measure the amount. Repeat for a 3rd discharge. Calculate the average of the three, one-minute measurements.

(j) With the above procedure, the average discharge of an 8002 nozzle is about 750 ml per minute. If the discharge is incorrect, check the nozzle and the screen filters to ensure they are not clogged. If necessary replace nozzle. Repeat the calibration.

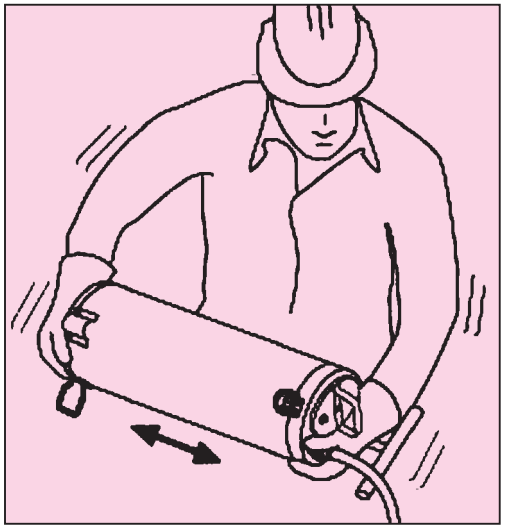
**If the nozzle is clogged**

The opening in a nozzle is very small and must not be damaged. Clogged nozzles should be put in a container with water for several hours before the blockage is removed by a very soft toothbrush. Nozzle should never be cleaned with a hard pin or a piece of wire.

Mixing, handling and spray techniques

Prepare the insecticide spray according to the manufacturer's instructions. The insecticide may be mixed separately in a bucket and poured into the sprayer. Water soluble sachets, tablets and insecticides granules are added directly to the water filled tank. These formulations mix readily with water and reduce the hazards associated with handling and mixing in a separate container. When the sprayer has been filled with water to the maximum level indicated on the tank, the lid of the tank is fitted and the sprayer pumped to a pressure

Fig - 13

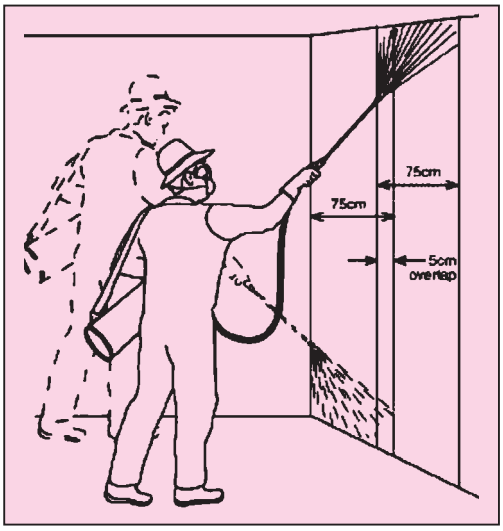


of 55 psi by pumping 55 times (700 g/sq cm). The contents of the tank should be thoroughly mixed by shaking the tank before starting to spray (Fig - 13).

Spraying in a room should commence from the backside of a door clockwise completing the plain surfaces of walls. Then the crevices on the walls and inside portion of windows etc. should be sprayed. Then the pillars, under surfaces of furniture and lastly the ceilings should be taken for spray.

Spray is done from roof to floor, using downward motion, to complete one swath; then stepping sideways and spraying upwards from floor to roof. Spray is applied in vertical swaths 52-56 cm wide. Swaths should overlap by 5 cm and spraying should be undertaken as shown in Fig - 14. Normal swath coverage will take 2.7 sec and hence in one minute 22-23 swaths will be required to cover a wall of

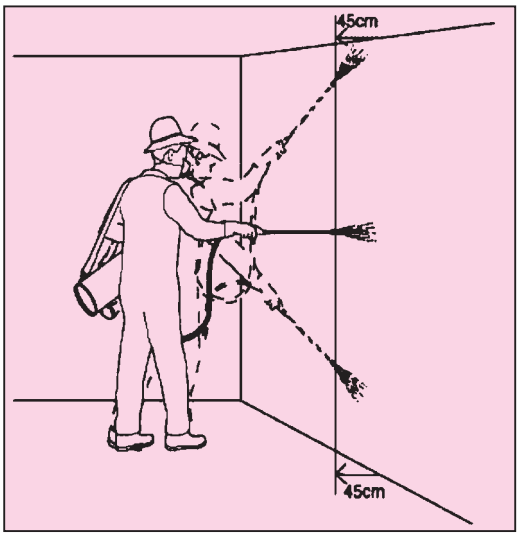
Fig - 14



10-11 metres length and 3 metres height i.e. 30-33 sq m. It takes about 5 minutes to spray a house with an average surface area of 150 sq. metres.

To ensure the correct swath width, keep the spray tip

Fig - 15

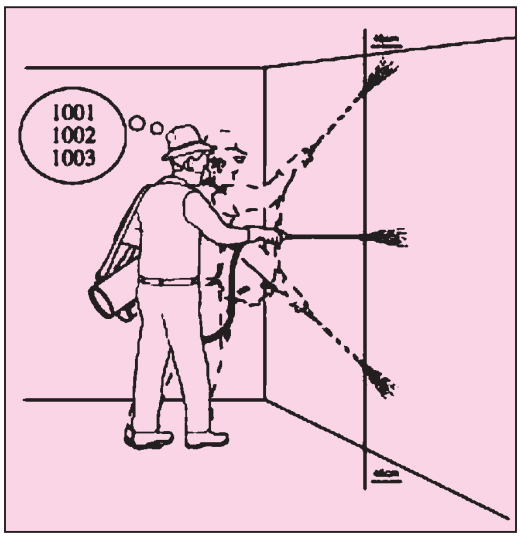


about 45 cm from the wall. Lean forwards as you spray from top of the wall & move back as you bring the nozzle downwards (Fig - 15)

The flow of liquid from the nozzle tip at 700 g/sq cm pressure is 750 ml/minute. Hence 30 sq m surface will be covered with 750 ml of the insecticide solution. Time your spray speed to cover one swath every 3 seconds, for a 3 m high wall. Timing may be aided by mentally counting “one thousand and one, one thousand and two, one thousand and three -...”. Adjust the mental counting procedure according to the local language (Fig - 16).

If spray stops due to a blockage in nozzle, unscrew the nozzle cap, remove blocked nozzle and replace with a new

Fig - 16



one. The blocked nozzle should be cleaned as explained above. Do not let spray drip on the floor. Re-pressurize the tank when the pressure falls.

Procedures after spraying

(a) Advise the occupants to stay outside until the spray is dry.

(b) Instruct the householder to sweep or mop the floor before children or pets are allowed to re-enter.

(c) Instruct the householder not to clean the sprayed surfaces

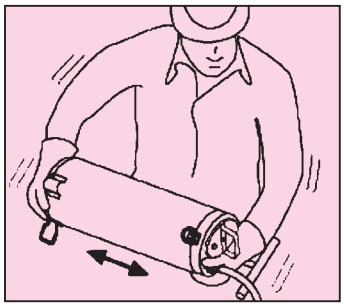
**Disposal of remains of insecticides and empty packaging**

At the end of the day's work, put the washings from the sprayer into pit latrines, if available, or into pits dug especially for this purpose and away from sources of drinking water. Dilute any insecticide with more water before putting into pits. It is advisable to prepare only sufficient insecticide to avoid disposal of remaining. Never pour the remaining insecticide into rivers, pools or drinking water sources. All empty packaging should be returned to the supervisor for SAFE disposal. Never re-use empty insecticide containers. Empty insecticide containers should NOT be burned or buried.

Maintenance of equipment

After completing the day's work, de-pressurize the tank and empty any remaining insecticide, following the instructions given in the previous section. Clean the tank as explained below: Fig- 17

Fig - 17



(a) De-pressurize the tank.

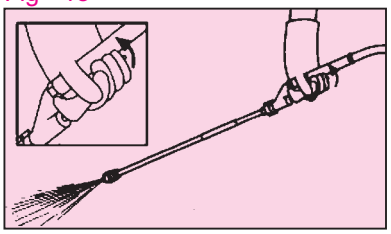
(b) Fill the tank half-full with clean water.

(c) Replace the lid.

(d) Shake the tank so that all inside surfaces are washed (Fig - 17).

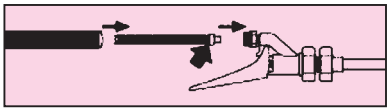
(e) Pump up to 700 g/ sq cm pressure. Spray water through nozzle (Fig - 18).

Fig - 18



(f) De-pressurize the tank and pour out any remaining water into pit latrines or into a pit away from sources of water.

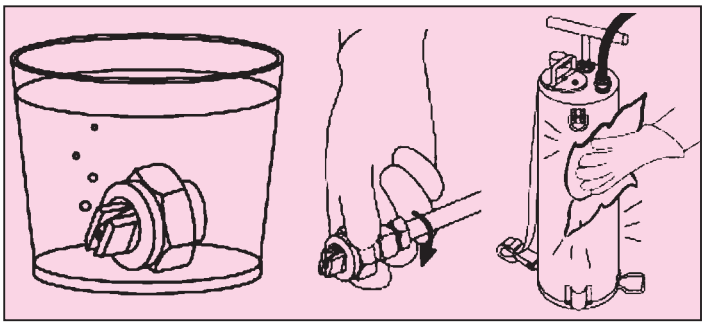
Fig - 19



(g) Unscrew trigger on/off valve handle and check and clean the strainer.

(h) Reassemble the trigger on/off valve (Fig - 19).

Fig - 20 (j)Remove the nozzle tip and wash



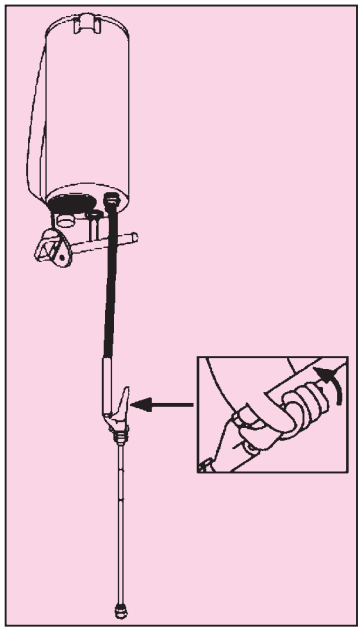
(k) Refit the nozzle (Fig - 20).

(l) Clean outside of tank.

(m)With lid open, turn tank upside down, open the on/off valve and let all the water drain out of the hose and lance (Fig - 21)

(n) Ensure the lance is parked to protect nozzle when not in use.

Fig. - 21



(o) When storing the sprayer for a long period, hang it upside down with lid open to allow air circulation. Allow lance to hang from D-ring on the tank with the trigger valve kept open (Fig - 21).

Insecticides used for residual spraying and anti-larval activities (8, 19, 23, 24, 25, 26)

The insecticides used for anti-larval and anti-adult activities with special reference to mosquitoes are presented in Table 1 and 2. The insecticides used for the other vectors with their dosages are

Table - 1 : Insecticides used for indoor residual spray with dosage and residual efficacy (ai = active ingredient)

| Insecticide | Preparation of suspension in water | Dosage of a.i. / sq m | Residual effect in weeks | No. of spray rounds / annum | Area to be sprayed by 10 lit of suspension | Remarks |
|---|---|---|---|---|---|---|
| DDT 50% WP | 1 kg/ 10 lit | 1 g | 10 – 12 | 2 | 500 sq m | In North East only |
| Malathion 50% EC | 1 lit/ 10 lit | 2 g | 6 – 8 | 3 | 250 sq m | In DDT resistant areas |
| Deltamethrin 2.5% WP | 400 g/ 10 lit | 20 mg | 10 – 12 | 2 | 500 sq m | In Malathion resistant areas |
| Cyfluthrin 10% WP | 125 g/ 10 lit | 25 mg | 10 – 12 | 2 | 500 sq m | In Malathion resistant areas |

Table - 2 : Insecticides used for mosquito larval control

| Insecticide | Dilution rate | Dosage /sq m | Area in linear metre to be sprayed by 10 ltr of solution/ suspension | Frequency of application | Remarks |
|---|---|---|---|---|---|
| MLO | As it is | 20 ml | 500 | weekly | Applied along shore of water |
| Temephos (Abate) 50% EC | | 20 ml | 500 | weekly | Applied in all water bodies |
| Fenthion 82.5% EC (Baytex 1000 EC) | 5 ml in 10 ltr for water depth up to 10 cm. 25 ml in 10 ltr for depth up to 50 cm | 20 ml | 500 | weekly | Not used in potable water |
| Fenthion 2% G - | - | 5 Kg per hectare for water depth up to 10 cm. 25 Kg per ha depth up to 50 cm | - | - | Used for larval control in water with organic pollutants |
| *Bacillus thuringiensis var israelensis* (Bti) (12 AS) | 250 g in 10 ltr | 20 ml | 500 | Bi weekly | Not used in potable water |
| *Bacillus sphaericus* | 500 g in 10 ltr | 20 ml | 500 | Tri-weekly | Not used in potable water |

**Note:** dose of each of the formulation is 20 ml of final solution per sq mtr of the water surface (10 ltrs of the prepared solution per 500 sq mtrs or 500 linear mtrs).

presented in chapters referring to those vectors/ pests.

### Space Spraying

It is an ideal method for bringing about rapid control of vectors in emergency or epidemic situations and may also be used for seasonal control of flying insect pests or vectors. An additional objective may be to reduce or interrupt the transmission cycle of insect-borne diseases. However, it may not be ideal for all vectors or situations and as such may not be an economical method of control. Among the disease vectors affecting public health, the most important and widespread are mosquitoes, houseflies, sand-flies and other biting flies; some of these may be targeted for space treatment (19, 27).

Immediate killing of actively flying insects requires a cloud of insecticide droplets that they will encounter in flight. To be cost-effective and obtain good biological efficacy, space spraying requires:

(a) Knowledge of the behaviour and biology of the target species to understand where and when space treatments will be effective.

(b) Knowledge of insecticides and formulations most suitable for space spraying.

(c) Knowledge of pesticide application technology to know which equipment is needed and how to use it.

(d) Monitoring and surveillance of the target species and vector-borne disease problem, to evaluate the efficacy of the programme.

A space spray, technically a fog (sometimes referred to as an aerosol) is a liquid insecticide dispersed into the air in the form of hundreds of millions of tiny droplets less than 50 µm in diameter with a view to cause by contact, immediate knock down of the flying or resting insects in confined spaces. Space sprays, even when they settle on surfaces do not have much residual action. It is only effective while the droplets remain airborne. Therefore, they have to be repeated at frequent intervals. Space sprays are applied mainly as thermal fogs or cold fogs.

Thermal fog

Thermal fog is produced by special devices known as thermal foggers that use heat to break up the chemical into very small droplets (usually in 5-30 micron diameter range) which then disperse in the air. When the chemical (usually diluted with oil-based carrier) is heated, it is vaporized in a combustion chamber and then expelled via an outlet tube to form a dense fog cloud when it condenses on contact with cool ambient air.

The insecticide used in thermal fogs is diluted in a carrier liquid, which is usually oil-based. Hot gas is used to heat the pesticide spray, decreasing the viscosity of the oil carrier, and vaporizing it. When it leaves the nozzle, the vapour hits colder air and condenses to form a dense white cloud of fog. Most of the droplets are smaller than 20 µm. The droplet size is affected by the interaction between the formulation, the flow rate and the temperature at the nozzle (usually > 500°C). The volume of spray mixture applied in vector control is usually 5-10 litres per hectare, with an absolute maximum of 50 litres per hectare. The hot emission gas is obtained from engine exhaust, friction plate/engine exhaust or from a pulse jet engine.

**Advantages**

(a) Easily visible fog, so dispersal and penetration can be readily observed and monitored.

(b) Good public relations in some circumstances as people can see something being done about the problem.

(c) Low concentration of active ingredient in the spray mixture and reduced operator exposure.

**Disadvantages**

(a) Large volumes of organic solvents are used as diluents, which may have bad odour and result in staining;

(b) High cost of diluents and spray application;

(c) Householders may object and obstruct penetration of fog into houses by closing windows and doors;

(d) Fire risk from machinery operating at very high temperatures with flammable solvents; and

(e) Can cause traffic hazards in urban areas.

Cold fog

The cold fog is produced by a special device (cold fogger) that breaks up the chemical into microscopic droplets by mechanical means, basically with a high-pressure pump and an extreme fine nozzle. The spray droplets are generated without any external heat. With cold fogs, the volume of spray is kept to a minimum. Ultra - low - volume insecticide formulations are commonly used for such applications. The cold fogger may dispense formulations in a very concentrated form and generate the droplets (usually in the 5-30 micron diameter range) in a precise manner. However, its ability to penetrate dense foliage or obstacles is not as good as that of the thermal fogging. Cold fogging is sometimes called Ultra Low Volume (ULV) treatment as it allows the utilization of only a very small amount of chemical for coverage of a large area.

Like thermal fogging, cold fogging also does not have lasting residual effects. It is, therefore, essential to carry out fogging at the time when the vectors are most active to hit them directly.

**Advantages**

(a) The amount of diluents is kept to a minimum, resulting in lower application cost and increased acceptability. Some formulations are ready to use, thereby reducing operator exposure.

(b) Water-based and water-diluted formulations, may be used which pose a low fire hazard and are more environmentally friendly.

(c) Because a lower volume of liquid is applied, application is more efficient.

(d) No traffic hazard as the spray cloud is nearly invisible.

**Disadvantages**

(a) Dispersal of the spray cloud is difficult to observe

(b) Higher technical skills and regular calibration are required for efficient operation of equipment.

Space spray equipment

Selection of appropriate equipment for space spraying depends on the size and accessibility of the target area as well as the human resources and operational capacity of the programme. Sometimes smaller machines may be needed in conjunction with vehicle-mounted equipment to treat narrow pathways and other areas inaccessible to vehicles or sheltered from prevailing air movements. Cold fog equipment is recommended where thermal fogs may cause a traffic hazard. Aerial application of space sprays may be justified where access with ground equipment is difficult and/or extensive areas need to be treated very quickly.

Equipment for thermal fogging

**Hand-carried thermal foggers**

These are used for treating houses and certain outdoor areas of limited size or accessibility, e.g. markets, hotel

Fig - 22: Hand held Thermal Fogger

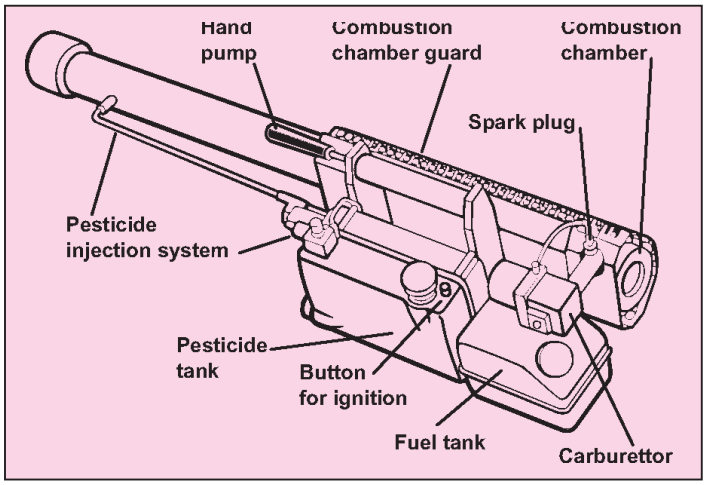


Fig - 23: Hand carried cold fogger

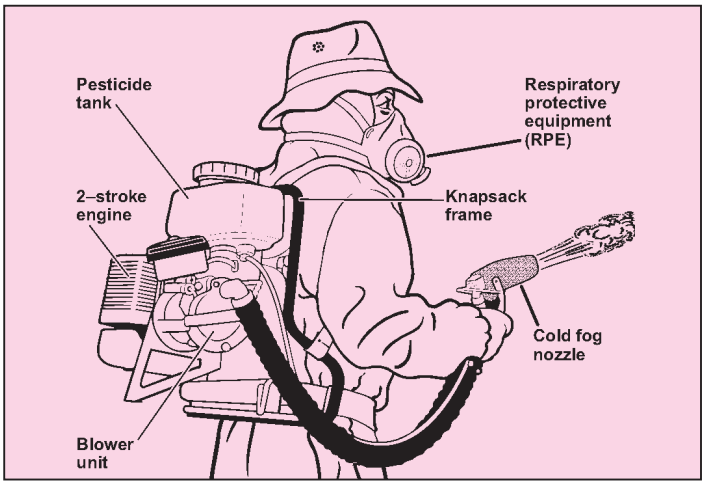


grounds and parks. There are two types of hand-carried thermal foggers; pulse jet and friction plate (Fig - 22).

**Vehicle-mounted thermal foggers**

Large thermal fog generators use an air-cooled motor to run an air blower, fuel pump and insecticide pump. Air from the "roots type air blower" is delivered into the combustion chamber. There it is mixed with gasoline vapour and ignited, so that temperatures reach 426-648 °C. The diluted insecticide liquid is pumped via a simple flow delivery valve and injected into a cup in the fog head or directly into the nozzle. The insecticide liquid is vaporized by the blast of hot gases. Despite this high temperature, insecticides show very little degradation of active ingredient. This is because the time spent at that temperature is only a fraction of a second, which is not long enough to cause serious degradation. The hot gases then pass out of the machine. As the hot oil vapour is discharged through a relatively large nozzle into the cooler outside air, it condenses to form very small droplets of thick white fog. Delivery rates of up to 10 litres per minute can be achieved with larger machines.

**Aircraft application of thermal fogs**

For aircraft application of thermal fogs, the diluted insecticide formulation is fed into the aircraft exhaust. The exhaust is adapted with vanes to swirl the fog droplets as they are formed. The application of thermal fogs by aircraft has been very limited.

Equipment for cold fog application

**Hand-carried cold foggers**

Most of these machines have gasoline engine or electric operated which drives a blower unit to discharge air through the nozzle. Air may also slightly pressurize the insecticide formulation tank so that the liquid is fed via a restrictor to the nozzle. However, negative pressure generated by the air flow passing through the nozzle allows liquid to flow from the tank. In addition to hand-carried units, knapsack cold fogging units are also available (Fig - 23), as are several electrically driven models.

**Vehicle-mounted cold foggers**

A high volume air blower, forces air at a rate of approximately 6 $m^3$ per minute at low pressure to nozzle. The pesticide container may be pressurized to force the formulation to the nozzle, or positive-displacement pumps may be used.

Alternatively a high-pressure, low-volume air source is used with an air compressor, rather than a blower. On these machines, nozzles ranging from the standard industry "paint gun nozzle" to proprietary nozzles that atomize well up to a flow rate of 0.5 litre per minute are available. Another design uses a rotary nozzle coupled with an electric motor which operates at a very high speed.

**Aircraft application of cold fogs**

Both fixed-wing aircraft and helicopters have been used to apply cold fogs. Conventional low-volume nozzles (e.g. flat fan) have been used on fixed wing aircraft to create fine sprays, using moderate or high pressures. However, the droplet spectrum is generally poor so preference is given to the use of rotary atomizers or very-high-pressure systems.

Insecticide products for space spraying

Space-spraying formulations are generally oil-based. The oil carrier inhibits evaporation of small fog droplets. Only insecticide products with high flash points are used for thermal fogging. Diesel is used as a carrier for thermal fogging, but creates a thick smoke and oily deposits, which may lead to public rejection. For environmental reasons, water-based formulations have been made available in recent years. These formulations may also contain substances that prevent rapid evaporation. Table 3 lists selected insecticides suitable for space spraying against mosquitoes. These insecticides may also be used against other insect pests and vectors, but different dosages may be required.

Space spray treatments : General considerations

**Optimum droplet size**

Table - 3 : Insecticides used for space spraying

| Sr. No. | Insecticide | Dilution | Equipment required | Remarks |
|---|---|---|---|---|
| 1 | Pyrethrum 2% Extract | 1 ltr in 19 ltr Diesel or Kerosene | Flit gun / Thermal Fogging machine | For space spray indoors (Keep rooms closed for 30 |
| 2 | Pyrethrum 2% EC | 1 ltr in 19 ltr Water | ULV Fogging machine | For space spray indoors |
| 3 | Malathion Tech | 5 ltr in 95 ltr Diesel (5%) | Thermal Fogging machine | For space spray outdoors |
| 4 | Deltamethrin 1.25 ULV | 1 ltr in 199 ltr Diesel | Thermal Fogging machine | For space spray outdoors |
| 5 | Deltamethrin 1.25 ULV | 1 ltr in 19 ltr Water | ULV Fogging machine | For space spray indoors |

Space treatments are only effective while the droplets remain airborne. Droplets fall by gravity and some are deposited on horizontal surfaces while the majority is lost to the atmosphere especially in outdoor spraying. Droplets bigger than 30 µm in diameter are less effective as they do not remain airborne for sufficient time. Droplets smaller than 5 µm in diameter do not readily come in contact with flying insects, as the movement of the smallest droplets is affected by the air turbulence created by the insect's flight. It is generally accepted that droplets should be generated at 10-30 µm so that, even with some evaporation and after some time, they remain in the correct range for optimal airborne suspension and insect impact. The optimum droplet size for space spraying against mosquitoes is 10-20 µm.

**Spray concentration**

For a flying insect to be killed, it must acquire a lethal dose of insecticide in the droplets that impact on it. The lower the concentration of active ingredient, the larger the number of droplets of a given size required to achieve a lethal dose. Ultra-low-volume spraying aims, largely for operational reasons, to minimize the total volume of diluted insecticide applied (usually < 2 litres per hectare).

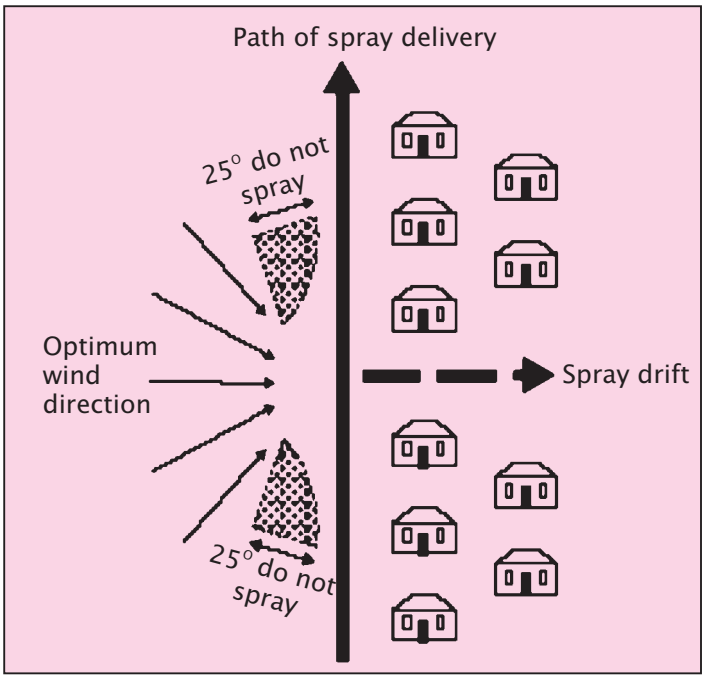
**Wind speed**

Wind speed has a profound effect on droplet distribution and impingement on insects. Spraying should not take place when wind speed exceeds 15 km/hour. The type of terrain and vegetation affects air movement and hence the distribution of the droplets. In open terrain with relatively sparse vegetation, wider effective swaths can be obtained than in urban areas where the obstruction of buildings alters the flow of air.

**Wind direction**

With vehicle-mounted and aerial spraying the spray route must take account of the wind direction to maximize the distribution of the spray throughout the target area. Fig - 24 illustrates the spray application route relative to wind direction.

Fig - 24 : Spray application route relative to wind direction



**Temperature effects**

In direct sunlight the ground is heated. This causes air to rise. In the middle of the day outdoor space spraying will largely be wasted as the spray droplets will tend to rise upwards rather than drift horizontally. Ideally an inversion is needed, i.e. colder air closer to the ground. This generally occurs early in the morning after the ground temperature has fallen during the night, but can also occur in the evening when the sun has set and ground temperatures begin to fall.

**Time of treatment**

Knowledge of the time of peak flight activity of the target species is crucial to ensure that space treatments are planned to coincide, as far as possible, with these times. Fortunately, peak flight activity of many vectors is around dusk and/or dawn, when weather conditions are often favourable for space treatment. *Aedes aegypti* and *Aedes albopictus,* mosquito vectors of Dengue fever and Chikungunya, are active during daytime, with peak flight activity in the morning and afternoon. With these species a compromise is usually made outdoors by spraying in the early morning or late afternoon. The timing is less important if indoor spraying is conducted.

Indoor fogging

Personnel conducting this work require training on the safety measures to be followed. Several rules apply:

(a) Protect all water containers and foodstuffs.

(b) Remove fish or cover fish tanks.

(c) Ensure all occupants and animals remain outside the house during spraying and stay outside for 30 minutes after spraying. Ensure that the building is ventilated before reoccupation.

(d) Close all doors and windows before spraying and keep them closed for 30 minutes after spraying to ensure maximum efficacy.

(e) Spray operators should work backwards and away from the fog to minimize exposure.

(f) For small single-storey houses, the spray can be delivered from the front door or through an open window without having to enter every room of the house, provided that adequate dispersal of the insecticide droplets can be achieved.

(g) For large single-storey buildings, it may be necessary to apply the spray room by room, beginning at the back of the building and working towards the front.

(h) For multi-storey buildings, spraying is carried out from top floor to the ground floor and from the back of the building to the front. This ensures that the operator has good visibility at all times.

Outdoor ground fogging

Advanced route planning should precede outdoor ground fogging operations and may require a combination of vehicle-mounted and hand carried or knapsack equipment in areas with difficult or limited vehicle access. Consideration must also be given to the following:

(a) Spraying should not be undertaken when it is raining, when winds exceed 15 km/hour, or in the heat of the day.

(b) Doors and windows of houses and other buildings should be open to allow penetration of the spray cloud for improved efficacy.

(c) For vehicle-mounted equipment, in areas where the roads are narrow and the houses are close to the roadside, the spray should be directed backwards from the vehicle. In areas where the roads are wide, with buildings far from the roadside, the vehicle should be driven close to the roadside and the spray should be directed at an angle (downwind) to the road rather than directly behind the vehicle.

(d) The nozzle of vehicle-mounted cold fog machines may be directed upwards at an angle when there are barriers that impede airflow, e.g. boundary walls and fences; for vehicle-mounted thermal foggers, the nozzle should be directed horizontally.

(e) A track spacing of 50 metres is generally recommended, with the vehicle moving upwind so that the fog drifts downwind away from it and the operators.

Aerial application of fogs

Suppression of vector populations over large areas can be carried out using space sprays released from aircraft, especially over areas where access with ground equipment is difficult and extensive areas need to be treated very rapidly.

Evaluation

Evaluation of the efficacy of spray operations is carried out using techniques that are largely specific to the target insect. Space sprays are transient and only insects flying at the time of the application are affected.

Area Spraying

This is carried out for treatment of land against mites and ticks and also as an anti-larval measure over vast water surfaces. Against mites and ticks, suspensions are used on land and vegetation; WDP is used for anti-larval treatment of lakes and swamps. Aerial spraying is resorted to for agricultural purposes and sometimes for veterinary and rarely medical purposes. Dusts are applied to manure yards and dry refuse yards to control flies and other pests. For all such uses power driven sprayers and dust guns are used. The larvicidal oils are applied by spraying it on the surface of water by means of a knap-sack sprayer or hand pumps or by a mop stick.

**Resistance of vectors to insecticides**

Ever since the introduction of the potent synthetic insecticides into public health programmes at the close of the Second World War, the main problem has been the development of resistance to them by the arthropods they formerly controlled. In 1947, DDT resistance was discovered in the housefly and *Culex molestus* in Italy. In 1951, DDT resistance was noticed in body louse in Korea and in *Anopheles sacharovi* in Greece. In 1955, Dieldrin resistance was discovered in *Anopheles gambiae* in Northern Nigeria. In 1959, in Western India the oriental rat flea was found to have developed resistance to DDT. The number of arthropods showing resistance is on the increase (28)

Definition

Resistance is defined as "The development of an ability in a strain of insects to tolerate doses of toxicants which would prove lethal to the majority of individuals in a normal population of the same species". The word tolerance is normally used when the increase in $LC_{50}$ is less than the indicated minimum for the tests, but is nevertheless statistically significant. Vigour tolerance is a term, which has been applied to enhanced insecticidal tolerance resulting from extra vigour of the strain rather than from any specific defence mechanism.

Types

Resistance is of two types i.e. physiological and behaviouristic. Physiological resistance is the one described above. Behaviouristic resistance means the development of ability to avoid a lethal dose. This term is applied most often to mosquitoes in relation to DDT.

Nature and Cause

**Genetic**

Resistance develops in arthropods after a long period of insecticidal pressure. It is brought about by the accumulation of the contributing genes through

successive selection with a number of insecticides, each of which confers some cross-resistance. This is called polygenic resistance. In contrast, the resistance may be due to a single gene and bear no similarity to the complexities involved in the polygenic resistance. Monogenic resistant strains are more vulnerable to counter measures such as addition of synergists; hence the importance of distinction between the two types.

**Biochemical**

Many causes of resistance have been defined although several defy explanation in biochemical terms. Resistance to DDT and Dieldrin due to the gene Kdr does not involve detoxification, and is thought to be due to an altered site of action. On the other hand, an altered site of action as a cause of resistance has been definitely established with cholinesterase inhibitors. In these cases a mutant cholinesterase is produced that is inhibited more slowly than the normal enzyme in susceptible strains. This produces resistance against a large number of compounds and the resultant extensive cross-resistance makes it a serious type of resistance.

**Increased Detoxification**

Detoxification enzymes in resistant strains are generally more efficient and are not necessarily produced in higher amounts; oxidases are particularly important as they affect a wide variety of insecticides. The following enzymes or classes of enzymes are known to be of importance: -

(a) DDT dehydrochlorinase or DDTase which affects DDT and several analogues.

(b) Hydrolases which affects phosphate esters or carboxylic ester groups in OP compounds and in some pyrethroids.

(c) Glutathion S transferase affects OP compounds.

(d) Oxidases affect Carbamates, OP compounds, DDT and its analogues, as well as pyrethroids

**Dynamics**

(a) If the genetic potentiality to development of resistance to a given insecticide is present, the rate of development of resistance will depend upon factors such as the frequency of resistant genes and their dominance, the selection pressure, previous history of exposure to insecticides, isolation, inbreeding and reproductive potential of the arthropod population.

(b) The rate of development of resistance in previously unselected populations is normally very low at first. During the period when the frequency of major genes for resistance is gradually increased and the genetic background is progressively organized towards greater fitness in the contaminated environment, the rate of development of resistance accelerates rapidly, often leading to failure of control measures.

## Biological Control

Intentional manipulation of populations of living beneficial organisms, called natural enemies, in order to reduce the numbers of pests or amount of damage is called Biological Control (29-32).

Natural control strategies that employ biological agents for pest suppression are classified as biological control tactics. In conventional usage, this term usually refers to the practice of rearing and releasing natural enemies: parasites, predators, or pathogens. Biological control is a particularly appealing pest control alternative because, unlike most other tactics, it does not always have to be reapplied each time a pest outbreak occurs. However, Biological control is not a "quick fix" for most pest problems. Natural enemies usually take longer to suppress a pest population than other forms of pest control and therefore often regarded as a disadvantage or limitation of biological control. It also may be difficult to "integrate" natural enemies when pesticides are still in use. Beneficial insects are often highly sensitive to pesticides and their resurgence (recovery to pre-spray densities) is usually much slower than that of pest populations. Rapid pest resurgence often leads to a vicious cycle of continued chemical usage that prevents natural enemies from ever becoming reestablished.

The biological agents are broadly classified as Predators, Parasites and Pathogens.

**Predators**

Predators are insects or other insectivorous animals, each of which consumes much insect prey during its lifetime. Predators are often large, active, and/or conspicuous in their behavior, and are therefore more readily recognized than are parasites and pathogens. Most commonly used predators are the larvivorous fishes for the control of mosquitoes.

**Larvivorous Fish**

There are areas and habitats where larvivorous fish, such as *Gambusia affinis* (Fig - 25) and *Poecilia reticulata* (Fig - 26), can make considerable contribution to vector control. The larvivorous efficiency of *Gambusia* is due to the fact that a single full grown fish eats about 100 to 300 mosquito larvae per day, is a surface feeder, hence it is suitable for feeding on both Anophelines and Culicines, is small and inedible and can tolerate salinity. Poecilia's larvivorous efficiency is due to its capability to negotiate margins of ponds more easily, tolerate handling and transportation very well, survives and reproduces when introduced into new water bodies, survives in new places (water bodies) and multiplies easily and can survive in good numbers for years and does not require constant care.

Fig - 25

Fig - 26

Release of fishes is done at the rate of 5-10 fish per linear

meter. If the larval density is high, up to 20 fishes can be released. Fishes should be released in the morning hours or in the evening.

Criteria for selecting a water body for a fish hatchery are

(a) It should be a permanent water body.
(b) Depth of water should be at least 1.5 metre or more.
(c) Water should be confined and without big natural outlet.
(d) The minimum size of water body should be at least 5 m X 4 m. The water body of 10 m X 5 m can support 50000 fish.
(e) It should be free from other carnivorous fish.
(f) Water should not be contaminated by chemical or other harmful substances.
(g) Easily accessible for daily or periodic inspection and for collection of fish.
(h) De-weeding in ponds and shallow water bodies and cleaning of margins should be carried out periodically.

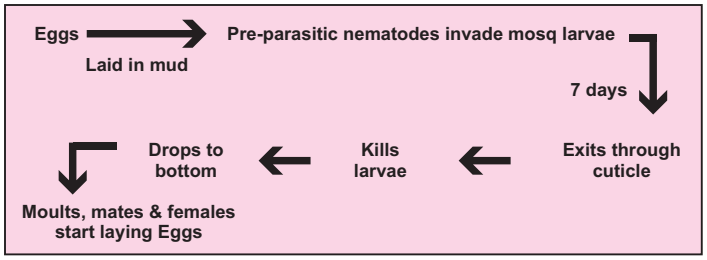
### Parasites

Parasites are those organisms which depend on their host for shelter or food. Many parasites are very specific to the type of host insect they can attack, and they are not harmful to humans. Although insect parasites are very common, they are not well known because of their small size. Some of the categories of Parasites are as follows:

Nematodes

Nematode *Romanomermis culicivorax* and *R iyengari* have been evaluated and have been found to give variable

Fig - 27



control of mosquitoes. The mode of action of the nematodes is presented in Fig - 27.

Fungi

Fungal agents *Laegenidium* and *Culicinomyces* have shown immense potential as mosquito larval control agents and can be exploited for use against mosquitoes.

### Pathogens

The pathogens which have been found promising are the Bacterial agent's *Bacillus thuringiensis* var *israelensis* and *Bacillus sphaericus* in mosquito larval control. However, these have been classified as Biocides or Microbial insecticides and have been discussed earlier. Viruses like Nuclear Polyhedrosis virus and Irido virus have also shown promise against mosquito larvae.

## Genetic Control

This is defined as "the use of any condition or treatment that can reduce the reproductive potential of noxious forms by altering or replacing the hereditary material". The various methods of genetic control fall into two general groups: those leading to population control, reduction, or elimination through the release of partially or completely sterile insects in sufficient numbers to overcome the reproductive capability of the natural population; and those leading to population control or population replacement through the release of partially sterile or fully fertile genetically altered insects (33).

New genetic control methods, such as those involving sex distortion mechanisms or the selection and release of strains refractory to pathogens, sensitive to selected ecological factors, or susceptible to insecticides, are being tested under field conditions. However, unless some new and revolutionary ideas emerge, the genetic control measures so far known are capable of achieving only "management" or "manipulation" of insect population rather than complete suppression or reduction in densities.

## Personal Protective Measures

The role of personal protective measures in arthropod-borne disease control is to prevent the arthropod vector from biting and feeding on its host, whether susceptible or already infected, thereby blocking the chain of transmission of disease from one host to another. Biting can be prevented either by protective clothing or chemically by using appropriate repellents (34 - 38).

### Protective Clothing

Individual personal protection against bites of arthropods can be achieved by use of mosquito net, wearing of long trousers, rolled down sleeves of shirts, socks, shoes and anklets, particularly when going out on patrols and exercises in areas heavily infested with arthropods. These measures will vary according to the nature of problem faced in a particular locality. Specific personal protective measures have been described as part of control measures in chapters dealing with those vectors.

### Repellents

Insect repellents are chemicals which repel insects when applied to body surfaces or clothing. The suitability of substances for use as repellents is dependent primarily on their inherent repellency and duration of effectiveness. The important factors are the ease of application on the skin; odour, appearance or feel on the skin e.g. oily or greasy; the likelihood of being rubbed off, or absorbed by the skin; irritant effect or toxicity if absorbed; and its stability under high humidity, high temperature, rain and perspiration. The efficacy may also be influenced by the amount of sweating, rubbing and the avidity of the insect itself. Moreover as is the case with insecticides, repellents exhibit specificity of action so that some species of insects are more sensitive to one and some to other repellents.

Common Repellents

The following compounds are among the most effective when used alone as repellents against one or more groups

of arthropods: benzyl benzoate, DEET (N, N-diethyl-m-tolumide), dibutyl phthalate, DEPA (di ethyl phenyl acetamide) and Neem oil. Repellents are formulated as liquids, gels, creams and in pressurized containers. Some of the common compounds are discussed below:

**(a) N, N-diethyl m-toluamide (DEET)**

DEET has been reported to be an outstanding all-purpose repellent. It provides 6-8 h of protection against mosquitoes, 2-3 hour against Chrysops, 9 hour against Culicoids. It feels less oily on the skin than the other repellents. DEET can also be used very effectively for impregnation of clothing. In experiments conducted at AFMC it has been shown to provide repellence up to two launderings of the clothing. As a skin application DEET may be used for protection against mosquitoes, sand flies, fleas and other biting Diptera. It is a good repellent against all haematophagous arthropods and also against leeches.

**(b) Dibutyl Phthalate (D.B.P.)**

It is more persistent but somewhat less rapid repellent. When smeared on clothing, its effect lasts up to 2-4 washes Ironing destroys it. It is specifically useful against ticks and mites as it is acaricidal as well as a repellent. DBP is a good repellent against leeches and Dimdam flies.

**(c) Benzyl Benzoate**

The oily liquid has a faintly pleasant aromatic odour and sharp bitter taste. It has been applied in 5 percent emulsion to skin as repellent for many arthropods. Clothing impregnated with benzyl benzoate show repellence to fleas, chiggers and other arthropods. A mixture of equal parts of Diethyltoluamide and Benzyl benzoate with the addition of an emulisifier acts as a good impregnant for clothing against trombiculid mites.

**(d) Diethyl phenyl acetamide (DEPA)**

This product has been indigenously developed by DRDE Gwalior. It is a colourless oily liquid. This repellent has been specially formulated for the Armed Forces and is available as lotion, cream and sprays (20%). It is a broad spectrum repellent and can be used for topical application against mosquitoes, ticks & mites or any other haematophagous arthropod and leeches. It can also be applied on clothing/uniform as repellent. It can withstand 2-3 launderings and ironing. It matches DEET in its spectrum and efficacy.

Application Procedures

**Skin Application**

Repellents like DEET and DEPA are applied to the skin either undiluted or diluted in various solvents, ointments, creams, etc. The vehicles should be suitable for smearing over the exposed skin surface. These are generally effective against such pests as midges, mosquitoes, sand-flies, and so on. A good repellent applied in this way will give protection from insect bites for about five to seven hours.

Impregnation of Clothing

Application to clothing is carried out when longer protection against insects is required. Application of DBP, DEET or DEPA to clothing to protect one self from mites and ticks is much more persistent than skin treatment and remains effective for a period up to a month

**Hand Application (Repellent Drill)**

Hand Application of repellent is the simplest way to treat the clothing. The fingers of one hand are dipped into the chemical in an open container or a few drops of the chemical are poured into one hand, both the hands are rubbed together and then they are wiped lightly on the inside and also on the outside of all the openings of all garments to produce a thin layer of the chemical on them. The chemical should be applied more particularly to the opening such as inside the neckband of shirts and the fly and turn ups of trousers and tops of socks turned inside out. 60 ml per man per fortnight of DBP is enough to impregnate two shirts, two pairs of trousers, 2 pairs of socks, anklets and two sets of underclothing. The application should be started a fortnight before the mite borne disease (like scrub typhus) season in any area begins, and repeated every fortnight thereafter until the season lasts. This should be done on a parade as a drill supervised by a JCO or an NCO who has had training and experience of the procedure. The repellents DEET, DEPA require lesser quantities for impregnation

**Spraying**

The chemical can be applied to the entire clothing by spraying or the clothing can be impregnated with a solution or emulsion of the repellent when large quantities of clothing are treated at formation levels. Clothing should be soaked in the solution, then wrung out lightly and dried. DEPA is now available as spray formulation for treatment of uniform.

**Barrier Application**

Considerable protection may also be obtained by treating only the openings of the clothes inside the neckband and cuffs of shirts, inside the waistband, fly and turn ups of trousers and on the socks above and inside the shoes and below its tongue. These methods, called the barrier application, are particularly useful when troops have to move at very short notice during an emergency and there is no time for regular repellent drill or when sufficient supplies of repellents are not available.

**Mosquito nets**

Mosquito nets are very effective means of protection against the bites of haematophagous arthropods. Untreated or insecticide treated nets may be used as per the availability. Insecticide treated bednets may be manually treated with Synthetic pyrethroids like Deltamethrin 2.5% SC or Cyfluthrin 05 EW. These nets have to be treated every six months. The newer concept of Long Lasting Nets (LLN's) has been launched. These nets may also be treated manually or may be pretreated with insecticide Permethrin or Deltamethrin for such

**Steps for treatment of bednets**

(a) Measure the total area of the net in $m^2$.

(2 x length x height + 2 breadth x height + length x breadth) in metres.

Average area of a single net is 10 sq m

(b) Measure the absorption capacity

(i) Measure 1 litre of water and take in a tub.

(ii) Immerse the dry net, when completely wet, take it out by gently wringing the net to prevent dripping of water.

(iii) Measure the remaining water in the tub. 1 litre minus the remaining water gives us the absorption capacity of the net.

(c) Wash the net to be treated and dry it.

(d) Calculate the dosage of the insecticide required

(i) Deltamethrin 2.5% SC - dosage required 25 mg a.i. per sq m. 1 ml of the 2.5% insecticide contains 25 mg; therefore the dosage will be 1ml per sq m to give the dosage of 25 mg a.i. /sqm. So if the net is of 10 sq m and the absorption capacity is say 500 ml then we need to add 10 ml of insecticide in 500 ml of water to give the required dosage.

(ii) Cyfluthrin 05% EW- dosages required 50 mg a.i. / sq m. 1 ml of the 05% insecticide contains 50 mg; therefore the dosage will be 1ml per sq m to give the dosage of 50 mg a.i. /sqm. So if the net is of 10 sq m and the absorption capacity is say 500 ml then we need to add 10 ml of insecticide in 500 ml of water to give the required dosage.

(e) Put the net in the insecticide solution prepared as per the procedure given above and knead it well to ensure the net is completely soaked in soln.

Take out the net and spread it in shade, once semi dry it can be hung for drying.

treatment. The shelf life of these nets is 5 years. Steps of treatment of bed nets is given in the box

## Integrated Vector Management

Development of resistance, effects on non-target organisms, and damage to the environment can all be minimized with selective and judicious use of multi-faceted control tactics. This approach, commonly known as **integrated control**, requires an understanding of ecological principles as well as a thorough knowledge of the pest's life history and population dynamics. Today, integrated pest control forms the foundation of Integrated Vector Management programs (IVM) that take a comprehensive and multi-disciplinary approach to solving pest problems. These programs emphasize management rather than eradication. They take a broad ecological approach to pest problems, focusing on all members of a pest complex in an effort to identify the optimum combination of control tactics that will reduce vector populations below economic thresholds and maintain these levels with the least possible impact on the rest of the environment(32, 39).

IVM is a dynamic approach which requires a broad knowledge of vector biology, ecology and behaviour on the one hand and that of system analysis approach on the other so that a variety of control measures, such as environmental, chemical, biological, genetic and personal protective measures can be integrated with a view to achieve the ultimate aim of combating human disease. Whereas, chemical and biological methods may provide temporary control of vectors, environmental control measures may lead to permanent control. In this approach initial costs may be high and programmes may require years for implementation, but commanders at all levels should be advised to include environmental changes and improvements relating to vector control in all long term planning. However, these methods require elaborate organization, longer time and liberal finances. Species control and vector control are the two modifications circumscribing the wider concept of vector management.

## Future Policy

The aim of future vector control by use of insecticides should be to reduce the intensity of chemical selection by reducing the frequency and coverage of insecticide sprays in public health programmes, minimizing the agricultural use of persistent chemicals as far as possible and by supplementing the chemical control methods by other methods whenever feasible. There is a need to strengthen existing surveillance methods and incorporating the benefits of the newer methods like Remote sensing, Geographical Information System, Global Positioning System, etc whenever and wherever feasible. There is a continued effort to evolve safer alternatives for vector control coupled with the intensive research using molecular biology tools to address the problems of vector control.

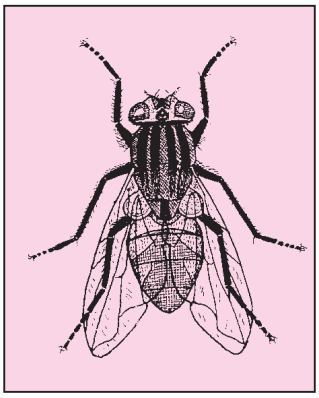
Dr (Mrs) Rina Tilak

# Housefly

Houseflies live in close association with man. Despite the best and most extensive efforts taken to control it, housefly control has remained a challenge. The important genera include Musca, Fannia and the biting flies, Stomoxys, Sarcophaga and the various blowflies viz. Chrysomya, Calliphora and Lucilia. However, the most abundant and widely distributed is the Housefly (1-4, 8, 40).

## Morphology

Fig - 1

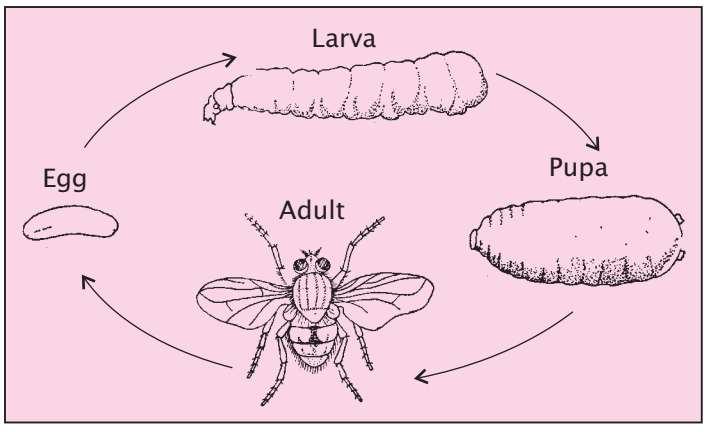


Adult houseflies are 6-9 mm in length, grayish in colour, with 4 distinct longitudinal black stripes on the thorax. The head bears a pair of compound eyes which are close together in males but are widely separated in females. The mouth parts, collectively known as the proboscis are capable of considerable extension and retraction. The thorax bears a pair of clear transparent wings, three pairs of legs - each terminating in five segments of tarsus; the last segment bears a pair of claws and pair of pad-like 'pulvilli' provided with a large number of glandular hairs. These secrete a substance which keeps the pads wet and sticky for clinging to vertical and smooth surfaces. The abdomen is short, broadly oval with five visible segments and is studded with ochre coloured bands or patches (Fig - . 1).

## Life History

The life cycle of housefly undergoes complete metamorphosis with egg, larva, pupa and adult stages (Fig - 2). Houseflies breed in decaying organic matter of animal or plant origin. The eggs are pearly white, oval in shape and measure about 1 mm in length. They are laid in cracks & crevices in moist manure heaps or any decaying animal or vegetable matter. A female fly may lay 300 to 900 or more eggs in 3 to 10 batches during her life time. In summer, the eggs hatch after 8-12 h, whereas in winter it may take 2 to 3 days. There are three larval stages or instars in the life of a fly. The larvae are photophobic and thus are found in the deeper layers of the manure. After 3-5 days, the third stage larvae moves from deep moist burrows to the neighboring dry soil and contracts to form a dark brown barrel shaped pupa about 6 mm in length. The pupa neither feeds nor grows. Within 2-5 days, the adult fly emerges out of the pupal case. Under favourable conditions of temperature and food supply, the whole life cycle from egg to adult may be completed in about less than a week's time. During winter it may take as many as 20 to 22 days.

Fig - 2



## Bionomics

The housefly has a remarkable capacity to reproduce. It is estimated that at an average of 7 day's developmental cycle for each generation, one female housefly, laying about 120 eggs, could produce a progeny of 5,598,72000,000 adult flies by the end of 5 months in summer. A high percentage of flies remain near the breeding places. Depending on the prevailing wind and availability of food, some of them may migrate up to 20 km from breeding places. High temperature is lethal to larvae and so the heat generated in tightly packed manure heap quickly kills them. The adult houseflies are attracted to light. The housefly is omnivorous and a voracious feeder. It is particularly partial to faecal matter, sputum, discharges from wounds and open sores. It is also easily attracted to sugars, milk and other articles of food meant for human consumption. The solid or semi-solid foods are softened by extrusion of a vomit drop and then sucked up. Well fed fly defaecates every 5 min, particularly while feeding and vomits every 2-3 minutes.

## Vector Potential

Immediately after visiting a dirty place, the fly may rest on any foodstuff or drink meant for human consumption or an exposed part of body e.g. mouth, eyes or a wound, and deposit the disease producing organisms. The housefly is thus a mechanical carrier of the causative organisms of diarrhoeas, dysenteries, gastroenteritis, cholera, enteric group of fevers, intestinal worms, poliomyelitis, viral hepatitis A, other entero viruses, trachoma, conjunctivitis, anthrax, yaws and tuberculosis. At times, the housefly may cause conditions known as internal and external myiasis in which the flies breed in sloughing wound, intestinal contents and suppurating cavities.

## Fly Control (41-47)

### Environmental Control

The best control of houseflies is to eliminate their breeding places and to maintain a high standard of environmental sanitation, especially by proper disposal of human and animal excreta, swill and garbage and all other decaying organic rubbish, offal and carcasses. Access of

flies to faeces should be prevented by fly proofing the latrines and latrine pans and prompt removal of faeces. Their access to food is prevented by fly-proofing cook houses and messing blocks and by use of fly-proof cupboards and containers. The doors of all entrances and windows should open outwards and preferably should have vacuum levers especially in cookhouses. Constant vigilance is necessary to destroy all flies that gain entrance otherwise the fly-proofed rooms become large fly-traps. In pantries and mess rooms, fly-proof cupboards for food storage and wire guaze, weighted with beads, afford protection to food in jugs or bowls, but their repair and cleanliness require constant supervision. When the table is being laid, cups should be inverted in saucers, and bowls should be kept either upside down or under cover when not in use.

Insecticidal Control

**(a) Space Spray**

For immediate destruction of flies and especially for suppression of fly borne epidemics, pyrethrum (0.1%) spray is useful, mainly in cook houses and dining rooms before meal times and in canteens. Certain combinations of space sprays containing Pyrethrum or Synthetic pyrethroids and/or Organophosphorus / Carbamate compounds are available commercially.

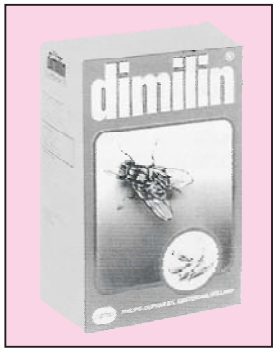
**(b) Baits**

Propoxur baits have in use since long for fly control. Recent introduction in this concept is Imadacloprid baits containing Imidacloprid as the toxicant with Pheromone Muscalure, which helps in attracting the flies to the bait. This bait ( Quickbayt ® ) has been evaluated at AFMC and found to be effective for use in areas with low to moderate fly infestation. However, while using these baits in cookhouses/ dining areas, care should be taken that they are not placed close to cooking or serving place.

**(c) Cord and Ribbons**

During the night, houseflies prefer to rest on strings and hanging wires or any object; this fact is utilized for killing them by use of insecticide treated cords and strips which are hung from ceilings in kitchens, dining halls, store rooms, diary farms and poultry houses to provide effective control during the fly season. Dark coloured material is preferred for treatment @ 1m cord or strip for each square metre of floor space. The period of effectiveness ranges from 1 to 6 months. For this any insecticide with high vapour pressure and quick knock down effect should be used. These treated materials should not be hung over food containers, watering troughs or within reach of animals or pets. Curtains treated with Synthetic pyrethroids will be of additional benefit.

**(d) Larvicides**



Insecticides such as DDVP (0.5%), Fenthion (4%) have been used as larvicides to control fly breeding but the use of larvicides may favour the development of resistance, the choice should therefore be made carefully. Insecticides like Dimilin (IGR) may be used to retard development of resistance. Larvicides should be applied at a rate sufficient to wet the upper 10-15 cm of the breeding medium thouroughly i.e. 0.5 - 5 l/$m^2$.

**(e) Paints**

The concept of using insecticidal paint for housefly is catching up. Imidacloprid baits wetted with water may be used as paint on housefly resting places.

**(vi) Residual Spray**

The housefly has developed resistance to most of the Organochlorine as well as Organophosphorus and Carbamate group of insecticides routinely used in public health. Residual sprays are ideally not recommended for fly control.

Mechanical Control

**(a) Fly Traps**

Various types of fly traps such as the cage trap and the kerosene tin trap were used in the past with fairly good results. These are no longer in use because of the availability of more potent and convenient methods mentioned above. Newer mechanical fly catching devices have been developed which have bags with attractants inside which attract the houseflies and on entry inside the bag, they get trapped and eventually are killed.

**(b) Swatting**

It is used in situations where infestation is so low that routine fly control measures are either not indicated or feasible. However, it is important to remember that fly population of a cook house or dining room cannot be greatly reduced by persistent swatting. A good swat is the one, which is resistant enough to affect a rapid hit. The flaps should be perforated and washable.

**(c) Fly Paper**

Commercially available fly papers may be used or alternately sticky fly papers can be prepared by mixing 8 parts of powdered resin and 5 parts by weight of crude

castor oil and heating the same in a water bath while stirring constantly. The paste mixture is spread on glazed paper. The latter can be prepared by coating an ordinary paper with a hot solution of 1 g of glue in 3ml of water and allowing it to dry. The

fly papers do not give lasting results and hence are not much in use. They are best used for monitoring fly density.

Physical Control

Use of light traps (electrocutors) is very useful in the dining areas & other public eating places. The light traps should be placed away from dining tables & food.

| Insecticide | Formulation | Dosage | Area to be sprayed |
|---|---|---|---|
| Cyphenothrin | Gokilaht-S 5EC | 10ml + 990 ml of water | 500ml/sq m |
| Diflubenzuron | Dimilin 2.5%WP | 8 g in 1 l water | 500ml/sq m |
| Diflubenzuron | Dimilin 5% G | As it is | 50 g/sq m |
| Imidacloprid | Quick bayt | As it is | 20 g / bait station |
| Propoxur bait | Baygon bait 2% | As it is | Moisten and keep in bait stations |

Dr (Mrs) Rina Tilak

# Mosquitoes

Mosquitoes belong to phylum Arthropoda, class Insecta, order Diptera and family Culicidae. The family culicidae is divided into sub-families - the Culicinae, the Chaoborinae and the Dixinae. Of these only the sub-family Culicinae, which comprises all the true mosquitoes, is of medical importance. Amongst the mosquito genera, only *Anopheles, Culex, Aedes* and *Mansonia* are of importance in India. The mosquitoes are further classified as 'Anophelines', which comprises only one important genera - *Anopheles* and 'Culicines' comprising three important genera viz. *Culex, Aedes* and *Mansonia.*

## Morphology

Mosquitoes are about a centimetre long and grayish black in colour. The division of the body into the head, thorax and abdomen is sharply defined. The head bears two large compound eyes, a pair of antennae and the mouthparts which are collectively called 'proboscis'. The mandibles and maxillae of only the female are developed for cutting the human skin; therefore only the female mosquitoes can suck the blood and transmit diseases (1-4, 48).

Males can be identified by their antennae, which are densely haired and look like moustache, whereas, in females the antennae is sparsely haired. The abdomen of mosquitoes consists of 10 segments of which 7 or 8 are clearly marked out and the terminal ones form the male and female external genitalia.

## Life History

Mosquitoes undergo complete metamorphosis through the stages of egg, larva, pupa and adult. Water is required for egg laying. The number of eggs laid at each oviposition varies between 50 and 150. The eggs hatch into larvae in one to two days, but in cold weather the hatching may be delayed. Mosquito larvae feed voraciously on microorganisms, water algae or other organic matter, and breathe through spiracles. They move actively with wriggling motion, hence are known as "wrigglers'. Larvae pass through four stages or “instars” in five days depending on the species, the temperature of the water and availability of food supply. At the end of the fourth instar, the fully grown larva casts its skin and becomes a pupa. During this stage it undergoes transformation to the adult usually within 1-2 days. The adult mosquito wriggles out of the pupal skin. The total duration of the life cycle varies between seven days to one month; however it could be up to a maximum of 6 months in the temperate zones, but in the tropics they seldom survive for more than a month.

## Bionomics

The females of all the medically important mosquitoes are normally bloodsuckers, as they require a blood meal for maturation of eggs. Females are fertilized during swarming (nuptial dance) at dusk. Those feeding on human blood are called anthropophilic and those feeding on animals are called zoophilic. Majority of species are nocturnal in their feeding habits, some are diurnal while others feed indiscriminately by day or night. Some are outdoor biters (exophagous) and some are indoor biters (endophagous). After blood meal, female goes in search of a quiet place indoors (endophilic) or outdoors (exophilic) to rest for a variable period, usually 2 days and matures her eggs, which are thereafter laid in water collections. Male mosquitoes feed on flower-nectar and plant-juices and do not survive long after fertilizing the female mosquito.

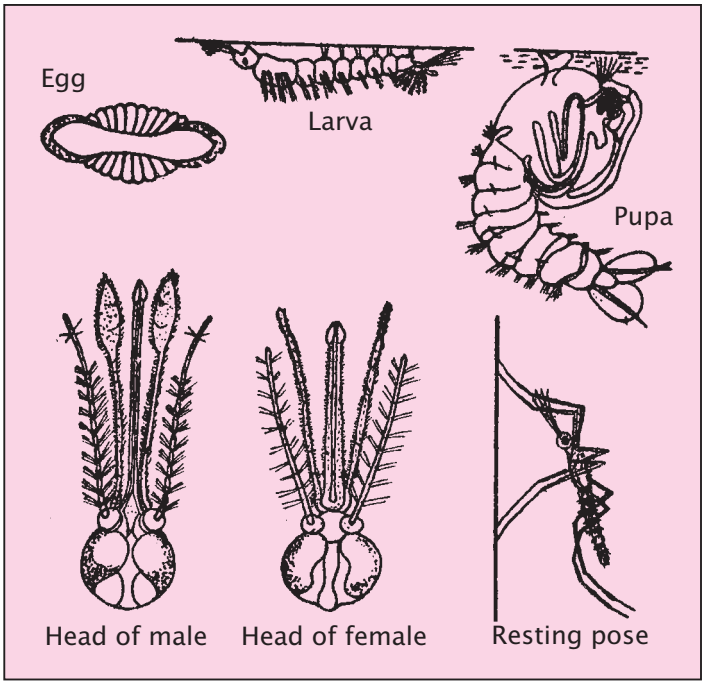
## Vector Potential

Certain species of Anopheline mosquitoes are vectors of Plasmodia causing human malaria. Some species of Culicine and Mansonoides mosquitoes cause human filariasis. Aedes mosquitoes cause yellow fever, dengue, dengue haemorrhagic fever and chikungunya. Many species of mosquitoes belonging to the genera Culex and Aedes are the vectors of a number of viral encephalitides. Vector potential is posessed only by certain species of a particular genus and for specific infection only. All species are not efficient in spreading the particular infection. The potential generally depends upon the feeding, breeding and resting habits and the biological capability of serving as a host to an aetiological agent. A short description of the important genera is given below.

### Genus Anopheles

Members of this genus have 58 species in India. Females of only nine species of Anopheline mosquitoes are the vectors of human Plasmodia in India. In certain parts of the world, some species of Anopheline mosquitoes are the

Fig - 1 : Genus Anopheles



vectors of *W bancrofti* and *B malayi* infections as well. Anophelines mostly breed in fresh, unpolluted and oxygenated water. The larvae of a few species like *A subpictus* may be found in polluted water.

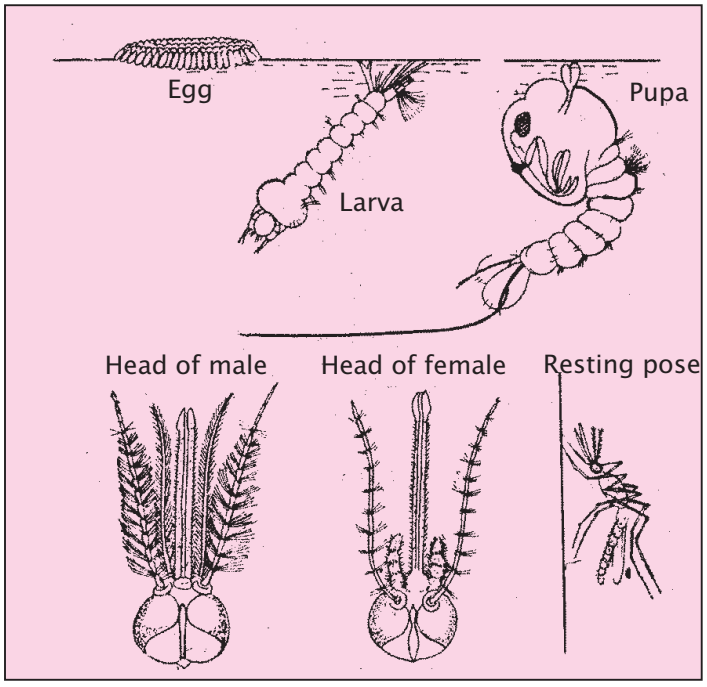
An identification kit for common Anophelines of India is presented at the end of the chapter.

**Genus Culex**

Members of this genus are found in temperate and tropical zones throughout the world. There are 240 Indian species in this Genus. Adult mosquitoes of this genus are generally dull in colour and inconspicuous due to unspotted wings. Their breeding sites vary from clear water, such as wells and springs, to collections of muddy, brackish or polluted water; but unlike Anopheline mosquitoes these mosquitoes generally prefer stagnant and muddy pools. *C quinquefasciatus* is prevalent universally. It is a night biting mosquito and is the most important vector of *W bancrofti.*

**Genus Aedes**

Fig - 2: Culex Mosquito

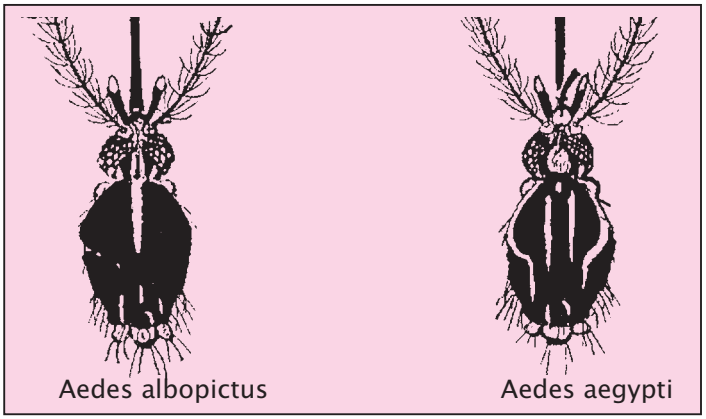


Some members of the genus *Aedes* have almost worldwide distribution while others have restricted habitats. The chief species in India are *Aedes aegypti, Ae albopictus* and *Ae vittatus.* They are black or dense brown and medium sized mosquitoes with silvery white scales forming patterns on the thorax, bands on the legs and rings around each abdominal segment (49).

These are container breeders. The cigar shaped eggs are laid singly on damp surfaces on stagnant water. These mosquitoes are mostly anthropophilic and are adapted to domestic or semi-domestic environments. During the pre-monsoon period the breeding is restricted to water collections meant for domestic use. Communities or sections of the cities with water scarcity, which leads to water storage practices, are mostly harassed by *Ae aegypti.* In the shore areas, barges and country crafts provide ample places for *Aedes* breeding. They are well adapted for breeding in small collections of water in a wide variety of natural and artificial containers such as masonary tanks, earthenware pots, small and large tins, barrel drums, coconut shells, stored or discarded motor car tyres, discarded polythene packs, junk and hardware, flower pots, fire buckets, depressions in tree trunks, axils of leaves and so on. They may breed in tree holes if these are within about 20 m of houses. The eggs after maturing may remain viable for considerable periods even after drying-up of the breeding sites, and hatch out during rains. Such surviving eggs rapidly build up the adult mosquito population when rains come. Their capacity to complete life cycle indoors enables them to breed in urban areas throughout the year, irrespective of the prevailing external climate. They are generally diurnal feeders. They may feed indoors or outdoors and rest near the breeding places in dark, shady corners and such places as behind cupboards, hanging clothes, inside shoes, umbrellas, below the furniture, and in containers providing breeding sites. *Aedes* mosquitoes are the vectors of urban and rural yellow fever, dengue, dengue haemorrhagic fever and chikungunya. *Ae niveus* has been reported as vector of *W bancrofti* (diurnally sub periodic) infection in Nicobar Islands.

*Ae aegypti,* and *Ae albopictus,* the two important vector species can be easily distinguished by their thoracic pattern. *Ae aegypti* has sickle or lyre shaped pattern on the thorax, whereas *Ae albopictus* has a single central mark present on the thorax (Fig - 3).

Fig - 3 : Thoracic pattern of *Ae aegypti* and *albopictus*

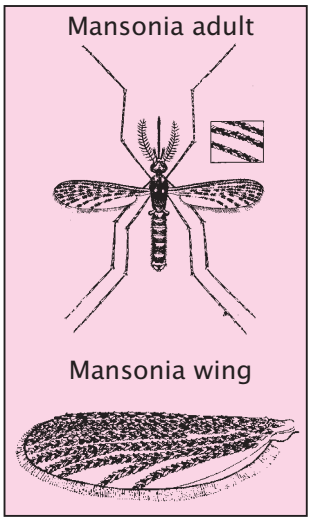


**Genus Mansonia**

This has wide distribution in tropical countries. In India, M annulifera, M uniformis and M indiana are the prevalent species in Kerala. The adult mosquitoes are robust and yellowish brown. The wings are covered with flat, broad scales, which give the wings a speckled appearance as if dusted with mixed salt and pepper. The female lays eggs in cluster anchored to the under surface of the leaves of aquatic plants such as Pistia straitiotes, Lemna, Eichornia, Salvinia and so on. On hatching out, the larvae obtain oxygen from the plant cells through their modified siphon

tubes by attaching themselves to the rootlets of these plants. The pupae are similarly attached to the plant stems by the modified breathing trumpets. When matured they detach themselves and come to the water surface. The adults then emerge and fly away. They are persistent biters, particularly during darkness. Mansonia mosquitoes are the vectors of B malayi infection of filariasis in several pockets in rural areas of Kerala, Tamil Nadu, Andhra Pradesh, Madhya Pradesh, Assam and West Bengal. (Fig - 4)

Fig - 4 : Genus Mansonia



Some of the important differences between Anopheline and Culicine mosquitoes are shown in Table-1

## Mosquito Control (8, 12-15, 19, 23-25)

Anti-adult measures and anti-larval measures are the two most important mosquito control measures. Personal protection against their bites aids these measures in control of disease. Methods related to environmental management by way of minor manipulations or major engineering steps should always be an important consideration in overall anti-malaria plan.

### Anti-adult Measures

Residual Insecticides

Indoor residual spray is considered to be the most important tool for controlling mosquito borne diseases. As per National Policy, indoor residual spray is to be carried out in all rural areas during malaria transmission season. This is a more practicable and simpler method of interruption of transmission of disease. For the limited objective of disease control it is not necessary to carry out the work throughout the year or in the entire territory but only in houses and shelters in endemic zones during the transmission season. However, there are certain conditions under which the absolute efficacy of this procedure may be doubted, for instance, where vector is exophilic though biting indoors or where the surfaces sprayed are subject to frequent mud plastering or white washing. Even when local conditions do not appear to be absolutely favourable, the application of residual insecticide gives relative success in disease control. DDT, Malathion and the members of synthetic pyrethroids like Cyfluthrin, Deltamethrin etc are the residual insecticides of choice depending upon the susceptibility of the vectors. The different insecticides used for indoor residual spray are presented in chapter on principles of vector control in this section.

Space Sprays

Space treatments are usually designed to provide a rapid knock-down and mortality with little or no residual effect. Such treatments must be considered in conjunction with other control methods as part of an integrated vector management programme. There are two types of fogging viz. Thermal and Cold fogging which are routinely used in the field of mosquito control; the details are given in chapter on principles of vector control in this section.

Table - 1 : Important differences in anopheline and culicine mosquitoes

| Stage | Anopheline | Culicine |
|---|---|---|
| Egg | Boat shaped; laid singly with lateral floats. | Elongated. Aggregation occurs into rafts of hundreds of eggs in Culex. Aedes eggs are laid singly, Mansonia eggs are laid on undersurface of leaves of aquatic plants in star shaped clusters. |
| Larva | No siphon tube but only apertures on 8th abdominal segment. Larvae rest parallel to the surface of water and swim with swift wriggling movements. Palmate hairs for floatation arranged in pairs on all abdominal segments. | Single siphon tube on 8th abdominal segment. In Culex, siphon tube is long and narrow whereas, in Aedes it is short and broad. Mansonia larvae are attached to roots of aquatic plants. Culicine larvae rest at an angle to surface and swim with slow snail or worm like movements. No palmate hairs for floatation. |
| Pupa | Mosquito pupa is comma shaped. In Anophelines, spiracles are longer, spiracle is short stumpy and funnel shaped. | In Culicines, slender and trumpet shaped. |
| Adult | Wings usually spotted. Rests at an angle to | Wings usually not spotted. Rests parallel to the surface. |

Thermal fogging is a space treatment against adult mosquitoes. It can even reach air spaces in areas obstructed by dense vegetation or other objects. When the mosquitoes in flight come into contact with the droplets, they will be knocked down and killed. Thermal fogging can quickly reduce the number of biting mosquitoes but does not have lasting residual effects. As adult mosquitoes must come into contact with the pesticide, the timing of application is critical. While different mosquito species are active during different periods of the day, it is essential to fog at the right time to get effective control of the target species.

Thermal fogging is very susceptible to wind and thermal air currents. If applied during unfavorable conditions, such as during a hot day, the fog may be carried up and over the target places and the application will become ineffective. If applied in a very windy day, the fog will drift out of the area that you want to treat. Application should therefore be carried out when the air is calm and the temperature is not too high, such as during the evening or early in the morning when the fog is more likely to be held close to the ground.

Cold fogging is also very effective in bringing down the infective vector population and is considered more environment friendly as compared to Thermal fogging. Details on space spraying and the insecticides with their dosage are given in chapter on principles of vector control in this section.

Genetic Control

The control of adult mosquitoes by means of 'Sterile Male Release' (SMR) technique and other genetic methods such as cytoplasmic incompatibility, chromosomal translocations, sex distortion and gene replacement have been attempted in the past. However, all these methods have still to prove their worth and utility in the field. The scope of recombinant DNA technology is immense and research is being carried out to use this tool for vector control.

### Anti-larval Measures

Larval control is the only effective method of radical mosquito control. In urban areas, like cantonments, garrison stations and base areas, this method complements the adult mosquito control. Anti-larval work is carried out by preventing breeding and destruction of larvae and pupae.

Vector Engineering

Avoidance of man-made mosquitogenic conditions is of primary importance. Mosquito breeding prevention should be deliberately incorporated in the planning and execution of all engineering constructions and town planning schemes like River valley projects, dams and barrage constructions, road and railways, railway constructions and irrigation systems. Besides these, indiscriminate digging, disposal of discarded tins, containers and water collections, overhead storage tanks and septic tanks without covers are potential mosquito breeding places in urban areas. Clean edging and water de-weeding, channelling, filling or draining, exposing to sunlight, shading or covering are the usual methods adopted. Underground drainage constitutes the best method of bio-engineering for control of mosquito breeding.

Dry Day

Intermittent drying once a week is an effective method of prevention of breeding by observance of a weekly 'dry day'. It should ideally fall on the day when the anti-mosquito staff is due to visit that area for anti-larval work. All fire fighting tanks, ornamental ponds or water storage tanks, fire buckets, and all domestic water containers should be emptied and allowed to remain dry for a few hours on the weekly 'dry day'.

Larvicidal Measures

Destruction of larvae is achieved by application of larvicidal oils, Organophosphorus insecticides, use of Insect Growth Regulators, biocides and use of larvivorous fish. The list of anti-larval chemicals along with their dosages is presented in Table in chapter on principles of vector control in this section.

**Larvicidal Oils**

Oiling of the breeding places with larvicidal mineral oils like 'malariol' has been the mainstay of the antilarval measures in all sorts of mosquito breeding places, except those which are used for drinking, agricultural, horticultural and piscicultural purposes or in the ornamental, fire fighting and overhead water storage tanks. Oils act primarily by suffocating and poisoning the larvae and denying them the surface tension required for floatation. 10 ltr of oil is required to treat 500 linear metres. Oil is applied once a week with a broom or a mop tied at the end of a long handle. The drawback of this method is that the oil film may be broken by wind or raindrops. It is also not very effective in the presence of excessive weeds and other vegetation.

**Insecticides**

Organophosphorus compounds viz. Temephos (Abate) and Fenthion (Baytex liquid and Baytex granules) are routinely used for antilarval activity in India. Biocides (Bti) are the recent introduction as larvicides in the National programme as well as in the Indian Armed Forces. Insect growth regulators (IGR's) viz. the chitin synthesis inhibitors (Dimilin, Novaluron) and the juvenile hormone mimics (Pyriproxyfen) are being proposed and being promoted as safer alternatives besides Temephos and Biocides for use as larvicides.

**Biological Control**

Various predators, parasites and pathogens have been evaluated for mosquito control. Larvivorous fishes like *Gambusia affinis, Poecelia reticulata* and *Aplocheilus lineatus* have been found effective and are being used for mosquito larval control in India. Various other fungal agents' e.g *Lagenidium, Coelomomyces, Culicinomyces* along with nematodes *Romanomermis culicivorax* and *R iyengari* are promising bioagents. Protozoans- Nosema, Thelohania and viruses like Cytoplasmic polyhedrosis

virus and Iridovirus also hold great promise.

**Personal Protection**

Individual personal protection against mosquito bites is achieved by use of mosquito nets, repellents and protective clothing. Screening the houses and hospital wards has been practiced on a restricted scale.

Mosquito Nets

The use of mosquito nets is one of the most effective personal protective measures. Net should be put up before dusk and tucked all round under the bedding. They should always be maintained in a good state of repairs by patching holes and tears and not by stitching or knotting. Mosquito net inspection should be held regularly as a drill. Definite arrangements should be made to fix the nets in barracks, huts and tents.

One of the latest strategies for prevention against mosquito borne diseases is use of treated nets called Insecticide Treated Bed Nets or ITN's. The nets are manually treated with synthetic pyrethroids like Deltamethrin, Cyfluthrin etc. These ITN's provide an irritant and excito-repellent effect besides contact action. An additional collateral benefit is also provided against pests like bed bugs, houseflies, sandflies etc. These nets are safe for use by pregnant women, the infirmed & small children.

Advancement in ITN technology has come in the form of **Long Lasting Nets** or LLN's. A LLN is a ready-to-use pretreated mosquito net, which requires no further treatment during its expected life span (average 4 to 5 years). This advancement has obviated the need to treat the nets every six months. Of the available LLNs, "Olyset Net" is made of polyethylene with 2% Permethrin incorporated, while "Perma Net" is a regular polyester net treated with Deltamethrin 50 mg / sq mtr.

Repellents

Repellents should be applied by all on exposed parts of the body during evenings and when not under mosquito net during night. Repellent application is also advised during daytime, in areas where Dengue/ Chikungunya outbreak has occurred or threat exists. Repellents available for application are Diethyl toluamide (DEET), available as brand name Mosfree and Odomos and DEPA (Diethyl phenyl acetamide), which has been indigenously developed by DRDE, Gwalior and found at par with DEET in efficacy and spectrum, in the trials conducted at AFMC and in the field. DEET & DEPA have been found to be very effective when applied on uniform as lotion or sprays against all haematophagous arthropods as well as leeches.

Protective Clothing

The wearing of long trousers and shirts with rolled down sleeves after dusk should be enforced in all malarious areas and when personnel move by rail or road. Added protection is given by wearing web anklets. Implementation of barrier clothing in daytime is also advised in Dengue sensitive areas.

Screening of Houses and Barracks

This measure is effective only when all doors, windows and ventilators in the building are screened by wire mesh of proper gauge and size (1.2 to 1.5mm).

## Vectors of Malaria (23, 25, 50)

Table - 2 : List of malaria vectors of india and the vectors of local importance

| S No. | Name of Species | Role in transmission |
|---|---|---|
| 1 | *A stephensi* | Primary urban vector in most of India except North-East and in Rajasthan |
| 2 | *A culicifacies* | Primary rural vector all over India except North-East |
| 3 | *A fluviatilis* | Primary rural vector in foothill areas of the country |
| 4 | *A minimus* | Primary vector in North Eastern regions, West Bengal |
| 5 | *A phillippinensis* | Primary vector in rice field ecosystem of North Eastern regions |
| 6 | *A dirus* | Primary vector in regions of evergreen forests in the North East |
| 7 | *A sundaicus* | Primary vector in Andaman & Nicobar Islands |
| 8 | *A varuna* | Eastern ghats (Andhra Pradesh), Singbhum hills (Bihar) & Kerala |
| 9 | *A annularis* | Secondary vector in rice field ecosystem in Uttar Pradesh and coastal areas of Orissa |
| **Vectors of local importance** | | |
| 1 | *A aconitus* | Orissa, Assam |
| 2 | *A jeyporiensis (var candidiensis)* | In certain localities in Kerala, Karnataka and Assam |
| 3 | *A maculates* | In certain localities in Assam & Meghalaya |
| 4 | *A tesselatus* | Lakshadweep Islands (on epidemiological grounds) |

There are 58 species of anopheline mosquitoes in India but only 9 are incriminated as vectors and another 5 species have been found to be of local importance in transmission of malaria. The list of these vectors is presented in Table - 2. The following characteristics of vector mosquitoes play an important role in the epidemiology of malaria.

| | |
|---|---|
| (a) Slow moving water, seepages, terraced rice fields | A fluviatilis |
| (b) Brackish waters | A sundaicus |
| (c) Wells, cisterns and over head tanks | A stephensi |
| (d) Tanks, pools, burrow pits and ditches | A philippinensis<br>A annularis |
| (e) Forest pools, streams and slit trenches | A dirus |

Breeding Habits

The breeding habits of mosquitoes show a lot of variation. Hence, vector mosquitoes tend to be confined to certain geographical areas only. A few examples are given in a box below.

Density

For effective transmission of malaria in a locality, the mosquito vector must attain and maintain a certain density. This is called critical density and it varies from one mosquito to another and also under different environmental conditions. A culicifacies needs a very high density for transmission of malaria.

Longevity

A mosquito, after an infective blood meal, must live for at least 10 days to complete the development of malaria parasites.

Tropism

Some mosquitoes like *A fluviatilis* prefer human blood and are called anthropophilic. Others like *A culicifacies* preferably feed on animal blood and are called zoophilic. This preferential feeding habit is called tropism. It has obvious bearing on the transmission of malaria.

Biting behaviour

Some vector mosquitoes bite at or soon after dusk, others either during late night or early hours of the morning. However, some species may be active at two different periods during the same night.

Resting Habits

A female mosquito after a blood meal rests either indoors (endophilic) or outdoors (exophilic) for maturation of its eggs. Knowledge of these habits is necessary for organizing antiadult measures. The common resting places are either human dwellings, cattle sheds or mixed dwellings.

Flight Range

The range of flight and dispersion varies from one vector to another. Some have a short flight range e.g. *A dirus, A annularis* and *A fluviatilis* upto 1 km distance; *A culicifacies* and *A stephensi* up to 2 km; and A sundaicus up to 8 or 10 km.

Resistance to Insecticides

When a vector mosquito in a locality becomes resistant to a particular insecticide, use of an alternative insecticide is recommended.

## Vectors of Filariasis

*Culex quinquefasciatus*

This species is the main vector of bancroftian filariasis in India. It preferentially breeds in dirty water collections such as in drains, cesspools, soakwells and septic tanks. When denied such opportunities, it can also breed in clean water.

Mansonoides

Mansonoides species are the vectors of *B malayi* infection in India. In Kerala, *M. annulifera* and *M. uniformis* are the major vector species. These mosquitoes are associated with aquatic plants like *Pistia stratiotes, Eichornia speciosa* and *Salvinia auriculata.*

*Aedes niveus*

This species has been incriminated as a vector of diurnally subperiodic form of Bancroftian filariasis in Nicobar group of islands.

## Vector Control

The best and permanent method of vector control is to prevent breeding of vector mosquitoes by underground drainage schemes. Because of financial constraints in a developing country like India, this may not be feasible in the near future. The temporary measures anti-adult and anti-larval measures which are on the same lines as have already been outlined under anopheles control measures.

## Mosquito Surveillance (51, 52)

Places which are endemic for mosquito borne diseases or outbreak prone, it is deemed mandatory that mosquito surveillance system be established. The aim of the surveillance should be to forecast an impending outbreak and to recommend appropriate strategies for mosquito control which would prevent outbreak.

### Steps for establishing mosquito surveillance system: Guidelines for Specialists in Preventive medicine (SHOs / DADsH)

It needs no emphasis that all specialists in Preventive Medicine in Armed Forces (SHOs / DADsH) develop an ongoing, simple, practicable but regular surveillance on disease vectors, especially mosquitoes. The guidelines for planning, organizing and implementing the same are being suggested in the succeeding paragraphs. It is also desirable that Sr Advisors in PSM check the records (Entomological adult and larval surveillance registers) and the practical implementation, as and when they visit the

Table - 3 : Adult Mosquito Surveillance Register

| Date | Sector No. | Species | Fixed Catching Station | | | Random Catching Station | | | Total | | | | Density per Man hour |

* Remarks to include details of House index, Container and Breteau index for Aedes if situation warrants.

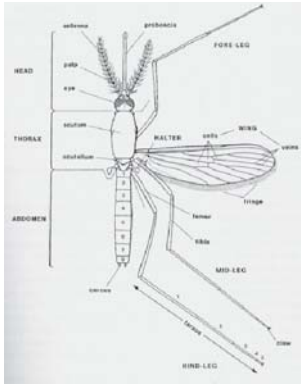
PSM specialists in their jurisdiction. The proposed format of these two registers are given in Table - 3 & Tabe - 4.

**Basic steps in identification**

Acquaint yourself with basics of mosquito identification both larval and adult mosquitoes up to genera level (*Culex, Anopheles* and *Aedes*) and mosquito bionomics.

Adult

Fig - 5



**Identification of mosquito**

Mosquitoes are identified from other such flies by the presence of forward projecting mouthparts or proboscis, wing veins (veins 2, 4 and 5 are branched) and a fringe of scales along the posterior margin of wings (Fig - 5).

**Identification of male & female mosquito**

The mosquito sexes can be identified by their antennae. It's bushy in males and not so bushy in females.

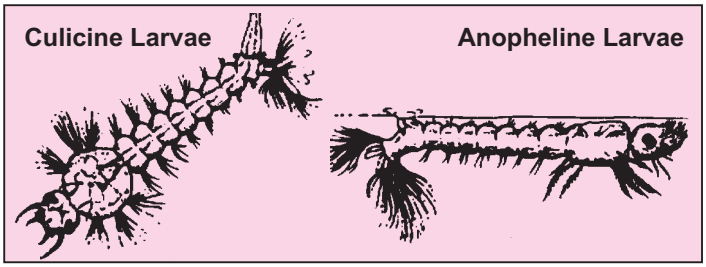
**Identification of *Anopheles, Culex* and *Aedes***

If the wings are spotted, it is an anopheline vector species; whereas, if the legs are striped it is *Aedes* and if there are no spots on the wings or stripes on legs, it is *Culex* adult.

Larvae

If the larvae have siphon tube it belongs to Culicine group and could be *Culex* or *Aedes*. If the siphon tube is long and narrow, it is *Culex* species, whereas short and broad siphon tube indicates it is *Aedes*. It is also important to remember that *Aedes* is essentially a container breeder and will be found only in artificial or natural containers. The culicine larvae float at an angle to the water surface. Anopheles in contrast will have no siphon tube and will be floating parallel on the surface of water as shown in Fig - 6.

Fig - 6



Sector allocation and mapping

Once armed with the basic information, start by dividing the entire Cantonment into five sectors and make a map of the sector. Each sector should be covered every fortnight or at least once a month for surveillance.

Conduct a preliminary survey

First a baseline survey (larval and adult) is conducted to determine the prevalence, abundance and distribution of the vector species.

Data compilation and preparation of spot map

The data collected in step one is compiled and analyzed to determine the above mentioned variables and a spot map is prepared with clearly marked out areas where density is high, medium or low or where potential of breeding exists.

Establish monitoring/ catching stations

In each of the five sectors, establish four fixed stations (min two if manpower is less) with preferably two from the high density and two from medium density spots and an equal number of random stations (2 each from high density and medium density areas). Poor or worst ventilated houses located close to breeding places, discarded bathrooms, abandoned buildings are considered ideal for room selection, the room which has fewer openings is selected.

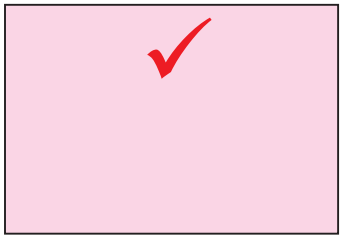
Conduct fortnightly surveys

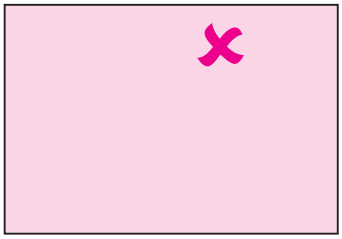
Conduct surveys in the fixed and random stations and record your data in the adult and larval surveillance registers as per format given earlier.

Larval sampling procedure

The mosquito larval sampling will be done by standard larval ladles available with all SHOs. The method is as follows :

(a) **Dip the ladle sideways** : A minimum of five dips may be taken for calculation of larval density.





(b) **Transfer the larvae in enamel bowl** : count the total number of larvae and pupae in the bowl after five dips.

(c) **Calculate larval density** : it is done by the following method:

Total number of larvae counted - 50

Total no. of dips taken - 5

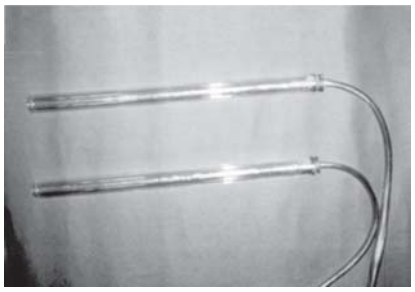
Larval density (Total no. of larvae / no. of dips) -50/5 = 10

Other larval sampling procedures like larval nets (when the water body has vegetation) or well nets (when mosquito breeding is noticed in wells) may be used in specific situations. The density is calculated in the same way and given as larvae/ larval net or well net.

Adult sampling procedure

It is done by various methods viz. aspirators, total catch, light trap, window traps, direct bait collection, whole night collection or use of magoon trap or drop net traps.

**Aspirators / Suction tube**



This is the most common method of sampling adult mosquitoes. It is normally undertaken in the mornings. Before using suction tube ensure that muslin cloth or gauge piece is placed between the glass tube and the rubber tubing to prevent mosquitoes being sucked inside your mouth.

(a) With the aid of a torch look for resting mosquitoes on the walls, ceilings (when it's low), behind and under furniture/ wall hangings etc.

(b) For practical purposes, while undertaking mosquito surveillance, one insect collector should spend at least 15 min in each of the 4 fixed and each of the 4 random stations. Thus, 2 insect catchers should be deputed, one for the 4 random stations and one for the fixed stations ( 15 mts at each station) on the day surveillance is being conducted in that sector.

(c) While using suction tube, keep the end of rubber tubing in your mouth and place the opening of the glass tube 1-2 cm from the resting mosquito. Move the end closer to the mosquito by applying gentle suction to draw the mosquito inside the tube, now place your finger over the tube to keep the mosquito from flying away.

(d) Do not collect more than five mosquitoes in one tube. After collection, transfer the mosquitoes in transport cages by gentle blowing.

$$\text{Density (Per Man hour)} = \frac{\text{Total No. of mosquitoes collected}}{\text{Man Hour spent in collection}}$$

(e) Density of mosquitoes is calculated by the following formula:

(f) If 2 persons have collected 18 mosquitoes and each man has spent 1 hr each (15 mts per station), the density is calculated by the following method:

2 Persons X 1 hr= 2 Man Hour

Total mosquitoes collected in 2 Man Hour - 18

Mosquitoes collected Per Man hour (PMH) - 18/2 = 9

Density = 9 PMH

Total Catch or spray sheet collection

Involves the use of Pyrethrum for collection of mosquitoes resting indoors. This is a more efficient method of sampling as it can also collect those mosquitoes which are hiding under furniture or resting on high ceilings or where the density of mosquitoes resting is low. However, this method is tedious and is recommended for use by SHOs / DADsH under supervision of a splt in PSM, when an outbreak is impending. For routine surveillance by SHOs / DADsH, the method of suction tube and larval dip is the most practical.

**Total Catch Method**

- Remove all animals, small items of furniture, food items. Close all windows and doors and close / cover all openings with cloth.
- Spread white cotton bed sheets to cover the entire surface area (no. of sheets will depend on the size of the room). Ensure that sheets have been placed under furniture also. Sheets placed on furniture should not touch the floor as it will prevent the insecticide from reaching underneath.
- Prepare the Pyrethrum solution from 2% Pyrethrum extract available to a workable strength of 0.2% by mixing 100 ml of Pyrethrum with 900 ml of Kerosene to make a total volume of 1 ltr of prepared soln. of 0.2%.
- Use a hand sprayer (Flit gun) for spraying. The person after entering the room should first close the door of the room and then start spraying in open spaces and holes in the wall and thereafter proceed to apply spray towards the ceiling until the room is filled with fine mist; always taking care to move in a clockwise direction. After spraying he should close the door and come out and keep the room closed for at least 10 min.
- After 10 mins, open the door, move gradually from the doorway picking up the mosquitoes by forceps in a

Other types of mosquito sampling devices

The other sampling tools are the window traps, magoon traps, direct bait collection and light traps.

### Surveillance of Aedes mosquitoes (53-56)

Larval survey

Three indices are commonly used to record Ae aegypti and Ae albopictus density levels.

**House index (HI)**

$$HI = \frac{\text{No of houses positive for Aedes larvae}}{\text{No of houses inspected}} \times 100$$

Percentage of houses or premises positive for Aedes larvae. The HI is calculated as follows :

$$CI = \frac{\text{No of positive containers}}{\text{No.of containers inspected}} \times 100$$

**Container Index (CI)** : Percentage of water-holding containers positive for Aedes larvae. CI is calculated as follows :

$$BI = \frac{\text{No of positive containers}}{\text{No.of houses inspected}} \times 100$$

**Breteau Index (BI)** : Number of positive containers per 100 houses in a specific location. BI is calculated as follows :

(A HI > 5% &/or a BI > 20 for any locality is an indication that the locality is dengue sensitive and therefore adequate preventive measures should be taken).

Adult surveys

Human bare-leg catches (landing catches) of *Aedes* adults (both males and females) or indoor resting collections of adults are normally used to assess adult *Aedes* populations. The data collected are calculated to reflect the number of female *Aedes* mosquitoes landing / biting on single human bait per hour (e.g. number per man hour). The collectors should move from house to house and not collect in one place for more than 15 or 20 minutes. In a similar manner, indoor resting collections can be made and the data expressed as numbers collected per man-hour or per house.

Oviposition traps

"Ovitraps" provide a sensitive and economical method for detecting the presence of *Ae. aegypti* and *Ae. albopictus* in situations where the *Aedes* density is low and general larval surveys produce unsatisfactory results (e.g. when the Breteau Index is < 5). The standard ovitrap is a wide-mouthed glass jar of approximately 250 ml which is painted black on the outside to attract the *Aedes* females to oviposit. A piece of hardboard/ wooden paddle or filter paper is placed diagonally inside the glass as an oviposition substrate. In addition, the jar is partially filled with clean water for oviposition.

**Aedes Prevention & Control**

The only effective method of preventing dengue is the control of the vector mosquito *Aedes aegypti* and *Aedes albopictus*.

- Temephos is very effective as a larvicide. Oviposition attractant developed by DRDE has been found to be successful in initial trials at many places.
- Thermal fogging with Malathion or Deltamethrin/ Ultra low volume (ULV) fogging with Deltamethrin or Pyrethrum has been found to be highly successful in interrupting transmission.
- Insect growth regulators are increasingly being used against *Aedes* for prevention of Dengue & Chikungunya.
- Use of personal protective measures like barrier clothing and applying mosquito repellents are helpful during outbreaks.
- People should sleep under net, preferably treated net, especially infants and pregnant women.
- The patient should be treated under a mosquito net

Dr (Mrs) Rina Tilak

# Other Biting Pests

## Fleas

Fleas are one of the few important vectors which have been historically linked with the Armed Forces the world over. Plague, transmitted by rat flea, was one of the vector borne diseases which played an important role in redefining geographical boundaries post World War I and II.

### Classification and Distribution

Fleas are distributed all over the world and belong to the order siphonaptera comprising about twenty five hundred species and sub-species. Fleas can be classified into two main groups, 'combless' fleas and the 'combed' fleas. The combless fleas contain the important genus *Xenopsylla* which has about sixty species and sub-species including the well known vectors of plague viz, *X cheopis, X astia* and *X.braziliensis*. The oriental rat flea, *X cheopis,* is widely distributed in the tropics and is the principal plague flea in India. The combed fleas are the cat-fleas-*Ctenocephalides felis*, the dog flea, *C canis*, and the rat fleas of temperate zones, *Nosopsyllus fasciatus*. These fleas serve as intermediate host of certain veterinary cestodes (dog-tapeworm) but are more of a biting nuisance to man. The other important combless flea is *Pulex irritans,* which occurs only in the hills of the tropical countries of the Eastern Hemisphere. *Tunga penetrans*, a sandflea is found in tropical and sub-tropical regions of North and South Americas and Africa and occasionally in Western India.

### Morphology

Adult fleas are small, bilaterally compressed, highly chitinised, wingless, 6 legged, blood sucking ectoparasites of many warm blooded vertebrates (Fig - 1). The size varies from 1.5 to 6 mm in length and the colour from light amber to dark brown (57-58).

They have a compact appearance without a sharp division between the head, thorax and abdomen. The head is roughly triangular and bears a pair of three segmented antennae, the mouth parts and in a number of species, a row of powerful teeth like spines collectively known as the genal comb, arranged on the lower border of the head, and a set of pronotal combs on the thorax. However, the rat fleas are devoid of both these combs. The mouth parts are adapted for biting, piercing and sucking blood, which forms the only food for both sexes. The thorax of the flea is compact and consists of the pro, meso, and meta-thorax without any wings. The legs are long and powerful and are adapted for the purpose of hopping and jumping. The abdomen consists of 10 segments, the 9$^{th}$ and 10$^{th}$ being modified for sexual functions. The 7$^{th}$ segment in both sexes bears a pair of setae known as the antepygidial bristles, so named because the 9$^{th}$ segment bears the pygidium which is a pin-cushion like structure with a sensory function. In the female, the abdomen has a rounded terminal outline whereas in the male it has a rather cocked up appearance. The body and the legs are provided with stiff setae, which give the insect a bristly appearance. The tapering pharynx continues into the oesophagus leading into the conical proventriculus. This is lined with closely set, backwardly directed rods converging towards the centre. These rods are pressed together during the act of sucking blood to prevent regurgitation of the stomach contents. This is an important structure involved in the transmission of the plague bacilli.

### Life History

The flea undergoes a complete metamorphosis through the successive stages of egg, larva, pupa and adult (Fig - 2). When the female is ready to lay eggs it leaves the body of the vertebrate host and lays eggs in dark place in the host's nest, lair, rubbish, debris, accumulation of dust, in cracks or crevices in the floor of granaries etc. or under carpets in dwelling houses. During her lifetime of 6 months or a year, the female lays 300 to 500 eggs in small batches of about a dozen at a time. A temperature between 18° and 27°C and humidity about 70 percent favour egg laying. However, most of them complete their life cycle in one to two months. The eggs are just visible to

Fig - 1 : Adult rat flea

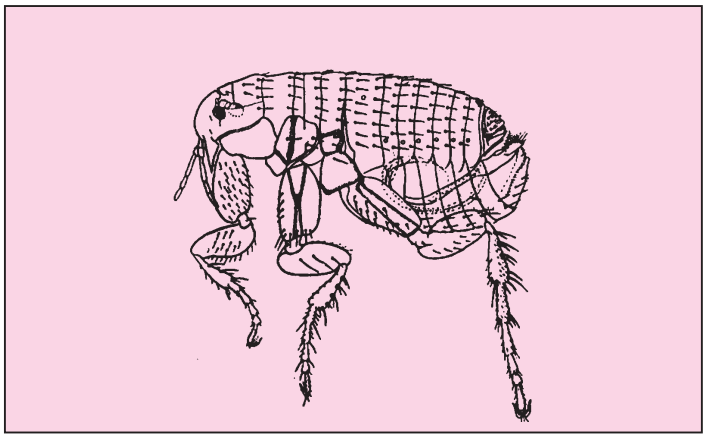


Fig - 2 : Rat Flea life cycle

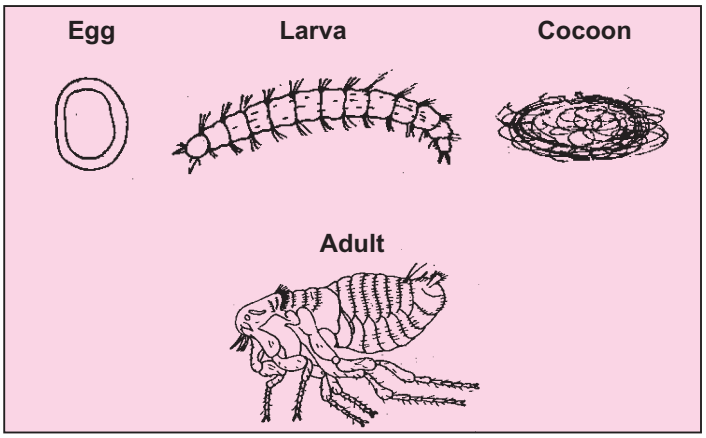


the naked eye. They hatch in 2-10 days depending on temperature and humidity. The larvae are very active, slender, 13 segmented and yellowish white with a number of bristles. They feed on the excreta of rodents and on partially digested blood discharged from the faeces of adult fleas. Larvae complete their development in a week or two and enter quiescent stage, spin cocoons which are whitish, translucent and so loosely spun that the pupae can be seen within them. Hence the pupa closely resembles the adult which usually emerges within a week. The whole metamorphosis takes two to four weeks, but may need several months under less favourable conditions.

### Bionomics

The fleas are temporarily parasitic on their host as their immature forms are free living and even the adults frequently leave it between blood feeds which, however, are obligatory for both sexes. After the death of the host its body becomes cold and then the flea seeks a new host. Fleas feed frequently and much more than their actual requirements, as a result of which much of the ingested blood is passed out in a semi-digested state. Fleas are not strictly host specific and may attack unusual hosts when hungry or with rise of ambient temperature, when they feed more frequently. They are very sensitive to light and air currents. They always hide under dark objects and when blown up they at once get agitated. They are able to jump up to 16 cm and hop 30 cm.

### Vector Potential

The flea transmits mainly the zoonoses to man, chiefly from rodents and also from the dog and cats. The most important microorganism that is conveyed to man from rat is the *Yersinia pestis* causing bubonic plague. The most important vector species i.e. *X cheopis, X astia* and *X braziliensis* are also effective vectors. *Rickettsia typhi* is also transmitted from its rodent reservoir to man by the same rat fleas. Cat and dog tapeworms use fleas as their intermediate hosts for their development of cysticercoid stages. Cats and dogs become infected by the ingestion of infected fleas. Children also get the infection similarly due to accidental ingestion of the infected fleas. The South American and African flea, *Tunga penetrans* burrows under the soft skin in between toes and under the nail bed and causes a disease called 'chigger', 'jigger' or 'chigoe' in endemic areas.

### Flea Control

Chemical control of fleas is one of the best methods of flea control. These are effective against both adult as well as larval fleas. The areas or places generally frequented by fleas are treated like rodent burrows and rat runs. The insecticidal treatment is either done in the form of residual sprays, dusting or treatment of rodent burrows. Dusting is done by applying a patch of insecticide dust of about 20-25 cm wide and 0.5cm thick in all infested areas. For rodent burrows, 30g of insecticidal dust is used. In Plague susceptible areas, treatment is undertaken when flea index exceeds 1. However, during an outbreak no rodent control activity is undertaken. In the event of a Plague case occurring, immediate treatment of the patients dwelling and of other dwellings within 200 m is undertaken (59-66).

#### Vector Control

Due to development of insecticide resistance, prior susceptibility tests should be carried out to find out the most effective insecticide. Indoor residual spraying at the lower one metre of the wall surface and adjacent floor area is effective. Patch dusting also brings about marked reduction in flea density. For this, dusts of Propoxur (1%), Malathion (5%) or Carbaryl (5%) may be applied at a dosage of 2 to 3 g per $m^2$ of surface area under grain bins, on rat runs, furniture, upholstery, rugs and bedding. The dust of Deltamethrin (0.05%) may also be used for dusting in rodent infested area.

#### Disinfestations

Disinfestations of pet animals like dogs and cats along with good environmental sanitation of the household and public places help in flea control. Pet animals may be treated with dusts, sprays or dips of Malathion, Propoxur, Permethrin or Pyriproxyfen. Animal premises may be sprayed with insecticides (Malathion, Deltamethrin, Pyrethrum etc) @ 4-8 l/100 $m^2$. Insecticidal treatment of animals and their premises should be carried out simultaneously.

#### Rodent control

It is an indirect method of flea control. Though a radically effective method during non-epidemic period, it is dangerous during epidemics, because the fleas leave dead rats quickly and start attacking human beings. However, a constantly sustained campaign keeps the rodent population down and aids significantly in keeping the flea index constantly low. In general, during control of urban plague, insecticides to kill rat fleas should be applied a few days earlier or at least at same time (and not after) when rat poison baits are being applied.

#### Personal Protection

This is achieved by the use of protective clothing such as wearing long trousers, socks and shoes. Use of a high charpoy with the net, and application of repellents DEET are necessary precautions while in endemic or epidemic areas of flea borne disease. Using flea collars for pets are effective means of keeping them free from infestation.

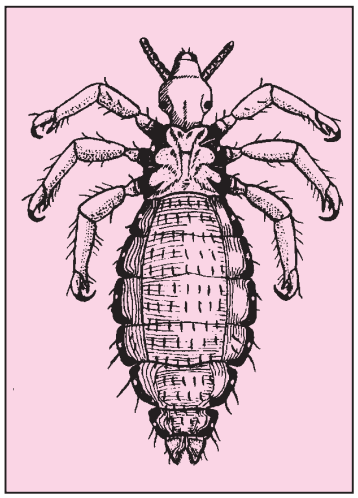
## Human Lice

Human lice are true ecto-parasites of man. There are three species of human lice viz. *Pediculus capitis* (head lice), *Pediculus humanus* (body louse) and *Phthirus pubis* (crab or pubic). All stages, females as well as males are haematophagous, however, only body louse has been incriminated as vector. The head louse infests the hair on the head and may be found in the neck region and behind the ears. The body louse infests the hairs of chest and axilla, seams of clothing in contact with the body, and sometimes linen. The crab louse infests the hair of the pubic region and occasionally invades eyelashes and eyebrows.

### Morphology

Lice are small, dorso-ventrally flattened, wingless insects with simple metamorphosis (Fig -3). They are permanent obligatory ecto-parasites living entirely on mammals. The mouthparts are of a sucking and piercing type. They have no eyes. The legs are short, stout, and thick with claws for grasping hairs and fibres. In the female the last abdominal segment is bilobed and in the male it is pointed from which the aedeagus (penis) projects. *Phthirus* resembles *Pediculus* in its general morphology, but its body is almost circular, all the three pairs of legs of *Pediculus* are equal whereas in *Phthirus* the first pair is less developed; *P capitis* has a smaller and deeply pigmented body, while that of *P humanus* is larger and non-pigmented. Abdominal segments of *P humanus* are rounded with shallower inter segmental indentations while those of *P capitis* are clearly marked and deeper. Antennae and legs of *P humanus* are longer and thinner than those of *P capitis* (67).

Fig - 3 : Head Louse



**Life History**

The life histories of all the three varieties are similar. After fertilization, the female lays eggs either on the hairs or under clothing chiefly along the seams of the vests, pants and shirts etc. They are firmly cemented to the hair or seams of the clothing, singly or in groups. Under optimum favourable conditions the louse lays 4 to 9 eggs in each batch. Total number of eggs laid during the life span of 4 to 5 weeks may be 300 in a body louse, 150 in a head louse, and 50 in a crab louse. The immature stages called nymphs begin sucking blood at once and throughout their development feed frequently during the day and night, mostly when the host is quiet. There are three nymphal stages and the young ones resemble the adults except in size. It takes about 18 days between hatching of the eggs and appearance of the adults.

**Bionomics**

Lice like warm and moist environments; 38° C is the optimum temperature. Higher temperature and death of the host are detrimental and make lice leave the body of the host. The average life of a louse is 30 to 50 days. Females live longer than the males. Once lice are acquired by a human host, their multiplication depends on the neglect of personal hygiene. Following factors are responsible for the dissemination of lice.

(a) Close contact with lousy persons; sharing the same bed and clothing in the household, barracks, underground shelters etc. In fact any prolonged crowding of human beings in unsanitary surroundings will spread lousiness. Hence lice and louse borne diseases are closely associated with wars and disasters among prisoners and refugees.

(b) Indirect contact - for example exchange of beddings, clothing, blankets, towels, hats, combs and brushes.

(c) Hair bearing eggs from lousy persons scattered in public conveyance are picked up from the seats and cushions of railways carriages and buses etc.

(d) Head lice easily pass from one child to another in school by close contact while playing and use of common combs.

(e) The pubic or crab lice spread through sexual contact and sometimes from toilet seats, beds and by close personal contact. Small children may become infested with crab lice on their eyebrows and eyelashes from their mothers or other close contact.

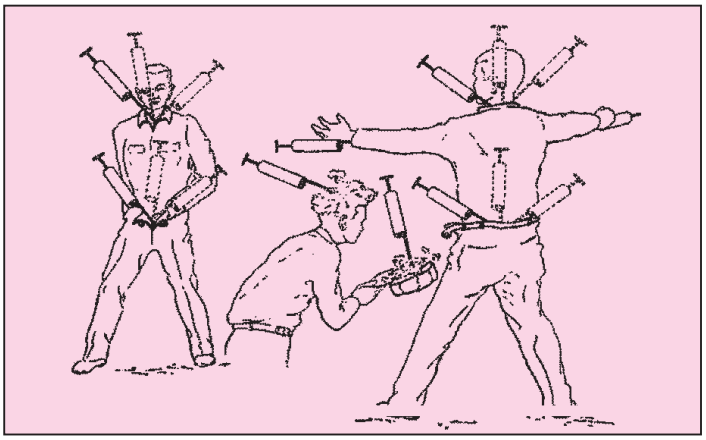
**Vector Potential**

Body lice are responsible for the transmission of *Rickettsia prowazeki,* causing Epidemic typhus, *Bartonella quintana* causing Trench fever, and *Borrelia recurrentis* causing Relapsing fever. The presence of lice on any part of the body is termed 'pediculosis' which causes irritation with loss of sleep and scratching which may lead to secondary infections. The skin of a heavily louse infested person becomes hardened and deeply pigmented and a condition known as 'Vagabonds' disease or melanoderma is developed.

**Prevention and Control**

Louse infestation should never occur among troops under static conditions where ample facilities for bathing and washing are provided and their regular use ensured. In mobile operations, however, when it may be difficult to provide these facilities adequately, the danger of louse infestation becomes imminent, particularly when contact with local civilians, refugees and P.O.W. is unavoidable. In order to prevent lousiness amongst troops, their contacts with refugees and local civilians should be reduced to the minimum. Regular hot baths and washing of clothes should be ensured. For this purpose field bath and laundry

Fig - 4 : Insecticidal dust application against body louse



units may be required.

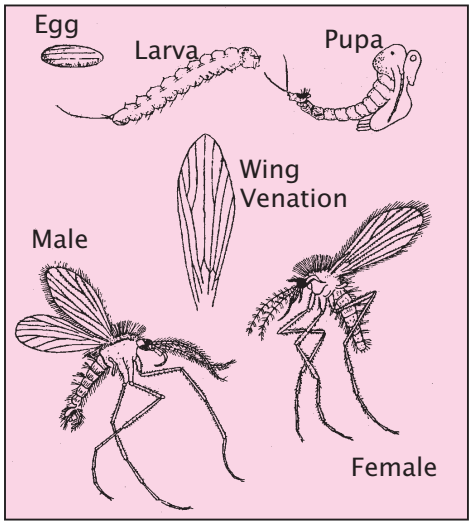
In the past, during mobile operations use of anti louse powder which has 10 percent DDT was used for reduction of infestation in a controlled community, by dusting the lousy individuals and garments. Currently, the insecticides of choice are Permethrin dust (0.5%), Propoxur dust (1.0%) for body louse and shampoo formulations like Phenothrin (0.2-0.4%), and Permethrin (1%) for head lice infestation. For mass treatments against body louse, dusts should be applied through neck openings, up sleeves and from all sides of the loosened waist of trousers (Fig - 4). Socks, head coverings, the inner surfaces of extra garments and bedding should also be treated.

For application on hair, the hair of the infested persons should be wetted thoroughly before application. Massage the shampoo thoroughly on the head and leave for 10 min. Thereafter rinse the shampoo from the hair, towel dry hair and use lice comb for removing dead lice. Treated uniforms with pyrethroids may be helpful against body lice in Armed Forces settings (68-71).

## Sand flies

The sand-flies belong to the subfamily Phlebotominae of the family Psychodidae. Species of three genera *Phlebotomus, Lutzomyia and Sergentomyia* are only haematophagous, whereas the former two are important as they are vectors of many diseases. The medically important vector species in India include *P argentipes, P papatasii, P sergenti and P braziliensis.*

Fig - 5 : Sand fly



### Morphology

The adult sand-fly is a small, greyish yellow to brown insect about 1.5 to 4.0 mm in size (Fig - 5). The insect is typically characterized by large conspicuous eyes and stilt like legs. The entire body is densely covered with hair. The antennae are long filamentous and give a beaded appearance. The mouth parts are very short and are adapted for biting and piercing in the females. The thorax is markedly humped and bears a pair of lanceolate wings held erect over the body when the fly is at rest. The wings are densely hairy and the second vein branches twice, the first branching in the centre of the wing and second at the margin. Legs are long, slender and used for hopping as sand-flies are poor fliers. The abdomen consists of 10 segments; the last two are modified for sexual functions. The abdomen of a female is rounded posteriorly; in the males it is modified and bears claspers (1-4, 8).

### Life History

The sand-flies prefer to breed in dark places rich in organic matter and moisture. Sand-flies lay torpedo shaped eggs in small batches which hatch out in one or two weeks under optimum favourable conditions. The larvae feed on organic excrement of lizards and mammals and other decaying material. Its life span is from 2 to 6 weeks, depending on the temperature and humidity. The larva bears two anal spines. The pupa is naked and requires about 10 days for development, after which the adult emerges. The total period required from egg to the adult stage is about 4 weeks under favourable conditions. In the tropics the breeding goes on throughout the year. In north India, they appear about the middle of March and persist until November, with their maximum density in March and April.

### Bionomics

The female has piercing mouth parts and is a blood sucker. Some species feed on cold blooded animals such as lizards and snakes; others feed on warm blooded animals including man. The males live entirely on plant juices or similar fluids from other available sources. The adults are weak fliers and generally confine themselves up to 50 yds from their breeding place and are not found resting beyond 3 ft on the wall. After fertilization and a blood meal the female lays eggs in shady, damp and warm places with sufficient supply of organic matter such as insect remnants and faeces, and excrements of tiny animals which form the future larval food. Such conditions are found under stones, in stables and poultry houses, around soakage pits, grease traps and water sinks, in hollowed trees and rodent burrows, bases of walls and embankments.

### Vector Potential

Sand-flies are responsible for the transmission of various species of Leishmania causing Kala-azar or Visceral leishmaniasis, Oriental sore or Cutaneous leishmaniasis, and Espundia or Mucocutaneous leishmniasis (naso-oral). Sand-flies also transmit the virus of sand-fly fever, also known as papatasi or Phlebotomus fever and the re-emerging viral disease Chandipura disease. It also transmits *Bartonella bacilliformis* or Oraya fever also known as Bartonellosis or Carrion's disease. In addition, the sand-flies have biting nuisance causing skin reactions (Herara) in sensitized persons(72-74).

### Phlebotomus Control

(a) Prevention of Breeding

This is primarily achieved by extremely good environmental tidiness. Places providing humidity, darkness and organic matter should be dealt with by removing all collections of rubble and heaps of rubbish; obliterating all cracks and fissures in the floors of buildings and indoor constructions, sides of culverts, gutters, nullahs, cattle sheds and poultry houses which

are common breeding places for sand-flies. Cracks and holes in the walls up to a metre from the ground should be sealed by plastering; the earthen floor of cattle sheds should be rammed down and made hard to make it difficult for the larvae to burrow. Empty buildings should be kept in good repairs; soak pits and grease traps should be well maintained.

(b) Antilarval measures

Anti larval measures are generally difficult to undertake as identification of larval breeding sites is difficult. Even if insecticidal control is planned, it has been found to be of little importance in the control of sand flies.

(c) Anti-adult Measures

Anti adult measures are based on the principle that sand-flies make short flights with relatively long pauses on entering or leaving any place or shelter. Therefore, any surface treated with residual insecticide on which the flies rest will have a lethal impact. The anti adult measures are the same as followed under the National Programme for Indoor residual spraying against mosquitoes; this strategy has proved to have a dramatic impact on the density of sand-flies in the area. If outdoor resting sites have been identified, they can also be sprayed with residual insecticides. Outdoor fogging may provide additional benefit in reduction of Sand-fly density.

d) Personal Protection

Use of repellents viz. DEET is one of the most efficient methods of preventing bites from sand-flies; the repellents may be applied topically or sprayed on the uniforms. A sand-fly net is useful, but it reduces air movements and causes great discomfort. Use of insecticide treated mosquito nets has been found very effective in protecting against bites of sand-flies. Personal protection may also be achieved by wearing shirts with sleeves rolled down and buttoned at the cuffs, and long trousers with socks tops drawn over the trouser cuffs and or anklets worn over them during evenings and nights.

e) Other Measures

**Strategies for control of sand-flies**

**Indoor Residual spraying**

As followed under National Programme for Mosquito Indoor Residual spray in sync with insecticide susceptibility status in the particular state or area.

**Personal protective measures**

Use of repellent DEET as topical application or as sprays on clothing/ uniform. Use of other insecticide treated material like bednets, curtains and insecticide treatment of clothes.

**Treatment of animals**

Earlier practice of culling of dogs or killing of rodents is no more undertaken. Dogs are treated by dipping in insecticide solution (Deltamethrin 50ppm) or applying insecticide solution (1-2 ml of 65% Permethrin or Imidacloprid 10%). Even insecticide treated dog collars and treatment of non-reservoir animals reduces transmission of Leishmaniasis.

**Space spraying**

Thermal and cold fogs can be undertaken as done in

These include encouragement of gardening (cultivation of ground) and planning of embankments with native aromatic plants. Free cross ventilation and ingress of sunlight keeps the sand-fly out of barracks, bashas and bunkers. Electric fans are useful as the air current drives them away. Electric light shades smeared with vaseline traps a large number of sand-flies. Siting of human habitation beyond 50 yards of the breeding place is an effective method of preventing transmission of sand-fly

Dr (Mrs) Rina Tilak

# Ticks and Mites

Ticks and mites belong to class Arachnida, which are characterized by the presence of two distinct body parts - cephalothorax and abdomen and four pairs of legs. Antennae are absent and eyes may or may not be present. There are two pairs of mouth appendages, the chelicerae and the pedipalps. The palps are sensory organs and the chelicerae are the actual cutting organs. Metamorphosis is incomplete and the adults resemble the nymphs except for the fact that nymphs lack genital aperture while in the adult the sexes are distinct. The larvae are morphologically distinct with three pairs of legs.

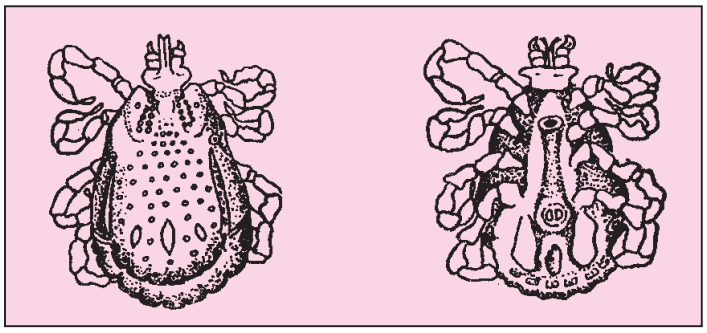
## Ticks

Ticks belong to the super-family Ixodoidea having more than 500 species of World wide distribution.

### Morphology

They are distinguished from other acarines by their relatively large size and absence of prominent hairs on the body. They are oval in shape and of varying colours, dorsoventrally compressed and slow in their movements. Females are larger than males and are capable of great distention. Both sexes thrive on blood alone and lead an intermittent parasitic life during a major part of their life cycle. The wide host range includes the cold blooded as well as the warm blooded animals. They are free living on the ground in between various moults during development. There are two families, Family Ixodidae which is the hard tick and Family Argasidae which is the soft tick. The hard tick is the jungle tick while the soft tick

Fig - 1 : Hard tick



is a domestic or household tick like a bedbug (1-4, 75-80).

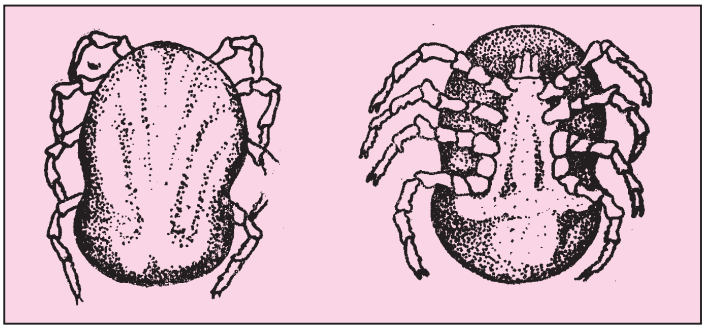
Ixodidae or Hard Ticks

The dorsum of the adult male is covered by a dark shield, like that of the tortoise, called the scutum. This may be ornate with grey or white 'patterns'. In females and immature males it covers only the anterior part behind 'the capitulum' which is the false head actually formed by the mouthparts anteriorly and, therefore, visible from above (Fig - 1).

Argasidae or Soft Ticks

These are oval with leathery cuticle, devoid of scutum.

Fig - 2 : Soft tick



Their mouth parts are placed ventrally and hence not visible from above and they possess no festoons (Fig - 2).

### Life History

All species of ticks pass through four stages during their development viz., egg, larva, nymph and adult. The total period required for full development of a tick is from six weeks to 2 years. Fully engorged fertilized female drops off to the ground and lays eggs in cracks and crevices in the soil under stones, or among roots of shrubs and grass and such other sheltered spots. Number of eggs laid varies from a few hundred in some species to several thousand in others. Hard ticks deposit all their eggs in a single act of oviposition after which they die. Eggs take a few weeks to several months to hatch. Larvae are six legged and do not feed for about a week after emergence. Thereafter, they become hungry and active and get attached to their animal hosts. They feed for some days and drop off when engorged and remain quiescent for digestion of blood. After the first moulting the nymphs emerge with their fourth pair of legs and seek a new host, feed and again drop off. They again moult and become sexually mature. Hard ticks have only one nymphal stage but soft ticks may have as many as five. Copulation takes place after the last moult; the male dies after fertilizing the female. The female engorges and then deposits eggs.

### Bionomics

A few species of hard ticks, mostly members of the genus *Boophilus,* spend the whole of their life cycle on the same host and are known as 'one host ticks'. Ticks of the Genera *Hyalomma* remain on the same host during the larval and nymphal stages but the adult form seeks a new host and is known as 'two-host ticks'. Ticks which feed on different animal hosts in the larval, nymphal and adult stages are known as 'three host ticks'. Medically important hard ticks of the genera *Ixodes, Haemaphysalis, Rhipicephalus* and *Dermacentor* are all three-host ticks. In soft ticks of the genus *Ornithodorus,* each stage of the five moults is completed on a different host; and adults may also feed intermittently on different hosts. Such ticks are known as 'multiple-host ticks'. Hard ticks are open jungle dwellers and thrive on animal hosts; hence they do not attach themselves to human beings voluntarily, except when a

person comes across them accidentally. Argasidae, although preferentially parasitic on animals and birds attack man voluntarily. These are found in human dwellings and cattle sheds and attack man and animals during their sleep. They however, live away from their hosts, like bedbugs, in cracks and crevices and only emerge at night to feed on the host. They all can survive starvation for long time even for 2 or 3 years in case of Argasidae.

### Vector Potential

Ticks produce diseases in man by transmitting viruses, rickettsiae, spirochaetes and bacilli of infectious diseases and through toxin present in their saliva. Some of the factors which account for high vector potential are that they feed entirely on blood and are persistent blood suckers; while feeding they attach firmly and cannot be easily removed. They are resistant to varying environmental conditions as nymphs and adults are sclerotized and thus relatively protected from natural enemies. A wide host range always ensures certainty of enough supply of blood; high production potential and long life. The transstadial and transovarian transmission of infection helps in maintaining infection for several years. Ticks have the power to regenerate lost parts such as amputated legs and also the ability to repair mutilated mouth parts, which conserves them for long.

#### Soft Ticks

Soft ticks of the genus *Ornithodorus* transmit various types of spirochaetae causing relapsing fevers in certain parts of the world. *O moubata* is the vector of *Borrelia duttoni* in Africa; *O hermsi* and *O turicata* are the vectors in America. *O tholozani* has a very wide distribution over a large area from Iran to Central Asia. *O lahorensis* has a very wide distribution in Central Asia and North West India. In India they are found in Kashmir and are known as *O crossi.*

#### Hard Ticks

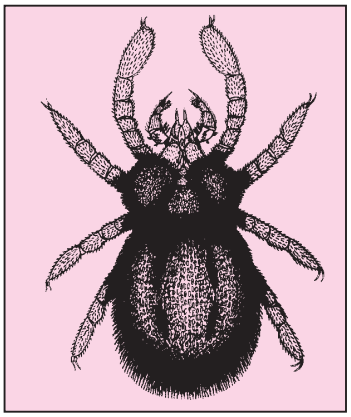
These are much more ubiquitous and produce larger varieties of human diseases. The most important of all are the various rickettsial infections transmitted by the hard ticks of the genera *Ixodes, Dermacentor, Amblyomma, Haemaphysalis, Rhipicephalus, Hylomma* and *Boophilus.* Viruses causing Kyasanur Forest Disease, Colorado tick fever and other Haemorrhagic fevers and Encephalitides are transmitted. These also transmit *P tularensis,* the causative organism of Tularaemia. Tick paralysis is an acute ascending flaccid paralysis due to an unknown toxin the ticks' saliva introduces through the bite of certain species of ticks of the genera *Dermacentor, Ixodes and Amblyomma.* It affects mostly children and young domestic animals in Australia, South Africa, North America, Southern U.S.A. and N.W. Pacific. Even a single tick bite may cause fatal paralysis. In certain cases, reaction from improper or partial removal of ticks or due to the bite itself may cause itching, swelling and ulceration at the site of the bite. Otoacarisis is an invasion of the auditory canal by ticks.

## Mites

Mites belong to the order Acarina and family Trombiculidae which comprises many hundreds of species of world wide distribution. They are found in great abundance in areas with hot, humid climate, thick vegetation and presence of small vertebrates like rodents. The foothills in subtropical and temperate regions offer them ideal conditions. In the tropics they are found even at heights in mountain valleys. These have also been found in the Alpine-subarctic terrain in the Himalayas as well as at the level of coniferous forest-glacial valleys in Pakistan. They are known by various names such as chiggers, harvest mites, Kedany or scrub mite. Important species of the genus *Leptotrombidium* are *L akamushi* which is distributed widely in Japan, Formosa, South East China, Korea, Malaysia and Philippines, and *L deliense* which is vastly distributed in the tropical regions of South East Asia, Indian sub-continent, Ceylon and Maldive Islands. In India, it is present in the whole of the Shivalik range from Kashmir to Assam, the Eastern half of the plains adjoining the foothill ranges, the Eastern and Western ghats and the Vindhyachal range in Central India (81-86).

### Morphology

Fig - 3 : Trombiculid Mite Adult



It has an oval body and eight legs and is densely covered with hair (Fig - 3). The mouth parts consist of a pair of chelicerae and a pair of palps, together giving the mite an appearance of having a false head. The adult resembles the nymph except that it is larger and more densely covered with hairs; 'Kedany' meaning hair in Japanese language. A cluster of 5 to 6 larvae is as big as a pin-head. When the cluster detaches, a scab is formed showing an evidence of recent infestation. The larva is ochre-yellow to orange-red in colour with a circular body bearing three pairs of legs which have six or seven segments and branched hairs on the body and on the legs. On the dorsal surface and placed well anteriorly, there is a roughly triangular dorsal scutum which bears 5 setae; the rest of the dorsal surface bears more than 30 setae arranged in definite rows. They are found in nature in the interior of ear cusps or on rumps of rats, mice, shrews, bandicoots and other small mammals, reptiles and birds in orange coloured clusters of as many as 50 to 200 larvae (75-80).

### Life History

The stages in the life history of a mite are egg, larva, nymph and adult. The eggs are laid singly on the surface of the soil. After about a week the egg-shell splits and the larva, although exposed, remains quiescent in the egg-shell for about a week or more (deutovum stage). After this the larva leaves the egg-shell and becomes very

active. Moving quickly over the surface of the soil and low lying vegetation, it seeks a suitable host such as rat, mouse, bandicoot and shrew and so on. Only the larval stages are parasitic. While feeding it buries the whole length of its chelicerae in the host's skin and injects an irritant secretion which causes tissue lysis. The larva feeds on the lymph and the tissue juice but not on blood. Therefore, the orange red colour of the larva is not due to ingested blood. The larvae feed for 2 to 3 days and then drop off to the ground concealing themselves in loose soil. They then enter the next quiescent stage known as 'nymphochrysalis' which lasts for another 7 days. The 8 legged nymphs develop within the larval integument. The nymphal stage lasts 14 days. During this period it is active on the soil and then enters another quiescent stage, known as the 'imagochrysalis'. After about a week or ten days the adult with sex differentiation emerges. Generally it takes 6 to 12 weeks for its development from egg to adult. The nymphs and adults are never parasitic. They exist free in the soil near the surface and feed on other small soil inhabiting arthropods and their eggs.

**Bionomics**

The whole life cycle is influenced by temperature, humidity and availability of food to the free living adults and nymphs and for the parasitic larvae. The environment, microclimate, vegetation and fauna of a place determine their abundance. The patches of ground known as 'Mite Islands' are characterized by thick vegetation cover, mainly the scrub jungles or other tall grasses, offering protection from direct sunrays and desiccation, 100 percent humidity at ground level and ambient temperature between 35˚C to 40˚C. Such conditions also provide sanctuaries for small vertebrate life such as rats, mice, bandicoots, and shrews which are hosts for larval mites. These animals are also the reservoirs of rickettsiae for which the trombiculid mites are vectors. Hence these mite islands may also become typhus endemic foci. Mites are most active during the whole rainy season and their prevalence in such mite islands in India is related to the intensity and length of the monsoons. In dry season, the adults migrate deeper into the soil, the egg laying ceases and the mite islands shrink; during monsoon, there is prolific activity and the mite islands expand. Patchy distribution of mite islands and their selective choice of locality explain the patchy nature of typhus endemic foci.

(a) The typical terrains favourable for the mite to thrive and propagate are as under:

(b) Man-made rural and urban wastelands like overgrown clearings produced by shifting cultivations.

(c) Domestic sub-urban waste lands produced around neglected patches in and around villages and even big towns, such as neglected gardens and plantations or overgrown clearings therein; deserted villages are heavily infested.

(d) Around the edges of moist depressions; water meadows; grassy but not swampy river banks; and moist sites such as seepages along over ground canal areas.

(e) The hedgerow types of features ranging from a simple bushy hedgerow to belts of forests following water courses and ravines which are commonly left in deforested areas in and below the foothills.

(f) The scrub at the outskirts of the forests" and low lying patches overgrown with elephant grass in sunny clearings inside thick forests.

**Vector Potential**

Larval mites belonging to several genera attack man but only the Genus *Leptotrombidium* contains species of medical importance. In India, *Leptotrombidium deliense* is the vector of *Orientia tsutsugamushi* causing Scrub typhus; in Japan the closely related variety *L akamushi* (kedani mite) transmits Scrub typhus. Rickettsiae taken up by larvae are carried through its nymph, adult and then its eggs. The larvae hatching out of these infected eggs are capable of transmitting the rickettsiae to the next host. The infection is thus transovarially transmitted for some generations and hence the mite also acts as a reservoir of infection. Larvae feed only once during the life time. Therefore, transmission of infection occurs in second or subsequent generations(1-4, 81-86).

**Control of ticks and mites (87-94)**

Insecticidal Control

**(a) Area Treatment**

This is the only reliable Acarine control method. Before the application of an insecticide to the areas infested with hard ticks and mites, clearing of bushes by cutting is advantageous. If possible a bulldozer should be employed. When the top soil is bare and dry, an area becomes considerably safe and more suitable for insecticidal action. Initial coverage of the area should be thorough. It may require repetition after 8 weeks and occasionally a third time during the hot-humid season. If men have to go to some nearby stream for bathing or washing their clothes, the selected area should be similarly treated, as the stream edges covered with vegetation are favourite sites for acarines. Malathion/ Fenthion may be used for treatment of area.

**(b) On Vegetation**

Control of ticks on vegetation can be achieved by insecticide dusting or spraying from the ground or air at the dosage varying from 0.5 to 2 kg/hectare. In woody and bushy areas, the dosage is increased proportionately. Malathion, Fenthion, Propoxur and Permethrin are suitable.

**(c) Premises**

Against soft ticks, applications of insecticide to floors and walls of infested premises on alternate days, after initial scraping and scorching, are necessary. Treatment for 2 weeks before occupation gives good control. During this period sweeping of floors should be discontinued. Such a series of applications repeated 6 weeks afterwards gives adequate protection to troops billeted in such huts. The

insecticides should also be applied to beds, mattresses, rugs and furniture. In known tick infested areas, particularly where there is a history of relapsing fever, infested caves, huts and houses should be avoided as far as possible. Organophosphorus compounds like Malathion and Fenitrothion or Carbamate compounds like Propoxur can be used either as 0.5 - 1.0 % spray or as 5 - 10 % dust.

**(d) Domestic Animals**

Dogs and other domestic animals can be freed of ticks by a wash or spray containing, 2 % Malathion, 1% Propoxur, Deltamethrin (0.025%) etc. Only half these concentration should be used if the animal is to be dipped; and the entire animal should be immersed except the head. Dusts containing 5 % of Malathion, Propoxur (1%), Cyfluthrin (0.1%), Deltamethrin (0.05%), Temephos (2%), Fenthion (2%) etc. may also be used. The premises which animal visits or is tied in, should also be treated.

Personal Protection

The repellant materials used for personal protection against ticks and mites are Dibutyl-phthlate (DBP) & Diethyltoluamide (DEET). These are more effective when applied to the clothing than to the skin. The effect may last for nearly six washings or weeks which ever is earlier. However, if it is ironed, the concentration falls below effective limits. DEET may be used for application on the exposed parts of the body to reinforce the use of protective clothing treated with DEET/ DBP, when working in an uncontrolled area, or under acute emergency when application of repellent on the clothing prior to entry in an unknown or uncontrolled area is absolutely impossible. Another indigenously produced repellent DEPA (Diethylphenyl Acetamide) has also been approved for use in the Armed Forces as a repellent against ticks & mites. It can be applied on the uniform as well as on the exposed parts of the body. The persistence of DEPA on ironing of clothes is superior to DEET, whereas for topical application both are equally effective. Trials in Indian Armed Forces have adequately demonstrated the efficacy of these repellants.

Wearing shirts with rolled down sleeves tightly buttoned at the cuffs, the lower ends of trousers tucked in socks and wearing of anklets considerably reduces the risk against ticks and mites.

Clothes for drying should be hung on ropes especially fixed for the purpose and not on the vegetation. Bush and grass on the periphery of a camp becomes infested by larval mites and ticks brought in by the rats migrating into the camp. Therefore, purposeless wandering in such areas should be discouraged.

More mites and ticks are picked up by standing or sitting than by walking over the infested ground. Therefore, while on patrols and marches it is unsafe to lie down on a grassy ground. The immediate vicinity of a tree base should be avoided for resting, so also the green edges of a stream or an irrigation channel. Open grassy grounds should be avoided in tick infested areas.

Before retiring at night or after leaving a tick infested area one should take a bath and carefully search one's body and clothing for presence of ticks. If a tick is found attached to the body it should be removed immediately, because every added moment of its attachment increases the danger of transmission of infection. Pulling of a tick has the danger of breaking off its parts, therefore, it should be removed by making the surrounding skin taut, slipping the point of a flat needle or a scalpel under the mouth parts and then removing the mouth parts by raising the point of the needle with a minimum of tissue damage. Iodine or any other antiseptic should then be applied to the site.

Use of mosquito net gives some protection against soft ticks.

Anti-Rodent Measures

Persistent anti-rat hygiene is of great value in reducing the risk of diseases conveyed to man through ticks and mites. The main object should be to reduce ingress of rodents by proper disposal of camp and kitchen refuse and removal of overgrown vegetation and rubble which afford them shelter. Rat destruction requires forethought; because, if the feeding of larval ticks and mites is interrupted by the death of rodent hosts, a number of released acarines may reattach themselves to another host, which may be man. Active rat destruction may be adopted when the first infestation is at its peak i.e. a month or so after the rain starts. It is better to trap and then destroy them so that their parasites do not escape. When dead rats are collected from any endemic foci the soil under and immediately around them should be treated with insecticide. Soft tick control is further achieved by rat-and-tick-proofing of dwellings. All cracks and crevices, fissures and other points of ingress should be closed and all doors should be made tight fitting to keep away rodents.

Camp Siting

Before any area in the known endemic tract is selected for camping or before the insecticide treatment is undertaken, the degree of risk should be assessed by determining the prevalence of adult and larval Acari.

**(a) Mite Survey**

Superficial layers of earth are scraped from moist areas around the roots of scrub and mixed with water in a bowl. Adult mites resembling a figure of 8 will float in a few minutes. Pieces of dark cardboard are placed edge wise forming tent fashion structures on the ground at intervals, larvae will crawl up the cardboard and congregate at its top edge within a few minutes. Rats caught from the area should be examined for the clusters of larvae or scabs in ear-cusps and shrews for clusters on their rumps. If the ears or rump is infested, they should be carefully cut with fine scissors and placed in 70% alcohol vials.

Rodent trapping is done in field (Op areas, Camps, fringe areas) by specialized traps called Sherman traps, whereas in peri-domestic areas Wonder traps may also be used. The trapping procedure is as follows:

(i) Number the Sherman traps with marking pens starting from 1-40.

(ii) Prepare flags bearing the same numbers i.e. 1-40 with cardboard pieces as per specimen provided.

(iii) Carry freshly prepared pakoras for the traps.

(iv) The laying of traps should be carried out in the late afternoons and should be completed before dusk.

(v) Personnel involved in laying/ collecting of rodent traps shall wear trousers tucked in boots/anklets and full sleeved shirt. Wear heavy duty gloves while laying/ collecting traps and use repellents on exposed skin.

(vi) Identify suspected mite islands (a patch of ground with vegetation, temp in the range of 27+ 50 C, Relative Humidity in the range of 80-100% and which provides an ideal place for rodents to hide).

(vii) Check the working condition of Sherman trap before placement.

(viii) Place pakora in traps, ensure it is placed at the closed end of the trap.

(ix) Place the trap in the bushes or where rodent is likely to be found. Place the trap with its opening facing the likely direction of rodent entry. Ensure the trap opening is not obstructed. The trap should be placed on flat ground so that the trap does not tumble if approached by rodent or any other movement in the area.

(x) Plant flag bearing the same number as the trap next to the trap so that it is visible from distance.

(xi) Tie a bandage to the bush to indicate the trap placement in the poor light conditions of dawn- the time for trap collection.

(xii) Make a spot map of trapping area with the trap numbers indicated on the map.

(xiii) Collect the trap before dawn next day.

(xiv) Use heavy duty gloves and a torch in the mornings for collection of the trap. (All protective measures as followed earlier should be ensured. If a trap is closed, do not try to open the trap, put it in a cardboard carton for transportation to the lab) (If a trap is open, fold it and collect it).

Once the traps are brought to the laboratory, the rats are transferred in to large polythene bags, anaesthetized and thereafter ectoparasite screening is undertaken and the remaining procedure as enlisted earlier is followed. For further details, the Dept of Community Medicine, AFMC, Pune may be approached.

**(b) Tick-survey**

Ticks are collected by sweeping flags made of white flannel across the vegetation. The larvae, nymphs and adults get attached to them and are easily detected against the white background of the flag. They should be picked up by forceps and placed in 70% alcohol vials. Parasitic stages of ticks on various animals can be collected by catching rodents, shrews and other animals.

(c) While carrying out the survey, one must protect oneself adequately with protective clothing and repellents. For confirmation of identification, the chopped ears of rats and shrews with attached larval mites and adult ticks should be forwarded to the Dept of Community Medicine, AFMC, Pune in 70% alcohol (methylated spirit) vials in separate screw capped bottles. A white paper label showing date and place of collection written with lead pencil should be placed inside the bottles.

(d) As a rough guide it can be said that the Scrub typhus risk in any area during the monsoon is considered low if only up to 10 % of the rats have been found infested on consecutive two surveys unless cases have occurred already; if 20-40 percent of rats have been found infested the contraction of infection is very probable; and if 50 percent or more rats have been found infested the risk is high and the site should be considered as dangerous. Similarly, even if a single rat is found infested with more than 100 larval mites the area should be avoided, being a very high risk area.

Dr (Mrs) Rina Tilak

## Some Annoying Pests

### Simulium Flies

Simulium flies are commonly known as Black flies. They have a world wide distribution. They belong to the family Simulidae, which contains over 1800 species; however, the important genera are only four, which bite humans and out of these four genera, Simulium is the most important.

#### Distribution

The members of this family are found from sea level to a height of 2000 m. In India, these have been reported from Kumaon Hills, Himachal Pradesh, Kashmir, Assam, Arunachal Pradesh, Manipur, Nagaland, Bengal, Bihar, Maharashtra, Tamil Nadu and Nilgiri Hills. In Arunachal Pradesh, they are known as Dimdam flies.

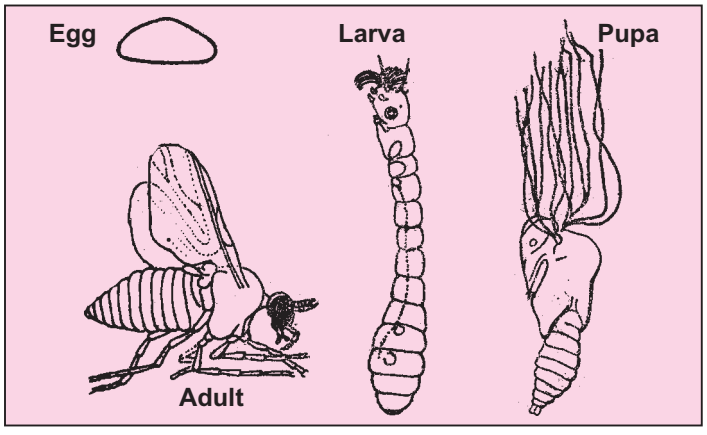
#### Morphology

The adults are small; stout bodied with a humped thorax and blood sucking flies varying in length from 1 to 5 mm. The colour varies from dark amber to bright yellow to orange. The name "black fly" is therefore a misnomer.

#### Life History

Simulium flies breed in fast flowing turbulent mountain streams and torrents because they require well aerated water. A female lives for 2 to 3 months and lays several batches of eggs under the rocks, stones, vegetation or debris submerged just below the water surface (Fig - 1). Eggs hatch in one to two days; in temperate zones the hatching period may be one week. The larvae are attached to submerged objects with their heads downstream. They feed on microscopic animals and plants and do not swim. The larva undergoes six moults in about 10 to 14 days in the tropics and 3 to 4 weeks in temperate regions. The silken pupa also is firmly anchored to the substratum. The pupal stage may extend from 4 to 5 days to 2 to 3 weeks. The imago emerges from the submerged pupal case and comes on to the water surface where it rests for a while and after sometime starts flying. In the tropics and subtropics breeding is continuous throughout the year. The life span of the adult is about three months (1-4).

Fig - 1 : Black Fly Life Cycle



#### Bionomics

Simulids are strong fliers. Their normal flight range is about 4 to 5 km. Flights up to 20 to 40 km with favourable wind are not unusual. Occasionally they fly in huge swarms. Both male and female simulids feed on plant juices, nectar and pollens of flowers; the females however, require blood meal for development of eggs and are voracious and persistent biters. They may enter through any opening in the clothing such as the sleeves or through the trousers lower opening for biting. They bite only by day in the open and are especially active on bright sunny days and retire at night to the neighbouring vegetation where the females mature their eggs.

#### Vector Potential

Several species of simulids are known vectors of Onchocerciasis, a filarial disease due to *Onchocerca volvulus* occurring in tropical Africa, Central America and Venezuela, where *S damnosum, S mettallicum and S neavei* are the vectors. In India, Simulids however, are not vectors of any known human disease. But the very annoying and persistent attacks in large numbers make working in the open virtually impossible. The immediate trauma caused by its bite produces a red haemorrhagic spot leading to papule formation. In certain cases, it may lead to secondary infections and ulcers like 'ulcus tropicum.' In sensitized persons allergic reactions like lymphangitis, lymphadenitis, rhinitis and fever may occur. Their bites are responsible for loss of livestock.

#### Control Measures

Control of the biting flies has been achieved by the use of larvicides and aerosol treatment. In the Onchocerciasis control programme in Africa, Temephos 200 g/l emulsion has been used as a larvicide with good results. BTI has also been used @ 0.54-0.72l/$m^2$ with great success. Aerosols and fogs produced by fogging machines are useful in killing adult flies. Clearing of vegetation around the perimeter also reduces the Dimdam fly nuisance. Other compounds like Permethrin and Etofenprox have also been evaluated. Use of protective clothing will prevent the flies from ascending up the sleeves and trousers or entering into the shirt front. Socks should be pulled over the bottom of trousers. Additional protection may be obtained by treating the clothing and the exposed parts of the body with any of the repellents such as DBP, Diethyl toluamide (DEET) or DEPA (95-96).

### Bugs

Bugs, belonging to the Order Hemiptera have been associated with man since antiquity. They have a world wide distribution and consist of two important families' viz. Cimicidae and Reduviidae. Family Cimicidae includes the 'bed bugs', *Cimex lectularius* of temperate regions and *C rotundatus* or *C hemipterus* of the tropics. Family Reduviidae includes the cone nose Triatomine bugs, also known as 'kissing' or Assasin bugs. In India, bedbugs have

a great nuisance value. The subsequent paragraphs will deal with Bedbugs, their bionomics and control.

### Morphology

Bed bugs are small; 5 to 6 mm long, dorso-ventrally flattened, wingless, dark brown insects with a mahogany tint. They have a very short and broad head attached to the thorax. The head bears the antennae and a pair of well developed eyes. On either side of the thorax, the stink-glands are situated which give off the nasty, pungent or offensive odour associated with this group (97, 98).

### Life History

A bed bug passes through the stages of egg and 4 nymphal stages. Metamorphosis is incomplete. The fertilized females lay flask shaped, operculated eggs singly, in hidden sites such as cracks and crevices in the walls and floorings, spaces in the wood work of furniture, behind pictures, mattresses, pillows etc. A female lays 2 to 10 eggs a day, a total up to 200 to 300 in her life time of 6 to 8 months. The eggs usually take 5 to 10 days to hatch. The nymph starts feeding within an hour or two after emergence and continues to feed intermittently in all the further stages of development. There are four nymphal stages, each lasting 6 to 7 days; at the end of each a skin is cast off. It takes 4 to 6 weeks for the development from egg to adult.

### Bionomics

Adults can subsist without food for months under favourable conditions. Bugs are disseminated through traveling bags, laundry, furniture, bedding, old charpoys, soiled clothing, infested household goods, public conveyance and public gathering places. Bed bugs, like lice have been companions of man for centuries. Hiding in cracks and crevices during the day, they become active during the night and come out of their hiding places to feed on hosts, and engorge completely in 3-6 min. They may travel long distances for sucking blood. They are gregarious, occurring in great assemblages. All stages are parasitic and thrive on human blood.

### Medical Importance

Bedbugs have all along been suspected for the transmission of various diseases but so far they have not been incriminated for any human disease. They are of public health importance primarily for their biting nuisance and demoralizing effect on the troops as their infestation may cause insomnia, pruritis, dermatitis, allergy and anaemia.

### Prevention and Control

The first and foremost principle for the prevention of bedbug infestation is to maintain a very high standard of hygiene. All furniture and belongings of new occupants should be thoroughly checked for the presence of bed bugs and immediate measures taken to prevent their multiplication by one of the appropriate insecticides. Residual insecticides applied directly into the hiding places control the bedbugs. Organophosphorus compound Malathion (2%) may be used, however, it is reported to be losing its effect at a number of places. In its place, Chlorpyrifos @0.5% may be used. Disinfestations of blankets, beddings, mattresses and mosquito nets may be carried out by subjecting them to heat at or above 70$^{0}$C. Synthetic pyrethroids like Bifenthrin (0.096%), Permethrin (0.125%), Cyfluthrin (0.04%) and Deltamethrin (0.03%) can also be used to achieve optimum results. Residual insecticidal spraying for malaria control undertaken systematically and methodically will also help in reducing the density of bed bugs as a collateral benefit. Pyrethroid impregnated bed-nets will also help in reducing the menace of bed bugs (8, 19, 99).

### Debugging

In the Armed Forces barracks, all furniture, charpoys, beddings, walls, floor and ceiling should be thoroughly inspected every week for the presence of bed bugs. The charpoy should be lifted to a height of about 1 metre by two persons holding it at opposite ends and gently dropped on the floor. This process repeated 2 to 3 times will result in the bugs falling on the floor from their hideouts. Whenever charpoys chairs and other items of furniture are found infested, these should be thoroughly sprayed with a residual insecticide. The charpoy need not be inclined against the wall nor the coir netting or niwar loosened. The cots should be thoroughly treated on all sides with insecticidal spray. All cracks and crevices should be fully flooded. The kit boxes, chairs, tables and other items of furniture may be similarly treated. The insecticide formulation may also be directly applied to the hiding places such as joints, cracks and crevices in the cots/chairs/tables and folds or creases in the mattresses and other items of beddings.

The studies carried out at the Armed Forces Medical College, Pune have shown that the slow drip technique involving the use of the common paint brush for treatment of the infested cots and other items of furniture is far superior as compared to the routine method of spraying with the compression sprayer. In this technique, the ready to use solution of insecticide in water is taken in a plastic mug of one litre capacity, a paint brush is dipped in the solution, and the solution so lifted is slowly drained into the cracks and crevices as well as the joint spaces from different directions. The process is repeated by turning the cot upside down so that all such hiding places are thoroughly flooded with the insecticide.

## Cockroaches

### Introduction

One of the most annoying pests encountered in an urban area are the Cockroaches. The common domestic species which infest buildings are *Blatella germanica,* the German roach; *Periplaneta americana,* the American roach and *Blatta orientalis,* the oriental roach. The German cockroach, although a native of Europe, is the most widely distributed species.

### Morphology

Cockroaches are dorso-ventrally flattened creatures with colour varying from dark brown to black. The head is flexed backward. The antennae are filiform. Most of the species have two pairs of wings. In some of them, the wings are vestigial. In the oriental cockroach the wings are

short in the females but much developed in the males which possess the power of flight (1-4, 100).

**Life History**

They have simple metamorphosis and lay 16 to 48 capsulated eggs. The eggs hatch out in 2-6 months in most of the species, depending on temperature and humidity. The young ones are almost white and wingless. They moult a number of times and the total developmental period may be 6 months to 1 year. They may produce three generations in a year and usually have a long life span.

**Bionomics**

They breed in warm moist places in the humid microclimate of the kitchen and pantry laying eggs in cracks, crevices and sinks. They can run swiftly by means of long well developed legs. They are highly gregarious and primarily nocturnal in habit, but may be seen during the day as well. The mouth parts are adapted for biting and chewing and they are omnivorous, feeding on any material meant for human consumption like meat, milk, grains and sugar.

**Disease potential**

They are filthy, annoying pests imparting a nauseating 'cockroach' odour to the food articles and utensils they come in contact with and the places they infest. They destroy food, damage fabrics, books and other household articles. They may enter houses and other buildings from outdoors through infested containers or from adjoining rooms and apartments or through drains. On account of their indiscriminate roaming and feeding habits, they may spread diseases like cholera, typhoid, dysentery, protozoal cysts, intestinal worms etc. by polluting food with filth carried on their legs and bodies (102, 103).

**Control Measures** (104-110)

(a) Prevention

(i) Good housekeeping is the key to cockroach control, whether in the home, restaurant, hotel or grocery stores.

(ii) All cracks and crevices should be properly filled up.

(iii) All areas should be kept thoroughly clean so that no food particles, debris, dust and rubbish remain to support and nourish cockroaches.

(b) Surveillance

(i) Use of sticky traps for surveillance.

(ii) Use of visual assessment method, whereby light is switched on late in night and the cockroaches counted for a stipulated time period, say five minutes. This method also indicates the hiding places in a room of the cockroaches besides indicating the level of infestation.

(c) Control

Cockroach infestation can be controlled with insecticidal sprays, dusts or baits. The insecticide should be applied thoroughly to runways, cracks, crevices, undersides of tables, and even under the table spreads, rear of sinks, meat safes and other harbourage areas. Use of 2-5 percent dust or 1-3 percent solution or emulsion of Organophosphorous compounds like Malathion or Carbamate insecticide such as Propoxur gives excellent results. To obtain a quick effect in heavy infestations or to drive them out from the hiding places a direct spray containing 0.3 % Pyrethrum or 0.5 to 1.0 % DDVP or Fenitrothion may be used. Small pills of flour containing boric powder left on dining table, food safes and pantry boards or under table cloth also kill cockroaches. Abermectin and Synthetic pyrethroids are currently being used for control. Newer insecticides, Fipronil and Imidacloprid have been found to be very effective in controlling cockroaches. Trials in Armed Forces have shown the efficacy of Fipronil in the control of German cockroaches. It needs to be taken note that chemical control with insecticides gives only temporary results and maximum efforts should be made to improve the environmental sanitation and housing conditions. Moreover, there are reports that the German cockroach has become resistant to several Organo-chlorine, Organo-phosphate, Carbamate and Pyrethroid insecticides.

Cockroach control

The control of cockroaches relies heavily on emphasis on maintenance of good hygiene conditions in the kitchens. The next best option is to use insecticides for the control of cockroaches. The insecticides recommended for control are:

| Insecticide | Concentration | Use |
|---|---|---|
| Boric acid | 100 % | Baits / sprinkle along corners |
| Imidacloprid Gel | 1.85-2.15% | Cracks and crevices |
| Fenitrothion | 1-2% | Spray |
| Malathion | 3% | Spray |
| Cyphenothrin | 0.1-0.5% | Spray |
| Deltamethrin | 0.03% | Spray |
| Fipronil Gel | 0.01-0.03% | Cracks and crevices. Has a cascade effect. |

## Scorpions

Scorpions are one of the commonly encountered venomous arthropods of the class Arachnida. The last segment of their bodies is modified to form a flexible tail, with a vesicle holding poison glands and a sharp spine. They vary in size from about 2 to 20 cm and are cryptozoic and nocturnal, spending the day concealed under stones or fallen tree branches or in burrows, venturing out after sunset in search of food. The common Indian species belongs to the genera *Buthus* (Mesobuthus) and *Palamnoeus*; the former are more poisonous.

Scorpion sting as a rule is not more dangerous than bee or wasp sting, as the chemical nature of the poison is similar to formic acid. It is, however, much more painful, and if sufficient poison has been injected, may cause distressing symptoms which may take twenty four hours to pass off. Cardiovascular effects like hypertension, arrhythmia, cardiac failure and pulmonary oedema may be

encountered following stings of Mesobuthus tamulus. Stings of red scorpion *(Mesobuthus tamulus)* can be serious, with release of catecholamines, producing raised BP, arrhythmias, cardiac failure and pulmonary oedema. Profuse sweating, dilated pupils and priapism can occur. There is no commercially available antivenin for treatment of *Mesobuthus tamulus* stings in India. The effects are more marked in children. It is, however, very rare that a fatal dose of the venom is injected. If the sting is on the extremities, an immediate ligature may be helpful. Application of a strong solution of ammonia relieves pain in a majority of cases; a series of injections of 1 % Novocaine or Lignocaine and Adrenaline at the spot and along the nerve may be necessary in others. Barbiturates in large doses are useful in reducing restlessness. Patients developing priapism, dilated pupils, sweating and bradycardia may require early energetic treatment with vasodilators. Preventive measures include alertness in avoiding contact with scorpions in infested areas, putting on clothes and shoes after shaking them well and proper housekeeping. Propoxur 2% or Chlorpyrifos @ 0.2-0.5% may be used. Synthetic pyrethroids are generally not used as they irritate the scorpions and risk is increased further (111).

#### Treatment of Scorpion Sting

(a) A Scorpion sting case needs immediate medical attention.
   (i) A local anaesthetic (1% Lignocaine) at the site of sting or a strong oral pain killer is advised.
   (ii) For stings with less pain, ice therapy works well.

(b) Prevention of scorpion stings by not encroaching their hiding places especially ill equipped (i.e. barefoot or wearing loose / open sandals) in areas with loose stones, fallen debris etc.

(c) Scorpions are active at nights. Always carry a torch while moving in infested areas at night.

(d) Erect barrier up to 20 cm by means of tiles at the base of walls and steps to prevent scorpion encroachment.

(e) Fill cracks and crevices to deny hiding places.

(f) People should sleep with mosquito nets properly tucked. It is advisable to use treated bed nets.

(g) Clear all junk and rubbish from around the house.

(h) Lastly use chemicals if problem still unresolved.

### Ants

Ants are common annoying insects. They have also been experimentally incriminated in the mechanical transmission of excremental infections. They should therefore, be kept away from foodstuffs by placing the legs of food safes, tables etc. in anti-formicas viz. bowls or tins containing water or waste crude oil. Insecticidal sprays like Pyrethrum or Malathion are effective. Ordinarily the ant-bite causes only a sharp stinging; the bites of some of the larger ants may be very painful involving faintness and shivering. Dilute ammonia or any other alkaline solution applied relieves the pain.

### Bee, wasp and hornet

The stings of these insects are often painful with local wheeling and redness. In sensitized individuals there may be alarming symptoms. The sting along with poison gland may be frequently left in the puncture, particularly by the honey-bee. It should be removed gently by pulling it out, care being taken not to squeeze the venom in the wound. Local application of an alkaline solution of sodium bicarbonate or ammonia or soap and applying pressure with a moistened piece of lint are useful in relieving pain. Papain diluted roughly 1: 5 with tap water is said to produce immediate relief of pain. Disturbing the honey-comb may bring the whole swarm on the person responsible, or any one who happens to be in the vicinity. Their stings may cause serious allergic symptoms requiring adrenaline and/or morphia administration.

Wasp's nests are generally destroyed at night when all wasps are inside. Insecticidal treatment includes use of 1% Dichlorvos, 0.015% Deltamethrin or 0.5% Chlorpyrifos.

### Centipede

Centipedes (Myriapoda) possess a pair of legs to each apparent segment of the body; the first pair is modified to form poison claws. The bites of small centipedes gives rise to mild local inflammation but the larger centipede *Scolopendra gigantia,* may cause a severe painful bite with marked local and general reaction. Solution of ammonia is useful for local application and in bites of the larger centipedes morphia may be necessary to allay the pain. 2-4% Malathion as spot application is very useful.

### Fish bites

There are many species of fish especially in tropical waters which possess poison glands in their mouths like a snake, or have poison spines or barbs. Their bites or stings may lead to severe consequences or even death. Certain jelly fish stings produce marked local reaction. In sensitized individuals more alarming symptoms may develop. Vinegar swabbed well over the whole area or applied by compress gives relief. Tetanus toxoid should also be given. Sedatives to relieve the pain and measures to prevent secondary infection may be indicated.

### Leech bites

Leeches (Hirudinea) are a class of Annelid worms. They are particularly troublesome near streams and rivers, in leafy forests and marshy jungles. The two important species are:

#### Haemadipsa zeylanica

It is the small land leech, about 2.5 cm long with great power of penetration into the interstices of clothing, putties or laced boots. They often drop from tree leaves onto man or animals passing by and suck blood. Leech bites are painless but the bleeding may be prolonged due to a powerful anti-coagulant, hirudin, present in its saliva.

#### Limnatis nilotica

It is the large aquatic leech which on being ingested fastens itself to the mucus lining of the mouth, pharynx, larynx, or nasal cavities of man or animal producing

prolonged bleeding unless removed.

Gum boots or jungle boots protect one from leech bite. A frequent search of the body for the presence of leeches should be made. The leech should not be dragged or pulled off the skin because of the risk of breaking and leaving behind its suction apparatus which is liable to cause inflammation and suppuration. Salt, vinegar or a tobacco infusion application, or a touch of the lighted end of a cigarette induces the leech to relinquish its hold. Subsequently, tincture of iodine should be applied to the bitten spot and a piece of adhesive plaster may be applied to the bitten spot. Repellents DEET & DEPA can be used to provide protection (112). The repellents can be applied on the clothing as well as topical application. At night a properly adjusted mosquito net; preferably treated variety affords good protection. Aquatic leeches can be removed from drinking water by filtering through a sieve or a piece of muslin.

## Lizards

The only poisonous lizard is the Gila monster *(Heloderma)* found in the desert of Mexico. Non-poisonous lizards sometimes bite man and may produce severe local sepsis of bacterial origin. All such bites should be cleaned thoroughly and dressed with an antiseptic. Treatment should consist of cleaning of the bitten area and application of tourniquet and measures to prevent secondary infection including tetanus and other supportive measures.

## Spiders

The true spiders (Arachnida) have poison glands and inject venom into their prey. The common species of spiders as a rule do note bite man. If by chance it happens to bite, the bite amounts to no more than a pin prick. Some spiders, especially those belonging to the genus *Latrodectus* produce severe effects in man. Important species are *L hasselti,* the 'red-backed' spider and *L mactans* the black widow, and the allied species. The acute symptoms generally subside after a few days but pain may persist for some time. In *Latrodectus* bites, the death rate may amount to 6 percent or higher. The 'tarantulas' of the tropics are loathsome spider like creatures, but contain no poison glands and are not dangerous, though they are severe biters. In case of a spider bite an immediate washing and ligation as for snake bite should be carried out. If pain is uncomfortable Aspirin may be given, however use of sedative is contraindicated. For local urticarial reactions, antihistamines will control the symptoms. Morphia may be necessary for relieving pain. A hot tub bath affords prompt but temporary relief. Intravenous Calcium gluconate or Magnesium sulphate also gives dramatic relief to cramps. Spot (Area) treatment with 3% Malathion, 0.03% Deltamethrin, Chlorpyrifos @ 0.2-0.5% has been found to be effective against spiders (19).

Dr (Mrs) Rina Tilak

## Key to the Identification of Adult Anopheles (female only) of India

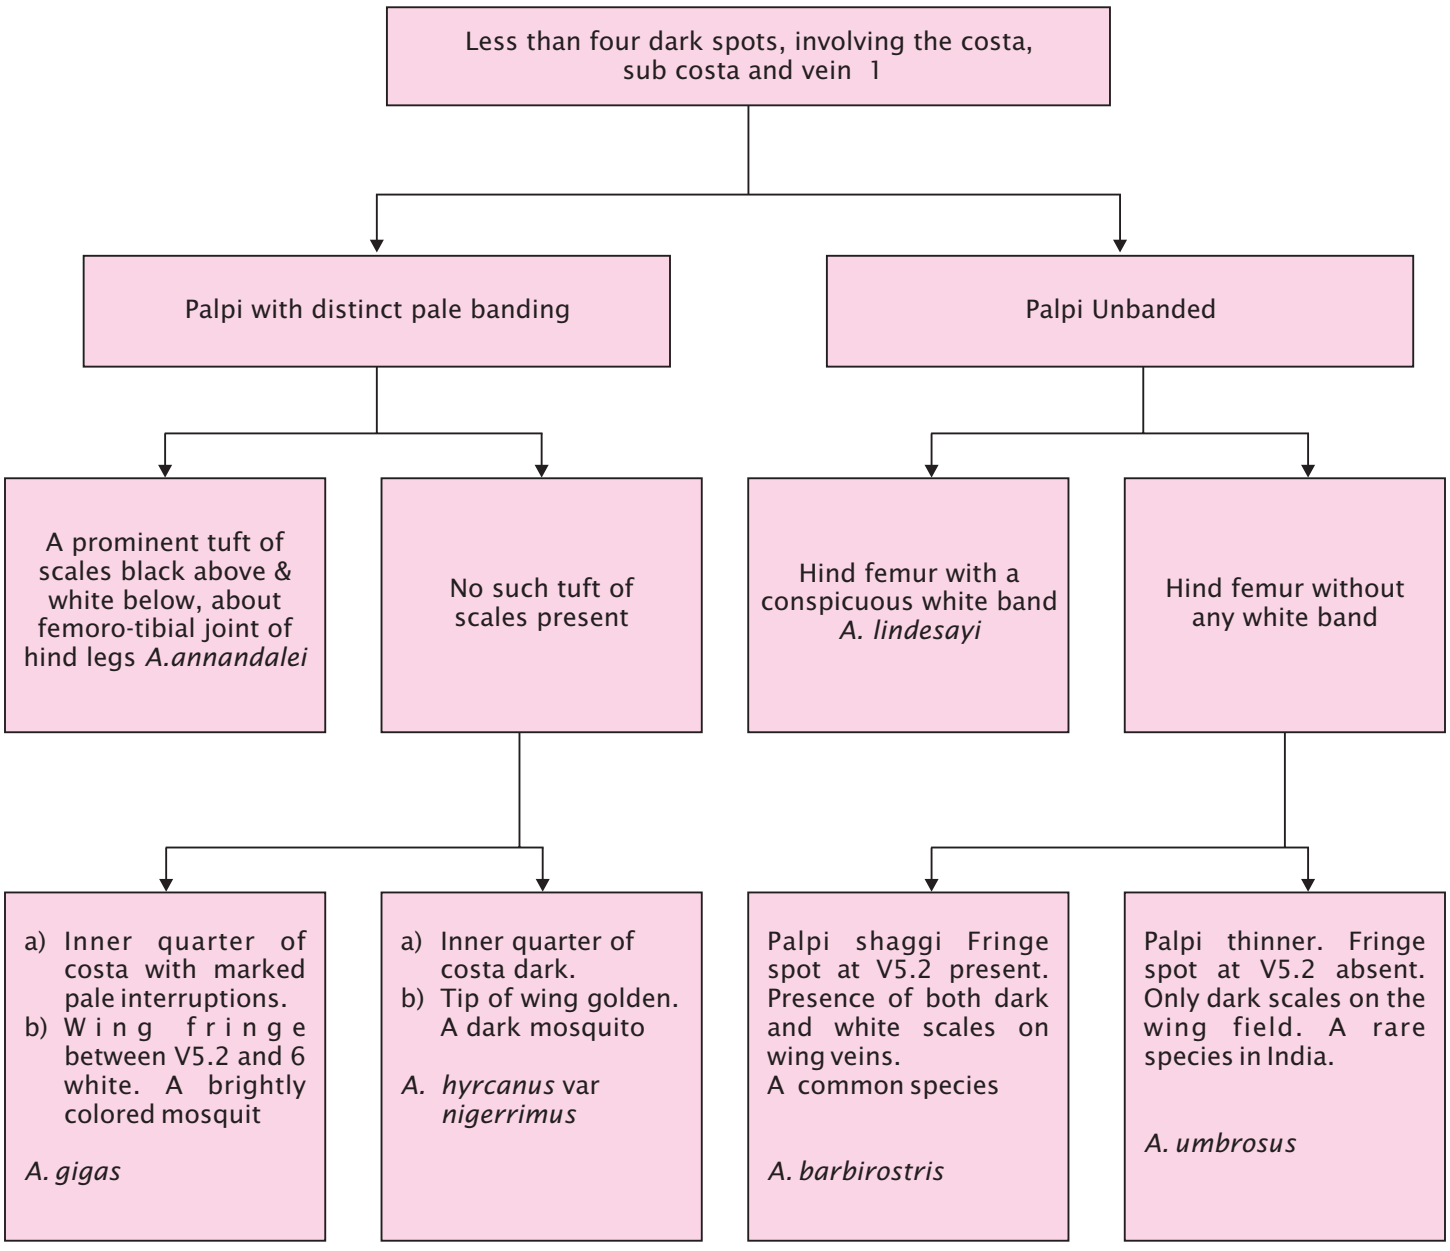
**Anopheles mosquitoes identification : Group - I**

Costa uniformly dark i.e. not interrupted by any pale spot. Also no white spot on the wing field

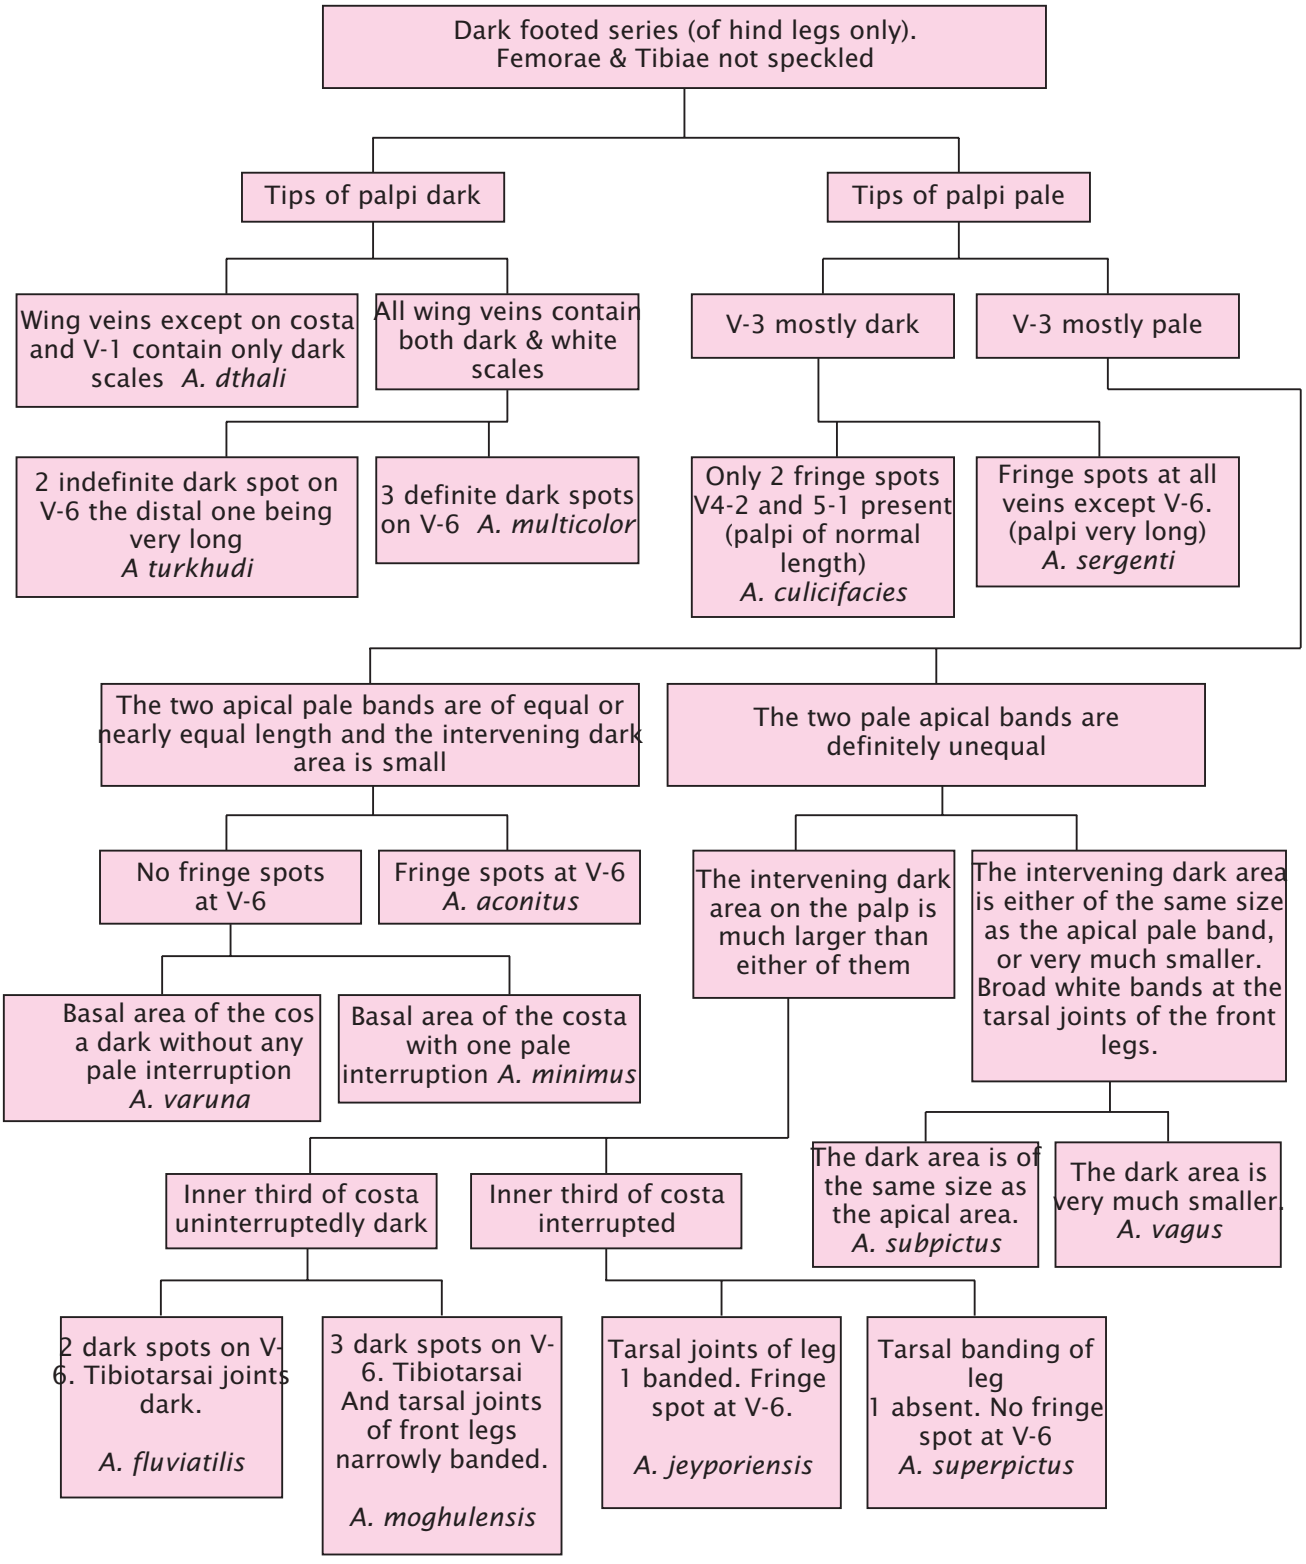
- Anterior forked cell much larger than the posterior *A. aitkeni*
- Anterior forked cell of nearly the same size as posterior
  - Distinct white banding at the distal end of hind femur; frontal white scale tuft present. *A. barianensis*
  - Banding absent. Scale tuft absent *A. culiciformis*

Group III to VI have at least 4 dark spots Involving the costa, sub Costa and vein 1.

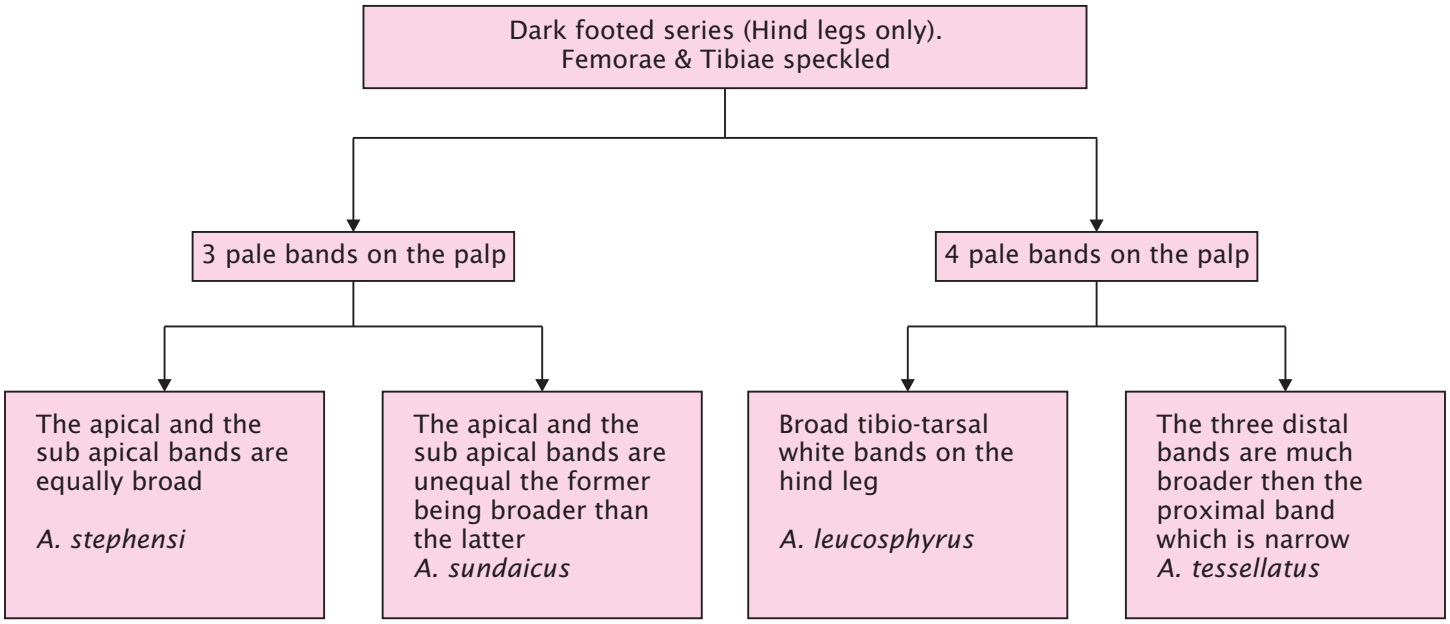
**Anopheles mosquitoes identification : Group - II**



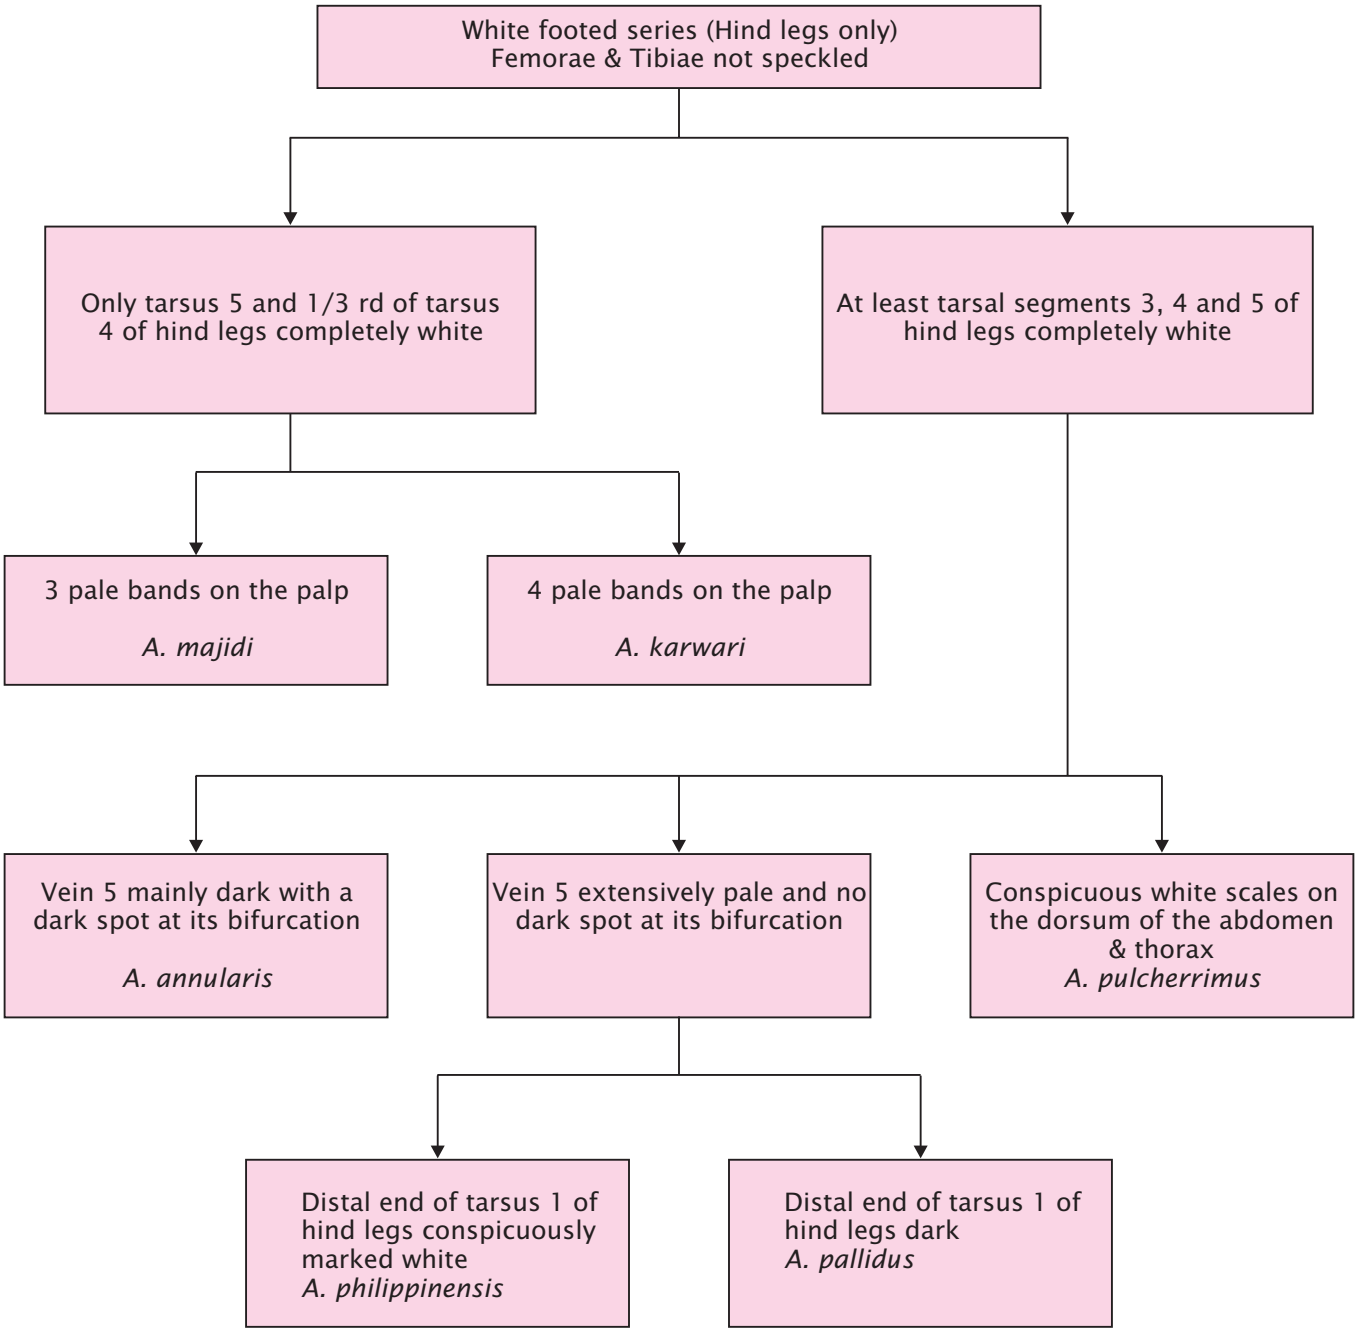
**Anopheles mosquitoes identification : Group - III**



**Anopheles mosquitoes identification : Group - IV**



**Anopheles mosquitoes identification : Group - V**



**Anopheles mosquitoes identification : Group - VI**

# Lymphatic Filariasis

## Introduction

Lymphatic Filariasis is widely known as Elephantiasis. More than a billion people in more than 80 countries are at risk of suffering from the disease. India accounts for one - third of the people infected with the disease (1). Filariasis is caused by three species of nematode worms belonging to the super family *Filarioidea* and family *Onchocercidae* which are transmitted to man by the bite of infective mosquitoes. The three species are *Wucheria bancrofti, Brugya malayi* and *Brugya timori. Wucheria bancrofti* is the most widespread among these three species (2). Several mosquito species are known to transmit the infection. However, *Culex quinquefasciatus* and *Mansonia annulifera* are the two most important vectors in India. In tropical and subtropical areas the prevalence of infection is continuing to increase. The major reason for this increase is the rapid and unplanned growth of cities which greatly enhances breeding of the mosquitoes that transmit the disease. This painful and profoundly disfiguring disease is usually acquired in childhood, but manifests its most disfiguring forms in adults (3, 4). The disease due to lymphatic filariasis is characterized by disfigurement of the limbs (elephantiasis) and genitalia (hydroceles and other anatomical changes in the male genitalia). Consequently, it often has adverse economic and psychosexual effects as well as medical consequences (5). Lymphatic filariasis is one of the six infectious diseases considered eradicable by WHO with the available tools (6).

## History

In 1863, Demarquay first described the microfilariae that are the larvae which live in the blood stream. Microfilariae were found in urine by Wucherer in 1868. Patrick Manson was the first to speculate in 1878 that filarial may be transmitted by mosquitoes (2).

The disease has been known in India since ancient times. It finds mention in “Susruta Samhita” which dates back to the 6th century B.C. Madhavakara, described the signs and symptoms of the disease in his treatise ‘Madhava Nidhana’ in 7th century A. D. In 1709, Clarke called elephantoid legs in Cochin as ‘Malabar legs’ (7)

## Epidemiology

Worldwide

According to the World Health Organization, about 1.25 billion people are at risk of suffering from lymphatic filariasis. As on 31 Dec 2006, 83 countries are considered endemic for filaria. The highest proportion of cases is in the WHO South - East Asia Region with 64% followed by the WHO African Region with 32%. The WHO European Region remains free of lymphatic filariasis transmission (8). Approximately one third of those at risk live in India, another one third in Africa and the remainder in other parts of Asia, the Pacific and the Americas. The most highly - endemic countries are Bangladesh, Democratic Republic of Congo, India, Indonesia, Madagascar, Nigeria and the Philippines (9). The total number of persons infected worldwide is estimated to be 120 million, one third of whom have serious disfigurement and incapacitation (1). Almost 25 million men suffer from genital disease, most commonly hydrocoele, while an estimated 15 million people, mostly women suffer from lymphoedema of the leg (elephantiasis). Among the three parasitic worms responsible for the disease, *Wucheria bancrofti* is the most prevalent particularly in hot and humid climates of Asia, Africa, the Americas and the Pacific. *Brugya malayi* is found in Southern India, South East Asia and South and Central China. *Brugya timori* has only been found in parts of Indonesia (2).

More than half of all cases of Lymphatic filarias is live in South East Asia. Of the estimated 700 million people living in endemic areas in the region, about 60 million are estimated to be infected or suffering from the disease (10).

India

One - third of the people infected with the disease live in India (1). The disease has been described as being second only to malaria as a major public health problem. The disease is endemic to most parts of the country. Indigenous cases have been reported from about 250 districts in 20 states / union territories. Local transmission is known to occur in Andhra Pradesh, Assam, Bihar, Chhattisgarh, Goa, Jharkhand, Karnataka, Gujarat, Kerala, Madhya Pradesh, Maharashtra, Orissa, Tamil Nadu, Uttar Pradesh, West Bengal, Pondicherry Andaman & Nicobar Islands, Daman & Diu, Dadra & Nagar Haveli and Lakshadweep. The North Western and North Eastern parts of India appear to be free from indigenously acquired filarial infection. These include the states of Jammu & Kashmir, Himachal Pradesh, Punjab, Haryana, Chandigarh, Rajasthan, Delhi, Uttaranchal Sikkim, Arunachal Pradesh, Nagaland, Meghalaya, Mizoram, Manipur and Tripura (7). Almost all the cases in India are caused by *Wucheria bancrofti* (99.4%) while the remaining) 6% are attributed to *Brugya malayi* (7).

Over 400 million people live in filariasis endemic areas in India. Three fourths of those at risk live in rural areas. An estimated 49 million individuals in India are infected. Of these, over twenty million people suffer from chronic forms of filariasis while another 28 million are thought to be microfilaria carriers (11-13).

## Economic and social impact

Lymphatic filariasis is primarily a disease of the poor as it occurs mostly in rural areas or urban slums. The increase in lymphatic filariasis over the past few years has been attributed to the expansion of slum areas and poverty, particularly India and Africa. As many filariasis patients are physically incapacitated, it has a significant economic impact. Lymphatic filariasis also exerts a heavy social burden. Among men, genital damage may be a severe handicap leading to physical limitations and social stigmatization. Enlargement of a leg or arm, the genitals, vulva and breasts may result in severe stigmatization of women (1).

## Agent

The three species of nematodes causing lymphatic filariasis, *W. bancrofti, B. malayi* and *B. timori* are threadlike in appearance. They have five stages in their life cycle. Unlike other vector borne diseases, the infective stage of the parasite is not injected into the human body by the mosquito vector. The Infective third - stage larvae are deposited on skin by the vector and penetrate on their own or through the opening created by mosquito bites within minutes to reach the lymphatic system. They then

proceed to shed their cuticle and develop a new surface as they moult into the fourth stage larvae (10). These fourth - stage larvae migrate to central lymphatic vessels and develop into sexually mature adult male or female worms over a period of approximately 9 months. The adult worms are significantly larger than larval stages, with male worms being 20 - 40 mm in length and female worms 40 to 100 mm in length. The adults reside mostly in the afferent lymphatics. The preferred sites for the adult worms seem to the lymphatics of the lower extremities, upper extremities and the genitalia.

The mean reproductive life span of adult worms is approximately 5 years. Following copulation female worms discharge large numbers (10,000 per day) of microfilariae measuring 150 X 7 µm into the blood stream via the lymphatics. The number of microfilariae in the peripheral blood is variable. There is usually a surge in their numbers during the night. These microfilariae are ingested by the mosquito vectors during feeding. The microfilariae exsheath in the mosquito stomach to become first stage larvae. They penetrate the stomach wall and move to the thoracic muscles of the mosquito where they moult twice to develop into the infective third stage larvae. The infective forms then move to the mouth parts of the mosquito and the cycle repeats. The extrinsic incubation period is usually two weeks (2, 3, 13).

### Vector

A wide range of mosquitoes can transmit the parasite, depending on the geographic area. The primary vectors for Filaria are the night biting Culex and Anopheles mosquitoes. *Culex quinquefasciatus* is the principal vector in urban areas in South East Asia. In rural areas of both Asia and Africa, Anopheles species are the important vectors particularly *Anopheles gambiae* and *Anopheles funestes* (2). Aedes and Mansonia are also responsible for transmitting the infection in the parts of Asia and the Pacific region (3).

In India, the most important vector for lymphatic filariasis is *Culex quinquefasciatus.* It is the vector for *Wucheria bancrofti.* It is a ubiquitous mosquito and is present all over the country. Culex breeds in polluted water. Important breeding sites are wet pit latrines, septic tanks, drains, disused wells and paddy fields. *Mansonia annulifera* and *Mansonia uniformis* are the vectors for *Brugya malayi* in India. Mansonia lay eggs on the under surface of the leaves of plants (7).

Filarial nematodes are poorly transmitted by the vectors. A very small proportion, usually less than 1% of mosquitoes are infective even in endemic areas (14). Repeated mosquito bites over several months result in lymphatic filariasis. People exposed to intense transmission for a long period are at the greatest risk for infection. Visitors to endemic areas from non endemic areas for short periods rarely develop disease (2, 15).

### Host

Varied patterns of infection and disease are seen in different endemic areas. Infection is usually acquired in childhood (16) The prevalence of infection rises with age from 5 years to 30 years beyond which it stabilizes. Prevalence may decline somewhat among the elderly. Signs of disease start becoming apparent during late adolescence and rise steadily with age (2). Both sexes are equally susceptible. Minor differences, however, are shown by various groups. It has been postulated that females in the reproductive age group may be more resistant to infection than males because of hormonal factors (17). Lymphatic filariasis is primarily a disease of the poor. The occupations which expose the person more to mosquito bites show a higher incidence. The disease is most prevalent in rural areas and urban slums. The World Health Organization states that the fight to eliminate lymphatic filariasis is also a fight against poverty (1).

### Environmental Factors

Environmental conditions that enhance vector breeding and survival increase infection rates. The optimum conditions for the breeding of the vectors and the development of parasites in them are temperature between 15°C and 35°C and relative humidity above 60%. The density of *C. quinquefasciatus* is at its minimum during the monsoon, but due to favourable atmospheric conditions, somehow the maximum infectivity rate in the mosquitoes occurs during this period. India, presents areas of widely variable endemicity because of its large size and variable climates from region to region (18).

### Clinical features

The incubation period is very variable stretching from eight to 16 months or even longer. The adult worms induce an immunological reaction. A wide variety of clinical manifestations can be seen in lymphatic filariasis. A large proportion of infected persons remain asymptomatic despite the presence of microfilariae. The manifestations result from either acute inflammation or chronic lymphatic obstruction. Clinical manifestations range from those without apparent clinical disease to those with lymphedema and severe disfigurement of the limbs and genitalia. Fever may or may not be present in both the acute and chronic forms. The various presentations can include lymphangitis and adenitis, funiculitis and hydrocoele, abscess formation, lymphadoema and elephantiasis, chyluria and monoarticular arthritis. Occult filariasis in which the classical features of the disease are absent and microfilaria can not be demonstrated in blood, can present as tropical pulmonary eosinophillia. About 40% of patients have renal involvement with proteinuria and haematuria (2, 4, 5, 14)

### Diagnosis

Diagnosis in symptomatic patients living in endemic areas is based on appropriate history and typical clinical findings. In patients above 15 years of age the appearance of lymphedema of the extremities or disease of the male genitalia is most likely due to filarial infection.

A definitive diagnosis can be made only by detection of the parasites. The standard method for diagnosing active infection is the identification of microfilariae in a blood smear by microscopic examination. The microfilariae exhibit nocturnal periodicity with surges of circulating microfilariae at night. Blood collection should be done at night to coincide with the appearance of the microfilariae. A small dose of Diethylcarbamazine (DEC) can increase microfilaraemia during the day as it causes the microfilariae to be expelled from the pulmonary vascular bed. A thick smear should be made and stained with Giemsa or Hematoxylin and Eosin. Microfilariae are sometimes detected in chylous urine, hydrocoele fluid and ascites fluid (19). An alternative to microscopic detection of microfilariae is provided by serologic techniques for the diagnosis of lymphatic filariasis. Patients with active filarial infection are found to have elevated levels of antifilarial IgG4 in the blood and these can be detected using routine assays (19).

The difficulty in detection of microfilariae led to the development of simple immunochromatographic tests. These are very sensitive, very specific and simple "card tests" to detect circulating parasite antigens without the need for laboratory facilities. They use only finger - prick blood droplets taken anytime of the day (1, 20). Adult worms are difficult to detect. Sonographic examination of the scrotum or breast using high frequency ultrasound may result in the identification of adult worms within dilated lymphatics (2, 5).

**Treatment**

Diethylcarbamazine (DEC) is the drug used most widely for treatment of lymphatic filariasis. It exerts no direct lethal action on the adult worms but changes them in a manner which makes their removal by the host's immune system possible (2). It is considered safe and effective against all filarial infections. The dose is 9 - 12 mg / kg orally in three divided doses for 14 or 21 days. The full dose must be reached slowly, starting with 50 mg daily to avoid side effects. For treatment of tropical eosinophillia, a 21 day treatment regimen must be followed. This course may be repeated twice at intervals of 4 - 6 weeks. Ivermectin has also been found effective in a single oral dose of 200 - 400 µg / kg body weight. Two drug regimens have also been found effective. The combinations that may be used include 400 mg albendazole with 6 mg / kg DEC or 400 mg albendazole with 150 µg / kg ivermectin once a year. Symptomatic treatment such as analgesics, antipyretics and antihistaminics may be required. Surgical procedures to correct elephantiasis must be preceded by drug therapy.

In filariasis endemic areas, the primary goal of community treatment is to eliminate microfilariae from the blood of infected individuals so that transmission of the infection by the mosquito can be interrupted. Recent studies have shown that single doses of diethylcarbamazine (DEC) have the same long - term effect in decreasing microfilaraemia as the 12 day regimens of DEC. The use of single doses of two drugs administered together (albendazole with DEC or ivermectin) is 99% effective in removing microfilariae from the blood (1).

Prevention and Control of Filariasis

Active disease surveillance, vector control, personal protection and mass treatment of communities in endemic areas are the corner stone of lymphatic filariasis control. The success of control measures depends on the level of co - operation by the public. The importance of health education cannot be overemphasized. Vector control and personal protective measure are dealt with in detail in the chapter on Entomology. In the Armed Forces, the Filaria survey is an important method of active surveillance.

Filaria Survey (21)

The objective of filaria survey is to find out the extent of filaria infection and filarial disease prevalent in a locality, factors responsible thereof and to recommend suitable control measures. Three main purposes of the survey are as under :

(a) To obtain baseline data on the prevalence and distribution of filariasis.

(b) To define the public health importance of filariasis in an area.

(c) To monitor and evaluate changes in endemicity including those due to control programmes.

Method of Survey

A filaria survey comprises of the following elements and procedures :

**(a) General**

This should include meteorological data, local morbidity, statistics, socio - economic aspects of local population such as occupation, income, literacy, social habits and attitudes, records of previous survey if any and any existing control measures. A close liaison must be established with local populations before starting the actual survey. A map should also be prepared.

**(b) Technique**

It should be a random representative sample of the area. All persons in a household should be examined. Following four types of surveys can be conducted :

(i) **Blood (Parasitological) survey** : The blood smears should be collected between 9. 30 p. m. to midnight. Approximately 20 $mm^3$ of blood (3 drops) from each person should be taken on a clean glass slide and made into a thick smear. After drying, a serial number is given as in the proforma. The slides are dehaemoglobinised, fixed and stained next day, preferably with JSB - I stain. The slides are then washed, dried and examined for microfilariae. The other methods employed in parasitological surveys are - counting chamber technique and membrane filter concentration method.

(ii) **Clinical Survey** : It is better if this is carried out separately during day time when all members of the family are present and detailed history of each case can also be taken. Each person's length of stay, history of fever, lymphangitis, chyluria and clinical signs of filarial disease are recorded.

(iii) **Skin Tests** : Recent studies have revealed that the intra - dermal tests are of considerable importance in detecting early cases of filariasis. Lack of standardized antigens and their specificity is the main drawback.

(iv) **Diethylcarbamazine Provocative Test** : This test is based on the principle that administration of hetrazan stimulates the appearance of microfilarae (MF) in the blood circulation.

(v) **Entomological Survey** : This should include types of vector breeding places, collection of larvae, adult collections and dissections, precipitin tests and bionomics of local vectors such as their density, resting habits and their biting / feeding behaviour.

(vi) **Zoonotic Infection** : To rule out the prevalence of any zoonotic focus of filariasis, the study may include a blood survey on the local animals and birds.

Filarial indices

The extent of filariasis problem in a given area before and after the institution of control measures can be assessed by certain indices which are defined as under :

**(a) Microfilaria Rate**

It is the number of persons showing microfilariae in a unit (20 $mm^3$) of blood expressed as a percentage of population examined.

**(b) Filarial Disease Rate**

It is the number of persons showing clinical manifestations of filariasis expressed as percentage of population examined.

**(c) Filarial Endemicity Rate**

It is the number of persons showing microfilariae in blood, or filarial disease or both per 100 persons examined during a survey.

**(d) Microfilaria Density**

It is the number of microfilariae present in a unit volume of blood (20 $mm^3$) from individual persons.

**(e) Average infestation Rate**

It is the average number of microfilariae per positive person in a sample.

**(f) Filaria Mosquito Infection Rate**

It is the number of mosquitoes found positive for all stages of developing larvae expressed as percentage of the total female mosquitoes dissected.

**(g) Mosquito Infectivity Rate**

It is the number of mosquitoes positive for infective stage of larvae expressed as percentage of the total female mosquitoes dissected.

WHO strategy to eliminate lymphatic filariasis

The WHO strategy of the Global Programme to Eliminate Lymphatic Filariasis aims to stop the spread of infection and morbidity control. To interrupt transmission, districts in which lymphatic filariasis is endemic must be identified and then mass treatment programmes implemented to treat the entire at - risk population. Mass Treatment involves once - yearly administration of single doses of two drugs given together, albendazole plus either diethylcarbamazine (DEC) or ivermectin. An alternative community - wide regimen with equal effectiveness is the use of common table / cooking salt fortified with DEC in the endemic region for a period of one year (1) This programme in operation on a national level in India (7, 22-24).

# Malaria

## Introduction

Malaria is a tropical disease caused by protozoan parasite of the genus Plasmodium and transmitted to man by the bite of certain species of infected female anopheles mosquitoes. It remains widespread throughout the tropics, but also occurs in many temperate regions. It exacts a heavy toll of illness and death especially amongst children and pregnant women. Treatment and control have become more difficult with the spread of drug resistant strains of parasite and insecticide resistant strains of mosquito vectors. The overriding importance of malaria for the mankind in general and, for our country and Armed Forces in particular, is evident from the fact that there a number of text books available on the subject of malaria. Interested medical officers are advised to refer to these texts.

## Geographical Distribution

Malaria is usually restricted to tropical and subtropical areas and altitudes below 1500m. However, the distribution might be affected by climatic changes esp global warming and population movement. *P. falciparum* is the predominant species in world. *P. vivax* and *P. ovale* are traditionally thought to occupy complimentary niches with *P. ovale* predominantly in Sub Saharan Africa. *P. malariae* has wide global distribution being found in South America, Africa and Asia.

## Magnitude of the problem

(a)Global

Malaria is endemic in over 105 countries and is responsible for over 300-500 million clinical cases and over a million deaths annually. Out of around 3000 deaths a day, over 90% are in Sub Saharan Africa.

(b) SEAR

Out of the 11 countries of the SEAR, 10 are malaria endemic. Maldives has no endogenous transmission since 1984. SEAR accounts for 30% of global morbidity and 8% of global mortality due to malaria. An estimated 82. 8% of the total population here is at risk of malaria. Out of the total population, 41. 5% are at mod-high risk, 41. 7% are at low risk while remaining only 16. 8% are free from malaria.

(c) India

Malaria transmission occurs in almost all areas of India except areas above 1800 meters sea level. Countries 95% population lives in malaria risk prone areas. Malaria in India is unevenly distributed. In most parts of India about 90% malaria is unstable with relatively low incidence but with a risk of increase in cases in epidemic form every 7-10 yrs. This depends on the immune status of the population and the breeding potential of the mosquitoes, rainfall being the leading cause of malaria epidemic as it increases vector density. In North-East states efficient malaria transmission is maintained during most months of the year. Intermediate level of stability is maintained in the plains of India in the forests and forest fringes, predominantly tribal settlements in 8 states (AP, Gujarat, Jharkhand, MP, Chattisgarh, Maharashtra, Orissa and Rajasthan).

The reported incidence is between 2-2. 5 million cases annually with some fluctuations every year for last over two decades. out of these 44. 3% are *P falciparum* cases. Malaria situation in India in last few years is given in the Table - 1 :

Table - 1

| Year | Malaria Cases (in million) | Pf Cases (in millions) | Deaths (exact numbers) |
|---|---|---|---|
| 1995 | 2.93 | 1.14 | 1151 |
| 1996 | 3.04 | 1.18 | 1010 |
| 1997 | 2.57 | 0.99 | 874 |
| 1998 | 2.09 | 0.91 | 648 |
| 2002 | 1.84 | 0.87 | 973 |
| 2003 | 1.87 | 0.85 | 1006 |
| 2004 | 1.92 | 0.89 | 949 |
| 2005 | 1.82 | 0.80 | 963 |
| 2006 | 1.75 | 0.76 | 890 |

(d) Armed Forces

In 2006, malaria ranked 4th amongst top 20 causes of hospital admission contributing to 3.86 % of total admissions of serving personnel in Armed Forces. It featured second only to intestinal infections in communicable diseases category. Average duration of hospital stay due to malaria was 11.54 days in 2006. The decadal incidence is shown in Table - 2.

Table - 2 : Decadal Incidence of Malaria in Army Personnel 1996 To 2006 (Rate Per 1000)

| Year | Total |
|---|---|
| 1996 | 12.87 |
| 1997 | 8.62 |
| 1998 | 7.03 |
| 1999 | 6.03 |
| 2000 | 4.32 |
| 2001 | 4.08 |
| 2002 | 4.67 |
| 2003 | 5.53 |
| 2004 | 5.67 |
| 2005 | 4.63 |
| Average for 10 Yrs | 6.35 |
| 2006 | 4.07 |

**Agent Factors**

The disease is caused by the haemoparasites of genus Plasmodium. There are four species: *P. vivax, P. falciparum, P. malariae,* and *P. ovale*. The first two are the commonest; the third is of focal distribution and the fourth is rare. The cyclopropagative life cycle of the plasmodium occurs in two stages (Fig - 1 ). The sexual stage starts with the 'gametogony' in the human host and progresses through 'sporogony' in the mosquito. The asexual stage starts with injection of sporozoites by the infective mosquito into the human host and progresses through three phases of 'schizogony'. The broad outline of events occurring during the two stages is as follows.

(a) Sexual Cycle in Mosquito (Sporogony)

The vector female anopheline mosquito ingests male and female gametocytes from a malarial subject. In the mosquito's stomach the male gametocyte becomes rounded, its chromatin splits into 5 to 8 particles, which get arranged along its edge. Cytoplasm around each chromatin particle elongates into a 'flagellum' and together with chromatin separates from the main mass as a 'microgamete'. Female gametocyte extrudes polar bodies and becomes a 'macrogamete' ready to be fertilized. Syngamy of microgamete and macrogamete forms 'zygote'. This becomes an elongated, motile 'Ookinete'. Penetrating the stomach wall, this comes to lie under its external basement membrane, becomes rounded & develops into 'oocyst' measuring 6 to 12. As the oocyst matures, it increases in diameter from 6 to 60 and rapidly undergoes division and subdivision to form a large number of haploid sporozoites (varying from new hundreds to thousands). Finally, the oocysts rupture, releasing the elongated sporozoites into the body cavity, majority of which find their way into the salivary glands. Sporozoites injected in human host through the mosquito bite start schizogony.

(b) Pre-erythrocytic Phase

Sporozoites injected by infective mosquito into human body circulate for approximately 30 minutes and thereafter leave the peripheral blood. Fully matured, pigmentless schizonts, containing cryptozoites are seen in the parenchymal liver cells. The cycle lasts approximately 8 days in *P. vivax*, 6 days in *P. falciparum* and 9 days in *P. ovale.* On full maturity of the pre-erythrocytic schizonts, the liver cells rupture and cryptozoites enter the erythrocytes.

(c) Erythrocytic Phase

Th earliest intracorpuscular form of parasite is the 'trophozoite' which has a fine ring of cytoplasm with a small chromatin dot. It grows in the parasitised RBC that becomes pale and, in some species, enlarged or distorted. The haemoglobin changes into haemozoin pigment and is seen in the cytoplasm of the parasite as black or brown granules. Fully developed trophozoite fills the RBC and undergoes segmentation. The chromatin divides into a number of particles which migrate towards the periphery. The cytoplasm around each particle separates off forming merozoites; the pigment concentrates in the centre of the RBC. This is called 'rosette' or 'schizont'. The parasitised RBC eventually ruptures releasing merozoites which enter other RBCs repeating the asexual cycle. Each asexual cycle is completed in 48 hours in *P. falciparum, P. vivax* and *P. ovale* and in 72 hours in *P. malariae*.

(d) Gametogony

After a few cycles of erythrocytic schizogony, male and female gametocytes appear in the blood. The female macrogametocyte has a dense and deeply staining cytoplasm and a small compact nucleus, while the male microgametocyte has a less dense and faintly staining cytoplasm and a relatively large and diffuse nucleus. The gametocyte of *P. vivax* is large and round filling the enlarged RBC, the gametocyte of *P. falciparum* is sausage or crescent shaped. Gametocytes remain within the corpuscles until taken up by the mosquito or their final disintegration.

(e) Persistent Tissue Phase (Exoerythrocytic phase)

After the establishment of blood infection the initial tissue phase (pre-erythrocytic phase) disappears completely in P. falciparum, whereas in *P. vivax, P. ovale* and *P. malariae* it continues in the form of a persistent tissue phase in the liver. These exoerythrocytic forms never arise from the merozoites of erythrocytic schizogamy and are now considered responsible for relapses of vivax , ovale and quartan malaria.

Reservoir and Source

For human plasmodia the only reservoir is a malaria case. In some parts of Africa Chimpanzees may act as reservoir of P. malariae. The source of infection is a malaria case with adequate number of mature viable gametocytes circulating in the blood. It has been estimated that in order to infect a mosquito, the blood of a human carrier must contain at least 12 gametocytes per $mm^3$ and the number of female gametocytes must be more than the male gametocytes.

Communicability Period

The human case of malaria becomes infective to mosquito when mature, viable gametocytes develop in the blood of the patient in sufficient density. Gametocytes of *P. vivax* appear in peripheral blood 3 to 5 days after the initial appearance of the asexual forms of parasites where as in falciparum infections they do not appear until 10-14 days after the first appearance of asexual parasites.

**Host Factors**

Age

All ages are equally affected. Children are usually effective carriers of gametocytes.

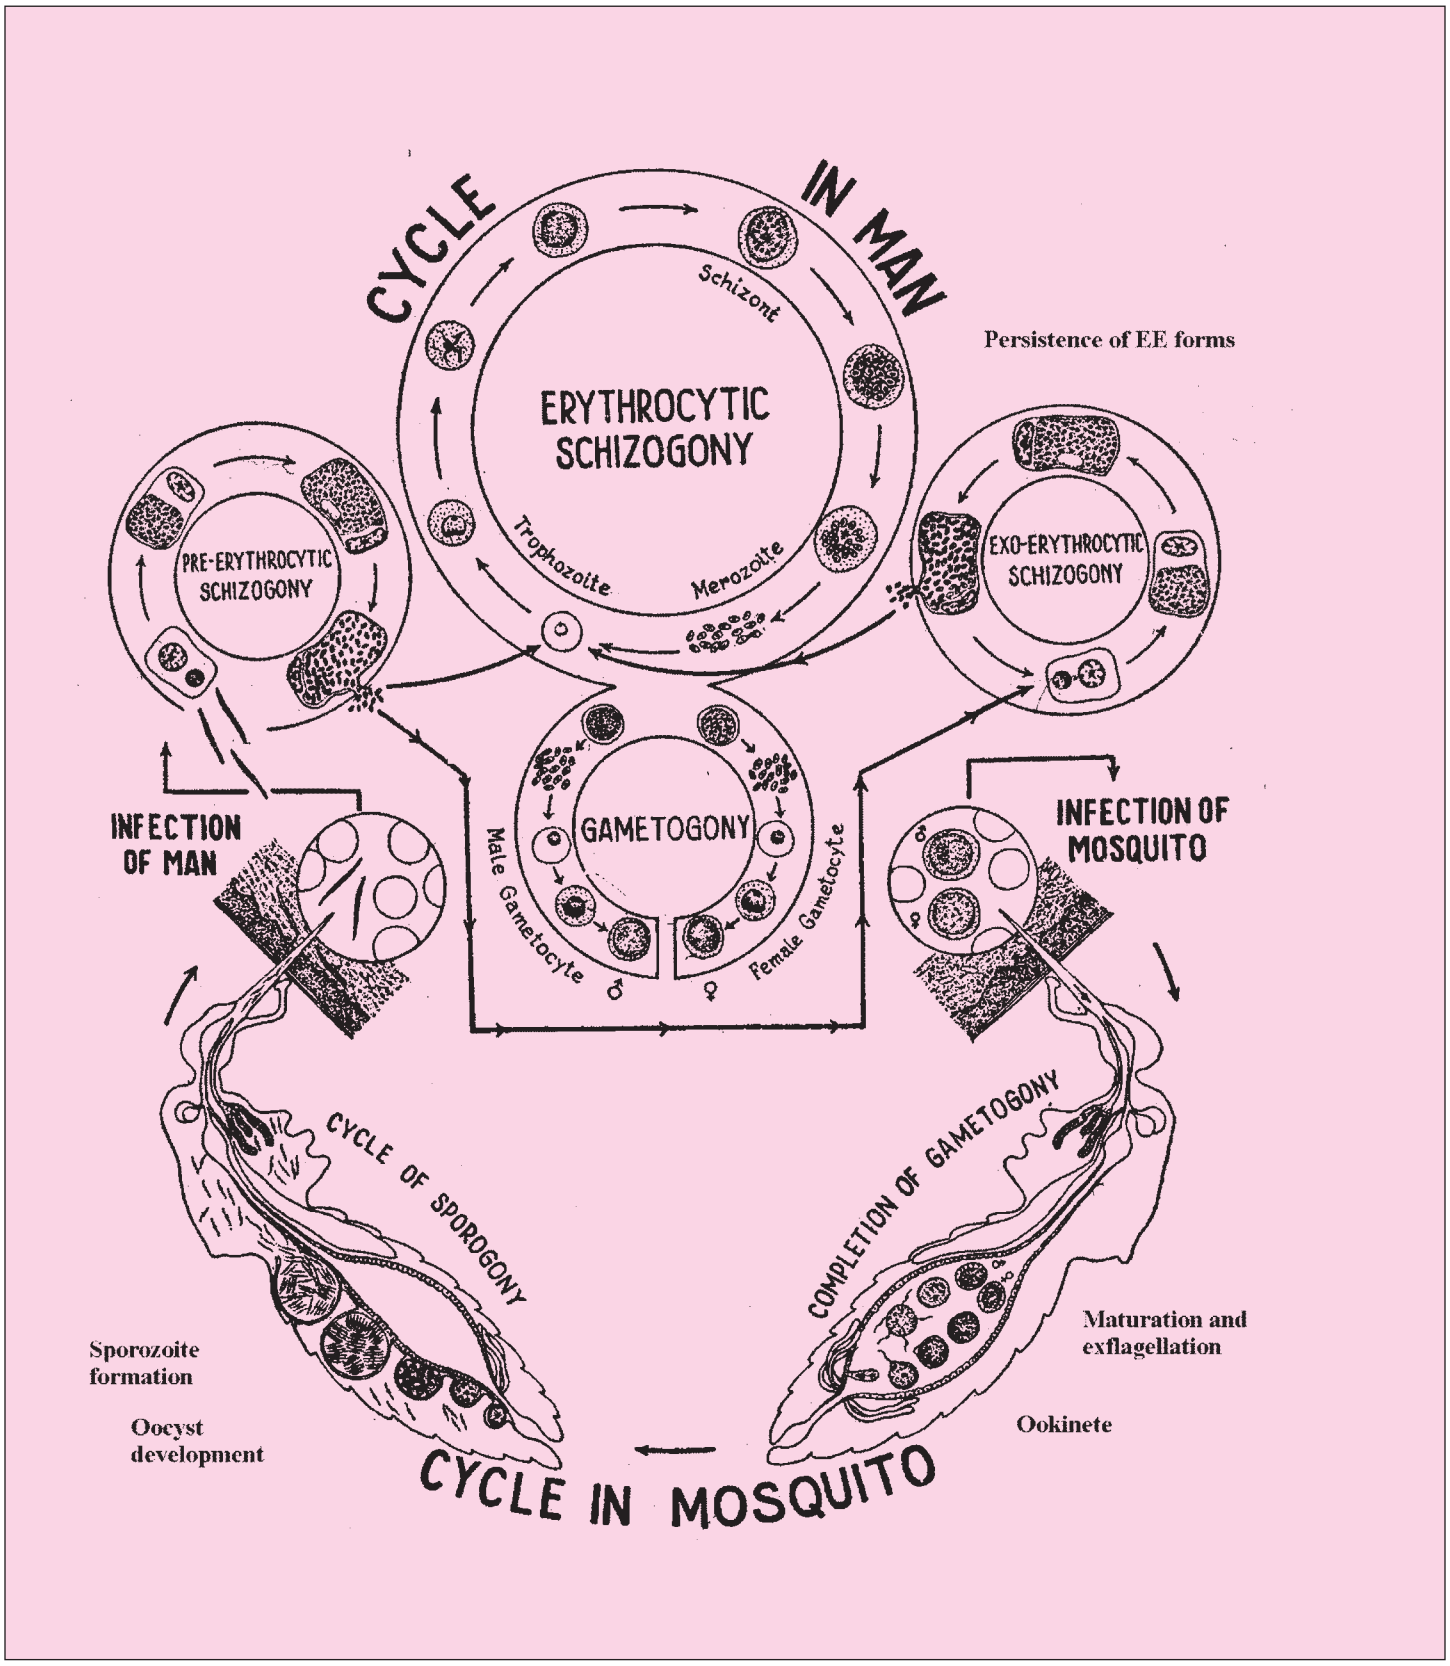
Sex

It makes no difference except by way of clothing and the occupation which have a bearing on the man-mosquito contact.

Race

Racial immunity against one or more species of malaria parasite has been observed in certain parts of the world. Negroes with sickle cell trait have been found to be relatively immune to *P. falciparum* infection. Recent

Fig - 1 : Life cycle of the malaria parasite



studies indicate that HbE, or thalassaemia traits do not confer any selective advantage or disadvantage in malaria. Persons with G6PD deficiency suffer more from *P. Vivax* infection. They are not protected from *P. falciparum* infection.

Economic Status

It is inversely related mainly because of poor housing. Ill ventilated and poorly lighted houses provide ideal resting places for mosquitoes.

Movements

Migration of populations due to natural calamities, aggregations of labourers and movements of nomads may lead to reintroduction of malaria into areas where the disease has already been eradicated or effectively controlled.

Habits

Habits of sleeping outdoors without mosquito nets, ignorance and apathy, social and religious beliefs, all these factors may either create malariogenic conditions or lead to perpetuation of malaria transmission in a locality.

Aquired Immunity

Man possesses no natural immunity. In areas with high falciparum transmission, newborns will be protected during the first few months of life presumably by maternal antibodies transferred to them through the placenta. As these antibodies decrease with time, these young children become vulnerable to disease and death by malaria. If they survive to an older age (2-5 years) they will have reached a protective semi-immune status. Thus in high transmission areas, young children are a major risk group and are targeted preferentially by malaria control interventions. In areas with low transmission, malaria is found in all age groups.

Pregnancy and Malaria

In pregnancy malaria is more common due to immunosuppression. It is more atypical and severe .The parasitemia is ten times higher and thus all the complications of falciparum malaria are more common. As some antimalarials are contraindicated in pregnancy, the treatment is also more difficult.

Genetic Factors

Biologic characteristics present from birth can protect against certain types of malaria. Two genetic factors, both associated with human red blood cells, have been shown to be epidemiologically important. Persons who have the sickle cell trait (heterozygotes for the abnormal hemoglobin gene HbS) are relatively protected against *P. falciparum* malaria and thus enjoy a biologic advantage. Persons who are negative for the Duffy blood group have red blood cells that are resistant to infection by *P. vivax.*

**Environmental Factors**

Environmental factors influence the bionomics of the vector species of anopheline mosquito and the habits of human host. In most parts of India the meteorological and physiographical conditions are favorable to the occurrence of malaria.

Climate

The topography, weather, flora and fauna modify the life cycle of the mosquito. There are seasonal variations in their density, resting, feeding and biting habits, longevity and flight capabilities. Malaria is therefore, seasonal in most parts of the country. In most of the states the maximum transmission is during the period July to November.

Temperature

An optimum temperature of 20˚ to 30˚ C is necessary for completion of the sporogonic cycle of malaria parasite. P. vivax is, however, adapted to lower temperatures and may complete its developmental cycle at 15˚ C. Although these temperatures may suggest limits for survival of the parasites, the temperature and humidity in the actual surroundings of vectors, particularly their day time resting places, are more important. This microclimate plays a vital role on longevity and biting habits of mosquito, sporogonic development of malaria parasite and consequently on the transmission of malaria.

Humidity

Humidity plays a vital influence on the life of a mosquito by determining the speed of its development, its daytime resting habits, its biting activity and also on the development of parasites in its gut. A relative humidity (RH) of 60 percent is considered optimum for transmission of malaria.

Rainfall

It has influence on the breeding of vectors and hence on the incidence of malaria. However, the correlation is not always obvious. While heavy rains in certain areas may discourage stream breeders, intermittent moderate rain with intervals of sunshine may be conducive to anopheline breeding. Similarly, droughts may either precede or eliminate vectors in other areas. The influence of rainfall should, therefore, be assessed only in relation to the local pattern of vector breeding. Rainfall also increases the atmospheric humidity, which has already been discussed above.

Wind

While it favours the dispersal of adult mosquitoes, it has an adverse effect on ovipositing. The wind being minimum as a rule at dawn and dusk, it favours man mosquito contact at these hours.

Topography

Altitude, configuration and character of water collections determine the transmission of malaria to a great extent. Transmission decreases with increasing altitude and as a rule and it stops above the heights of 2000 m.

Man-made Malaria

Construction of roads, railways, irrigation works, dams and barrages, deforestation and other engineering projects have resulted in creation of mosquito breeding place in many new areas. All these ecological changes have led to an increase in the incidence of malaria.

### Vectors of Malaria

There are 56 species of anopheline mosquitoes in India but only 6 are regarded as primary vectors and another 3 or 4 as secondary or local vectors. The following characteristics of vector mosquitoes play an important role in the epidemiology of malaria.

Breeding Habits

The breeding habits of mosquitoes show a lot of variation. Hence, vector mosquitoes tend to be confined to certain geographical areas only. A few examples are as follows :-

(a) Slow moving water, seepages, terraced rice fields - *A fluviatilis*
(b) Brackish waters - *A sundaicus*
(c) Wells, cisterns and over head tanks -*A stephensi*
(d) Tanks, pools, burrow pits and ditches - *A philippinensis*, *A annularis*
(e) Forest pools, streams and slit trenches - *A dirus*

Vectorial Capacity

Why only certain species and not others act as vectors is not exactly known. A complexity of factors determines the vectorial status of a mosquito. Certain new species are emerging as secondary vectors in different parts of the country.

Density

For effective transmission of malaria in a locality, the mosquito vector must attain and maintain a certain density. This is called critical density and it varies from one mosquito to another and also under different environmental conditions. *A culicifacies* needs a very high density for transmission of malaria.

Longevity

A mosquito, after an infective blood meal, must live for at least 10 days to complete the development of malaria parasites.

Tropism

Some mosquitoes like *A fluviatilis* prefer human blood and are called anthropophilic. Others like *A culicifacies* preferably feed on animal blood and are called zoophilic. This preferential feeding habit is called tropism. It has obvious bearing on the transmission of malaria.

Biting Behaviour

Some vector mosquitoes bite at or soon after dusk, others either during late night or early hours of the morning. However, some species may be active at two different periods during the same night.

Resting Habits

A female mosquito after a blood meal rests either indoors (endophilic) or outdoors (exophilic) for maturation of its eggs. A knowledge of these habits is necessary for organizing antiadult measures. The common resting places are either human dwellings, cattle sheds or mixed dwellings.

Flight Range

The range of flight and dispersion varies from one vector to another. Knowledge of this is important for planning control measures. Some have a short flight range e.g. *A dirus, A annularis* and *A fluviatilis* upto 1 km distance; *A. culicifacies* and *A. stephensi* upto 2 km; and *A. sundaicus* which may fly even upto 8 or 10 km.

Resistance to Insecticides

When a vector mosquito in a locality becomes resistant to a particular insecticide one has to use an alternative insecticide. A close liaison with local NAMP unit is necessary for knowing the susceptibility/ resistance status of the vectors to various insecticides.

As per the global classification, India is covered by 3 out of the 12 epidemiological zones. The present distribution of malaria vectors in these zones is given below :

Northern and Peninsular India

(a) **Main Vectors**
*A. culicifacies, A stephensi, A. fluviatilis.*
(b) **Local Vectors**
*A sundaicus, A. annularis and A. varuna.*

Eastern India

**(a) Main Vectors**
*A dirus, A sundaicus, A. philippinensis, A. minimus, A maculatus.*

Andaman and Nicobar Islands

(a) **Main Vector**
*A sundaicus*
(b) **New Vectors**
*A dirus, A. maculatus* and *A tesselatus.*

### Mode of Transmission

(a) By Vector

The most prevalent mode of transmission of malaria is through the bite of certain species of infected female anopheles mosquito. It is infective only if the sporozoites are present in its salivary glands.

(b) Direct Transmission

Malaria can be transmitted by intravenous or intramuscular injection of infected blood or plasma in an otherwise healthy person. The parasite can stay alive for nearly two weeks at -4°C in bottled blood.

(c) Congenital

Although rarely but transmission can also occur from infected mother to the newborn.

### Incubation Interval

Incubation interval denotes the duration of the full cycle of malaria parasite. It is the sum of the time taken for the development of the parasite in the mosquito and that in the human being. The incubation interval in case of *P. vivax* is approximately 22 days while for *P. falciparum* it is 35 days.It is important as the surveillance cycle of less

than one incubation interval will catch most of the secondary cases before the commencement of next cycle. Through this activity, the malaria surveillance can be measured. Technical justification for a fortnightly blood smear collection is based on this transmission dynamics of malaria

The intrinsic incubation period in human host in the case of *P. vivax, P. ovale* and *P. falciparum* is 10 to 14 days; whereas in *P. malariae* it may vary from 18 days to 6 months. The incubation period is also prolonged when prophylactic doses of antimalarial drugs are administered.

### Malaria Survey

Survey is carried out for assessing extent and intensity of malaria in an area, distribution and period of transmission, and establishing the identity and bionomics of mosquito vectors. Detailed surveys are carried out by examination of the population, especially children, for the spleen and parasite rate; collection of mortality and morbidity data; enquiries into past surveys, hospital admission records and dispensary attendance; scrutiny of meteorological conditions in relation to mosquito genesis and bionomics; collection and identification of larvae and adult mosquitoes; dissection of adult mosquitoes, studying their bionomics and determine the feeding habits and host preference of mosquitoes. Study of topography is important. Rapid diagnostic kits namely immunochromatographic test and dipstick antigen captive assay are sensitive kits for rapid diagnosis of P. falciparum malaria in field. Details of undertaking malaria surveys are also provided in Govt of India publication.

### Malariometry

Prevalence

During an emergency when it is not feasible to carry out a detailed malaria survey, it is possible to assess the prevalence of malaria in an area in a short time by the collection of following data.

**(a) Spleen Rate**

It is expressed as the percentage of children between two and ten years of age showing enlargement of spleen. A child spleen rate above 10 is considered high warranting implementation of control measures in the Armed Forces.

**(b) Parasite Rate**

It is expressed as the percentage of children between two and ten years of age showing malaria parasites in their blood films. The child parasite rate is a true index of local prevalence of malaria because the children do not possess premunition and are less likely to have contracted the infection outside the area.

**(c) Infant Parasite Rate**

It is defined as the percentage of infants below the age of one year showing malaria parasites in their blood films. It is regarded as the most sensitive index of recent transmission of malaria in a community.

**(d) Proportional Case Rate**

It is expressed as the number of cases diagnosed as clinical malaria for every 100 patients attending the outpatient departments of hospitals and dispensaries.

Incidence

The indices described above indicate the prevalence of malaria in a locality as judged from a sample of the population. A new tool of evaluation has been introduced under the National Programme, which measures not prevalence but the incidence of malaria. This method is called case detection or surveillance and is expressed as Annual Parasite Incidence (API).

**Annual parasite index** is calculated as under

**Annual Blood Examination Rate (ABER)**

Malaria surveillance presumes that every malaria case will present itself with symptoms of fever at some point of

$$API = \frac{\text{Confirmed cases of Malaria during one year}}{\text{Population under surveillance}} \times 1000$$

time during the course of infection. Therefore, if all fever cases occurring in the community are kept under surveillance over a period of time and their blood smears are examined for malaria parasite, the total malaria parasite load can be examined

The value of API is linked with adequacy of coverage of the population under surveillance in respect of blood examination. This is indicated by ABER. It is recommended that the monthly number of blood smears examined should be at least 1 percent of the population. For accurate estimates of malaria endemicity, the blood smear examination rate specially the Monthly Blood Examination Rate (MBER) rate should be equal to fever rate of the month in the community. Therefore it is necessary to ensure that all persons having fever during malaria transmission months are included in the total blood slides examined during the year. ABER is the cumulative sum of monthly rates during the year. ABER/ MBER is an index of operational efficacy of the programme. The Annual Parasite Incidence (API) depends upon the ABER

**Slide Positivity Rate (SPR)**

The Slide Positivity Rate among the blood smears

$$ABER = \frac{\text{Number of blood smears examined During an year}}{\text{Population under surveillance}} \times 100$$

$$MBER = \frac{\text{No. of blood smears collected during a month}}{\text{Population covered under surveillance}} \times 100$$

collected through both active and passive surveillance gives more accurate information on distribution of malaria infection in the community over a period of time. Monthly SPR can be calculated to find out the seasonal rise and fall in malaria prevalence in the community. SPR

among children 2-9 years of age can be utilized for comparison with pre-control Child Parasite Rates to assess the impact of control measures on local malaria endemicity and transmission. SPR in the age group of less than one year (Infant Parasite Rate) can be utilized for assessment of the impact of control operations. Trends in SPR can be utilized for predicting epidemic situations in the area. If monthly SPR exceeds by 2 ½ times of the standard deviation observed in SPR of the preceding 3 years or preceding 3 months of the same year, an epidemic build up in the area can be suspected. Monthly or yearly trends of SPR are utilized to study the impact of control operations. SPR is measured as follows:

**Clinical Features**

(a) Uncomplicated Malaria

$$SPR = \frac{\text{No. of blood smears found positive for malaria parasite}}{\text{No. of blood smears examined}} \times 100$$

The classical (but rarely observed) malaria attack lasts 6-10 hours. It consists of :

**Cold Stage**

There is a general sensation of cold followed by rigors. The temperature rises to 40º C and stays for nearly 1 hour. At this time parasites are demonstrable in the blood.

**Hot Stage**

In this stage there is fever, headaches and vomiting. Skin feels hot and dry .This lasts from 2-6 hours.

**Sweating Stage**

The patient sweats profusely and temperature returns to normal. This stage lasts from 2-4 hours.

Classically the attacks occur every second day with the "tertian" parasites (*P. falciparum, P. vivax,* and *P. ovale*) and every third day with the "quartan" parasite (*P. malariae*). More commonly, the patient presents with a combination of symptoms of fever, chills, sweats, headaches, nausea, vomiting, body aches and general malaise. Physical findings may include elevated temperature, perspiration, weakness, enlarged spleen etc. In P. falciparum malaria, additional findings may include mild jaundice, enlargement of the liver and increased respiratory rate. Diagnosis of malaria depends on the demonstration of parasites on a blood smear examined under a microscope. In *P. falciparum* malaria, additional laboratory findings may include mild anemia, mild decrease in blood platelets (thrombocytopenia), elevation of bilirubin, elevation of aminotransferases, albuminuria, and the presence of abnormal bodies in the urine (urinary casts").

(b) Severe Malaria

Severe malaria occurs when *P. falciparum* infections are complicated by serious organ failures or abnormalities in the patient's blood or metabolism. The manifestations of severe malaria include cerebral malaria, with abnormal behavior, impairment of consciousness, seizures, coma, or other neurologic abnormalities, severe anemia due to hemolysis, hemoglobinuria, pulmonary edema or acute respiratory distress syndrome (ARDS), which may occur even after the parasite counts have decreased in response to treatment, abnormalities in blood coagulation and thrombocytopenia, cardiovascular collapse and shock.

**Relapse**

In cases of *P. vivax* and *P. ovale* infections, recurrent attacks could be due to re-activation of hypnozoites in the liver. This can occur any time after 30-180 days of the primary attack. The relapses have the characteristic symptoms of malaria. Splenomegaly may be a prominent feature in these patients. Such long-term relapses commonly occur in patients who have either not taken primaquine or taken incomplete treatment.

**Recrudescence**

In *P. falciparum* and *P. malariae* infections, the parasites can remain in the blood for months or even years and cause recurrent symptoms from time to time. In falciparum malaria, such recrudescence can occur within 28 days of the primary attack and may indicate partial resistance to chloroquine. However, treating every case of recurrent *P. falciparum* as resistant malaria is unjustified. One should consider the possibility of re-infection in most of these cases.

**Diagnosis**

Peripheral smear examination for malarial parasite is the gold-standard in confirming the diagnosis of malaria. Thick and thin smears prepared from the peripheral blood are used for the purpose. The thick smear of correct thickness is the one through which newsprint is barely visible. Thick smears are used to detect infection, and to estimate parasite concentration. Thin film examination is the gold standard in diagnosis of malarial infection.

The QBC Test, developed by Becton and Dickenson Inc., is a new method for identifying the malarial parasite in the peripheral blood. It involves staining of the centrifuged and compressed red cell layer with acridine orange and its examination under UV light source. It is faster and easier.

The other tests include Para Sight F test, OptiMal Assay, the immuno chromatographic test (ICT Malaria P.f. test), Polymerase Chain Reaction, detection of antibodies by Radio immuno assay, immunofluorescence or enzyme immuno assay.

Rapid Diagnosis of Malaria (Dipstick Test)

The immunochromatographic tests for the detection of malaria antigens, developed in the past decade, have opened a new and exciting avenue in malaria diagnosis. However, their role in the management and control of malaria appears to be limited at present. Immunochromatographic tests are based on the capture of the parasite antigens from the peripheral blood using either monoclonal or polyclonal antibodies against the parasite antigen targets. Currently, immunochromatographic tests can target the histidine-rich protein 2 of *P. falciparum,* a pan-malarial Plasmodium aldolase, and the parasite specific lactate dehydrogenase. These RDTs are kit based, much faster and need only little training. A potential problem with the dipstick test is that

the circulating antigen will be detectable for many days even after the elimination of viable *P. falciparum* from the blood stream. A positive test therefore may not always indicate an active infection. Species differentiation and quantification are also not possible.

### Prevention and Control Measures

The malaria prevention and control measures aimed at breaking the 'man-mosquito-man' cycle of transmission include a number of methods which are complimentary to each other. None of the measures will be successful if applied alone in any given environment. At the same time use of all of them together may not be feasible for technical or administrative reasons. Local environmental conditions, resources and feasibility will have to be studied before optimum measures may be implemented. A survey enables us to plan and organize antimalaria measures. In practice the majority of schemes will include all these measures in various grades. For the details of all malaria control measures interested readers are advised to refer to AO 27/2004/DGMS on prevention of malaria and other mosquito borne diseases.

### Personal Protective Measures

Individual personal protection against mosquito bites is achieved by use of mosquito nets, repellents and protective clothing. The feeding and resting habits of the vectors and the cultural practices and sleeping habits of people are important determinants of the efficacy of personal protective measures. These will be most effective when the vector is endophilic/endophagic and the people are protected during the active period of vector.

#### Mosquito Nets

The use of mosquito net is the most effective personal protective measure. Net should be put up before dusk and tucked all round under the bedding. They should always be maintained in a good state of repairs by patching holes and tears and not by stitching or knotting. Mosquito net inspection should be held regularly as a drill. Definite arrangements should be made to fix the nets in barracks, huts and tents. Mosquito nets should be used in all cases of clinical/slide positive malaria cases admitted in the hospital to prevent transmission.

For making the mosquito nets more effective, the nets are now being treated/medicated with synthetic pyrethroids like deltamethrin, cyfluthrin etc. These insecticide treated bednets (ITBN) provide an irritant and excitorepellent effect besides the contact action. An additional collateral benefit is also provided against pests like bed bugs, houseflies etc. These ITBN's can be used even if torn slightly. They prevent mosquitoes from entering from any hole or biting through the net, and kill any mosquito that comes in contact with the net. These nets can be used by pregnant women & small children. These nets are also effective against sand flies. Now pretreated mosquito nets (Long Lasting Insecticidal Nets-LLINs) are also available, with a shelf life of 5 years.

#### Repellents

Diethyl toluamide (DEET) is a repellent, which is reputed to be even better than DMP Di-methyl-phthalate. A new repellent DEPA (Diethyl phenyl acetamide), indigenously manufactured by DRDE, Gwalior, has been found to be at par with DEET in efficacy and spectrum, in the trials conducted at AFMC and in the field. DEET & DEPA have been found to be very effective when applied on uniform against all haematophagous arthropods as well as leeches Repellents are used to prevent biting in the early evening before people retire to bed or into houses .

#### Protective Clothing

The wearing of long trousers and shirts with rolled down sleeves after dusk should be enforced in all epidemic areas and when personnel move by rail or road. Added protection is given by wearing web anklets.

#### Screening of Houses and Barracks

This measure is effective only when all doors, windows and ventilators in the building are screened by wire mesh of proper gauge and size (1.2 to 1.5mm).

### Anti-larval Measures

Larval control is the only effective method of radical mosquito control. In urban areas, like cantonments, garrison stations and base areas, this method complements the adult mosquito control. Anti-larval work is carried out by preventing breeding and destruction of larvae and pupae. For long term and permanent mosquito control, greater emphasis should be placed on the prevention of breeding during non-transmission season than on larvicidal measures during breeding season.

#### Vector Engineering

Avoidance of man-made mosquitogenic conditions is of primary importance. A positive aspect of mosquito breeding prevention should be kept in view and deliberately incorporated in the planning and execution of all engineering constructions and town planning schemes like River valley projects, dams and barrage constructions, road and railways constructions and irrigation systems. Drainage in water supply projects may lead to mosquitogenic conditions. Besides these, indiscriminate digging, disposal of discarded tins, containers and water collections, overhead storage tanks and septic tanks without covers are potential mosquito breeding places in urban areas. Clean edging and water deweeding, channelling, filling or draining, exposing to sunlight, shading or covering are the usual methods adopted. Underground drainage constitutes the best method of bio-engineering method for control of mosquito breeding.

#### Dry Day

Intermittent drying once a week is an effective method of prevention of breeding. This principle is applied for the control of breeding in irrigated areas and also in domestic breeding places by observance of a weekly 'dry day'. It should fall on the day when the anti-mosquito staff is due to visit that area for anti-larval work. All fire fighting tanks, ornamental ponds or water storage tanks, water coolers, fire buckets, and all domestic water containers should be emptied and allowed to remain dry for a few hours on the weekly 'dry day'.

### Larviciding and Biological control

Larval control with chemical or biological agents is relevant as the sole method of vector control only if a high proportion of breeding sites within mosquito flight range of the community to be protected can be located and are accessible, and the breeding sites are of manageable size.

### Insecticides

Use of organochlorine insecticides as contact and oral poisons to mosquito larvae has been stopped due to emergence of a genotype of resistance. Organophosphorus compounds like Temephos (Abate), Fenthion (available as Baytex liquid and Baytex granules), Pirimiphos methyl and Dursban are being used as larvicides in some countries. The Insect Growth Regulators (IGR's); the Chitin Synthesis Inhibitors and the Juvenile Hormone Mimics are the safer alternatives available for larval control.

### Biological Control

Various predators, parasites and pathogens have been trial evaluated for mosquito control. Larvivorous fishes like Gambusia affinis, Poecelia reticulata and Aplocheilus lineatus have been found effective and are being used for larval control in India. There use could complement other methods in an integrated control approach to increase an impact on vector population.

The other promising & effective agents are the biocides, Bacillus thuringiensis var israelensis and Bacillus sphaericus. These biocides are spore producing bacteria and when ingested they kill the mosquito larvae by causing internal lysis of gut due to the action of delta endotoxin. Floating layer of polystyrene beads prevent mosquito breeding for long periods when used in confined sites such as cesspits and water tanks.They may be used effectively against *An. stephensi , Ae. Aegypti* and *Culex quinquefasciatus.*

## Anti-adult Measures

### Indoor residual spraying

The principle of malaria control by intercepting its transmission, by shortening the life span of the vector species to a period shorter than the extrinsic incubation period of the parasite, has come to be established. This principle has been successfully employed by the application of residual insecticides to the resting places of mosquitoes, viz. the inside of all the walls of habitations. For the limited objective of disease control it is not necessary to carry out the work throughout the year or in the entire territory but only in houses and shelters in endemic zones during the transmission season. However, there are certain conditions under which the absolute efficacy of this procedure may be doubted, for instance, where vector is exophilic or though biting indoors it does not rest indoors, or where the surfaces sprayed are subject to frequent mud plastering or white washing. Even when local conditions do not appear to be absolutely favorable, the application of residual insecticide gives relative success in disease control. DDT, Malathion and the members of synthetic pyrethroids like cyfluthrin, deltamethrin etc are the residual insecticides of choice depending upon the susceptibility of the vectors. At least 85% of the dwelling units should be covered for effective control. Residual spray is of limited value where the vector species are exophilic. To select an insecticide one must consider its residual effectiveness, safety/toxicity, vector susceptibility, its impact on disease incidence, cost effectiveness, resistance status and consumer acceptability.

### Space Sprays

Space spraying of insecticides can be used against adult mosquitoes. Pyrethrum in the strength of 0.1 percent is an excellent space spray. It is used mainly when an uncontrolled, unknown or infected area has to be occupied at a short notice or when an unforeseen epidemic breaks out. Space spraying carried out more often results in better mosquito control. Aerosols are also used as space insecticides under emergency conditions in small enclosed places. In some areas spraying of organophosphorus compounds such as Malathion by ground generated fogs and aerial ultra low volume (ULV) application has been tried with varying results. The spraying operation should be timed to coincide with the peak activities of the vectors. The operational costs are high and the residual effect is low. Thus, it may be more relevant in urban areas where large numbers of people congregate outdoors at night or during epidemics to contain transmission.

### Genetic Control

The control of adult mosquitoes by means of 'Sterile Male Release' (SMR) technique and other genetic methods such as cytoplasmic incompatibility, chromosomal translocations, sex distortion and gene replacement have been attempted in the past. However, all these methods have still to prove their worth and utility in the field. The scope of recombinant DNA technology is immense and research is being carried out to use this tool for vector control.

### Insecticide Resistance in Malaria Vector

Insecticide resistance has been commonly recorded by laboratory tests in many malaria vector populations throughout the world. Resistance can be due either to detoxification of insecticide by enzymes or by mutation on its target site: sodium channels for DDT and pyrethroids (kdr), and acetyl-cholinesterase for organophosphates and carbamates. It is considered that the most practical approach to resistance management in residual spraying programmes is the rotation of unrelated insecticides according to a pre-arranged plan or the switching of insecticides in response to the results of resistance tests. The use of mixtures of unrelated insecticides or treatment of different parts of a net with different insecticides is thought to be promising. The combination of two safe and effective insecticides on the same net offers great potential.

## Environmental Management

Environmental management approaches to vector control aim at modifying the environment to deprive the target vector population of its requirements for breeding,

resting and feeding purposes. This reduces human-vector contact and renders conditions less conducive for disease transmission. These include periodic flushing in streams by means of small dams with siphons and sluice gates, changing the salinity of breeding habitats of *A. Sundaicus* , the location of housing to avoid proximity to major breeding sites, intermittent irrigation, proper lining and shaping of irrigation canals etc.

#### Chemoprophylaxis

Chemoprophylaxis is a valuable supplementary measure under high risk situations, but not a substitute for other control measures. It reduces clinical attacks by suppressing the schizogony. Extent of suppression depends upon the virulence of the local strain, the state of herd premunition, the density of infected mosquitoes and the sporozoites introduced per infected mosquito bite. These are high at the height of the malaria transmission season. Chemoprophylaxis is begun one week before entering a malarious area and is continued until four weeks after leaving it.

#### Early Case Detection and Chemotherapy

In all cases of fever reporting to MIRoom /hospital malaria has to be kept as a provisional diagnosis. A peripheral blood smear will be taken in all fever cases and presumptive treatment given as per the drug policy.In case of a positive slide report, radical treatment will be instituted.

Armed Forces Policy on chemoprophylaxis and chemotherapy is given in the DGAFMS Medical Memorandum No. 81.

#### Malaria Vaccine

Significant progress has been made in the development of the malaria vaccine during the last 20 years. An ideal malaria vaccine is one that would prevent the infection at the first instance and if this is not possible, should decrease the intensity of infection and should be successful in preventing malaria transmission. The most well identified difficulty in vaccine research is the rapid alteration in its antigenic determinants. Vaccines based on a single antigen have a limited role to play in malaria because not all people respond to the same antigen. Further plasmodia can create antigen variants to elude immune system surveillance. So efforts have been directed to develop multi-stage, multi-component vaccine, incorporating multi-antigenic sequences from different asexual and sexual stages of plasmodia. About nine different malaria antigens have been identified so far, which may not be the end of the road (Table - 3).

### Malaria Control in the Armed Forces - Basic Principles

Malaria control measures in civilian or military life, in peace or war, in garrison stations or operational areas are based on the same scientific principles. Circumstances, however, may require emphasis on a particular control measure to be employed and its implementation, which should be suitable to the specific requirement of the particular area occupied. Medical Officers are advised to refer to the detailed Army Order on Prevention and Control of Malaria and other mosquito Borne Diseases.

In garrison peace stations and cantonments, long term mosquito control should be carried out by prevention of breeding through permanent engineering anti-mosquito methods and by application of other anti-larval measures; use of residual insecticides should be the second line of defence. Personal protection by the use of a mosquito net or repellents may be needed for greater safety. In the endemic areas, in base camps, at command zones and in static formations, greater emphasis and reliance should

Table - 3 : Classification of Malaria Vaccines

| Stage of Plasmodium | Antigens | Salient features |
|---|---|---|
| Pre-erythnocytic infection of abort an | Irradiated sporozoites, Circum Sporozoite Protein (CSP) or peptides, Liver stage | Stage/species specific; antibody blocks liver; large immunising dose required; can infection |
| Merozoite and Erythrocytes thus | Antigens -1 (LSA-1) Erythrocyte Binding Antigen (EBA-175), Merozoite Surface Antigen 1&2 (MSA-1&2); Ring Infected Erythrocyte Surface Antigen (RESA); Serine Repeat Antigen (SERA); Rhoptry Associated Protein (RAP); Histidine | Specific for species and stage; Cannot abort an infection; Prevents invasion of erythrocytes, reducing severity of infection |
| Gametocytes & gametes this maturation in | Rich Protein (HRP); Apical Membrane Antigen-1 (APM-1) Pfs 25, 48/45k, Pfs 230 | Prevents infection of mosquitoes; antibody to antigen prevents either fertilization or of gametocytes, zygotes or ookinetes; is of use endemic areas but not suited for travelers; antibody blocks transmission cycle |

be placed on anti-adult measures by residual insecticide spraying, anti larval measures and personal protection against mosquito bites. In order to achieve perfect safety the surroundings villages should also be included in the insecticidal spraying programme. Close collaboration and in certain cases, integration of anti-malaria scheme with the local civil anti malaria organization is essential. Their representative should be co-opted on the 'Station Health and Anti-malaria Committee.

In operational areas, personal protection by the use of mosquito nets gives maximum protection, provided its use is not hampered by intolerable heat, rain, night air attacks and other unfavourable conditions. Repellents are useful under high risk situations. Residual insecticidal spraying carried out with good organization and efforts keeps malaria incidence very low even in the operational areas.

**Chemoprophylaxis (Suppressive Treatment)**

Chemoprophylaxis is indicated only when there is a high degree of malaria risk in an area. The regime consists of a 4 aminoquinoline drug like chloroquin sulphate 300 mg or amodiaquin 400 mg given on a fixed day of the week at a formal parade under the supervision of an officer, JCO or an NCO. The treatment will be instituted under the orders of the GOC-in-C Command on the advice of his DDMS. Some of the situations under which chemoprophylaxis may be recommended are as follows:

(a) When troops are about to enter an operational area in which malaria risk at the time of entry is high.

(b) When troops in occupation of an area liable to high seasonal malaria incidence have to remain in that area during the whole or part of the malaria season

(c) When personnel in malarious areas, already on suppressive treatment, are proceeding on temporary duty/annual leave to stations in non-malarious areas.

(d) When personnel from non-malarious area are proceeding on temporary duty to stations in malarious areas where suppressive treatment is already in force.

(e) Personnel or body of troops, not on suppressive treatment, when moving out on exercise/training in uncontrolled area where there is risk of contracting malaria.

(f) At the termination of malaria season or on withdrawal of troops from a malarious area to a non-endemic area, suppressive treatment will be stopped and one time radical treatment consisting of 600 mg of chloroquin and 45 mg of primaquin will be given under strict medical supervision. Break through cases, if any will be given radical treatment for 5 days (Army Order 25/S/71, 6/79 and 27/2004/DGMS on Prevention and Control of Malaria and other mosquito borne diseases).

A camp site which affords little chance to mosquitoes for breeding and biting should be selected for occupation in operational and training areas. If tactical reasons demand siting of camps in malarious areas, the least dangerous site should be selected. The camp or its sectors should be at least one and a half km away from habitation and from any collections of water likely to breed vector species. The camp should preferably be on high ground and the direction of the prevailing wind should not be from the village or breeding places. Troop movements towards villages from dusk to dawn should be forbidden. For deciding on a suitable camp site, antimalaria measures, and for subsequently assessing the success of such measures, an investigation into the local malaria risk is necessary.

**Immediate Measures in Case of a Focal Outbreak**

Malaria often presents as a focal outbreak in one or more of the units, whether in peace or field areas. All medical officers must keep themselves well prepared to promptly undertake control measures in such situations. Equally important is to have, in place, an efficient surveillance system to keep a track of cases of malaria / fever so as to have an early warning of increase in incidence. Prompt investigations and control measures should be applied at the earliest indication of an increase in incidence rather than waiting for the full fledged epidemic to evolve. The surveillance should be at all levels by RMOs, OC ADS, SMOs / SEMOs, CO Hospital, and at Fmn HQs by Specialists in Preventive & Soc Medicine. The following steps should be quickly undertaken in the event of an impending outbreak or if a focal outbreak has occurred :

(a) Define the population (subunit / unit/ Garrison / Station) which forms a part of the epidemic so that concerted efforts can be focused to this population / area.

(b) Quick survey, preferably a total population survey

**Measures for Prevention and Control of Malaria**

**(a) Personal protective measures**
- (i) Use of mosquito nets ITBNs and LLINs
- (ii) Use of repellents DEET, DEPA, etc.
- (iii) Protective clothing
- (iv) Screening of houses and barracks

**(b) Anti - larval measures**
- (i) Vector Engineering
- (ii) Dry Day
- (iii) Use of Insecticides
- (iv) Biological Control

**(c) Anti - Adult measures**
- (i) Indoor Residual Spray
- (ii) Space Spray
- (iii) Genetic Control

**(d) Environmental management including source reduction**

**(e) Chemoprophylaxis**

**(f) Early Case Detection and Chemotherapy**

**(g) Outbreak control measures**

or at least a fever survey, taking blood slides of the total population / of fever cases, along with a rapid clinical examination. This survey should be completed within 7 to 10 days and definitely within 15 days.

(c) For all cases of fever, a blood slide must be taken and presumptive treatment with oral chloroquin to be given. Cases positive on PBS to be admitted for radical treatment.

(d) Cases of fever not responding to routine treatment within 48 hours (irrespective of whether blood slide is positive or negative) to be admitted to the military hospital / ADS for management.

(e) Mass Radical Treatment can be considered if large number of troops are being affected or the epidemic is evolving very rapidly, by the fmn cdr, depending on the assessment of situation / advise of Sr Advisor in Preventive & Social Medicine at Fmn HQ.

(f) Outdoor thermal fogging with malathion 95% technical or deltamethrin 1.25% ULV will be undertaken to decrease the adult population at dusk and dawn as an immediate measure. The residents will be advised to open all doors and windows while the operation is in progress. Fogging machine may be mounted on a motorcycle or small vehicle running at a speed of not more than 6Km/hr. Fogging machines may be procured/ kept servicable from local resources in advance before beginning of malaria season.

(g) Space spray with 0.1% pyrethrum solution at dusk, in all living areas (units, barracks) as well as in offices where night duty personnel are staying, for the next 15 days or till epidemic starts declining, which ever is later.

(h) Residual insecticide spray (usually Malathion 50%) on the inner surfaces of all tents / living-in barracks, as a special round, irrespective of the earlier rounds already conducted.

(j) Strict enforcement of antimalaria discipline: Proper clothing, keeping exposed body area to the minimum.

(k) Enforcing 100% use of mosquito nets by troops while sleeping, unless operationally impossible.

(l) Ensuring that all troops, while outdoors, from dusk to dawn, apply repellants (Odomos / DEET/DEPA/ Mosfree) on exposed body parts.

(m) Quick and detailed search for mosquito breeding spots in and within one Kilometre around the affected area and coverage of all areas with Fenthion / Temephos (for potable water) within the next 15 days. Simultaneously, mosquito surveillance activities to be started.

(n) Impregnation of mosquito nets with Deltamethrin / Cyfluthrin.

(o) For troops deployed outdoors, the following measures can be tried :-

(i) Cloth patches impregnated with deltamethrin, stuck to uniforms with a Velcro, around the collar, around the jungle hat, sleeves and lower ends of trousers.

(ii) Impregnation of camouflage nets (often used at sentry posts) with Deltamethrin / cyfluthrin.

(p) Ongoing monitoring of the incidence, while the control measures are being enforced, and thereafter.

Several of the measures enumerated above will be instituted together for immediate control of an outbreak. Finally, the success of all measures depends upon the discipline and cooperation of all ranks and a well-organized execution of all measures. Discipline depends mainly on training. Well trained and disciplined troops have a lower incidence of malaria than ill trained and indisciplined personnel. Training in the prevention and control of malaria should be an essential part of all 'training for war'. All ranks must receive frequent practical demonstrations in the correct method of using a mosquito net, protective use of clothing and application of insect repellent. Unit spraying squads must be drilled in the proper method of spraying in barracks, tents, bashas, bunkers and bivouaces. Spraying equipment must be used properly and always maintained in working condition; the squad must be adequately trained to do this. Commanders should be constantly advised in the principles of camp selection and siting, anti-malaria measures and discipline. Full cooperation of all ranks will not be obtained unless officers and men realize the seriousness of the malaria menace to war efforts, if it breaks out among troops; and the importance and the

**Outbreak Control Measures**

(a) Define the population at risk.

(b) Disease Management - A rapid fever survey and presumptive treatment of all fever cases in the affected area.

(c) Reduction of transmission through vector control

(i) Outdoor Thermal Fogging

(ii) Indoor Knockdown Space Spray

(iii) An additional round of Indoor Residual Spray

(iv) Larviciding and abolition of all breeding spots in 1 Km area around affected place.

(d) Strict enforcement of anti malaria discipline

(e) Impregnation of mosquito nets, cloth patches, Camouflage nets etc.

(f) Consider mass radical treatment

(g) Consider chaemoprophylaxis for high risk groups like pregnant women and non-immune people

(h) Educate the environment at all levels.

(j) Ongoing monitoring of incidence and control measures

necessity of prevention of its occurrence under the present unbalanced state of malaria eradication in our country.

**Anti-malaria Organization in The Armed Forces**

(a) In cantonments and garrisons the Station Commander, under the advice of the SEMO, is responsible for the initiation and execution of all control measures, broadly based upon the current formation orders and instructions in collaboration with the Station Health Committee.

(b) This committee scrutinizes the proposed anti-malaria measures, notes the progress of the campaign and remedies any observed defects, in the months prior to the beginning of the malaria season and in the month preceding the one in which malaria incidence is usually at its maximum. It reviews the results of the anti-malaria measures and formulates a tentative scheme for the following year in the month after the termination of the malaria season.

(c) Officers commanding the units are responsible for all anti-malaria measures within their units and in the adjoining area placed under their charge.

(d) Every unit has an anti-malaria squad under the supervision of the trained regimental anti-malaria officer.

(e) In operational areas the formation Commander may call similar meetings of unit commanders and representatives of the medical and engineering services to discuss similar subjects whenever necessary.

(f) Technical medical staff officers (DADH/ADH) and the officers Commanding Station and Field Health Organization assist the Commanders in planning control measures, advise unit commanders, maintain scrutiny regarding anti-malaria measures within their respective zones, and co-ordinate control in different sectors of the station or area into a closely integrated scheme.

(g) The station, camp, base or comn zone and its periphery for 1 km in depth is divided into a number of circles depending upon the size of the station or area and the degree of prevailing malaria. Each is further sub-divided into five zones, each of which is capable of being treated on one working day by the available labour gang or unit squad.

(h) In endemic areas the following records should be maintained by units/formations:

(i) A chronological diary showing the principal events in the malaria season, the programme and progress of anti-malaria work, meetings held, state of equipment, initiation and termination of anti-larval measures and of spraying campaign, initial determination and periodical check of spleen and parasite rates in villages.

(ii) Weekly meteorological records correlating the number of adult anophelines (by species) caught per collection in any catching stations ear marked, incidence of malaria cases by units and sub units.

(iii) The records regarding the dates, dosage and number of rooms, houses, huts and tents treated with insecticide.

(iv) A large scale map of the area showing temporary or permanent (potential and actual) breeding places and a unit spot map showing each case by barracks and quarters for indicating the effectiveness of control measures.

(v) Malaria case register showing the personal, clinical and epidemiological particulars of each case with columns showing number rank, unit/sub unit, date of onset of fever, date of admission to hospital, date of positive microscopic diagnosis; the species of Plasmodium, relapse or fresh; if relapse the previous dates of fever or hospital admission for malaria, movements during the previous three months to determine the probable place of infection and whether the transmission is local or the case is imported from another locality, indication of the personal

# Leishmaniasis

## Introduction

Leishmaniasis encompasses a varied collection of diseases ranging in severity from a spontaneously healing skin ulcer to overwhelming visceral disease (1). The disease is named after Leishman, who first identified the organisms in smears taken from an man who had died of "Dum Dum" fever in 1901 (2) An estimated two million cases of all forms of Leishmaniasis taken together occur worldwide very year (3, 4). The disease is caused by 21 species of the genus Leishmania which are pathogenic to humans and transmitted by the bite of 30 species of the phlebotomine sandfly (3, 4, ). There are four main types of the disease: Cutaneous, Diffuse cutaneous, Mucocutaneous and Visceral Leishmaniasis which is commonly called Kala azar (3). Leishmania species are members of the family Trypanosomatidae, order Kinetoplastida. They reside as intracellular amastigotes within macrophages in mammals and as extracellular promastigotes in the gut of their insect vectors, phlebotomine sand flies (5). Leishmaniasis has also emerged as an AIDS - associated opportunistic infection (6).

## Epidemiology

World

Leishmaniasis is endemic in 88 countries on five continents. More than 90% of Cutaneous Leishmaniasis cases occur in Iran, Afghanistan, Syria, Saudi Arabia, Brazil and Peru. More than 90% of Visceral Leishmaniasis cases occur in Bangladesh, Brazil, India and Sudan. The World Health Organization estimates that 350 million people are at risk of Leishmaniasis world wide. The true incidence and prevalence are uncertain because of the large number of undiagnosed cases, the lack of screening, and underreporting (7-9). Every year, an estimated one and a half to two million children and adults develop symptomatic disease and the incidence of infection is substantial when sub - clinical infections are included. The number of new cases of Cutaneous Leishmaniasis each year in the world is estimated to be about 1.5 million while the number of new cases of Visceral Leishmaniasis is estimated to be about 5,00,000. An estimated 12 million people are presently infected worldwide. Leishmaniasis is associated with about 2.4 million disability - adjusted life years and around 7,00,000 deaths per year (7-9). Since 1993, the geographical distribution of Leishmaniasis has expanded significantly.

The disease is endemic in three countries of the WHO South East Asia Region, Bangladesh, India and Nepal. Approximately 200 million people in the Region are "at risk" from the disease. The disease is reported in 45 districts in Bangladesh, 52 in India and 12 in Nepal. Of the estimated 5,00,000 people in the world infected each year, nearly 1,00,000 are estimated to occur in the Region (10).

India

India is one of the world's largest foci of Visceral Leishmaniasis, accounting for 50% of the total burden of this disease. Leishmaniasis is endemic in eastern States of India. A total of 52 districts in the country are considered endemic for the disease. An estimated 165. 4 million population is at risk of Kala Azar in four states. In India, about 1,00,000 cases of Visceral Leishmaniasis are estimated to occur annually. Of these, the State of Bihar accounts for more than 90 per cent of the cases. Cutaneous Leishmaniasis usually occurs in the dry, north eastern states of India, bordering Pakistan extending from Amritsar to Kutch and Gujrat plains. Cases of Anthroponotic Cutaneous Leishmaniasis has been reported from Bikaner city (10, 11).

## Agent

The disease is caused by 21 protozoan species of the genus Leishmania (order Kinetoplastida). The amstigote forms are obligate intracellular parasites while the promastigotes are extracellular in the arthropod vectors.

These human pathogens include the *Leishmania donovani* complex with three species (*Leishmania donovani, Leishmania infantum* and *Leishmania chagasi*). The *Leishmania mexicana* complex has three main species which are *Leishmania mexicana, Leishmania amazonensis* and *Leishmania venezuelensis.* The other major pathogenic species are *Leishmania tropica, Leishmania major* and *Leishmania aethiopica.* The different species are morphologically indistinguishable, but they can be differentiated by isoenzyme analysis, molecular methods, or monoclonal antibodies. In India, *Leishmania donovani* is the only parasite causing this disease.

The life cycle is relatively simple. Amastigotes are oval or round in shape and approximately 2 to 3 µm in diameter. They have a large, eccentrically located nucleus, a specialized mitochondrial structure, the kinetoplast, which contains a substantial amount of extranuclear DNA and a flagellar pocket and flagellum, which lie within the confines of the cell. They multiply by simple binary division. In the gut of the sand fly, leishmania live and multiply as extracellular, flagellated promastigotes that vary morphologically from short, stumpy forms to elongated ones ranging from 10 to 15 µm in length and 2 to 3 µm in diameter. A single flagellum extends from the anterior pole. After development in the sand fly gut, which takes approximately 1 or 2 weeks depending on the Leishmania species, infectious metacyclic promastigotes migrate to the proboscis (5, 12, 13).

Vector

Leishmania species are transmitted by female sand flies of the genus Lutzomyia in the Americas and Phlebotomus in other parts of the world. Depending on the species, sand flies live in forested areas, rodent burrows, or debris in peri - domestic habitats. Sandflies breed in cracks and crevices in the soil and buildings, tree holes, caves. They are weak fliers, but they can be carried considerable distances by the wind. Sand flies probe

with their proboscis to form a venous pool, from which they obtain blood by capillary action (5, 14, 15). A total of about 30 species in Phlebotomus genus (old world) and Lutzomyia genus (new world) have been identified as vectors. Sandflies are active in the evening and night - time hours. In India, *P. argentipes* is a proven vector of Kalazar. Cutaneous Leishmaniasis is transmitted by *P. papatasi* and *P. sergenti.*

Host Factors

Most leishmaniases are zoonotic and humans become infected only when accidentally exposed to the natural transmission cycle. The animal host may be wild animals, such as rodents, and domestic animals, such as dogs. However, in the anthroponotic forms humans are the sole reservoir host. Indian Kala - azar is anthroponotic with humans beings as the only known reservoir of infection.

Infection can occur in all age groups and both genders. In India peak age of infection is 5 to 9 years. Males are affected more often than females probably due to greater exposure. Population movement is important in spreading infection between endemic and non endemic regions. The disease usually strikes the poorest of the poor (10, 16, 17). It is common in various farming practices, forestry, mining and fishing who have greater risk of being bitten by sand - flies. Recovery from kala - azar gives a lasting immunity.

Environmental Factors

The disease is mostly confined to the plains. It does not occur in altitudes over 2000 feet. Prevalence usually shows a rise during and after rains. The diseases are largely confined to rural areas and those urban areas where opportunities for breeding of sand flies exist. Overcrowding, poor ventilation and accumulation of organic matter in the environment facilitates transmission. Developmental projects like forest cleaning, and cultivation projects, large water resources schemes, and colonization and resettlement programmes are bringing human beings into areas of high vector and reservoir concentration (5, 18).

Mode of Transmission

The disease is transmitted by the bite of infected female sandflies. Rarely other modes of transmission might result in infection. Visceral Leishmaniasis can be directly initiated by amastigotes via blood (shared needles, transfusion, transplacental spread) or organ transplantation. Cutaneous infection can develop after inadvertent needlestick injury if the needle or syringe contains infected material (6, 12-14).

Clinical features

The outcome of leishmanial infection is dependent on a series of complex and only partially understood interactions between Leishmania species - specific virulence factors and the genetically determined cell - mediated immune responses of their mammalian hosts. The incubation in man is extremely variable. It usually ranges from 3 to 8 months but can be as short as 10 days to as long as2 years

Leishmaniasis has several diverse clinical manifestations: ulcerative skin lesions, destructive mucosal inflammation, and disseminated visceral infection (kala azar). Epidemiology, immunopathology, and outcome are similarly diverse, since infection occurs in multiple endemic regions, in both children and adults, and is caused by nearly two - dozen distinct Leishmania species. Nevertheless, all forms of this protozoal infection share three pathogenetic features: resident tissue macrophages are targeted and support intracellular parasite replication; the host immunoinflammatory response regulates expression and outcome of disease; and persistent tissue infection is characteristic (6, 12, 13). Each of the three major clinical syndromes can present with a wide spectrum of findings. Each of these syndromes is associated with more than one Leishmania species, and any given species is capable of producing more than one syndrome. Variations are common, particularly among people who are concurrently infected with HIV or other immunosuppressive illness (5, 12, 13).

Cutaneous Leishmaniasis (5, 12)

The typical lesion of Cutaneous Leishmaniasis develops at the site where promastigotes are injected by the vector. Promastigotes are taken up by mononuclear phagocytes. They transform to amastigotes and multiply within the macrophages. A papule is formed at the site of inoculation. The papule enlarges and then ulcerates. Multiple lesions may be present in the same patient. Depending on the location, Old World Cutaneous Leishmaniasis is known locally as Oriental sore, Bouton d'Orient, Bouton de Crete, Bouton d'Alep, Bouton de Briska, Aleppo evil, Baghdad boil, and Delhi boil.

There can be marked variation in the appearance of the lesions. The classic wet lesion of *L. major* and *L. braziliensis* is "pizza - like" with a raised outer border, granulating base, and overlying white, purulent exudate. Infection by *L. tropica* produces dry lesions in the Middle East and India. The ulcer tends to be smaller and covered with a crust. Contiguous mucosal involvement may be seen in some patients. Some leishmanial lesions are papular or nodular, without ulceration. Cutaneous lesions persist for months, and in some cases years, before they heal, leaving flat, atrophic scars as evidence of disease. Once a lesion has resolved, the person is usually left with immunity against the infecting Leishmania species. Cutaneous Leishmaniasis should be considered in the differential diagnosis of subacute or chronic skin lesions in people who have lived, worked, or traveled in endemic areas.

Mucosal Leishmaniasis (Espundia)

A small proportion of people infected with *L. braziliensis* develop mucosal lesions in the nose, mouth, pharynx, or larynx months to years after resolution of the primary skin lesion. The condition is known as espundia in Latin America. Mucosal Leishmaniasis often begins with nasal stuffiness and inflammation. Ulceration of the nasal mucosa and septum follows. The lips, cheeks, soft palate, pharynx and larynx may eventually be involved, resulting in substantial disfigurement. Mucosal involvement is also observed with other Leishmania species, although the pathophysiology may be somewhat different. Destructive involvement of the nose and mouth has been reported with *L. tropica* in Saudi Arabia. Mucosal involvement has been reported rarely in immunocompetent people and more frequently in those who are immunosuppressed with neoplasms or AIDS (5, 12).

Visceral Leishmaniasis

The majority of infections of Visceral Leishmaniasis are sub clinical. Only a minority of those infected develop full - blown Visceral Leishmaniasis, or kala - azar. The disease is characterized by fever, weight loss, and hepatosplenomegaly.

Malnutrition, which is known to suppress cell - mediated immune responses and may contribute to progression to

symptomatic Visceral Leishmaniasis. The incubation is typically weeks to several months, but it may be as short as 10 days or as long as several years. The onset of Visceral Leishmaniasis is usually insidious, but it can be abrupt, with high fever. Full - blown, progressive Visceral Leishmaniasis, or kala - azar, is associated with fever, abdominal enlargement, weakness, loss of appetite, and weight loss. The clinical findings are similar with *L. donovani* and *L. infantum / chagasi.* Symptoms may be present for weeks to months before patients come to medical attention in rural, endemic areas. The fever pattern may be intermittent, remittent or rarely continuous. The spleen is firm, non - tender, and over time becomes massively enlarged. There is hepatomegaly with the enlarged liver having a sharp edge and smooth consistency. Some patients in India develop hyperpigmentation leading to the name kala - azar, which means "black fever" in Sanskrit. The late stages of disease are characterized by malnutrition, severe wasting, and progressive debilitation. Stunting may be seen in children. Death often occurs due to a secondary bacterial infection, such as pneumonia, septicemia, dysentery, or tuberculosis, or with measles or other viral infection.

Laboratory findings include anemia, neutropenia, thrombocytopenia & pronounced hypergammaglobulinemia. The anemia is usually normocytic, normochromic, unless there is concomitant iron deficiency. Leukopenia can be profound with white blood cell counts below 1000/mL. The globulin level can reach 9 or 10 g/dl.

Post - Kala - Azar Dermal Leishmaniasis.

Some patients of Visceral Leishmaniasis in India and Africa develop skin lesions following treatment, ranging from hyperpigmented macules to frank nodules. Skin lesions typically appear in India 1 or 2 years after treatment and may persist for as long as 20 years. Persistence of lesions beyond one year is associated with high anti - leishmanial antibody titers and negative leishmanial skin test responses. Anti - leishmanial treatment is indicated in Indian post - kala azar dermal Leishmaniasis. In a few instances in India, Visceral Leishmaniasis has recurred in patients with post - kala - azar dermal Leishmaniasis. The differential diagnosis includes leprosy (5, 12, 13).

HIV - Visceral Leishmaniasis co - infection

Leishmania with HIV co - infection is has emerged as a serious new disease and is increasingly frequently being reported. Immunocompromised individuals progess to full blown Visceral Leishmaniasis far more often than immunocompetent people who get infected. AIDS and Visceral Leishmaniasis are mutually reinforcing. Visceral Leishmaniasis quickly accelerates the onset of AIDS and shortens the life expectancy of HIV - infected people. Similarly AIDS increases the risk of Visceral Leishmaniasis by 100 - 1000 times in endemic areas. This combination of HIV and Leishmaniasis produces cumulative deficiency of the immune response since Leishmania parasites and HIV destroy the same cells, exponentially increasing disease severity and consequences. Visceral Leishmaniasis is considered a major contributor to a fatal outcome HIV in co - infected patients. Another implication of this combination is that Leishmaniasis can be transmitted directly person to person through the sharing of needles, as is often the case among intravenous drug users (13, 19).

Diagnosis

Cases of Leishmaniasis should be confirmed by demonstration of the parasite, which is straightforward if parasites are plentiful as in Visceral Leishmaniasis but can be difficult otherwise.

Parasite Identification

The diagnosis of Leishmaniasis is most often confirmed by identifying leishmania amastigotes in Wright–Giemsa - stained touch preparations or tissue sections or by isolating the parasite in culture. Amastigotes are seen in macrophages in tissue sections, but they may appear to be extracellular in touch preparations. Leishmania can be grown as promastigotes in NNN medium, Schneider's insect medium, and other tissue culture media. The cultures are incubated at 24 to 26°C to approximate sand fly temperatures.

Serology

Antileishmanial antibody titers are typically present in high titer in people with Visceral Leishmaniasis and at low titer or undetectable in those with Cutaneous Leishmaniasis. They can be measured by a number of assays. Enzyme - linked immunosorbent assay (ELISA), indirect immunofluorescent tests, and agglutination assays have all been used (20)

Skin Test

The intradermal leishmanin (Montenegro) skin test is positive in the majority of people who have asymptomatic, self resolving *L. donovani* and *L. infantum / chagasi* infections and in people with Cutaneous or Mucosal Leishmaniasis. The skin test is negative in people with progressive Visceral Leishmaniasis or Diffuse Cutaneous Leishmaniasis, but it becomes positive in the majority of people who are successfully treated for Visceral Leishmaniasis.

Treatment

The drug of choice for the treatment of Visceral Leishmaniasis is Sodium stibogluconate, a pentavalent antimonial compound except in regions that are considered Sodium stibogluconate unresponsive. The dose is 20 mg Sb/kg/day IV or IM daily for 20 - 30 days. However, resistance is on the rise and resistance levels as high as 43% have been reported from Bihar where Visceral Leishmaniasis is endemic. Patients resistant to stibogluconate should be treated with alternative agents, such as liposomal amphotericin (0.5 - 3 mg/kg) on alternate days or pentamidine (2 - 4 mg/kg) on alternate days for 15 doses. Amphotericin B deoxycholate is the drug of choice in India, whereas the lipid formulation liposomal amphotericin is used in Europe (2). The dose of Amphotericin B used in India is 1mg/kg IV infusion daily or alternate day for 15 - 20 infusions. The dose can be increased in patients with incomplete response with 30 injections. Miltefosine, the first effective oral treatment for Visceral Leishmaniasis, including for antimony - resistant infection has been approved for self - administered outpatient therapy (13, 21, 22). The drug is to be used in a dose of 100 mg daily for four weeks. Supportive treatment includes rest, high - calorie diet, blood transfusions, and treatment of secondary infections.

Prevention and Control

Leishmaniasis can be prevented by interrupting sand fly transmission or by removing or treating reservoirs of infection

(18, 23). The short - term visitor to an endemic area should use personal protective measures to avoid sand fly bites. Sand flies tend to bite from dusk to dawn. The application of DEET (diethyltoluamide) - containing insect repellents to exposed skin and under pant and shirt cuffs, the use of fine - mesh screens or insect nets, and the application of insecticide (usually permethrin or other pyrethroids) to clothing and bed nets–decrease the risk of transmission of Leishmaniasis. Further details on vector control are given in the chapter on Entomology.

Vaccine

There is experimental evidence to indicate that Leishmaniasis should be vaccine preventable. However, there is currently no vaccine against any form of Leishmaniasis for general human use. One major factor may be the lack of a conceived market for human Leishmaniasis vaccines. Leishmaniasis is a considered a local/regional problem and not a global one (24). A number of candidate vaccines are undergoing clinical trails. Killed parasites as vaccines produced encouraging results in Brazil in the 1970s. Trials have tested autoclaved *L. major* plus BCG versus adjuvant (BCG) alone. In Ecuador, two doses of a killed multi-leishmania species cocktail plus BCG reduced Cutaneous Leishmaniasis incidence by 73% the first year (13,25).

# Rickettsial Diseases

## Introduction

Rickettsial diseases are widely distributed throughout including large parts of the Indian subcontinent. As re-emerging diseases they represent some of the oldest and most recently recognized infectious diseases (1,2) Of the 14 currently recognized rickettsioses, six have been described within the last 12 years (1). Rickettsia are morphologically and biochemically similar to other Gramnegative bacteria. These obligate intracellular parasites are arthropod-associated bacteria, but they are also capable of infecting vertebrates, including humans, usually as accidental hosts (3). The geographic distribution of rickettsial diseases is largely determined by their vectors (4).

## General Considerations

### Bacteriology

Rickettsiae are a diverse collection of organisms with several differences. The common threads that hold the rickettsiae into a group are their epidemiology and their obligate intracellular lifestyle. Phylogenetically they occupy a position between bacteria and viruses. The genus Rickettsia is included in the bacterial tribe Rickettsiae, family Rickettsiaceae, and order Rickettsiales. They include the genera Rickettsiae, Ehrlichia, Orientia, and Coxiella. Rickettsia are small (0.3 X 2 µm) aerobic, obligate intracellular parasites. They are Pleomorphic, usually cocobacillary. They appear blue with Geimsa's stain and their growth is enhanced in the presence of sulphonamides.

### Host Factors

Groups at risk for exposure to agents of rickettsial diseases are travellers, wood cutters, farmers and army personnels as their occupational or recreational activities bring them in contact with habitats that support the vectors or animal reservoir species associated with these pathogens (5).

### Pathogenesis

Rickettsiae are transmitted to humans by the bite of infected ticks and mites and by the faeces of infected lice and fleas. The rickettsiae present in the dried excreta of insects may also enter through the conjunctivae or even through inhalation. After entering the body rickettsia spread through the bloodstream to infect vascular endothelium in the skin, brain, lungs, heart, kidneys, liver, gastrointestinal tract and other organs.

### Distribution

The geographic distribution, epidemiological and clinical aspects of rickettsial agents are described below in the Table - 1 and Table - 2.

## Epidemiologic Features of Rickettsial Diseases

Table - 1 : Epidemiologic Features of Rickettsial Diseases

| Antigenic group | Disease | Agent | Vector | Animal reservoir | Geographical distribution |
|---|---|---|---|---|---|
| Typhus fevers | Epidemic typhus | *Rickettsia prowazekii* | Human body louse *(Pediculus humanus corporis)* , | Humans, | Mountainous regions of Asia, and Central and South America, Africa India:J&K, Himachal, Uttarakhand,W Bengal, Arunachal Pradesh. |
| | Murine typhus | *R. typhi* | Rat flea *(Xenopsylla cheopis)* | Rats mice | Worldwide |
| Spotted fevers | Indian Tick Typhus | *R. conorii* | Tick *(Ixodes sp Boophilus sp Hemophysalis sp)* | Dogs, rodents | Africa, India, Europe, East, Mediterranean. India:Uttaranchal |
| | Rickettsial pox | *R. akari* | Mite | House mice | Russia, South Africa, Korea, Turkey, Balkan countries |
| | Rocky Mountain spotted fever | *R. rickettsii* | Tick | Rodents | Mexico, Central, and South America |
| Orientia | Scrub typhus | *Orientia tsutsugamush* | Mite *(L deliense)* | Rodents | Asia and Australia India: J&K, Himachal, Uttarakhand,W Bengal, Arunachal Pradesh |
| Coxiella | Q fever | *Coxiella burnetii* | Inhalation of infectious aerosols; tick | Goats, sheep, cattle, domestic cats. | Worldwide |
| Bartonella | Cat-scratch disease | *Bartonella henselae* | Cat flea | Domestic cats | Worldwide |
| | Trench fever | *B. quintana* | Human body louse | Humans | Worldwide |

Table - 2 : Clinical Features and Treatment of Rickettsial Diseases

| Disease | Predominant symptoms | Treatment | Incubation period | Vaccine | Weil Felix Reaction |
|---|---|---|---|---|---|
| Epidemic typhus | Headache, chills, fever, prostration, confusion, photophobia, vomiting, rash (generally starting on trunk) | Doxycycline 100mg BD for 7-10 days or till person is afebrile. Chloramphenicol 60-75mg/kg/day in 4 divided doses for pregnant women | 6 – 15 days | + | OX-19 |
| Murine typhus | As above, generally less severe | -do- | 8 – 16 days | - | OX-19 |
| Indian Tick Typhus | Fever, eschar, regional adenopathy, maculopapular rash on extremities | -do- Alternative-Ciprofloxacin | 5 – 10 days | - | OX-19 or OX-2 |
| Rocky Mountain spotted fever | Headache, fever, abdominal pain, macular rash progressing into Papular or petechial (starting on extremities) | -do- | 2 – 14-days | - | OX-19 or OX-2 |
| Scrub typhus | Fever, headache, sweating, conjunctival injection, adenopathy, eschar, rash, respiratory distress | Doxycycline 100mg BD. Rifampicin 600-900mg/day, Azithromycin and Ciprofloxacin are other alternatives | 6 – 21 days | - | OX-K |
| Q fever | Fever, headache, chills, sweating, pneumonia, hepatitis, endocarditis | Doxycycline. Rifampicin, Ciprofloxacin are other alternatives | Acute Q fever-3 -30 days | + | None |
| Trench fever | Fever, headache, pain in shins, splenomegaly, disseminated rash | Tetracyclines | - | - | None |

Epidemic Typhus

Epidemic typhus is the classical form of rickettsial disease. It is characterized by sub-acute onset, with fever interposed by rigors, accompanied by headache, nausea, giddiness, vomiting and flushed dry skin. On the third day, the temperature rapidly rises up to 40° C, face and eyes become suffused, headache and bodyache become severe, and the peculiar stuporose, drunken, confused and delirious state, similar to that found in enteric fever is seen. The patient has a foul smell and heavily coated tongue. The spleen is enlarged and haematuria and albuminuria occur. Blood pressure falls. Temperature remains high for 12-14 days. Rash occurs on 5th or 6th day. The case fatality varies widely and is influenced by the nutritional state and age of patient. In healthy, well fed young adults the case fatality is less than 5 percent. Diagnosis is confirmed by microscopic agglutination (MA), complement fixation (CF) and fluorescent antibody (FA) tests. About 30 million cases including 3 million deaths occurred in the Soviet Union & Eastern Europe during 1918-1922. During World War II, typhus struck heavily in concentration camps in Eastern Europe and North America. No case has been reported in the Indian Armed Forces since 1970.

Mode of Transmission

Human body louse, *P. humanus corporis* transmits *R. prowazekii.* Rickettsiae multiply enormously intra cellularly in the midgut of the louse. Within 10 days, they rupture, releasing a large number of rickettsiae in the body fluid and in the insects faeces. The infection is transmitted by the entry of the infectious faeces, the gut contents, or the body fluid of the crushed louse through abrasion on the skin caused by simultaneous scratching. The rickettsiae present in the dried excreta of insects may also enter through the conjunctivae or even through inhalation. The infected lice remain infective throughout their remaining life. Usually they die in a week to 12 days.

Host

Man has no natural immunity; one clinical attack confers high immunity but not life long and a second attack may occur. All ages and sexes are susceptible. The immunity is type specific; therefore, an attack does not confer immunity against other rickettsial diseases.

Communicability Period

The case is infectious to the louse during the last two or three days of the incubation period, and throughout the febrile period, for a total of about 12 to 13 days.

Prevention and Control

A high standard of personal hygiene to prevent louse infestation, avoidance of contact with those likely to be infected with the

disease and infested with louse and preventive immunization are the important preventive measures.

**(a) Personal Hygiene**

In order to reduce the likelihood of troops getting infested a very high standard of personal hygiene should always be ensured. Louse infested areas should be put out of bounds to troops.

**(b) Delousing**

Treatment of louse infested individuals can be carried out by application of dust of 10% DDT, 1% malathion or 1% lindane powder, propoxur (1%) to the person as well as his clothing. Treatment can also be done with phenothrin dust 0. 3-0. 4%. Other lotion or shampoo formulations can also be applied for better results e. g. permethrin lotion (1. 0%), deltamethrin lotion (0. 03%) etc.

**(c) Immunization**

A formalin inactivated epidemic typhus vaccine prepared from rickettsia grown in embryonated eggs was used to protect troops during World War II. It is given in 2 subcutaneous injections of 1 ml each at an interval of 10 to 14 days. Booster doses are recommended every 6 months. A recent advancement is the development of a vaccine consisting of live attenuated strain 'E' rickettsial organisms. It has been tried extensively and appears to be effective when tested under field conditions. It is not yet available for general use.

Murine Typhus (Endemic Typhus)

It is an acute febrile illness caused by Rickettsia typhi and transmitted to humans by the rat flea *Xenopsylla cheopis*. The mode of transmission is by contamination of the broken skin by rickettsia-laden faeces, and dried flea faeces gaining entry through conjunctivae or the upper respiratory tract by aerosol. Complement fixing antibodies against murine typhus have recently been detected in paired sera from local cases of PUO by workers of NIV, Pune. Similar studies elsewhere indicate that murine typhus is endemic in practically every town of India especially where rats abound. Control measures should be directed against rodents and rat fleas. There is no specific vaccine. Epidemic typhus vaccine does not protect against murine typhus. However following attack by one disease, there is some cross-protection against the other disease.

Srub Typhus

It is a rickettsial infection with a broad clinical spectrum. There may be many inapparent or mild infections. A severe attack of the disease is characterized by fever, headache, conjunctivitis, lymphadenopathy and a local vesicular lesion at the site of mite attachment which turns into an ulcer or eschar. A macular rash may appear on the body on 5th to 7th day and last for a few hours to a few days. Complications such as pneumonitis, myocarditis, encephalitis and peripheral circulatory failure may occur. With modern therapeutic agents, the case fatality and period of convalescence have been markedly reduced. The diagnosis can be confirmed by Weil-Felix (WF), fluorescent antibody (FA), complement fixation (CF) or microscopic agglutination (MA) test. Of late, PCR has become one of the important diagnostic techniques for scrub typhus. Ready to use ELISA kits are also available for the same. Geographical Distribution

The disease is limited to Southeastern and Eastern Asia, Northern Australia, India, Pakistan, Ceylon and other islands in the region. In India it is present in whole of the Shivalak range from Kashmir to Assam, Eastern and Western Ghats and the Vindhyachal and Satpura ranges in the central part of India. The distribution of the disease corresponds with the distribution of *Leptotrombidium deliense* and *L. akamushi*. The vector mite is now known to be present in diverse ecological niches such as equatorial rain forests, semi-deserts and Alpine subarctic terrains in the Himalayan regions. Endemic foci are usually associated with specific habitats such as abandoned plantations, gardens or rice fields, overgrown forest clearings, shrubby fringes of fields and forests, river banks and grassy fields. These ecological patches which attract the natural host of mite vectors are called "mite islands". Within the mite islands there may be a limited area of intensive transmission of rickettsiae called "Typhus Island".

Incidence

The outbreaks of scrub typhus have been reported in India both among civilians and personnel of the Armed Forces. During 1965 Indo-Pak conflict, large number of Indian troops suffered from this disease in Jammu-Sialkot sector. An unusual incidence of seropositive cases of scrub typhus was also reported during 1971 Indo-Pak conflict in the Eastern and Western borders. During peace time the incidence has been low, being always less than 0. 1 per 1000 strength. In the recent past incidences of scrub typhus from J&K and north eastern sector have been reported indicating a scrub typhus active zone but in 2006 there were no admissions due to scrub typhus in the Armed forces. Scrub typhus has been of particular interest to various workers in Indian Armed Forces as evidenced by a number of published papers on the epidemiology, management and prevention (6 -11).

Agent

*Orientia tsutsugamushi* is the agent of scrub typhus in India. It differs from other rickettsiae in its antigenic structure. At least eight serotypes are recognized. Infection with one strain does not produce immunity against infection by others.

Reservoir and Source

Permanent reservoirs of infection are many species of wild rodents, other mammals and birds. The infection is transmitted through the larval mites or "chiggers" belonging to the family *Trombiculidae*, genus and subgenus *Leptotrombidium*. More than 150 species have been described but only a few are known to be of importance to man. About 204 trombiculid mite species have been described from India so far. The important mite species are *L. deliense, L. akamushi, L scutellare*, *L pallidum* and so on. The rodents and acarine hosts do not succumb to the disease. Transovarian transmission of rickettsiae occurs in mites for at least 12 generations. Thus the field rodents and the vector mites act as a reservoir and between the two the infection perpetuates in nature. The migration of infested or infected rodents leads to establishment of new foci of disease. The immediate source of infection for man is the infected larval mites.

Mode of transmission

The infection is transmitted to man through the bite of infective mite larvae, which feeds on lymph and tissue fluid rather than blood. Human infection takes place when man accidentally picks up an infective larval mite while walking, sitting, or lying on the infested ground.

Immunity

Man has no natural immunity. All ages and both sexes are equally susceptible. Infection with one strain does not produce immunity against that by other strains.

Communicability Period

No person to person spread occurs.

Prevention and Control

**(a) Camp site selection**

Before occupation, the camp site should be first examined for typhus risk by assessing mite infestation of rats and soil and scrutinizing records of previous units for typhus incidence. As far as possible the infested areas should be avoided. If it must be occupied, it should be cleared and treated with insecticide (HCH insecticides Malathion / Fenthion) before occupation. This may be repeated if necessary at intervals specified by local medical authorities, depending on the density of infestation and extent of typhus risk. All mite infested areas may not be typhus areas.

**(b) Treatment of clothing**

Repellents like DEET & DEPA should be used for personal protection. Manual application of repellents to all the clothes normally used when working outdoors has always caused a reduction in the infection rate. The process is tedious and very seldom carried out thoroughly. Barrier treatment is less laborious and easily implemented in an emergency. Impregnation of clothing by mixing DBP in soap water while washing or by mechanical means has been thought of from time to time. But this has presented several difficulties including that of a heavy financial burden. Until such time as a more convenient method is not available, a systematic manual application on a parade is the only sure way to reduce the incidence of scrub typhus, especially when area treatment is not possible when engaged in active operations.

**(c) Antirodent measures**

These measures help to maintain low level of mite infestation in an area. Anti-typhus precautions should be observed by personnel during the periods and in localities as per instructions issued from time to time.

Action on occurrence of cases

On occurrence of the disease, the patient should be admitted to hospital. Isolation and disinfection are unnecessary as the patient is not infectious. Attendants and contacts do not require any special precautions. Notification of the clinical diagnosis as Gp B disease should be immediately communicated to the unit, ADMS, DDMS and DGMS and equivalent appointments in Navy and Air Force without waiting for serological confirmation. Units require early notification for taking necessary remedial and control measures. Technical staff officers should keep a spot map of case incidence as they require a general picture of endemicity of the areas successively occupied by troops keeping in view the patchy distribution of the disease. The general measures of importance under the operational conditions are (12, 13).

**(a) Camp Siting**

Mite avoidance by proper site selection, and personal precautions.

**(b) Housekeeping**

Persistent anti-rodent hygiene by denying shelter and food to rodents by proper storage of food, hygienic disposal of refuse and keeping the area and lines cleared of all junk, rubble, vegetation and by good house keeping.

**(c) Rodent Control**

Active anti-rat measures to reduce the rodent population wherever feasible. This should be carried out during the dry season.

**(d) Vector Control**

Use of HCH WDP insecticides e. g. Malathion/ Fenthion on the ground after thorough clearing, before occupying the area in an endemic zone. This has to be carried out every year before the monsoon starts and repeated as required until risk exists.

**(e) Repellents**

Application of repellants to all clothing is the most important single preventive measure while preparing for combat in or occupation of uncontrolled area.

Q fever

It is an acute infectious disease caused by *Coxiella burneti* and characterized by fever, malaise, myalgia, headache, weakness, anorexia, loss of weight and interstitial pneumonitis. Case fatality is low but convalescence is prolonged. Complications such as hepatitis, endocarditis, thrombosis, heamorrhages and meningitis may follow. The diagnosis is confirmed by CF tests. Phase II antibodies develop by the 4th week. Phase I antibodies indicate past infection, presence of chronic infection or immunity due to immunization. Radiological findings resemble those of primary atypical pneumonia.

Geographical Distribution

The disease has world-wide distribution. During World War II it was a cause of major epidemics in Europe (Balkan grippe). In Australia, the disease is enzootic in animals, especially bandicoots, and is transmitted in nature by ticks. Sheep, goats and cows are found naturally infected in North America and Europe.

Incidence

Apart from two case reports, studies on human Q fever in India have been mainly limited to sero epidemiological surveys in several parts of the country. Isolation of *C. burneti* and demonstration of its antibodies from human milk have also been reported

Agent

The causative organism of Q fever was described by Derrick in Brisbane, Australia in 1930s and named as *Rickettsia burneti.* It was later renamed *Coxiella burneti.* It is resistant to heat, drying, chemical agent and UV light. The antigen of *C. burneti* isolated from ticks, animals or man and maintained in laboratory animals is called phase I. It does not react with convalescent sera from Q fever cases. After adaptation to egg embryos, the antigen is changed into phase II, which is used for serological tests.

Reservoir and Source

Small mammals and possibly some birds are the permanent

reservoirs of infection with some Ixodid and argasid ticks acting as vectors. From the wild animals the infection spreads to cattle, sheep and goats. The immediate source of infection to man is the dust contaminated by products of domestic animals particularly placental tissues and fluids and raw milk. Other sources are animal carcasses, contaminated straw, wool and so on.

Mode of Transmission

The mode of transmission for humans is by inhalation of infected dust, by handling infected materials and possibly by drinking contaminated raw milk.

Human Host

Focal outbreaks or sporadic cases may occur amongst people who have close contact with infected cattle, sheep and goats. Thus it is an occupational hazard for dairy workers, farmers, veterinarians and laboratory workers.

Incubation Period

It ranges from 15 to 26 days; average incubation period is approximately 19 days.

Communicability period

The disease is not transmitted from man to man.

Prevention

The disease can be prevented by avoiding exposure to infected aerosols. Milk from infected cattle must be boiled or pasteurized. Persons at risk such as dairy workers, butchers, wool sorters, farmers, cowherds and laboratory workers can be protected by immunization with specific vaccines such as those prepared from phase I rickettsiae. Human cases of Q fever should be treated with tetracyclines or chloramphenicol.

Brill-Zinsser Disease

It is a recrudescent episode of epidemic typhus which occurs years after the initial attack, in persons who have recovered from the epidemic disease acquired while residing in the endemic country (14, 15). The recurrence is presumed to be precipitated by stress or a waning immune system. The illness is similar to louse borne typhus but is usually milder. Weil-Felix reaction may be negative in very low titre.

# Dengue and Dengue Hemorrhagic Fever

## Introduction

Dengue is a vector borne viral disease which occurs in tropical and sub - tropical regions around the world, predominantly in urban and semi - urban areas. Dengue fever is the most rapidly spreading vector borne viral disease and is a major international public health concern (1, 2). The disease is caused by the four serotypes of the Dengue virus which are arboviruses of the genus *Flaviviruses*. The principal vector for the disease is the *Aedes aegypti* mosquito. The disease can present in several forms, from asymptomatic illness to life threatening diseases like Dengue Heamorrhagic Fever (DHF) and Dengue Shock Syndrome (DSS).

The virus is widely distributed in the tropical and subtropical regions of the world. The global prevalence of Dengue has grown dramatically in recent decades. The World Health Organization reports that the disease is now endemic in more than 100 countries in Africa, the Americas, the Eastern Mediterranean, South - East Asia and the Western Pacific. South - East Asia and the Western Pacific are most seriously affected. WHO currently estimates there may be 50 million cases of Dengue infection worldwide every year. 2.5 billion people live in Dengue endemic countries and are at risk of acquiring the infection (4, 5).

## Epidemiology

### World

The geographical extent of the disease has risen significantly in the recent past. It has spread to new areas and reemerged in areas where it appeared to have been controlled. Tropical areas in South - East Asia, Africa, Western Pacific and the Mediterranean are most seriously affected. Prior to 1970 only nine countries had experienced DHF epidemic, a number that had increased by more than four times by 1995.During 1998 over 1.2 million cases with 3,442 deaths were reported to WHO which is the largest for any single year. WHO currently estimates there may be 50 million cases of Dengue infection worldwide every year with around 24,000 deaths (5). The rapid rise in the geographical extent of the disease has been attributed to the enhanced geographic distribution of the four Dengue viruses and of their mosquito vectors, particularly the predominantly urban *Aedes aegypti*. A rapid rise in urban population particularly urban slums has contributed to the rise in the number of cases (3, 5). The WHO expects the spread of the disease to continue because of increasing urbanisation, increasing population movement, and proliferation of man - made larval habitats of the mosquito vector.

1.3 billion people living in South - East Asia are at risk of Dengue fever. In 2003 only eight countries in South - East Asia Region reported Dengue cases. By 2006, ten out of the 11 countries which form part of the WHO South - East Asia region were reporting the disease. Bhutan reported the first Dengue outbreak in 2004. An outbreak, with a high case fatality rate (3.55%) was first reported in Timor-Leste in 2005. Nepal reported Dengue cases for the first time in November 2006 (6-8).

### India

Large parts of India are endemic for Dengue Fever. The disease is reported from most parts of the country except those at high altitudes. The first major outbreak in India was reported during 1963 in Kolkata. The next major outbreak of Dengue / Dengue Haemorrhagic Fever was reported in Delhi and neighboring states in 1996. Following this outbreak, the reporting of Dengue fever was made mandatory to ensure early preventive measures in case of outbreak. Out of 18 endemic states, the most affected states are Delhi, West Bengal, Kerala, Tamil Nadu, Karnataka, Maharashtra, Rajasthan, Gujarat and Haryana (9). Data for the last 10 years reveals that the largest number of cases and deaths due to Dengue/DHF were reported in 1996 while the next increase was in 2003. 12,317 cases with 184 deaths were reported to the National Vector Borne Diseases Control Programme in India in 2006 (9). Delhi recorded several outbreaks of Dengue fever between 1967and 2006. The outbreak in 2006 was estimated to have resulted in 10, 344 cases and 162 deaths (10, 11).

## Agent

DF / DHF is caused by Dengue virus which belongs to genus *Flavivirus* family *Flaviviridae* and includes serotypes 1, 2, 3 and 4 (Den - 1, Den - 2, Den - 3 and Den - 4). The Dengue virus is composed of single - stranded RNA. Each serotype provides specific lifetime immunity and short - term cross - immunity. All serotypes can cause severe and fatal disease. There are genetic variation within the serotypes. Some genetic variants within each serotype appear to be more virulent or have greater epidemic potential. When a person has had classic Dengue, a second infection later by another serotype increases the likelihood of suffering from DHF as explained by the immune enhancement mechanism (1, 2, 4).

## Vector

*Aedes aegypti* is the main vector of Dengue transmission in India. Another important vector is the *Aedes albopictus*. The mosquito is a peri - domestic and domestic breeder. Mosquito breeding can occur in any water - storage containers, such as desert coolers, flower vases, coconut shells, construction sites, overhead uncovered or partially covered water tanks, discarded buckets, tyres, utensils and large containers used for collecting rain water which are not emptied and cleaned periodically. The mosquitoes rest indoors on various objects, in closets and other dark places. Outside, they rest where it is cool and shady. Aedes mosquito can fly upto a limited distance of 400 metres but can spread over vast distances mechanically in various types of vehicles used by man. *Aedes aegypti* is

primarily a day time biter (4, 6, 12, 13).

### Environmental Factors

The outbreaks of DF/DHF are most likely to occur in post - monsoon period when the breeding of the mosquitoes is highest. High temperature and high humidity during these seasons prolongs the life span of the vector. The spread of Dengue has resulted from several factors including human behavior, climate and movement of humans. Usually urban areas, having high population density, poor sanitation and large number of desert coolers, flower vases, construction sites, overhead tanks etc which promote mosquito breeding, are at high risk. Dengue fever/DHF can also occur in rural areas where the environment is friendly for mosquito breeding like storage water for cattle feeding and drinking, cement cisterns and underground cemented water sumps (4, 6, 8).

### Transmission

The infection is transmitted by the bite of an infected female mosquito *Aedes aegypti*. Mosquitoes acquire the virus while feeding on the blood of an infected person. After an extrinsic incubation period of 8 to 10 days, an infected mosquito can transmit the virus for the rest of its life. Trans - ovarian transmission of the Dengue virus in mosquitoes maintains the virus in nature. Humans are the main host of the virus, although studies have shown that in some parts of the world monkeys may become infected. The virus circulates in the blood of infected humans for two to seven days (4, 6, 12, 13).

### Clinical manifestations

The incubation period of Dengue fever is usually 5 - 6 days, but may vary from 3 to 10 days. Infection with Dengue virus can result in four different clinical syndromes. They are undifferentiated fever, the Classic Dengue fever, Dengue Hemorrhagic fever (DHF) and Dengue Shock syndrome (DSS) (14-16).

#### Undifferentiated Fever

This is the most common manifestation of Dengue infection. Almost 90% of those infected remain either asymptomatic or only mildly symptomatic. The patient has fever, headache, body ache and may develop a mild rash.

#### Classic Dengue Fever

This is characterized by abrupt onset of high fever, severe headache, severe muscle and joint pain (Break Bone Fever), rash and other haemorrhagic manifestations.

#### Dengue Hemorrhagic Fever

DHF is a potentially deadly complication that is characterized by high fever, accompanied by headache, anorexia, vomiting and abdominal pain. Petechiae on the extremities, face, and trunk are the manifestations of haemorrahage. Bleeding from nose, gums and gastrointestinal tract may be found. In moderate cases, spontaneous mucocutaneous bleeding, nasal bleeding and GI bleeding usually occurs. In severe cases, the patient's condition may suddenly deteriorate after a few days of fever. Any case with fever, or recent history of acute fever, hemorrhagic manifestations, low platelet count (100,000/$mm^3$ or less), and objective evidence of "leaky capillaries" in the form of elevated hematocrit (20% or more over baseline), low albumin, or pleural or other effusions meets the case definition for DHF.

#### Dengue Shock Syndrome

Patients may rapidly develop varying degree of circulatory disturbances and go into a critical state of shock. Patients with DHF who develop evidence of circulatory failure manifested indirectly by rapid and weak pulse, narrow pulse pressure (< 20 mm Hg) or hypotension for age, cold, clammy skin and altered mental status meet the criteria for DSS. Frank shock is direct evidence of circulatory failure. Prolonged shock is often complicated by metabolic acidosis and severe bleeding. Case fatality rates can exceed 20% in such patients. A major cause of deaths due to DHF is leakage of plasma in the pleural and abdominal cavities leading to hypovolaemic shock. Encephalitic signs associated with intracranial haemorrhage, metabolic and electrolyte disturbances, and hepatic failure may occur.

### Differential diagnosis

Differential diagnosis must include all other arboviral fevers, measles, rubella and other systemic febrile illnesses, especially those accompanied by rash (6). The presence of marked thrombocytopenia with concurrent haemoconcentration differentiates DHF / DSS from other syndromes such as endotoxic shock from bacterial or meningococcaemia.

### Alarming signs in Dengue

(a) Minute spots on the skin suggesting bleeding within the skin.

(b) Nose bleeds and gum bleeds, haemetemesis.

(c) Abdominal pain and/or passage of black tarry stool.

(d) Refusal to food or drink.

(e) Abnormal behaviour or drowsiness.

(f) Difficulty in breathing or cold hands and feet, reduced amount of urine being passed.

### Diagnosis

Patients suspected to be suffering from Dengue fever must undergo repeated clinical laboratory tests : Complete Blood Counts including WBC, platelets, hematocrit, Liver function tests, and urine analysis for microscopic hematuria. These blood tests may indicate a diagnosis of Dengue fever and DHF / DSS. Thrombocytopenia (100,000 cells or less per $mm^3$) and haemoconcentration as evidenced by a greater than 20% rise in average haematrocrit for age and sex are the hematological criteria for diagnosis.

Laboratory tests essential for confirmatory diagnosis of Dengue infection include isolation of the virus, demonstration of a rising titre of specific serum Dengue antibodies, and demonstration of a specific viral antigen or RNA in the tissue or serum. Virus isolation can be done by inoculation of clinical material in tissue culture,

mosquitoes or suckling mice and further detection is performed using fluorescent antibody test or haemagglutination inhibition test. Viral antigen can be demonstrated by doing direct fluorescent antibody test using specific monoclonal antibodies for Dengue virus. Viral RNA or genomic sequence can also be detected in autopsy specimen, serum, CSF or culture supernatant by doing Polymerase Chain Reaction (PCR) and gene sequencing.

Serological diagnosis is based on detection of IgM antibodies. IgM antibodies against Dengue virus appear around 5 days after onset of symptoms and are detectable for one to three months after the illness. The tests employed are IgM capture ELISA test and Rapid IgM strip test. IgM capture ELISA test kit is available from NIV Pune and commercial sources and Rapid IgM Strip Test kit is available commercially.

### Treatment

The basics of management of cases of Dengue fever are fluids, rest, antipyretics (avoid aspirin and non - steroidal anti - inflammatory drugs) and close monitoring of blood pressure, hematocrit, platelet count and level of consciousness. Liberal fluids intake including home available fluids like rice water, kanji, fruit juices, plain water or ORS solution are recommended for patient with excessive sweating, nausea, vomiting or diarrhoea to prevent dehydration (1, 3). Monitoring must be continued after defervescence. If the level of hydration falls intravenous fluids, guided by serial hematocrits, blood pressure, and urine output must be given. The volume of fluid needed is similar to the treatment of diarrhea with mild to moderate isotonic dehydration.

### Management of DHF

Patients of DHF need regular assessment by serial haematocrit levels. Urine output should be monitored closely in areas where serial haematocrit estimation is not possible. A rise in haematrocrit of 20% or more or single haematocrit value of more than 40%, platelets count of 50,000/cmm or less and spontaneous haemorrhage are all danger signs.

### Management of Dengue Shock Syndrome (DSS)

DSS patients present with shock. Volume replacement is the most important treatment measure and immediate administration of intravenous fluids to expand plasma volume is essential. Close observation with good nursing care is imperative. Blood transfusion should be given in case with significant haemorrhage. Fresh frozen plasma or concentrated platelet transfusion may be given when disseminated intravascular coagulation causes massive bleeding. Readers may refer to standard texts for details on management of patients (3, 4, 14 - 17)

### Immunity

Infection with one serotype provides life - long homologous immunity but does not provide protection against other serotypes, and instead may exacerbate subsequent infection (4, 6, 7).

### Prevention and control

Vector Control

Vector control and personal protective measures are the mainstay of prevention of Dengue infections. Both aspects are dealt with in detail in the chapter on Entomology.

Surveillance

Epidemiological surveillance of the disease as well as the vector form an important part of control measures. The disease surveillance should include fever surveillance, diagnosis based on standard case definitions, and reporting of DF/DHF cases to state health authorities. Vector surveillance includes both larval and adult vector surveillance (18).

A number of indices have been described and are currently used to monitor the vector population :

#### House index

Percentage of houses positive for larvae of *Aedes aegypti*. House index of more than 10% indicates high risk of transmission

#### Breteau index

Number of positive containers for *Aedes aegypti* per 100 houses. An index of more than 50 indicates high risk of transmission while index below five indicates low risk of transmission.

Notification

Dengue is a cross border disease. With massive air travel, outbreaks can rapidly cross international borders. Outbreaks must, therefore, be notified at the earliest to both the national as well as international health authorities.

Vaccine

No effective vaccine is available for Dengue. Research into Dengue vaccines has focused on the use of live attenuated or inactivated vaccines, infectious clone derived vaccines, and nucleic acid vaccine (19).

# Japanese Encephalitis

## Introduction

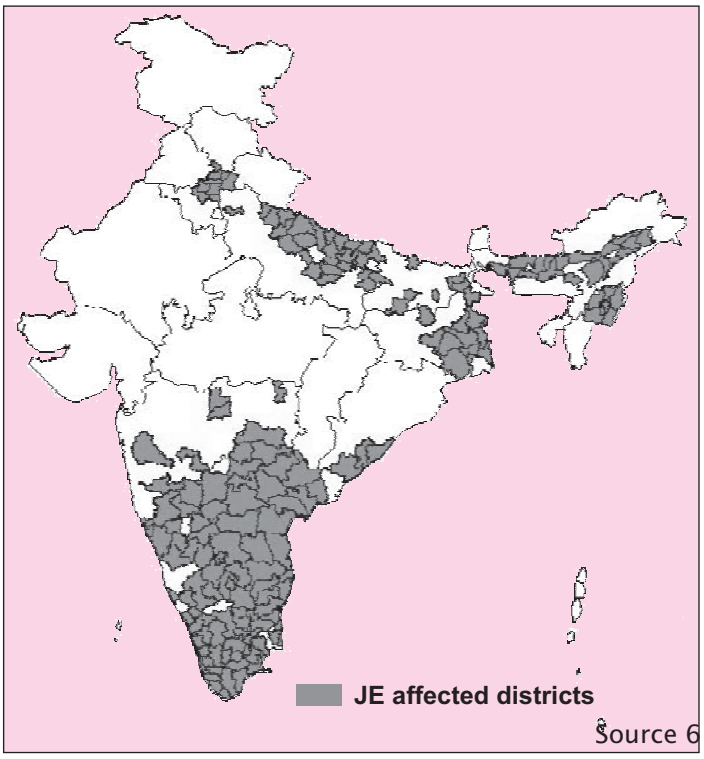
Japanese encephalitis is an arboviral disease spread by culicine mosquitoes. The disease presents periodically in epidemic form in areas such as northern India, parts of central and southern India. An overwhelming majority of the infections are asymptomatic. However, among symptomatic individuals case fatality rates may be higher than 20%. The public health importance of this vaccine preventable disease lies in the fact that most infections occur among children and that a sizeable proportion of the survivors are left with permanent neurological and/or psychiatric sequelae (1). The incidence of Japanese encephalitis has shown an increasing trend in recent times and the disease is fast becoming a major public health problem in India (2).

## Epidemiology

Japanese encephalitis infections occur throughout the temperate and tropical zones of Asia. The annual incidence of Japanese encephalitis disease varies considerably from one country to the other as well as within affected countries, ranging from less than 10 to more than100 per 100 000 population. Nearly 3 billion people or close to half the global population live in Japanese encephalitis endemic regions. Over 50, 000 cases are reported worldwide every year with 10, 000 deaths (3). The disease periodically becomes hyperendemic in areas such as northern India, parts of central and southern India, southern Nepal, and northern Viet Nam (3). Other countries reporting large number of cases of Japanese encephalitis include Philippines, Thailand, Cambodia, Mynamar, and Sri Lanka. Though named Japanese encephalitis, the disease is now rare in Japan, due to extensive vaccination and adequate vector control.

In India Japanese encephalitis was first reported in 1955 from Vellore in Tamil Nadu (4). Currently this disease is reported from 26 states in India. Of these, only 15 states are reporting JE regularly. The total population at risk is estimated 160 million (5). A disturbing feature of Japanese encephalitis reporting in India has been the occurrence of several large outbreaks from different parts of the country. The first major outbreak of was reported from West Bengal in 1973 in two districts followed by another outbreak in 1976. Subsequently outbreaks have been reported from the states of Bihar, Uttar Pradesh, Assam, Manipur, Andhra Pradesh, Karnataka, Madhya Pradesh, Maharashtra, Tamil Nadu, Haryana, Kerala, West Bengal, Orissa and union territories of Goa and Pondicherry (2). In the recent past the reported annual incidence in India has ranged between 1765 and 3428 and deaths between 466 and 707 (6). The current Japanese encephalitis situation in India is shown in Fig - 1.

Fig - 1 : Japanese Encephalitis in India



## Agent

Japanese encephalitis virus belongs to the family Flaviviridae, which are single - stranded RNA viruses. Like other flaviviruses, the Japanese encephalitis virus is an enveloped, plus sense virus. It is antigenically related to several other flaviviruses including dengue virus, St. Louis encephalitis virus, Murray Valley virus and West Nile virus (2). The envelope glycoprotein of the JE virus contains specific as well as cross - reactive, neutralizing epitopes. The virus contains several structural and non - structural polypeptides, which are encoded by a single long open reading frame (7). The virus has two sub types, Nakayam amd Jagar - 01 (2). The major genotypes of this virus have different geographical distribution, but all belong to the same serotype and are similar in terms of virulence and host preference (3).

## Vector

Anthropophilic culicine mosquitoes transfer the virus to humans from animal amplifying hosts, principally domestic pigs and wading birds. The virus is transmitted chiefly by the bites of mosquitoes of the *Culex vishnui* complex; with individual vector species differing in specific geographic areas. In India and many endemic areas in Asia, *Culex tritaeniorhyncus* is the principal vector. This species feeds outdoors beginning at dusk and

during evening hours until dawn. It breeds in water pools, marshes, flooded rice fields, and small stable collections of water around cultivated fields. This vector has a wide host range, including domestic animals, birds, and humans. In temperate zones, the vectors are present in greatest numbers from June through September and are inactive during winter months (8).

### Host

Pigs and aquatic birds (mainly herons and egrets of the Ardeidae family) are the natural hosts for the virus. Pigs are considered amplifying hosts since they allow manifold virus multiplication without suffering from disease and maintain prolonged viraemia (6). Viraemic adult pigs remain asymptomatic, but pregnant sows may abort or deliver still births. Humans are dead end accidental hosts.

Among humans, the virus has no specific age or sex predilection. In areas where the virus has been recently introduced, all age groups are affected equally. In endemic areas, however, most people are infected below the age of 15 years. In hyper-endemic areas, half of all Japanese encephalitis cases occur before the age of four years, and almost all before 10 years of age. Only 1 in 250 to 500 JE viral infections result in symptomatic disease. Those endemic regions where childhood JE vaccination has been widely implemented have experienced a shift in the age distribution of cases towards older children and adults (3). In India, Japanese encephalitis is considered to be a largely pediatric problem. Young children below 10 years of age are more likely to die, and if they survive, are more likely to have residual neurological sequelae (2).

### Environment

Environmental factors related to transmission of JE are related principally to temperature and humidity conditions conducive to breeding and survival of the vector. In tropical and subtropical areas, transmission intensifies in the rainy season. In temperate locations, transmission usually starts in April and may last until October. In irrigated areas, transmission may occur even in the dry season (3). Habitats supporting the transmission cycle of JE virus are principally in rural, agricultural locations. In many areas of Asia, appropriate ecologic conditions for virus transmission occur near and even within urban centers (8). In many Asian countries, major outbreaks of JE occur at intervals of 2–15 years (3).

### Clinical Features

The incubation period of Japanese encephalitis ranges from four to 14 days (3). The virus initially multiplies at the site of the bite and in the draining lymph nodes. Subsequently, viremia develops, leading to inflammatory changes in the heart, lungs, liver, and reticuloendothelial system. Most infections are cleared before the virus can invade the central nervous system (CNS). However, neurologic invasion can develop leading to involvement of large areas of the brain, including the thalamus, basal ganglia, brain stem, cerebellum, hippocampus, and cerebral cortex (9). Most infected persons develop mild symptoms or no symptoms at all. Symptoms soon after exposure appear 6 - 8 days after the bite of an infected mosquito. The disease is characterized by sudden onset of fever, chills, body ache and mental confusion. Severe cases may progress to coma. In children, gastrointestinal pain and vomiting may be the dominant initial symptoms. Irritability, vomiting and diarrhea or an acute convulsion may be the earliest objective signs of illness in an infant or child. JE may present as a mild disease, leading to an uneventful recovery, or may rapidly progress to severe encephalitis with mental disturbances, general or focal neurological abnormalities and coma.

Out of the approximately 50 000 cases of JE that are estimated to occur each year, about 10 000 end fatally, and about 15 000 of the survivors are left with neurological and/or psychiatric sequelae, requiring rehabilitation and continued care (2, 3). Approximately 33 - 50% of patients who survive have major neurologic sequelae at one year, including seizure disorders, motor or cranial nerve paresis, or movement disorders. Nearly 75% of symptomatic patients with JE who are evaluated five years after the disease score lower than uninfected subjects on standardized tests (9).

### Diagnosis

JE is clinically indistinguishable from other forms of viral encephalitis. History of exposure to mosquitoes in an endemic area or during an epidemic may be elicited. A CBC count often shows nonspecific modest leukocytosis in the first week of illness. A mild anemia also may be present. Some studies have reported thrombocytopenia in children with Japanese encephalitis (9). Neutrophils predominate in early CSF samples but a lymphocytic pleocytosis is typical. CSF protein is moderately elevated in about 50% of cases (2).

Confirmation of a suspected case of Japanese encephalitis is mainly based on serology using IgM - capture ELISA which detects specific IgM in the cerebrospinal fluid or in the blood of almost all patients within 7 days of onset of disease. Other methods include conventional antibody assays on paired sera for the demonstration of a significant rise in total JE - specific antibody, as well as a dot - blot IgM assay, suitable for use in the field (3).

### Case definitions for JE Diagnosis and Reporting (6)

Clinical Suspect

Febrile illness of variable severity associated with neurological symptoms ranging from headache to meningitis or encephalitis. Symptoms can include headache, fever, meningeal signs, stupor, disorientation, coma, tremors, paralysis (generalized), hypertonia, loss of coordination (Patient with fever, altered sensorium lasting more than 6 hours, no skin rash and other known causes of encephalitis excluded).

Probable

A suspected case with presumptive laboratory results : Detection of an acute phase anti - viral antibody response through IgM in serum/ elevated and stable JE antibody titres in serum through ELISA/HI/Neutralizing assay.

Confirmed

A suspect case with confirmed laboratory result : JE IgM in CSF or 4 fold or greater rise in paired sera (acute &

convalescent) through IgM/IgG ELISA, HI, Neutralization test or detection of virus, antigen or genome in tissue, blood or other body fluid by immuno - chemistry, immunoflourescence or PCR.

### Treatment

There is no specific anti - viral medicine available against JE virus. The cases are managed symptomatically. Clinical management of JE is supportive and in the acute phase is directed at maintaining fluid and electrolyte balance and control of convulsions, if present. However, treating raised intracranial pressure and convulsions have been reported to decrease the mortality and morbidity significantly (10).

### Prevention and Control

Vector control and vaccination are the two primary strategies for control of Japanese Encephalitis. In countries such as Japan and Korea the incidence of JE has decreased during several decades, primarily as a result of extensive use of JE vaccines. Improved socioeconomic conditions, changed life styles and control measures such as centralized pig production and the use of insecticides may also have contributed to this development (3). Details on vector control are available in the Chapter on Entomology.

### Vaccines

Three types of vaccines are currently in use against Japanese encephalitis. The mouse brain - derived, purified and inactivated vaccine, which is based on either the Nakayama or Beijing strains of the JE virus and is produced in several Asian countries including India. Another inactivated vaccine is the cell culture - derived, vaccine based on the viral Beijing P - 3 strain. A live attenuated vaccine widely used in China is the cell culture - derived vaccine based on the SA 14 - 14 - 2 strain of the JE virus (3).

The mouse brain - derived JE vaccine is used in India. It is produced by the Central Research Institute, Kasauli. Three doses are required to produce primary immunization. Two doses of 1 ml (0.5 ml for children below three years) are administered sub - cutaneously within a gap of 7 - 14 days followed by third dose any time after one month and before one year of the second dose. A booster is required after 3 years (6). Several othe Asian countries have adopted a similar schedule of two primary doses four weeks apart, followed by a booster after one year. In some countries, subsequent boosters are recommended, usually at about 3 - year intervals up to the age of 10 to15 years (3). For travellers aged more than one year visiting rural areas of endemic countries the established practice is to administer 3 primary doses at days 0, 7 and 28 or two primary doses preferably four weeks apart.

The mouse brain - derived JE vaccine is been considered safe. Local reactions such as tenderness and swelling occur in about 20% of vaccinees. Mild systemic symptoms, including headache, myalgia, gastrointestinal symptoms and fever may also occur. Being a killed vaccine, only contraindication to the use of this vaccine is a history of hypersensitivity reactions to a previous dose. Pregnant women should be vaccinated only when at high risk of exposure to the infection. The vaccine can be given to HIV infected individuals (3). The biggest limitation of the mouse derived killed vaccine is that rapid large scale production of the vaccine is not feasible.

The live attenuated vaccine was licensed in China in 1989. Extensive use of this and other vaccines has significantly contributed to reducing the burden of JE in China. The vaccine has recently been licensed for use in India. It is administered in two doses at an interval of one year.

### WHO position on JE vaccines

The World Health Organization recommends that JE immunization should be integrated into the EPI programmes in all areas where JE constitutes a public health problem. The most effective immunization strategy in JE - endemic settings is one time catch - up campaignsincluding child health weeks or multi - antigen campaigns in the locally - defined primary target population, followed by incorporation of the JE vaccine into the routine immunization programme (3).

# Chikungunya

## Introduction

Chikungunya fever is an arboviral illness characterized by severe, persistent joint pains, fever and rash. The disease resembles dengue fever and is spread by the bite of infected mosquitoes. It is rarely life - threatening. However, widespread occurrence of the disease causes substantial morbidity and economic loss. Chikungunya virus disease has occurred sporadically in India and Southeast Asia for at least 200 years. Epidemics with symptoms resembling Chikungunya fever have been recorded as early as 1824 in India (1). Over the last 40 years, several widespread epidemics have occurred in many cities of India and Southeast Asia affecting thousands of people (2, 3) Occasionally, epidemics of Dengue and Chikungunya have occurred simultaneously in the same community, making clinical differentiation of the two diseases difficult. Unlike Dengue which has become endemic in many parts of Asia, Chikungunya virus disappears and reappears at irregular intervals.

The name Chikungunya originates from Swahili, and means "that which bends up, " which refers to the characteristic posture assumed by patients suffering severe joint pains. Chikungunya virus was first isolated during a 1952 epidemic in Tanzania (2, 3).

## Epidemilogy

### World

The Chikungunya virus is probably maintained in nature by transmission between jungle primates (4). The disease displays a striking epidemiological profile with major epidemics appearing and disappearing cyclically, usually with an inter - epidemic period of 7 - 8 years and sometimes as long as 20 years (1). Currently, Chikungunya is a major arboviral disease in urban parts of Africa and Asia. The known geographic distribution of the virus includes large parts of Sub - Saharan Africa, Southeast Asia including Indonesia, Philippines, and India, as well as islands in the South - west Indian Ocean (2, 3). Other affected regions include Mauritius and Seychelles in the Indian Ocean. Imported cases have been reported by European countries like France, Germany, Italy, Norway and Switzerland (5-7) .

### India

The virus was first isolated in India from Kolkata in 1963 (8). In the mid sixties outbreaks resembling Chikungunya were reported from various parts of India including Vellore, Kolkata and parts of Maharashtra (1). The last outbreak of Chikungunya virus infection was reported in 1971. There has been no active or passive surveillance of Chikungunya and therefore, it appeared that the virus had disappeared from the country (9). Since 2005, however, there have been several reports of outbreaks from widespread parts of the country and the re - emergence of the virus has been confirmed (10-12). In the present outbreak, 151 districts of eight states of India have reported Chikungunya fever as of Oct 2006. The affected states are Andhra Pradesh, Andaman & Nicobar Islands, Tamil Nadu, Karnataka, Maharashtra, Gujarat, Madhya Pradesh, Kerala and Delhi. More than 1.25 million cases have been reported from the country with 7,52,245 cases from Karnataka and 2,58,998 from Maharashtra. In some areas attack rates have reached up to 45% (1).

## Agent

The Chikungunya virus is an arbovirus belonging to the group alphaviruses of the family *Togaviridae.* It is believed that there are two distinct lineages of the Chikungunya virus, one containing Western African and the second comprising all Southern and East African strains. The virus originated in Africa and was subsequently introduced into Asia (12).

## Vector

Chikungunya is transmitted by mosquitoes, including many Aedes species which bite during daylight hours. In some parts of the world Culex species are important vectors. In India, the two important vectors are *Aedes aegypti* and *Aedes albopictus*, both of which also transmit dengue virus (13).

## Transmission

There appear to be two distinct transmission cycles for Chikungunya virus. A sylvatic cycle between wild primates and arboreal Aedes mosquitoes, similar to that of sylvatic Yellow fever virus in the same region has been seen in Africa. Urban Chikungunya outbreaks are associated with *Aedes aegypti* transmission in a human - mosquito - human cycle. Urban outbreaks are sporadic in occurrence but explosive in nature. Till recently it was believed that there is no direct person - to - person transmission. However, vertical maternal foetal transmission of the virus has been documented in an outbreak at La Reunion Island (14). The virus has been isolated from monkeys in Africa (15). There is a risk for travelers in areas where Chikungunya is endemic and in areas affected by epidemics (16, 17) .

## Clinical Features

The Incubation period is usually 2 - 3 days with a range of 1 - 12 days (3). The onset is with fever, chills, headache, photophobia, backache, nausea, vomiting, arthralgia, and rash. The acute illness usually lasts about 3 to 5 days but can be very severe. Most patients recover completely within 5 to 7 days. More than three fourths of the patients complain of severe arthralgia. One or more joints may be involved, with swelling and redness. Another characteristic feature is the rash which is maculopapular and mainly involves the trunk. In some cases the joint pains may persist for week, months or even longer. Chikungunya may also be asymptomatic (2, 5, 18-21). Children may suffer from febrile convulsions. Infrequently, hemorrhagic manifestations (petechiae, purpura, epistaxis) also have been reported.

### Diagnosis

Any illness with the classical triad of fever, rash, and joint pains in endemic areas must give rise to suspicion of Chikungunya. The definitive diagnosis can only be reached by serology or isolation of the virus. Alphaviruses can usually be recovered from blood taken during the first few days of illness. Seroconversion can be shown in acute and convalescent serum samples drawn two weeks apart. Virus - specific IgM antibodies can be detected by capture ELISA in patients recovering from Chikungunya infection and they decline within 3 - 6 months. Haemagglutination inhibition antibodies appear as the viraemia declines. Patients usually become positive by the 5th to 7th day of illness. RT - PCR can be used for molecular diagnosis at specialized centre (12, 20).

### Differential Diagnosis

Chikungunya infection is often mistaken for dengue, which has a similar distribution in Asia and Africa. It may also can be confused with West Nile virus infection.

### Treatment

Treatment is symptomatic and includes antipyretic and anti - inflammatory drugs. Aspirin should be avoided because of reports of mild hemorrhagic manifestations. Movement and mild exercise tend to improve stiffness and morning arthralgia, but heavy exercise should be avoided as it may exacerbate rheumatic symptoms. Although the joint symptoms may persist for months, Chikungunya is generally an acute, self - limited infection with no deaths reported. Patients should be nursed under mosquito nets during the viraemic stage to avoid transmission of the disease (2, 5, 21).

### Prevention and Control

There is no vaccine against this arboviral disease. No specific treatment is available. Prevention is entirely dependent upon taking steps to avoid mosquito bites and elimination of mosquito breeding sites. Control measures consist of vector control activities. Details about vector control and personal protective measures are given in the Chapter on Entomology.

# Yellow Fever

## Introduction

Yellow fever was the first viral hemorrhagic fever to be described. It is a mosquito - borne infection endemic to Africa and South America. Its presentation is widely variable ranging from a minimal flulike illness to a fulminant disease characterized by hemorrhage, hepatic failure, renal failure and death. The Yellow Fever virus is an arbovirus, of the family *Flaviviridae* (1). Despite being currently restricted to parts of Africa and South America, Yellow fever has the potential to cause large outbreaks in other areas dur to the presence of suitable vectors and climatic conditions (2). Yellow fever has been cited in historic texts dating back to 400 years ago. The "yellow" in the name originates from the jaundice that occurs in seriously ill patients. Although an effective vaccine has been available for 60 years, the number of people infected over the last two decades has increased and the World Health Organization considers Yellow fever to be a serious public health issue again (3). The virus is transmitted by several species of mosquitoes. The Aedes is the most important vector while Haemogogus species are responsible for the transmission in South America.

## History

Major epidemics of Yellow fever occurred in the 18th and 19th century in Africa, South America, the Caribbean, Europe and North America. In 1793, a major epidemic wiped out almost 10% of the population of Philadelphia. Mosquito - borne transmission of Yellow fever was first suggested by Carlos Finlay in 1881. In 1900, Walter Reed observed that the infectious agent was transmitted by means of a mosquito bite. Extensive mosquito control measures and widespread vaccination led to the elimination of Yellow fever in the early 20th century from most areas of the world except parts of Africa, South America and the Caribbean. The slackening of vector control measures has lead to the reinfestation of *Aedes aegypti* mosquitoes in South America (1).

## Geographical Distribution

Yellow fever is currently confined almost entirely to South and Central America and Africa. The virus is constantly present with low levels of infection in these areas. Periodically this viral presence amplifies into regular epidemics. Over 500 million people live in 33 endemic countries in Africa and are considered to be at risk of suffering from Yellow fever. All these countries lie within a band from 15°N to 10°S of the equator. In South America, Yellow fever is endemic in nine countries and in several Caribbean islands. The countries considered to be at high risk are Bolivia, Brazil, Colombia, Ecuador and Peru. A small numbers of imported cases also occur in countries free of Yellow fever. Yellow fever has never been reported from Asia. However, WHO considers this region to be at risk because the appropriate primates and vectors are present (3). The global incidence of Yellow fever fluctuates with the occurrence of large epidemics in Africa. The World Health Organization estimates that there are 2,00,000 cases of Yellow fever every year with 30,000 estimated deaths. However, due to underreporting, only a small percentage of these cases are identified (3)

## Agent

The viral pathogen is a *flavivirus* belonging to the family *Togaviridae*. It is a small (40 to 60 nm), single stranded positive sense, enveloped RNA virus. The envelope consists of a lipid bilayer containing an envelope glycoprotein and a matrix protein (4, 5).

## Mosquito Vectors

The virus is transmitted by several different species of the Aedes and Haemogogus (only in South America). These mosquitoes may be domestic (breeding close to and around houses), wild (breeding in the jungle) or semi - domestic types. In South America *Haemogoggus spegazzinii* is the principal vector for forest transmission. In Africa, the principal vectors for forest transmission are the *Aedes africanus* and *Aedes simpsoni.* In both the continents, the principal urban vector is the *Aedes aegypti.* Any region populated with these mosquitoes can potentially harbour the disease. Extensive vector control measures had successfully eradicated mosquito habitats in the past, especially in South America. However, slackening of these programmes over the last 30 years has lead to increase in the mosquito population (1). Female mosquitoes become infected by feeding on an infected host usually during the first to third day of fever. The extrinsic incubation period the mosquitoes can vary from four days to 18 days depending on the ambient temperature (6). During subsequent blood meals, the virus is transmitted to a new vertebrate host. In addition, Yellow fever virus can be transmitted transovarially, allowing viral survival in the absence of adult mosquitoes. Some populations of mosquitoes transmit Yellow fever virus more efficiently than others. The principal urban vector, *Aedes aegypti* is an inefficient vector of the Yellow fever virus. However, the anthropophilic nature of the vector and the high densities of the mosquito in urban areas make it an excellent vector for human - to - human transmission (5, 7)

## Hosts

Primates are the only vertebrate hosts for Yellow fever. Humans and monkeys are the principal hosts. The reservoir of urban Yellow fever is sub - clinical human cases. For rural Yellow fever the most important animal reservoir is the monkey. In endemic areas almost 30% monkeys may be infected. Monkey is the only reservoir for jungle Yellow fever (2, 5).

## Transmission

Three transmission cycles can be distinguished in Africa. The sylvatic, intermediate and urban. In South America,

only the sylvatic and urban Yellow fever cycles of transmission are seen. In all three cycles, Yellow fever virus is transmitted between primates by diurnally active tree hole - breeding mosquitoes. In all of these cycles, endemic and epidemic disease patterns can occur (4).

**(a) Sylvatic Yellow fever**

In forested areas, Yellow fever occurs in monkeys infected by wild mosquitoes. The infected monkeys can then pass the virus onto other mosquitoes that feed on them. These infected wild mosquitoes bite humans entering the forest resulting in sporadic cases of Yellow fever.

**(b) Intermediate Yellow fever**

In the Savannah region of Africa, semi - domestic mosquitoes infect both monkey and human hosts. This area is often called the "zone of emergence", where increased contact between man and infected mosquito leads to disease. It can shift to a more severe urban - type epidemic.

**(c) Urban Yellow fever**

Large epidemics occur when migrants introduce the virus into areas with high human population density. Domestic mosquitoes carry the virus from person to person. No monkeys are involved in transmission. There is evidence to suggest that Yellow fever virus can be maintained in one place until the amplifying primates become immune and then reemerge in areas where susceptible primates live. Yellow fever virus is maintained through the dry season by means of transovarial transmission. The normal low risk to travellers increases with travel to jungle areas in endemic countries and in or near cities during urban outbreaks. Areas where Yellow fever virus is present far exceed those officially reported. The risk of exposure to infection can be reduced by taking measures to prevent mosquito bites (4, 5, 7). The mosquito vectors of Yellow fever are mostly day biters. Although reported cases of human disease are the principal indicator of disease risk, some countries may have no reported cases, either because of a high level of vaccine coverage against Yellow fever in the population or because poor surveillance resulted in no cases being reported. However, the risk of Yellow fever may still persist as the virus, the vector or the animal reservoirs are still present (8-10).

**Incubation Period**

The intrinsic incubation period in human beings is between 2 and 6 days. The extrinsic incubation period in a mosquito varies from 4 to 18 days (average 12 days), with the temperature and humidity. Once the mosquito becomes infective, it remains so for the rest of its life (2).

**Communicability Period**

The case is infective to the vector mosquito during the later part of the incubation period and first three clinical days. An infected individual, therefore, can spread infection for about 4 to 6 days, starting 2 to 3 days after exposure to the infection. It is to prevent the entry of such individuals in India that rigorous rules and regulations are enforced (2).

**Clinical Features**

The disease presents in two phases. Some infections may be completely asymptomatic. Usually the first "acute" phase is characterized by fever, muscle pain, headache, loss of appetite, nausea and vomiting. The high fever may be paradoxically associated with a slow pulse. After three to four days most patients improve and their symptoms disappear. About 15% of patients enter a "toxic phase" within 24 hours. The patient rapidly develops jaundice and has abdominal pain with vomiting. Bleeding can occur from the mouth, nose, eyes and/or stomach. Blood may appear in the vomit and faeces. Kidney function deteriorates. About half of the patients in the "toxic phase" die within 10 - 14 days. The remaining recover without significant organ damage. Yellow fever is difficult to recognize, especially during the early stages. It can easily be confused with malaria, typhoid, rickettsial diseases, haemorrhagic viral fevers, dengue fever, leptospirosis and viral hepatitis (3).

Complications

Kidney, liver and myocardial damage may occur. Ischemic changes affect other organs as well as a result of widespread hemorrhages and the resulting shock. Coagulopathy may occur as a result of two processes - decreased hepatic synthesis of coagulation factors and the presence of DIC (1, 2).

**Diagnosis**

Baseline investigations must be carried out in suspected case. Leukopenia with relative neutropenia can occur. Thrombocytopenia can occur as part of a consumptive coagulopathy. Patients are also likely to have an elevated prothrombin time and prolonged clotting times. Renal damage, if present, results in grossly elevated serum creatinine levels and markedly elevated levels of urinary protein. In severe cases liver function tests are grossly deranged. Specific laboratory diagnosis relies on serology or on detection of the virus and viral antigens. Rapid detection methods include the detection of Yellow fever antigen by monoclonal enzyme immunoassay in serum specimens & detection of viral genome sequences in tissue or blood using polymerase chain reaction (PCR). Serologic studies include the Immunoglobulin-M (IgM) antibody - capture enzyme - linked immunosorbent assay (MAC - ELISA) used to detect the specific presence of IgM for Yellow fever. IgM appears 7 - 10 days following infection. A 4 - fold rise in hemagglutination inhibition, complement fixation, or neutralization of antibodies in acute and convalescent phases is also diagnostic of Yellow fever. The Yellow fever virus can be isolated from viral culture with the intracerebral inoculation of suckling mice or inoculation of mosquito cell cultures (1).

**Treatment**

As there is no specific treatment for Yellow fever, supportive care is critical. Dehydration and fever must be corrected with oral rehydration salts and anti - pyretics. Any superimposed bacterial infection should be treated with appropriate antibiotics. Intensive supportive care

may improve the outcome for seriously ill patients, but is rarely available in poorer, developing countries.

### Prevention and Control

Vector control and vaccination are the cornerstones of Yellow fever control. Vector control is considered in detail in the Chapter on Entomology.

### Yellow Fever Vaccine

During the 1930s, both wild - type Yellow fever virus strains, Asibi and French, were attenuated to derive live vaccines known as 17D and the French neurotropic vaccine, respectively (2) Currently, 17D is the only strain of Yellow fever virus used for vaccination. 17D vaccines are heterogenous mixtures of multiple virus subpopulations (10)

#### Immune Response

More than 95% of vaccinated people develop neutralizing antibodies within 10 to 14 days of immunization. The International Health Regulations stipulate that the vaccination certificate for Yellow fever is valid for 10 days after administration of 17D vaccine, corresponding to the time at which the majority of vaccinees are demonstrably immune. Immunity following 17D vaccination is remarkably durable and may be lifelong.

#### Vaccine Dose, Route of Administration & Preparations

A 17D vaccine dose contains approximately 105 PFU in 0. 5 mL and is given subcutaneously, usually in the upper arm. Because there is no preservative in the vaccine and because the vaccine rapidly loses potency after reconstitution, it must be refrigerated at the point of use and held on ice and used soon after reconstitution. Reconstituted vaccines must be discarded within 4 hours. The Vaccine is supplied in single and multiple - dose containers.

#### Vaccine Failure

Rarely, healthy people fail to develop neutralizing antibodies following 17D vaccination. This is not an absolute refractoriness; people who fail to develop antibody after their first vaccination may develop antibody upon revaccination (2, 4, 7).

#### Precautions and contraindications

Tolerance of the vaccine is generally good. Less than 5% of vaccine recipients have mild reactions, including myalgia and headache. Contraindications include true allergy to the constituents, cellular immunodeficiency and symptomatic HIV infection. Many industrialized countries administer Yellow fever vaccine to persons with symptomatic HIV infection provided that the CD4 count is at least 200 cells/$mm^3$ (11, 12) Asymptomatic HIV - positive individuals may have a reduced response to the vaccine. There is a theoretical risk of harm to the fetus if the vaccine is given during pregnancy, but this must be weighed against the risk to the mother of remaining unvaccinated and travelling to a high - risk zone. There have been recent reports of a small number of cases of serious disease, including deaths, following Yellow fever vaccination; most of these reactions occurred in elderly persons (12, 13-15). The risk to unvaccinated individuals who visit countries where there may be Yellow fever transmission is far greater than the risk of a vaccine - related adverse event and it remains important for all travellers at risk to be vaccinated. Nonetheless, Yellow fever vaccination should not be prescribed for individuals who are not at risk of exposure to infection (16-18). Yellow fever vaccination should be encouraged as a key prevention strategy, but it is important to screen travel itineraries, particularly of older travellers and carefully evaluate the potential risk of systemic illness after Yellow fever vaccination (2, 7, 10, 11).

### Mandatory vaccination

Mandatory vaccination against Yellow fever is carried out to prevent the importation of Yellow fever virus into vulnerable countries. These are countries where Yellow fever does not occur but where the mosquito vector and non - human primate hosts are present. Importation of the virus by an infected traveller could potentially lead to the establishment of infection in mosquitoes and primates, with a consequent risk of infection for the local population. In such cases, vaccination is an entry requirement for all travellers arriving from countries, including airport transit, where there is a risk of Yellow fever transmission. If Yellow fever vaccination is contraindicated for medical reasons, a medical certificate is required for exemption (19). The international Yellow fever vaccination certificate becomes valid 10 days after vaccination and remains valid for a period of 10 years. Travellers should be aware that the absence of a requirement for vaccination does not imply that there is no risk of exposure to Yellow fever in the country.

Yellow Fever Vaccination centres in India are as follows :

(a) National Institute of Communicable Diseases, New Delhi.

(b) All India Institute of Hygiene and Public Health, Kolkata.

(c) All major Airport Health Organizations.

(d) All Port Health Organizations.

(e) Armed Forces Clinic, New Delhi (this is the designated centre for Armed Forces)

### Prevention of Entry of Disease in India

In India, *Aedes aegypti* is wide spread and the people possess no immunity against Yellow fever. Yellow fever has not so far entered India due to the stringent regulations and their rigid enforcement. It is, however, interesting to note that Yellow fever never entered India even before these regulations were introduced. May be, this was due to the slow mode of voyage from the African coast to India. Due to faster means of travel the danger of its entry has increased. The details on International Health Regulations are given in the Chapter on Aviation Health.

# Anthrax

## Introduction

Anthrax (Greek : black) is a disease primarily of domestic herbivores caused by the bacterium *Bacillus anthracis*. The bacilli live in the topsoil and are ingested by animals while grazing. Infections to humans, though generally rare, have myriad presentations. Anthrax gained its popularity by the fact that it is probably the most suitable of all agents for germ warfare (1). Medical systems worldwide are facing the new threat of morbidity associated with the deliberate dispersal of microbiological agents by terrorists (2). Anthrax is also called as 'malignant pustule', 'woolsorter's disease' and 'rag pickers disease'(3).

During the great war, german scientists and officials applied anthrax in a widespread campaign of biological sabotage, their target being livestock. Large populations of livestock were ravaged when the spores were added to their feed (4). In 1936, japanese scientists were believed to have killed over 10, 000 human subjects in occupied manchuria, by testing lethality of various diseases like anthrax, plague and typhoid (5). Before the advent of anthrax use for bioterrorism, accidental contamination had already caused fatalities in pockets around the world. For e. g. a cloud of spores released from a faulty plant in Sverdlovsk in former USSR in 1979 caused many deaths in villages downwind from the plant (6). For more than two decades before 2001, bioterrorism experts all over the world were warning the environment, regarding use of anthrax in bioterrorism. A week after the infamous September 11 attack, the world was struck with incidences of letters containing anthrax spores being mailed. Eighteen people were affected and 5 died, besides hundreds of millions across the world who were struck by anxiety of the unknown (7).

## Geographical distribution

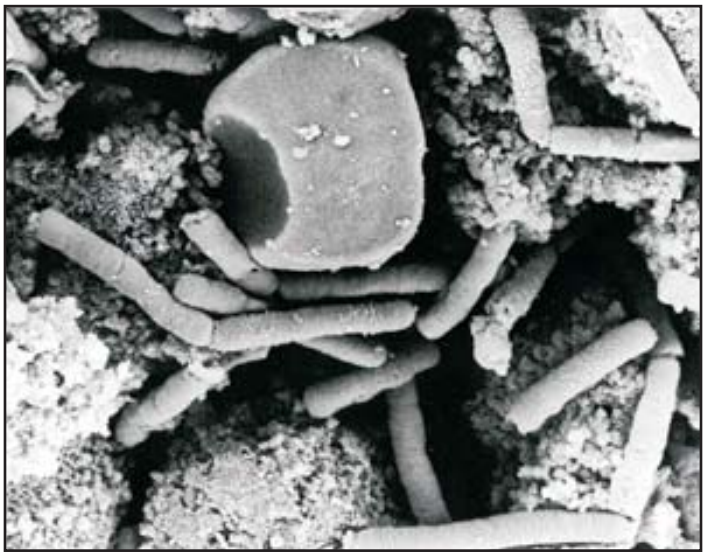
Anthrax is a documented occupational hazard, primarily of workers who are directly involved with herbivore animals e. g. Hide processors, hair and bone product workers, wool sorters, veterinarians, agricultural and wildlife workers. Personnel of armed forces handling animals especially at military farms and animal transport companies. Anthrax is endemic in Asia, Africa, South and Central America and Southern Europe (3). The disease killed over 1 million sheep in Iran in 1949 (8). Cutaneous anthrax is the most common form with around 2000 cases occurring worldwide per year (9). The largest human epidemic took place in Zimbabwe, Africa where over 10, 000 cases occurred between 1979-1985 (10).

## Epidemiology

### Agent and Transmission

*Bacillus anthracis* is a large, non-motile, brick shaped, aerobic, gram positive rod which has a capacity to make heat and dry-resistant spores under adverse conditions (Fig - 1). The spores are known to survive for decades in the topsoil and can resist temperature up to 140°C for 3 hours and even resist boiling water for 10 minutes (8).

Fig - 1 : Brick shaped bacilli on electron microscopy



Virulence is conferred by the capsule and a complex exotoxin.

Infection of the herbivorous animals is from minor trauma in the oral mucosa, which occurs due to chewing rough vegetation and soil harbouring the spores, which invariably get inoculated in the mouth. An infected animal that dies due to anthrax is loaded with vast number of bacteria and is potentially very infectious to any handler or scavenging animal (11).

Humans acquire infection by the following routes.

(a) Direct Inoculation : of spores through breaks in the skin.

(b) Inhalation of spores

(c) Ingestion of contaminated meat.

(d) Direct person to person transmission is rare but documented.

Incubation period : commonly 1 – 7 days, although incubation period extending up to 60 days has also been documented.

## Clinical presentation

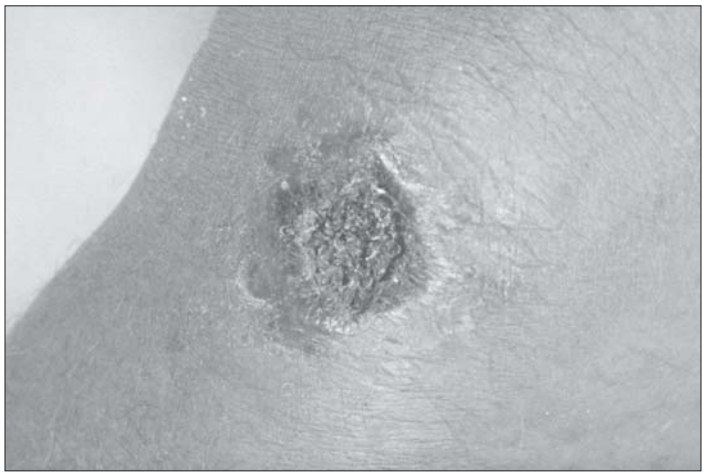
Anthrax is known to manifest in three forms; cutaneous, pulmonary and intestinal. A brief description of the various forms is as follows :

### (a) Cutaneous anthrax

The disease leads to the formation of a small papule, with a central vesicle at the site of inoculation. The following days lead to the formation of vesicles around the central lesions which ulcerate and dry out, leaving a black eschar (Fig - 2). There is generally no pain or discomfort and the lesions do not discharge pus. There is an inflammatory

response in the dependent lymph nodes. Anthrax cutaneous lesions are common on the head, neck and exposed arms, but rarely on the hands (3).

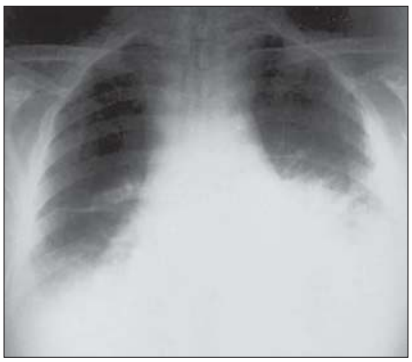
Fig - 2 : Eschar of cutaneous anthrax



(b) Pulmonary anthrax

This usually is due to inhalation of spores. The macrophages ingest the spores, many of which are destroyed. Remaining spores are transported by lymphatics to the mediastinal lymph nodes. The bacilli release exotoxins, which lead to haemmorhage, oedema and ultimately necrosis. Dose sufficient ot kill 50 % of persons exposed is 200 - 55, 000 inhaled spores (11). It commences with fever and chills. Often progresses to shortness of breath, cyanosis and respiratory distress. Lungs often get filled with interstitial fluid (Fig - 3). Death may occur within hours of onset of symptoms. Case fatality rate tends to be as high as 90 % in pulmonary anthrax (10).

Fig - 3 : Mediastinal widening seen in inhalational anthrax



**(c) Intestinal anthrax**

This form of anthrax is very common in Africa, mainly occurring due to consumption of contaminated meat. Presentation is generally non-specific, manifesting as vomiting, diarrhoea, dysentery, hematemesis and fever. Case fatality is high if not managed aggressively. Autopsy reveals an eschar in the gut.

**Management and prevention**

Diagnosis

It is mainly clinical and history based. However the confirmation of the organism is based on direct scraping from the lesion or aspiration, which can be subsequently cultured (13).

Notification

Anthrax is a notifiable disease as far as the armed forces are concerned and falls in the 'group B' of communicable diseases. On occurrence of a case of anthrax the authorities in the three services will be informed as per format on AFMSF - 73 (14).

Isolation

This is a standard precaution for the whole duration of illness, especially for cutaneous and inhalational anthrax. Standard barrier isolation practices are recommended for all hospitalized patients. The use of high efficiency particulate filter masks is not recommended (15). Though antibiotics sterilize lesions within the first 24 hours, the lesions progress through full natural course before subsiding. As human to human transmission is rare, there is no requirement of quarantine of contacts.

Specific treatment

On confirmation of diagnosis, aggressive treatment must be initiated, with a guard on vital parameters. Intravenous penicillins still remain the drug of choice. Oral amoxycillin and cotrimoxazole are good alternatives. However ciprofloxacin and doxycycline are recommended first line agents for chemoprophylaxis in individuals exposed to anthrax, but not symptomatic (14). CDC recommends that post-exposure prophylaxis should continue for 60 days (16).

Concurrent disinfection

It should be ensured that all discharges of lesions, soiled articles and linen of patients are disinfected. Sodium hypochlorite is the sporicidal of choice, however hydrogen peroxide and glutareldehyde are good alternatives. All soiled goods should also be steam sterilized (3).

Investigation and education of contacts

On occurrence of a case, rapid search should be undertaken to find all susceptible and exposed individuals. All contacts should be line-listed and followed up. Individuals involved in handling animals and animal products should be aware of anthrax. Special emphasis should be given on care of skin and personal cleanliness. Dust-control and proper ventilation should be mandatory in work areas of animal – products based industry.

Prevention in general population

The population should be encouraged not to eat the meat of animals that become ill or die (17, 18). On occurrence of anthrax deaths in livestock, the proper method of disposal of carcass must be as described later.

Anthrax vaccine

The first successful vaccines for animals against anthrax

were produced by Louis Pasteur in 1881. At present the single vaccine licensed for human use is produced from the cell free culture supernatant of an attenuated, non-encapsulated strain of *Bacillus anthracis* (Stern strain), referred to as the 'Anthrax Vaccine Adsorbed' (AVA). Clinical trials are at present underway to evaluate role of 'recombinant protective antigen' as an alternative to AVA (19). Anthrax vaccine are presently advocated for individuals having special risk of exposure i. e. Laboratory workers who handle *B. Anthracis* and workers in contact with animals (20).

**Disposal of anthrax carcass**

As anthrax is an aerobic bacillus, the spores require oxygen to multiply, which is not available in a closed carcass. Thus leading us to a conclusion that post-mortem of a suspected anthrax infected animal death is forbidden. The preferred method of disposal therefore is incineration, as it destroys all the spores. Incineration may sometimes be not possible due to either shortage of fuel or too large a number of carcasses to be disposed. In that case deep burial of the carcass must be resorted to. This is required as shallow burial will permit scavenging animals to exhume and feed on the infected carcass, thus spreading infection. The carcass should be disinfected with slaked lime before burial (13).

# Tetanus

## Introduction

Tetanus derives its name from the Greek word 'tetanos' which means 'to contract'. An acute disease induced by the exotoxin of the tetanus bacilli, which grows anaerobically at the site of injury. The disease is characterized by painful muscular contractions, primarily of the masseter and neck muscles, secondarily of the trunk muscles (1). Despite the WHO effort to eradicate the disease by 1995, tetanus remains one of the world's major preventable causes of death, estimated to cause up to 1 million deaths every year (2).

In 1880 Nicolaier demonstrated that soil contamination of wounds resulted in tetanus, but it was Kitasato who isolated the first pure culture of Clostridium tetani in 1889. In 1890 Faber discovered the tetanus toxin and Von Behring and Kiatsato then gave the world the first tetanus antitoxin. However it was 38 years later in 1928 that Ramon performed the first successful vaccination of humans (3).

The availability of the tetanus vaccine has enabled the developed countries to virtually eliminate the disease. However as C tetani can and will never be eliminated from the soil, whenever and wherever ineffectiveness or inadequacy of the vaccination effort prevails, tetanus will occur and cause mortality (4).

## Problem statement

The disease is primarily confined to developing countries, where immunization is either not available or vaccine supply is of poor quality. 80% of cases occur in Africa and South East Asia, with Neonatal tetanus being one of the world's most underreported notifiable diseases(5). Neonatal Tetanus (NT) is a killer disease, second only to measles among the six target diseases covered in the Expanded Programme of Immunization (EPI). Case fatality rate tends to be 80 - 90 %. The SEARO five countries namely Bhutan, DPR Korea, Maldives, Sri Lanka and Thailand have eliminated NT. The remaining four, namely Indonesia, Myanmar, Bangladesh and India bear the full brunt of the cases in the region (6).

## Factors specific to India

There are certain factors existing in our country, which greatly influence and enhance the presence of NT, some of them being

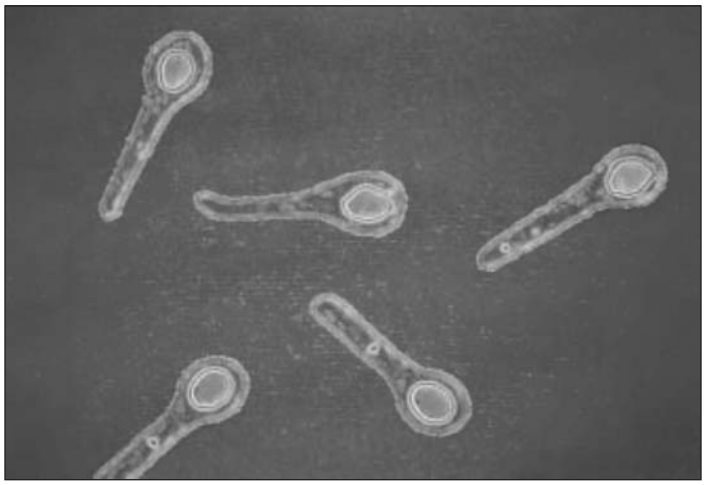
(a) Delivery practices in rural areas.
(b) Traditional birth customs.
(c) Immunisation uptake in community.
(d) Availability of EPI vaccines across the country, especially in rural areas.
(e) Behaviour and practices in rural areas, especially general hygiene, sanitation and hand washing.

## Epidemiology

### Agent

*Clostridium tetani* is a strictly anaerobic, Gram positive bacillus thriving in soil and animal faeces. When subjected to adverse conditions, rounder terminal spores are formed, giving the classical 'drumstick' appearance to the bacillus (Fig-1). If cultures are more than 24 hours old, the bacteria is readily decolorized, thus appearing to be Gram negative. It is susceptible to antibiotics like penicillin, erythromycin, clindamycin, tetracycline, chloramphenicol & metronidazole. The spores however are very resistant to physical and chemical agents and can even survive boiling water, though they are very susceptible to autoclaving. (7). The spores germinate under favourable anaerobic conditions to produce a potent exotoxin (tetanospasmin), which in lethality is second only to Botulin toxin (8). The toxin acts on the motor end plates, spinal cord, brain and the sympathetic system (9), principal action being to block the inhibition of spinal reflexes.

Fig - 1 : Bacilli of **Clostridium tetani**



### Host factors

Tetanus is primarily a disease of active age (5 – 40 years), as well as neonates. In India there is a documented male preponderance for NT, with no proven medical reason for increased male susceptibility. This male (sex) bias has been attributable to a social factor of aggressive health care seeking behaviour for a sick male neonate as compared to for a female (10). The disease has a definite rural preponderance with a predilection for individuals associated with agricultural related professions. (11). The personnel of the Armed Forces are also susceptible to tetanus, through various modes of exposure related to their profession.

### Environmental factors

The environmental and social factors are interlinked. Unhygienic customs, traditions and practices compounded by ignorance of infections and lack of primary health care facilities enhance the spread of the disease.

### Pathogenesis

*Clostridium tetani,* being anaerobic, requires low oxygen tension for germination and multiplication. In a well oxygenated, healthy tissue, germination will not occur and spores are quickly removed by phagocytosis.(12 )

Tetanus exotoxin enters the nervous system from adjacent muscle tissue, where it has been generated. It may also be disseminated by lymphatics and blood. Reduced inhibitions of the neuromuscular junctions and the GABA inhibitory neurons result in disinhibited motor neuron discharge, which gives the characteristic features of muscle rigidity and spasms. Muscle groups with shortest neuronal pathways are affected first, hence trismus and dysphagia are common early symptoms (13). The toxin also causes uncontrolled sympathetic and parasympathetic discharges.

### Types of Tetanus

Tetanus can occur in various forms, depending upon its mode of entry and targeted damage:

(a) **Traumatic Tetanus** : This is a major cause, sometimes resulting even from trivial wounds.

(b) **Puerperal Tetanus** : A major form of tetanus predominantly following abortions done under compromised conditions. It is rarely seen in normal labour in institutional deliveries, but non-institutional deliveries done with unhygienic practices cause a lot of cases.

(c) **Otogenic Tetanus** : Mainly a paediatric problem, which occurs through introduction of infection through the aural canal, by unhealthy practices inserting pencils, matches etc in the external auditory canal.

(d) **Idiopathic tetanus** : Mainly due to microscopic trauma, but many hold a view that it may be due to absorption of the tetanus toxin through the intestinal tract or the respiratory tract.

(e) **Tetanus Neonatorum** : Kills 85 % of those affected .

### Signs and Symptoms

There is an incubation period of 7-10 days, but this is variable and many patients cannot recall any injury. The disease is characterized by muscular rigidity and spasms. When it is confined to muscle groups adjacent to the site of wound, it is localized tetanus or cephalic tetanus, and generalized tetanus when it involves the whole body. In mild forms of tetanus, rigidity may be the only symptom. Spasms are most pronounced during the first 2 weeks of the disease and occur spontaneously or as a result of stimuli such as loud noises, bright lights or physical manipulation. Spasms can be strong enough to cause vertebral fractures and tendon avulsions, besides being excruciatingly painful. The classic reverse bending of a human spine during peak of spasm of the back and neck muscles, resembling a bow is seen. This is called 'opisthotonus'(Fig-2). Characteristic facial muscle involvement causes the 'risus sardonicus' or the 'sardonic smile'. Laryngeal spasms can lead to asphyxia.(1,4,14)

The advent of mechanical ventilation has led to a marked reduction in mortality from respiratory failure, but in doing so has unmasked another major cause of mortality; the syndrome of autonomic overactivity. This becomes evident during the second week of illness and expresses itself as sustained labile hypertension and tachycardia, pyrexia and profuse sweating (15). Autonomic dysfunction affects the GIT leading to diarrhoeas and is also associated with Acute Renal Failure.

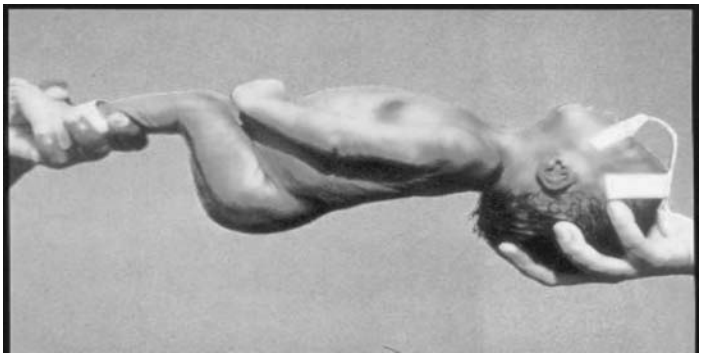
Fig - 2 : 'Opisthotonus' Painting by Sir Charles Bell- 1809

### Neonatal Tetanus

The symptomatology is generally similar to that of adults. As the name goes, mainly affects neonates (up to 28 days of age). It is seen that the neonates whose mothers have been vaccinated, experience a milder disease and better prognosis. Main symptoms among the neonate include stiffness(Fig-3), inability to feed and spasms.(1)

The diagnosis of tetanus is primarily clinical and a high degree of suspicion must be maintained by the treating physician, based on the history and the findings.(1,4)

Fig - 3 : Tetanus Neonatorum



### Prevention of Tetanus

Prevention of tetanus encompasses everything from educating the masses, provision of immunization facilities, early diagnosis and treatment of cases. It aims at decreasing the burden of disease on humanity as a whole.

Education and awareness

Educate public on the necessity for complete immunization with Tetanus Toxoid, the hazard of contaminated wounds, faulty practices and traditions

which propagate the disease. This also includes availability of TT vaccine for antenatal cases as well as newborns at all levels of healthcare. Full uptake of EPI vaccines by the community must be ensured.

Active immunization

This forms the most important preventive modality against the disease. A full course of immunization done with an adsorbed tetanus toxoid gives durable immunity for up to 10 years. The toxoid stimulates the production of an effective antitoxin. The vaccines available are the monovalent vaccines which may be either plain or adsorbed; or the combined DPT vaccine, which battles against Diptheria, Tetanus and Pertusis and forms part of the EPI vaccines. The adsorbed monovalent vaccine has Aluminium Hydroxide as adjuvant and is a cloudy uniform suspension in isotonic saline solution, which stimulates a higher and a longer lasting response than plain Toxoid. The schedule of active immunization is given in Table - 1.

While tetanus toxoid is recommended for universal use regardless of age, it is especially important for workers in contact with soil, sewage and domestic animals. Personnel of the Armed Forces also fall in a protected category due to a greater risk of occupation related traumatic injury. (1)

Passive immunisation

This can be done either by Human Tetanus Immunoglobulin (HTIG) or Anti Tetanus Serum (ATS). The HTIG is a sterile non-pyrogenic solution of hyperimmuneglobulins prepared from plasma of healthy volunteers specifically immunized against tetanus. The dose for prophylaxis in case of contaminated wounds is 250 - 500 I.U. IM. Theraupetic doses for Tetanus Neonatorum is 500 - 10,000 I.U. IM or 250 I.U. intrathecally. In adults and children also it is 500 - 10,0000 I.U. IM. The HTIG gives an effective passive protection for up to 30 days. The ATS is produced from horses and the standard dose is 1500 I.U. subcutaneously. Being equine based, ATS is documented to cause more sensitivity reaction than HTIG, so is generally avoided.

Combined immunisation

This is generally carried out for contaminated wounds in non-immunised persons or in persons whose previous immunization history is doubtful. It also serves as a guideline for all wound management (17). The schedule is as in Table - 2.

Prevention of tetanus also depends upon effective

Table - 1 : Schedule of active immunisation with Tetanus Toxoid

| Category | Primary Immunisation | | | Boosters | | |
|---|---|---|---|---|---|---|
| | 1st Dose | 2nd Dose | 3rd Dose | I | II | III |
| Epi Schedule Combined Vaccine DPT | 6th Week (DPT) | 10th Week (DPT) | 14th Week (DPT) | 16-24th Month (DPT) | 5th Year (DT) | 10th Year (TT) |
| Adults & Child above 10 Years (0.5 ml IM) | 0 Day | 4th -6th Week | 1st Year | Every 5 Years | | |
| Pregnant Woman (0.5 ml IM) | 20th Week | 24th-26th Week | | | | |

Table - 2 : Tetanus vaccination schedule for wound management

| Immunization Status | Tetanus Vaccination according to Type of wound | |
|---|---|---|
| | Clean Wound (Low Risk)* | Tetanus Prone Wound (High Risk)** |
| Documented primary series 250 DPT and reinforcing dose of TT within last ten years. | No Vaccination required | Human Tetanus Immunoglobulin (HTIG) –as I.U. in 1 ml IM in deltoid or gluteal region. > 24 hours have elapsed since injury, or risk of heavy contamination, or following burns, the recommended dose is 500 I.U. |
| Documented primary series and reinforcing dose of TT + HTIG. last dose more than 10 years | Toxoid Vaccine (TT) -0.5 ml IM. | Single reinforcing dose of Tetanus (See dosage above.) TT vaccine and HTIG must be given by separate syringes into separate sites |
| Not immunized or immunization course of TT Vaccine + HTIG status not known with certainty | 0.5 ml at intervals of not less than 4 weeks.(See dosage above) | Full course of TT Vaccine (3 doses) of |

management of wounds as described in the preceding paragraph, along with aggressive and effective wound toilet. Wound toilet is of paramount importance and special attention should be given to deep puncture wounds, burns, animal and human bites, contaminated wounds and chronic non healing wounds. Antibiotic prophylaxis is secondary to good surgical toilet as well as immunoprophylaxis. (18)

### Specific treatment

Along with concurrent active and passive immunization, under a constant watch for hypersensitivity reactions, specific treatment is required. This includes prompt debridement of wounds. Metronidazole is the drug of choice, although penicillin group is widely used. Patients treated primarily with metronidazole have lesser spasm and require lesser sedation(19). Maintain adequate airway, sedation and muscle relaxation in an isolated dark room so as to avoid provoked spasms.

### Prevention in the Armed Forces

All personnel in the Armed Forces fall in a category having a greater risk of infection with Clostridium tetani. All personnel are supposed to be immunized on entry to the Armed Forces and a booster is mandatory for all (Schedule as per Table 1). It is the responsibility of the CO of the unit, to ensure that all ranks in the unit are immunized as per schedule. The RMO / AMA of the unit ensures action on ground, and is supposed to maintain immunization record of all personnel of the unit. This is done by endorsing the individual's Personal Pay book (AB-64), Health Record card and the Immunisation register of the MI Room. The RMO / AMA is responsible for vaccinating all ranks, families and civilian employees under his medical charge. (Para 105 b, 115, RMSAF 1983). Personnel at greater risk than others like amimal handlers, military farm workers should get annual shots of the Toxoid.

# Rabies

## Historical Background

Rabies is a very old disease, perhaps as old as humankind. The word rabies has its origin in Sanskrit, 3000 years BBC: "rabhas" means "to do violence". The Greek word for rabies, "lyssa" derives from the root "lud" which means "violent". Thus, the family of viruses to which rabies belongs is lyssa. The first description of the disease dates from the 23rd. century BC in the Eshuma Code of Babylon. Antiquity, did know rabies as well as the link between human disease and animals, especially dogs. But, it is a famous Italian scholar, Girolamo Fracastoro, born in Verona, who described the disease, which obviously he had seen in many patients, and its routes of contamination in 1530, i.e. 350 years before Louis Pasteur. In the 19th. century, canine or street rabies was a scourge everywhere, especially in Europe. Fear of rabies, related to the mode of contamination, the absence of any efficacious treatment, was almost irrational. Patients killed themselves or were killed when bitten by a dog believed to be rabid. In this world of irrational terror the first post-exposure treatment was discovered in 1885 by Louis Pasteur.

## Introduction

Rabies is a acute viral disease, which causes encephalomyelitis in virtually all the warm blooded animals, including man. The causative agent is found in domestic and wild animals and is transmitted to other animals and humans through close contact with their saliva ( bites, scratches, licks on broken skin and mucus memberanes)

## Agent

Rabies viruses belong to the genus Lyssavirus of the Rhabdoviridae family. Currently, this genus comprises 7 genotypes, type 1 of which represents the classic rabies virus.

### Structure

This RNA virus is bullet shaped round at one end and flat at the other measuring 100-300nm in length and 75 nm in diametre. The virus is covered with a lipid envelope having spike like projections. It is composed of two structural and functional units:

(a) The outer envelope covered with spike-like projections (10 nm in length) corresponding to G-protein trimers which recognize specific viral receptors on susceptible cell membranes

(b) The internal helically packaged ribonucleocapsid, which is composed of the genomic RNA intimately associated with protein N, polymerase L and its cofactor protein P (formerly named M1). The ribonucleocapsid complex ensures genome transcription and replication in the cytoplasm.

Protein M (formerly named M2) occupies an intermediate position between the ribonucleocapsid and the envelope and is responsible for virus budding and the bullet-shaped morphology.

### Susceptibility to physical and chemical agents

The rabies virus is highly resistant to cold , dryness and decay. In cadavers, it may remains infectious for weeks. This virus is highly thermolabile with a half life of approximately 4 hours at 40°C and 35 seconds at 60°C. Serum proteins and other chelating agents diminish thermal inactivation. In brain tissue, at room temperature it can survive upto 1-2 weeks. (1)

The rabies virus remains stable for several days at 0-4°C, indefinitely at -70°C and when freeze dried. The virus cannot withstand pH less then 4 or more then 10. It is also susceptible to the action of oxidizing agents, most organic solvents, surface acting agents and quaternary ammonium compounds. Proteolytic enzymes, UV rays and Xrays rapidly inactivate the rabies virus. Soaps and detergents are effective against rabies virus because of their lipid eliminating property, which destroys the outer covering of the virus.

## Epidemiology

### Global Status

In >100 countries and territories, rabies is enzootic in animal populations with more than 3.3 billion people live in these regions.. Approximately 55,000 people die from rabies each year, the vast majority of these deaths occurring in Asia and Africa. In Africa, there are estimated at 24,000 (or 4 per 1,00,000 population)deaths annually. Although all age groups are susceptible, rabies is most common in children aged below 15 years, with 30-50% of post-exposure prophylaxis given to children aged 5-14 years, the majority being male. Annually, more than 10 million people, mostly in Asia, receive post exposure vaccination against rabies.

### Rabies in India

In India alone, 20,000 deaths are estimated to occur annually, i.e. 2 per 1,00,000 population. Almost 1.8 million people annually receive post exposure-prophylaxis against rabies. With the exception of Andaman & Nicobar islands and Lakshwadeep islands, human cases of rabies are reported from all over the country round the year. 96% of mortality and morbidity is associated with dog bites. Cats, wolf, mongoose and monkeys are other important reservoirs of rabies in India. Bat rabies has not been conclusively reported in India.

## Mode of transmission

Human infection usually occurs following a transdermal bite or scratch by an infected animal. Transmission may also occur when infectious material, usually saliva, comes into direct contact with the victim's mucosa or with fresh skin lesions. The virus cannot cross intact skin. Very rarely, rabies may occur through inhalation of virus - containing aerosol or via infected organ transplants.

## Incubation Period

The incubation period varies from 2 weeks to 6 years

(average 2–3 months) depending on the amount of virus in the inoculum and site of inoculation. The proximity of the site of virus entry to the CNS increases the likelihood of a short incubation period.

### Pathogenesis

On entering the human body, The virus then either replicates in non-nervous tissues or directly enters peripheral nerves and travels by retrograde axoplasmic flow to the central nervous system (CNS). The estimated speed of virus migration is 15–100 mm per day. The virus then moves from the CNS via anterograde axoplasmic flow within peripheral nerves, leading to infection of some of the adjacent non-nervous tissues: for example, secretory tissues of salivary glands. The virus is widely disseminated throughout the body at the time of clinical onset. The first clinical symptom is usually neuropathic pain at the wound site. This is caused by virus replication in dorsal root ganglia and ganglionitis. Major clinical signs are related to the virus-induced encephalomyeloradiculitis. Two major clinical presentations are observed: furious and paralytic forms that cannot be correlated with any specific anatomical localization of rabies virus in the CNS (4). Nevertheless, peripheral nerve dysfunction is responsible for weakness in paralytic rabies. In furious rabies electrophysiological studies indicate anterior horn cell dysfunction even in the absence of clinical weakness. Without intensive care, death occurs within a few days (1–5 days) of the development of neurological signs. Rabies is inevitably fatal.

### Clinical Diagnosis

Diagnosis of rabies based on clinical grounds alone is difficult and unreliable except when specific clinical signs of hydro or aerophobia are present. Some patients present with a paralytic or Guillain-Barre-like syndrome or other atypical clinical features (5). Classical signs of brain involvement include spasms in response to tactile, auditory, visual or olfactory stimuli (e.g. aerophobia and hydrophobia) alternating with periods of lucidity, agitation, confusion, and signs of autonomic dysfunction. These spasms occur at some time in almost all rabid patients in whom excitation is prominent. However, spontaneous inspiratory spasms usually occur continuously until death and their presence often facilitates clinical diagnosis. Excitation is less evident in paralytic rabies, and phobic spasms appear in only 50% of these patients. During the early stages of paralytic rabies, notable signs include myoedema at percussion sites, usually in the region of the chest, deltoid muscle and thigh, and piloerection. Atypical or non-classic rabies is being increasingly recognized and may be responsible for underreporting.

### Post Exposure Treatment in Humans

Local treatment of wounds

Elimination of rabies virus at the site of the infection by chemical or physical means is an effective mechanism of protection. Therefore, the Consultation emphasized the importance of prompt local treatment of all bite wounds and scratches that might be contaminated with rabies virus. Recommended first-aid procedures include immediate and thorough flushing and washing of the wound for a minimum of 15 minutes with soap and water, detergent, povidone iodine or other substances of proven

Table - 1 : Type of contact, exposure and recommended post-exposure prophylaxis

| Category | Type of contact with a suspect or confirmed rabid domestic or wild[a] animal, or animal unavailable for testing | Type of exposure | Recommended post-exposure prophylaxis |
|---|---|---|---|
| I | Touching or feeding of animals Licks on intact skin | None | None, if reliable case history is available |
| II | Nibbling of uncovered skin<br>Minor scratches or abrasions without bleeding | Minor | Administer vaccine Immediately[b]<br>Stop treatment if animal remains healthy throughout an observation period of 10 days[c] or if animal is proven to be negative for rabies by a reliable laboratory using appropriate diagnostic techniques |
| III | Single or multiple transdermal bites or scratches, licks on broken skin<br>Contamination of mucous membrane with saliva (i.e. licks)<br>Exposures to bats[d] | Severe | Immunoglobulin and vaccine immediately. Stop treatment is animal remains healthy throughout an observation period of 10 days or if animal is found to be negative for rabies by a reliable laboratory using appropriate diagnostic techniques |

(a) Exposure to rodents, rabbits and hares seldom, if ever, requires specific anti-rabies post-exposure prophylaxis.

(b) If an apparently healthy dog or cat in or from a low-risk area is placed under observation, the situation may warrant delaying initiation of treatment.

(c) This observation period applies only to dogs and cats. Except in the case of threatened or endangered species, other domestic and wild animals suspected as rabid should be humanely killed and their tissues examined for the presence of rabies antigen using appropriate laboratory techniques.

(d) Post-exposure prophylaxis should be considered when contact between a human and a bat has occurred unless the exposed person can rule out a bite or scratch, or exposure to a mucous membrane.

lethal effect on rabies virus. If soap or an antiviral agent is not available, the wound should be thoroughly and extensively washed with water. People who live in rabies-infected areas should be educated in simple local wound treatment and warned not to use procedures that may further contaminate the wounds. Most severe bite wounds are best treated by daily dressing followed by secondary suturing where necessary. If suturing after wound cleansing cannot be avoided, the wound should first be infiltrated with passive rabies immunization products and suturing delayed for several hours. This will allow diffusion of the antibody to occur through the tissues before suturing is performed. Other treatments, such as the administration of antibiotics and tetanus prophylaxis, should be applied as appropriate for other bite wounds.

Post Exposure prophylaxis (2)

Table - 1 should serve as a guide for post-exposure prophylaxis. In cases where exposure is questionable or a patient has a concurrent medical condition that may complicate post-exposure prophylaxis, an expert in the administration of rabies prophylaxis should be consulted.

**Rabies vaccines**

Immune response

During infection, rabies viruses are mainly intraneuronal, and antigens may therefore be concealed from immune surveillance. An antibody response is not usually detected in infected humans before the second week of illness. Modern CCVs induce a prompt and high virus neutralizing antibody (VNA) response to the G protein. Cell-mediated immunity may also play a role in protection against infection. Although a protective VNA concentration cannot be established for humans, a minimum level of 0.5 IU/mL is used as a correlate of protection. In healthy vaccinees, this level should be achieved by day 14 of a post-exposure immunization regimen, with or without simultaneous administration of RIG and irrespective of age.

Nerve tissue-based vaccines

More than 100 years ago, Louis Pasteur and his colleagues developed the first crude rabies vaccine for post-exposure prophylaxis based on attenuated virus in desiccated nerve tissue. Although continuously improved over the years, inactivated NTVs produced in the brains of sheep or goats (Semple) or suckling mice (Fuenzalida) are associated with neurological adverse reactions. Thus, in about 0.3–0.8 individuals per 1000 vaccinees, contaminating neuroproteins present in the vaccine cause severe allergic encephalomyelitis. Because NTVs are less potent than CCVs, they may require an immunization course of up to 23 daily injections. In recent years, India and Nepal have successfully phased out production and use of NTVs.

Cell culture-based vaccines

CCVs consist of virus that has been inactivated following propagation in cell cultures The human diploid cell vaccine was introduced in 1967. The more recently developed, and less expensive, purified chick embryo cell vaccine and purified Vero cell-based vaccines have characteristics comparable to the human diploid cell vaccines. CCVs are based on fixed viruses of genotype 1. The shelf-life of these vaccines is at least 3 years, provided storage at +2˚C to +8 ˚C and protection from sunlight. Under these conditions, the vaccines retain a potency of at least 2.5 IU per intramuscular dose (0.5 mL or 1 mL). Following reconstitution with the accompanying sterile diluent, the vaccines should be used immediately, or within a maximum of 6 hours when kept at +2˚C to +8˚C. The respective package inserts should be consulted for specific information and instructions regarding the individual vaccine. The internationally available CCVs have been administered to millions of people worldwide. In both pre and post exposure prophylaxis settings, they induce an antibody response in >99% of vaccinees. Prompt post exposure use of modern vaccines combined with proper wound care and RIG is nearly 100% effective in preventing rabies, even following high-risk exposure. However, delays in starting or failure in completing correct prophylaxis, especially with severe lesions on the head, neck, hands or multiple wounds, may result in death.

Factors that should be taken into consideration when deciding whether or not to initiate post exposure prophylaxis include the likelihood of the concerned animal being rabid, category of exposure (I–III), clinical features of the animal, as well as its availability for observation and laboratory testing. In most situations in developing countries, the vaccination status of the offending animal should not be taken into consideration to withhold prophylaxis.

Post Exposure Prophylaxis

**Intramuscular administration (3)**

The post exposure vaccination schedule is based on IM doses of 1 ml or 0.5 ml, depending on the manufacturer. The recommended regimen consists of either a 5-dose or a 4-dose schedule.

(a) The 5-dose regimen (Essen regimen): prescribes 1 dose injected into the deltoid muscle (or anterolateral thigh in children aged <2 years) on each of days 0, 3, 7, 14 and 28.

(b) The 4-dose regimen ("2–1–1" or Zagreb regimen): prescribes 2 doses on day 0 (1 in each of the 2 deltoid/thigh sites) followed by 1 dose on each of days 7 and 21.

**Intradermal administration**

The high cost of CCVs by the volume required for the standard IM route is prohibitive for widespread use in many areas where dog rabies is endemic. For some CCVs, equal immunogenicity has been demonstrated by ID using at least 60% less vaccine than by IM vaccination. ID vaccination offers a safer and more effective alternative to the use of NTVs and a more economical alternative compared with the IM use of CCVs. Since 1991, WHO has recommended the ID route of administration for rabies pre- and post-exposure prophylaxis. ID regimens have been successfully introduced for post-exposure prophylaxis in developing countries such as India, the Philippines, Sri Lanka and Thailand. Either the 8-site or the

2-site regimen should be used, as recommended by the respective vaccine manufacturer.

(a) The 8-site ID regimen: prescribes on day 0, injections of 0.1 ml given at 8 sites (1 in each upper arm, 1 in each lateral thigh, 1 on each side of the suprascapular region, and 1 on each side of the lower quadrant region of the abdomen); on day 7, 1 injection in each upper arm and each lateral thigh; and on each of days 30 and 90, 1 injection in one upper arm (6) The1 dose on day 90 may be replaced by 2 ID injections on day 30.

(b) The 2-site ID regimen prescribes 1 injection of 0.1 ml at 2 sites on days 0, 3, 7 and 28 (7).

**Previously Vaccinated Individuals**

For rabies-exposed patients who have previously undergone complete pre-exposure vaccination or postexposure prophylaxis with a CCV, 2 IM or ID doses of such a vaccine administered on days 0 and 3 are sufficient. RIG is not necessary in such cases. The same rules apply to people vaccinated against rabies who have demonstrated VNA titres of at least 0.5 IU/ml. Vaccination cards carefully recording previous immunizations are invaluable for correct decision-making.

**Rabies immunoglobulin for passive immunization**

RIG should be administered in all category III exposures and in category II exposures involving immunodeficient individuals. Given its relatively slow clearance, human rabies immunoglobulin (HRIG) is the preferred product, particularly in cases of multiple severe exposures. However, HRIG is in short supply and available mainly in industrialized countries. Where HRIG is not available or affordable, purified equine immunoglobulin (ERIG) or highly purified F(ab´)2 products of ERIG should be used. Most of the new ERIG preparations are potent, highly purifi ed, safe and considerably less expensive than HRIG. However, they are of heterologous origin and carry a small risk of hypersensitivity reactions.10 There are no scientific grounds for performing a skin test prior to administration of ERIG because testing does not predict reactions, and ERIG should be given whatever the result of the test. RIG for passive immunization should not be injected later than 7 days after the initiation of post-exposure vaccination.

**Dosage and administration**

The dose for HRIG is 20 IU/kg body weight, and for ERIG and F(ab´)2 products is 40 IU/kg body weight. As much of the recommended dose of passive immunization products as is anatomically feasible should be infiltrated into and around the wounds. Multiple needle injections into the wound should be avoided. If a finger or toe needs to be infiltrated, care must be taken not to cause a compartment syndrome, which can occur when an excessive volume is infiltrated under pressure and blood circulation is impaired. In the event that a remainder of passive rabies immunization product is left after all wounds have been infiltrated, it should be administered by deep intramuscular injection at an injection site distant from the vaccine injection site.

Animal bite wounds inflicted can be severe and multiple, especially in small children. In such cases, the calculated dose of the passive rabies immunization product may not be sufficient to infiltrate all wounds. In these circumstances, it is advisable to dilute the passive immunization product in normal saline to a sufficient volume to be able to inject all wounds. A full course of vaccine should follow thorough wound cleansing and passive immunization.

**Post-exposure prophylaxis of HIV-infected people and HIV/AIDS patients**

Several studies of patients with HIV/AIDS have reported that those with very low CD4 counts will mount a significantly lower or no detectable neutralizing antibody response to rabies. In such patients and those in whom the presence of immunological memory is no longer assured as a result of other causes, proper and thorough wound treatment as described above and antisepsis accompanied by local infiltration of a passive immunization product are of utmost importance. Immunocompromised patients with category II exposures should receive rabies immunoglobulin in addition to a full post-exposure vaccination series as listed above. An infectious disease specialist with expert knowledge of rabies prevention should be consulted.

**Pre Exposure vaccination**

Pre exposure vaccination should be offered to

(a) People at high risk of exposure such as those working in rabies diagnostic or research laboratories

(b) Veterinarians, animal handlers (including bat handlers), animal rehabilitators and wildlife officers

(c) People (especially children) living in or travelling to high-risk areas

Intramuscular administration

Pre-exposure rabies vaccination requires IM doses of 1 ml or 0.5 ml, depending on the vaccine type, given on days 0, 7 and 28 (day 28 preferable, but administration may be advanced towards day 21 if time is limited). For adults, the vaccine should always be administered in the deltoid area of the arm; for children aged <2 years, the anterolateral area of the thigh is recommended. Rabies vaccine should not be administered in the gluteal area, where the induction of an adequate immune response may be less reliable.

Intradermal administration

ID administration of 0.1 ml volumes on days 0, 7, and 28 (day 28 preferable, but administration may be advanced towards day 21 if time is limited) is an acceptable alternative to the standard IM route. However, ID administration is technically more demanding and requires appropriate staff training and qualified supervision.

Booster injections

Periodic booster injections are recommended only for people whose occupation puts them at continuous or

frequent risk of rabies exposure. In such cases, a booster dose should be given at intervals ideally dictated by regular testing for antirabies antibodies. Potential laboratory exposures to high concentrations of rabies virus motivates testing as often as every 6 months; VNA (Virus neutralizing Antibodies) titres of at least 0.5 IU/ml indicate protection. Where serological testing is unavailable, booster vaccination every 5 years may be an acceptable alternative.

A rabies pre-exposure certificate should be completed and given to the vaccine indicating the type of vaccine and vaccine regimen used, lot number of vaccine, and any adverse reactions that occurred during vaccination.

### Control of rabies in dogs

Canine rabies can be eliminated, as has been demonstrated in North America, western Europe, Japan and many areas in South America. However, canine rabies is still widespread, occurring in over 80 countries and territories, which are predominantly in the developing world. In more than 99% of all human rabies cases, the virus is transmitted from dogs; half of the global human population lives in canine rabies-endemic areas and is considered at risk of contracting rabies. Effective animal vaccines that provide a considerable duration of immunity have been developed and mass parenteral vaccination programmes remain the mainstay of canine rabies control. Dog destruction alone is not effective in rabies control. Canine rabies control programmes should incorporate three basic elements, with priorities varying according to the prevailing social, cultural and economic factors. The basic elements are:

(a) Epidemiological surveillance
(b) Mass vaccination
(c) Dog population control

**Epidemiological surveillance** : Rabies should be a notifiable disease within national health and veterinary systems. Rabies surveillance is still inadequate in many countries and this deficit should be addressed by national authorities, with the support of international agencies. Rabies can only be reliably diagnosed by laboratory tests and it is strongly recommended that, in countries where diagnostic facilities are inadequate or lacking, laboratory capacity be developed to permit effective rabies surveillance.

**Canine mass parenteral vaccination campaigns :** Mass canine vaccination campaigns have been the most effective measure for controlling canine rabies. At least 70% of the dog population in each community should be vaccinated in areas where canine rabies is endemic. High vaccination coverage (70% or higher) can be attained through strategies consisting of well-designed educational campaigns, intersectoral cooperation, community participation, local commitment in planning and execution, availability of recognized quality vaccine, media support and effective general coordination and supervision of the activities by the health services (9, 10). All dogs and cats, when presented, should be immunized, regardless of their age, weight or state of health. Given the high birth rates of many populations, particular attention should be paid to ensuring adequate vaccination coverage of puppies (8).

Supplementary measures

Oral vaccination of dogs

Oral vaccination of dogs offers a new approach that may significantly improve dog vaccination coverage (especially of free-roaming and poorly supervised dogs) when applied either exclusively or in combination with parenteral vaccination. As dog accessibility to vaccination by the parenteral route is one of the major obstacles for canine rabies control in many different parts of the world. Although the preferential vaccine for dog immunization should be parenteral (inactivated tissue-culture vaccines), oral vaccination should be used whenever there is high population of inaccessible dogs.

Dog population management and animal birth control (ABC) programmes

There is no evidence that removal of dogs alone has ever had a significant impact on dog population densities or the spread of rabies. The population turnover of dogs may be so high that even the highest recorded removal rates (about 15% of the dog population) are easily compensated for by increased survival rates. In addition, dog removal may be unacceptable to local communities. However, the targeted and humane removal of unvaccinated, ownerless dogs may be effective when used as a supplementary measure to mass vaccination. Three practical methods of dog population management are recognized:

(a) Movement restriction
(b) Habitat control
(c) Reproduction control.

### Laboratory diagnosis

Collection, preservation, packing and transportation of specimens

The acute infection nature of rabies does not require further elaboration . Therefore, in the collection of specimen from suspected cases of rabies-human or animal, it must be born in mind that highly dangerous material is being handled. It is imperative to follow all precautionary measures during collection, packing transportation and handling of specimen to avoid any serious mishap.

Specimen from human beings

From a clinical case (hydrophobia) the antemortem specimen that may be collected include saliva, corneal smear, skin biopsy, hair follicles, blood and cerebrospinal fluid. Postmortem specimen shall usually be if brain of spinal cord and sometimes other organs too. The specimens are collected as follows :

**Saliva / Sputum**

Saliva is collected from under the tongue:

(a) Wet a sterile cotton swab with tissue culture

medium or physiological saline and remove excess medium by squeezing on the sides of the vial.

(b) Swab under the tongue, rinse in the tissue culture medium or physiological saline containing two percent normal horse serum (NHS).

(c) Take another swab similarly and make two.

(d) Air dry the glass slides for 10 minutes.

(e) Discard the swabs in suitable disinfectant.

(f) Treat the slides immediately with chilled acetone and process or wrap in paper and dispatch to the laboratory.

Often due to dehydration, there is very little saliva in the mouth. The patient, if responsive, may be asked to cough and spit in Petri dish or beaker. Mix the sputum with a few ml of tissue culture medium or two percent NHS in physiological saline and transfer to a screw capped vial.

**Corneal smears**

(a) Retract the eyelids with thumb and one finger and press a clean marked slide against the cornea.

(b) Prepare two smears on each slide taking care to apply sufficient pressure to the smear.

(c) Avoid exerting too much pressure as it may damage the eye.

(d) Air-dry the smears for 10-15 minutes at room temperature.

(e) Treat with chilled acetone and process further.

**Skin biospy**

With very fine sharp scissors, collect small pieces of skin from the site of bite and the face near the mandible. Preserve in a vial containing 50 percent glycerol saline (prepared by mixing equal volumes of glycerol and physiological saline and sterilized by autoclaving).

**Hair Follicle**

Pluck a few hairs with the help of a forceps from the face and or behind the ear. Put in a vial containing 50 percent glycerol saline.

**Cerebrospinal fluid (CSF)**

The CSF in acute phase of the diseases is processed foe isolation of the virus and in the later phase for antibodies. It is collected by lumber puncture. Usually no preservative is used but, if required, 50 percent glycerol saline may be used.

**Blood**

Acute phase venous blood specimen is collected as soon as possible with the usual aseptic precautions. If the patient survives foe several days, a second sample is taken. In case the patient recovers another blood sample is taken before discharging the patient.

**Urine**

(a) Collect in wide-mouth containers.

(b) Mix with equal quantity of tissue culture medium.

(c) Centrifuge immediately and discard the supernate.

(d) Mix sediment with 2-3 ml of tissue culture medium and transfer to screw capped vials.

**Brain**

The brain is collected at autopsy. Many times the relatives do not agree for a full postmortem. In such cases Vim-Silverman needle may be used to collect a small pice of glycerol saline.

Collection of specimen from suspected rabid animals

The specimens useful for proper diagnosis of rabies in animals are mainly brain and salivary glands. Through it is risky to collect antemortem specimen, if required saliva and corneal smears may be collected as already described. The better course, however, is to permit the animal to die a natural death unless otherwise required ( see microscopic examination). Facilities for removal of the animal brain and salivary glands are not available in the laboratory, hence the whole brain or salivary glands should be sent to the laboratory after post-mortem.

If it is not possible to send the whole brain, pieces from Ammons horn of hippocampus, cerebrum, cerebellum, pons and medulla may be included.

Preservation

If possible the sample, of brain and salivary glands may be sent in wide mouth leak proof containers preserved on ice. However, if the samples are not to be sent long distance, these may be preserved by use of following:

(a) 10 percent formal saline/ Zenkers fluid for half of the brain

(b) 50 percent glycerol saline for other half of the brain and salivary glands.

(c) Tissue culture medium two percent NHS saline of saliva, CSF, urine etc.

Labeling

All the specimens, e.g. slides, vials must be labeled with number of specimen, name of the patient, or spices of the animal, type of preservative used, etc. permanent markers should be used. The parcels should also be labeled properly.

**Information to be enclosed**

(a) Hydrophobia : name, age, sex, treatment, taken, exposure to animal, etc. may be enclosed.

(b) Animal : The species and breed of animal, contact with other animals, symptoms, mode and date of death, vaccination status, etc.

Packing

(a) It should preferably be wide-mouth leak proof plastic containers.

(b) Seal the mouth of the container with tape or sealing paraffin.

(c) Pack in plastic bags and put in thermocol box with sufficient ice.

(d) If sending by post-pack in sturdy wooden boxes with sufficient packing material (preferably absorbent cotton/saw dust paddy husk).

Transportation

(a) By courier

(b) By air / by post.

Laboratory Test

Utmost urgency should be exhibited in transportation of these because any undue delay, especially in tropical climates, shall wither way the cooling effect of ice and result into putrefaction of the sample making it unsuitable for the diagnosis.

Several tests are necessary to diagnose rabies ante-mortem (before death) in humans; no single test is sufficient. Tests are performed on samples of saliva, serum, spinal fluid, and skin biopsies of hair follicles at the nape of the neck.

(a) Saliva : Tested by virus isolation or reverse transcription followed by polymerase chain reaction (RT-PCR).

(b) Serum and spinal fluid : Tested for antibodies to rabies virus.

(c) Skin biopsy specimens : Examined for rabies antigen in the cutaneous nerves at the base of hair follicles.

Techniques for intra vitam diagnosis of Rabies in humans

The sensitivity of techniques for rabies diagnosis varies greatly according to the stage of the disease, antibody status, intermittent nature of viral shedding and the training of the technical staff. While a positive result is indicative of rabies, a negative result does not necessarily rule out the infection. Brain biopsy taken solely for the diagnosis of rabies is not recommended (11).

**Antigen detection**

Viral antigen may be detected by using the FA test on skin biopsies from patients with clinical rabies. Skin biopsies are usually taken from the nuchal area of the neck, with hair follicles containing peripheral nerves.Examination of at least 20 sections is required to detect rabies nucleocapsid inclusions around the base of hair follicles. The quality of skin biopsy samples is of paramount importance. Though sensitive, this technique may not be practical in all settings, because of the need for a cryostat to prepare frozen tissue sections. FA testing on corneal impressions is rarely reliable in most clinical settings and is therefore not recommended.

**Virus isolation**

Rabies virus isolation can be performed using neuroblastoma cells or the intracranial inoculation of mice. Virus isolation is preferably performed on saliva samples or other biological fluids such as tears and cerebrospinal fluid. The success rate depends upon the antibody status (more positive results are obtained in antibody-negative patients) and on the intermittence of viral shedding. It should be noted that infectious virus may be absent from these specimens even during the late stage of the disease.

**Antibody titration**

Neutralizing antibodies in the serum or cerebrospinal fluid of non-vaccinated patients can be measured using a virus neutralization test such as the rapid fluorescent focus inhibition test (RFFIT) or the fluorescent antibody virus neutralization (FAVN) test. Virus-neutralizing antibodies in serum tend to appear on average 8 days after clinical symptoms appear. Rabies antibodies are infrequently found in cerebrospinal fluid.

An ELISA using purified rabies glycoprotein has been used to determine antiglycoprotein antibody levels in the serum of humans and of some animal species. This assay can be useful when the RFFIT is not available.

**Molecular techniques**

Molecular detection by polymerase chain reaction and nucleic acid sequence based amplification techniques has the highest level of sensitivity but requires standardization and very stringent quality control (12). Rabies virus RNA can be detected in several biological fluids and samples (e.g. saliva, cerebrospinal fluid, tears, skin biopsy sample and urine). Serial samples of fluids (e.g. saliva and urine) should be tested, owing to intermittent shedding of virus. Such techniques can produce false positive or false negative results, and should only be used in combination with other conventional techniques.

Techniques for postmortem diagnosis of rabies in animals and humans

**Antigen detection**

The fluorescent antibody (FA) technique is a rapid and sensitive method for diagnosing rabies infection in animals and humans (13). It is the gold standard for rabies diagnosis; however, the accuracy of this test depends upon the expertise of the examiner, and the quality of anti-rabies conjugate and the fluorescence microscope. The test is based upon microscopic examination under ultraviolet light of impressions, smears or frozen sections of tissue after they have been treated with anti-rabies serum or globulin conjugated with fluorescein isothiocyanate. Impressions (or smears) of tissue samples from brainstem, thalamus, cerebellum, and the hippocampus are recommended for increased sensitivity of the test.

Detection of lyssavirus nucleocapsid antigen by enzyme-linked immunosorbent assay (ELISA) has been described and used for many years in some laboratories (13).It is rapid and can be useful for epidemiological surveys

**Virus isolation**

Virus isolation may be necessary to confirm the results of antigen detection tests and for further characterization of the isolate (13). Virus isolation can be performed on neuroblastoma cells or upon intracranial inoculation of mice. Murine neuroblastoma (NA C1300) cells are more susceptible to field isolates of rabies virus than are other cell lines tested. Virus isolation in cell culture (with neuroblastoma cells) is at least as efficient as mouse

inoculation for demonstrating small amounts of rabies virus. It also reduces the time required for diagnosis from 10–15 days for the mouse inoculation test to 1–2 days using neuroblastoma cells.When compared with the FA technique, the gold standard, the sensitivity of virus isolation in neuroblastoma cells is higher than 98%.

**Detection by molecular techniques**

The use of the polymerase chain reaction (PCR) and other amplification techniques is not currently used for routine postmortem diagnosis of rabies. However, these molecular techniques can be applied for epidemiological surveys in laboratories with strict quality control procedures in place and that have experience and expertise with these techniques.

**Negri bodies examination**

This test is simple and quick in diagnosis of rabies and can be performed easily and a quick report can be given. The intracytoplasmic inclusion bodies called ' Negri bodies' can be detected by using various stains of which seller's stain is the simplest and the widely used. Both impression smears and section of tissues can be stained. The presence of these bodies depends on the time of death and the course of the disease. The chances of detection of Negri bodies increases if the animal is permitted to die its natural death. Nearly 70%of the specimen from rabid animals can be diagnosed by this test. Few characteristics of Negri Bodies are as follows.

(a) Oval, round or elongated

(b) Size 3-20 J.. µm

(c) Presence of basophilic inner granules and heterogenous matrix

(d) Mostly abundant in hippocampus.

# Leptospirosis

## Introduction

Leptospirosis is a zoonosis spread throughout the world. Often under reported, the disease is now a prominent re - emerging infection and surveillance data suggests that it may be the most common zoonosis in the world (1). It is primarily an infection in rodents and several other wild and domesticated animals. Leptospirosis occurs worldwide but is most common in tropical and subtropical areas with high rainfall. The disease is found wherever humans come into contact with the urine of infected animals. Occupational exposure probably accounts for 30 - 50% of human cases (1-3). Most human infections are asymptomatic and the disease presentation can vary from extremely mild illness to fatal illness (4).

## History

The severe form of the disease was first described by Adolf Weil as a disease entity in four men who had fever, haemorrhage and severe jaundice in 1886 in Heidelberg (5). His name is still attached to a serious form of leptospirosis called Weil's disease. Inada and Ido identified the causal organism in 1916 in Japan.

## Epidemiology

### World

Leptospirosis is endemic throughout the world. However, the incidence of the disease is significantly higher in tropical countries as compared to temperate regions. This is as attributed to both the favourable climatic conditions in tropical countries as well as the fact that the tropics have a greater proportion of developing countries which provide greater opportunities for exposure of the human population to infected animals. The peak incidence of the disease is in summer or fall in temperate regions, and during rainy seasons in warm - climate regions (6). The number of human cases worldwide is not known precisely. The World Health Organization estimates that incidences range from approximately 0.1 - 1 per 1,00,000 per year in temperate climates to 10 - 100 per 1,00,000 in the humid tropics. During outbreaks and in high - exposure risk groups, disease incidence may reach over 100 per 1,00,000 (7). Increased awareness of the disease has led to increased recognition (8).

### India

Though Leptospirosis is widespread in India, the true extent of the disease is not known because no large scale serological surveys have been carried out. However, a number of studies have reported outbreaks in different parts of the country since 1930 (9 - 18). Several epidemics of leptospirosis have occurred in Andaman and Nicobar islands and in southern and western parts of India during the past century. For the past 10 years, the city of Mumbai has been witnessing a seasonal increase in the number of cases of Leptospirosis (19). Large outbreaks have occurred following the monsoon flooding in the city. A post - cyclone outbreak was reported in Orissa, India in 1999.

## Agent

*Leptospira icterohaemorrhagiae* is the causal organism for Leptospirosis. It is a slender, closely wound, very actively motile spirochete varying in length from 6µ to 20µ. Before 1989, the genus Leptospira was divided into two species. *Leptospira interrogans* which were the pathogenic strains and *Leptospira biflexa* which were the saprophytic strains in the environment. Over 12 species with over 250 serologic variants (Serovars) of the pathogen have been identified. Serovars that are antigenically related have traditionally been grouped into serogroups. The serogroups are useful for epidemiological understanding (20 - 24).

## Hosts

A wide variety of animal species, primarily mammals, serve as the animal hosts for the pathogen and are the primary sources for human infection. Small mammal species, notably feral and peridomestic rodents (rats, mice) and insectivores (shrews and hedgehogs) are the most important hosts for maintaining the infection in nature. Domestic animals like cattle, pigs, dogs, sheep and even larger mammals like horses and buffaloes can be infected. Reptiles and amphibians have also been detected to carry leptospires.

Humans are a "dead end" for leptospires as they do not form an infection reservoir. Adult males are most affected due to occupational exposure. Occupations such as livestock farmers, sewer workers and abattoir workers are most affected. The names for some forms of Leptospirosis like rice field fever, cane cutter's disease, swineherd's disease, dairy farm fever, mud fever reflect transmission conditions. Some recreational activities like swimming in natural waters may also result in exposure. Children may acquire infection from dogs. People living in cities may also be exposed to animal hosts notably rats. Outbreaks of leptospirosis have been reported following natural disasters such as flooding and hurricanes (7).

## Environmental Factors

The pathogenic organisms can survive for weeks in soil and water contaminated with urine and faeces of reservoir animals. Poor housing, improper sewage disposal and unsafe water supply increase the risk of transmission. Warm, humid conditions are ideal for survival of the leptospires and consequently the disease shows a seasonal variation in India.

## Transmission

The leptospires have the ability to penetrate mucosa but not intact skin. However they can enter the body through broken skin and some researchers have suggested that they can penetrate through waterlogged skin. Human leptospiral infections result primarily from either direct contact with urine or tissue of infected animals or indirect contact through soil, water or vegetation that is contaminated with animal urine. They may occasionally

enter the human body via the inhalation of droplets of urine or via drinking - water. They can be transmitted from human to human by sexual intercourse, transplacentally from the mother to the fetus and via breast milk to a child. The urine from a patient suffering from leptospirosis should be considered infectious (7).

### Pathogenesis

On entering the human body, the organisms are carried by blood to all parts of the body. The leptospiremia can spread to any part of the body but particularly affects the liver and kidney. It causes a systemic vasculitis which allows entry of the spirochetes into different organs and tissues which accounts the broad spectrum of clinical presentation. Despite the possibility of severe complications, the disease is mostly self - limited and nonfatal.

### Clinical Features

The incubation period is usually between 5 - 14 days but can range from 2 to 30 days. The clinical presentation of the disease can be extremely variable. Most cases present with symptoms of sudden headaches, fevers, nausea and bodyache. 90% of cases have an acute febrile illness with a biphasic course, non - specific signs and symptoms and an excellent prognosis. The first stage is called the septicemic or leptospiremic stage. During this stage, which lasts about 4 - 7 days, the patient develops a nonspecific illness characterized by fever, chills, weakness, and body ache. These symptoms abate during a one to three day period. The fever subsides and the patient may become completely symptom free. The return of fever heralds the onset of the second stage. This stage is called the immune or leptospiruric stage. Disease referable to specific organs is seen. These organs include the meninges, liver, eyes, and kidney. About three fourths of patients complain of headache.

Less than 10% of patients suffer from Icteric leptospirosis or Weil's disease. The presentation includes fever, jaundice, renal failure and hemorrhage. Other organ systems (pulmonary, cardiac, central nervous) also are involved frequently. Weil's disease carries a mortality rate of 5 to 30% (4, 6, 7).

### Diagnosis

As the manifestations of Leptospirosis are non specific, laboratory investigations are essential to confirm the diagnosis. Routine blood and biochemical tests also reveal abnormalities that do not confirm the diagnosis. Patients will have raised ESR. Blood counts reveal thrombocytopaenia and leucocytosis while biochemical asssys may show hyperbilirubinaemia, elevated serum creatinine, elevated creatinine kinase and elevated serum amylase (19, 25-27).

Direct visualization, culture and serology have all been used to confirm the diagnosis of Leptospirosis. Dark field microscopy is required for direct visualization of spirochetes because of their size. Slides may be made from both blood and urine. Immunofluorescence staining and silver staining are used. However dark ground microscopy suffers from low sensitivity and specificity both. Samples for culture from blood, CSF or peritoneal fluid should be collected before antibiotic treatment has been started. Cultures take very long as initial growth is very slow, and hence are not a practical means of confirming the diagnosis. The most reliable serological test is the microscopic agglutination test (MAT). A four fold rise in the MAT titre or a single titre of at least 1:800 are diagnostic. Other tests include an indirect hemagglutination test and ELISA for specific IgM antibodies. Rapid commercial tests for leptospira antibodies have recently become available. PCR may be used for molecular diagnosis for epidemiological studies.

### Differential Diagnosis

The diseases which should be considered in the differential diagnosis of leptospirosis are : Influenza; Dengue and Dengue haemorrhagic fever; Yellow fever and other viral haemorrhagic fevers; Rickettsiosis; Borreliosis; Brucellosis; Malaria; Pyelonephritis; Aseptic Meningitis; Chemical poisoning; Food poisoning; Typhoid fever and other enteric fevers; Viral Hepatitis; (7).

### Treatment

The spirochetes are sensitive to several antibiotics. There is no need to wait for the conformation of diagnosis before starting antibiotic treatment. Severe cases of leptospirosis should be treated with high doses of intravenous penicillin. Less severe cases can be treated with oral antibiotics such as amoxycillin, ampicillin, doxycycline or erythromycin. Third - generation cephalosporins, such as ceftriaxone and cefotaxime, and quinolone antibiotics also appear to be effective. Aggressive supportive care with strict attention to fluid and electrolyte balance is essential. Peritoneal or haemodialysis is indicated in renal failure (2, 3, 7). Doxycycline 200mg orally once a week has been used for chemoprophylaxis. The drug should be given for a few weeks at a time.

### Prevention and Control

The control of Leptospirosis in reservoir animals is impossible because of their sheer variety and numbers. Prevention of human cases may be achieved by use of personal protective measures, avoidance of high risk exposure, immunization and chemoprophylaxis. Some degree of reservoir control can be achieved by rodent control and by reducing infection in domestic animals such as dogs or livestock by immunization (28). Risk of infection is minimized by avoiding contact with animal urine, infected animals or an infected environment. Protective clothing should be worn and wounds covered with waterproof dressings to reduce the chance of infection if occupational or recreational exposure is likely (29 - 33). In case of an outbreak, persons exposed to animal urine (wading through flood waters etc) may be given doxycycline chemoprophylaxis.

Killed vaccine is available against Leptospirosis. Due to the large number of serovariants, the effectiveness of the vaccine is limited. Protective antibodies are produced only against the serovars present in the particular vaccine used.

# Brucellosis

## Introduction

Brucellosis is a zoonotic infection of domesticated and wild animals, caused by organisms of the genus Brucella. It is transmitted from animals to humans by ingestion of infected food products, direct contact with an infected animal, or inhalation of aerosols. It is known by several names like Malta Fever and Undulant Fever. In 1954, Brucella were the first bacteria to be weaponised as biological warfare agents because aerosols are a remarkably efficient method of disease transmission. However, it's relatively long and variable incubation period and the fact that many infections are asymptomatic, has made it a less desirable agent for biological warfare. Four species of Brucella are known to cause human disease. They are *Brucella melitensis, Brucella abortus, Brucella suis* and, *Brucella canis*.

## History

Descriptions of the disease date back to Hippocrates. Brucellosis in humans has a strong association with military medicine (1) The disease was first described in 1751 by Cleghorn, a British army surgeon stationed on the island of Minorca. He described cases of chronic, relapsing febrile illness among the British soldiers stationed on the island (2). The early descriptions of the disease and the discovery of the causative organism come largely form British army doctors working on the Mediterranean island of Malta in the second half of the nineteenth century. In 1861, Marston described the clinical characteristics of the disease (3). In 1887, a British army doctor David Bruce, isolated the causative organism from the spleens of five fatal cases (4). The species was named Brucella after him. The term Undulant Fever was given by ML Hughes (5). Bang identified *Brucella abortus* as a cause of abortion in cattle in 1895 (6).

## Epidemiology

Brucellosis is a worldwide zoonosis. The highest incidence is seen in areas where cattle or other animal rearing is carried out. High rates of disease are observed in the Middle East, Mediterranean region, China, India, Peru and Mexico. Abortus fever occurs sporadically in all parts of the world including India. No epidemics have been reported from any part of the world but upsurge of the sporadic cases occurs in various parts from time to time. With the advent of animal vaccines and improvements in hygiene in animal rearing, the disease has declined in developed countries. However, the global burden of human brucellosis remains large. It is estimated to cause more than 5,00,000 infections per year worldwide. The number of reported infections is much lower because the diagnosis is often not confirmed.

In India, cattle in Maharashtra, Karnataka, Madhya Pradesh, Tamil Nadu and Orissa have been found infected. Very few surveys have been made. A few surveys in dairy farms show low incidence.

## Agent

Brucellae are small, nonmotile, nonsporing, nontoxigenic, nonfermenting, aerobic, Gram - negative coccobacilli. The outer cell membrane is similar to that of other Gram - negative bacilli with a dominant lipopolysaccharide (LPS) component and three main groups of proteins. Brucella species do not harbor plasmids naturally although they are known to readily accept broad - host - range plasmids (6, 7, 8).

The metabolism of the brucellae is mainly oxidative and they show little action on carbohydrates in conventional media. They are aerobes but some species require an atmosphere with added $CO_2$ (5 to10 percent). Multiplication is slow at the optimum temperature of 37°C and enriched medium is needed to support adequate growth. Brucella colonies become visible on suitable solid media in 2 - 3 days. The colonies of smooth strains are small, round and convex but dissociation, with loss of the O chains of the LPS, occurs readily to form rough or mucoid variants (9, 10).

Among the four species that cause disease in humans, *Brucella melitensis* is the most virulent and causes the most severe and acute cases. *Brucella suis* infection causes a prolonged course of illness and may be associated with suppurative destructive lesions. Mild - to - moderate sporadic disease, rarely associated with complications is the characteristic of *Brucella abortus*. Infection with *Brucella canis* results in a disease course that is similar to *Brucella abortus* infection. The onset of disease is insidious, marked by frequent relapses and does not commonly cause chronic disease.

## Host

Each Brucella species has a specific animal reservoir. The infection in the animal hosts result in chronic disease that persists for life. The organisms tend to localize in the reproductive organs of the animals, causing sterility and abortions. They are shed in large numbers in the urine, milk and placental fluid of the infected animals. This localization is responsible for the efficient spread of infection to workers who come in contact with these liquids. The specific animal reservoirs for the various Brucella species are shown in Table -1.

Human brucellosis is predominantly a disease of adult males. Farmers, shepherds, butchers, abattoirs workers, veterinarians and laboratory workers are particularly at special risk because of occupational exposure.

## Environment

The organism can survive for weeks under favorable conditions. High humidity, overcrowding of herds and poor hygienic conditions of milk and meat production are favorable for the transmission of infection.

## Transmission

Animals shed large amounts of Brucella organisms during septic abortion, at the time of slaughter and in their milk.

Table - 1 : Animal Reservoirs of Brucella

| Organism | Animal reservoir | Geographic distribution |
|---|---|---|
| *B melitensis* | Goats, sheep & camels | Mediterranean, Asia & Latin America |
| *B abortus* | Cattle,buffalo, and camels | Worldwide (Eliminated in Japan, Israel & several European nations) |
| *B suis* | Domestic & feral swine | South America, Asia & mid-western United States |
| *B canis* | Canines | Cosmopolitan |

Source (11)

The incidence of human disease is closely linked to the prevalence of infection in sheep, goats and cattle and to practices that allow exposure of humans to potentially infected animals or their products (12-15).

Brucellae can gain entry into humans through breaks in the skin, mucous membranes, conjunctiva, respiratory and gastrointestinal tracts. Ingestion of the organisms with milk or other contaminated animal products or by contact with contaminated fingers is the most common route of infection. Inhalation of aerosols containing the bacteria, or aerosol contamination of the conjunctivae, is another route. Percutaneous infection through skin abrasions or by accidental inoculation is a rare mode of transmission of infection (16).

**Pathogenesis**

On entry into the human host, Brucellae are rapidly phagocytosed by polymorphonuclear leukocytes. Brucellae possess the ability to survive and multiply within the phagocytic cells. It is believed that the organism can survive and multiply in these cells because they inhibit the bactericidal myeloperoxidase - peroxide - halide system by releasing 5' - guanosine and adenine. Soon after infection, the organisms become localized in the organs of the reticulo - endothelial system such as the spleen and lymph nodes. In animals the organisms also localize in the reproductive organs. The presence of meso - erythritol in the testicles and seminal vesicles of bulls, rams, goats and boars and in the products of conception in pregnant ruminants and pigs stimulates enormous multiplication of brucellae. Erythritol represents a potent localizing factor in the relevant species, but is absent in humans (17-20). Large granulomas serve as a source for persistent bacteremia. The specific host defenses against brucellae are similar to those against other intracellular bacteria and are both humoral and cell - mediated. Macrophages process brucellar antigen and present this to T lymphocytes which produce lymphokines. T cell - derived lymphokines are also involved in attracting cells to the foci of infection. This leads to granuloma formation.

**Incubation period**

The incubation period is extremely variable. Symptoms usually begin insidiously within two to four weeks but may start after as long as 6 months or more.

**Clinical Features**

The presentation of brucellosis is characteristically variable. Symptoms of brucellosis are protean in nature. The onset is usually insidious but rarely may be abrupt. Subclinical infections are common. The symptoms are non specific. Patients develop fever, malaise, headache, loss of appetite. Bodyache may be unusually severe. Sweating, including malodorous sweat and fatigue are common. The leukocyte count may be normal or reduced, with a relative lymphocytosis. Splenomegaly may often be the only clinical finding. If the disease is not treated, the symptoms may continue for 2 to 4 weeks and a characteristic undulant pattern of fever can be discerned. Many patients will then recover spontaneously but others may suffer a series of exacerbations. Most affected persons recover entirely within 3 to 12 months but some will develop complications marked by involvement of various organs and a few may enter an ill - defined chronic syndrome. Complications include arthritis, often sacroiliitis and spondylitis, central nervous system effects including meningitis, uveitis and occasionally, epididymoorchitis. In contrast to animals, abortion is not a feature of brucellosis in pregnant women (6). Depression, out of proportion to the symptoms has often been reported.

**Diagnosis**

Cases of Brucellosis are often not diagnosed because of the non specific presentation of the disease. A high index of suspicion and a detailed history of possible exposure, either occupational or during travel or of ingestion of contaminated foods are essential. However, at times patients can present several years after initial exposure making diagnosis difficult.

Definitive diagnosis is made by isolation of the organism. Blood culture is the method of choice but specimens need to be obtained early in the disease and cultures may need to be incubated for up to four weeks. Despite these precautions, failure to grow the organism is common, especially in cases of *B abortus* infection. Culture from bone marrow and from presenting foci may be successful. Presumptive identification of cultures can be made from morphology and slide agglutination with specific antiserum. Serology is the most commonly used method for confirming the diagnosis. However interpretation of the results should be done carefully. The tube agglutination test, which tests for anti-O- polysaccharide antibody is considered the best. A titer of 1:160 or higher of specific IgG and IgM is considered diagnostic. Most patients already have high titers at the time of clinical presentation, so a 4 - fold rise in titer may not occur. IgM rises early in disease and may persist at low levels for several months after treatment. While the SAT titers commonly decline after recovery from infection and antiglobulin test levels are maintained much longer, the

IgM antibody that is commonly measured by the SAT does not fall away as regularly as in some infections. Nevertheless, persisting levels of antibody may indicate a remaining focus of infection and specific IgG levels rise again with a true relapse (21). The diagnosis of the chronic Brucellosis Syndrome, without specific localization is difficult. If the cultures are negative and the results of serology are equivocal a confident diagnosis may not be possible (22, 23).

**Treatment**

The organism is susceptible to a variety of antibiotics. Doxycycline is usually drug of choice. Other antibiotics that may be used are Rifampicin, Gentamycin and Streptomycin. The use of a single drug has been found to have a high relapse rate, so combined regimens should be used whenever possible (24). A 6- week regimen of doxycycline 200 mg/day administered orally, with the addition of streptomycin 1 g/day administered intramuscularly for the first 2 to 3 weeks is effective therapy for adults with most forms of Brucellosis (25). The WHO recommended treatment regime is a combination of both rifampcin 600 to 900 mg/day & doxycycline 200 mg/day given orally for six weeks (6, 26). Some worker have reported that treatment with a combination of streptomycin and doxycycline may result in less frequent relapse than treatment with the combination of rifampin and doxycycline (27, 28). Endocarditis needs longer duration of treatment. Doxycycline along with a combination of two more drugs for six weeks may be required. Central nervous system disease also needs prolonged treatment with drug combinations like rifampcin and trimethoprim / sulfamethoxazole. In children below eight years of age, trimethoprim + sulfamethoxazole may be used. An alternate treatment in children is a five day course of gentamicin (29-32).

**Control**

Animals

Eradication of the infection from animal reservoirs is the most important means for preventing human brucellosis. Eradication of brucellosis from domestic animals reduces dramatically the threat to humans and has been successful in several countries. Vaccination of animals and improving the hygiene of slaughterhouses can markedly reduce the disease in animals. Animal vaccines are available against several strains of Brucella. Detection of infected herds and individual animals and their elimination are also important control measures.

Humans

A live vaccine is available only against a particular stain of *Brucella abortus* (Strain 19 BA). Early diagnosis and treatment of cases is important. Protection of dairy products and pasteurization or boiling of milk is also required for control of transmission. Personal protective measures in the form of wearing impermeable clothing, rubber boots, gloves and face masks, care during handling of carcasses and safe laboratory procedures also help in control.

# Plague

## Introduction

Plague is one of the oldest diseases known to man. (1) It is primarily a zoonotic disease that exists in nature between small mammals, usually wild rodents, and the fleas that they harbour. (2). Plague is endemic in many parts of the world and exits in many small natural foci. It is widely distributed in the tropics and subtropics and in warmer areas of temperate countries. The causative bacteria, *Yersinia pestis* can also infect humans. It is transmitted between animals and humans by the bite of infected fleas, direct contact, inhalation and rarely, ingestion of infective materials. Untreated plague can be a very serious disease with case fatality rates between 30% and 60% (3). Recent outbreaks have shown that plague may reoccur in areas that have long remained silent (1).

## History

Plague has been known as a dreaded killer from times immemorial. The first plague epidemic has been described in the Bible as the outbreak among the Philistines in 1320 BC. Over the last two millennia, plague has become widespread, affecting a large number of countries on most continents during several pandemics. The first pandemic, also called the Justinian plague took place in the sixth century and is reputed to have killed nearly a hundred million victims. The second plague pandemic is known as the "Black Death" of the fourteenth century which caused 50 million deaths. A quarter of the population of Europe is said to have been wiped out by this pandemic. The third pandemic began in Hong Kong in 1894. Within 10 years this pandemic had spread to all the continents. This pandemic resulted in 13 million deaths in India (1, 4).

During the third pandemic, the causal agent, *Yersinia pestis* was discovered In1894. It was also established that rats contract plague and that the rat flea *Xenopsylla cheopis* is the common vector (1, 4)

## Epidemiology

### Worldwide

The number of cases of human plague reported to the World Health Organization has remained stable in the recent past. The WHO believes that the number of cases officially notified is considerably lower than the actual number (5). Plague exists in natural enzootic cycles involving wild rodents and their fleas in several parts of the world. These natural cycles are usually hidden with no transmission to humans. Epidemics of plague occasionally occur when the disease spreads from wild rodents to rats that live in close proximity of human habitation.

Between 1989 and 2003, a total of 15 year period, 38,310 cases with 2845 deaths were recorded in 25 countries. In these 15 years the highest number of human plague cases was reported in 1991 and the lowest number 1989. Eight countries reported human plague almost every year. These countries were the Democratic Republic of the Congo, Madagascar and the United Republic of Tanzania in Africa; Peru and the United States in the Americas, and China, Mongolia and Viet Nam in Asia. An increase in the incidence of human plague has become apparent since the early 1990s, particularly in Africa. Three geographical areas experienced outbreaks of human plague after silent periods of about 30–50 years : India in 1994, Indonesia in 1997 and Algeria in 2003 (5-7). The total number of human plague cases reported to WHO in 2002 was 1925, of which 177 were fatal. In 2003, nine countries reported 2,118 cases and 182 deaths. 98.7% of those cases and 98. 9% of those deaths were reported from Africa. Today the distribution of plague coincides with the geographical distribution of its natural foci (3, 5).

### India

India suffered very large number of deaths during the third Plague pandemic. Plague outbreaks continued to occur, but with decreasing frequency during the first half of the 20th century. This is often attributed to the collateral benefit from the extensive insecticide spraying done as a part of the National Malaria Programme. India remained plague free for almost 30 years after the last human case was reported from Karnataka in1966.

In August–October 1994 human plague was reported in India. During this outbreak, 876 cases with 54 deaths were characterized as presumptive plague. Most cases were reported from Maharashtra (596), 151 from Gujarat, 68 from Delhi, 50 from Karnataka, 12 from Madhya Pradesh, and 10 from Uttar Pradesh. Almost all the deaths were reported from Gujarat. Several reasons have been put forth to explain this outbreak. Rat–fall was first reported from Mamla village in the Beed district of Maharashtra on 5 August 1994. This was followed by reports of flea nuisance. Three weeks later, suspected cases of bubonic plague were reported from Mamla village followed by reports from other villages in Beed and other districts. Beed has had sylvatic plague in the past. Ecological changes created by the earthquake in September 1993 and large scale storage of foodgrains probably contributed to a gradual growth of the rat population. The resurgence of plague in Surat, Gujarat, was related to a record high rainfall during the September monsoon. Floods in the Tapti river resulted in inundation of large areas. Many rodents were found dead when the water floods receded. Based on the clinical picture and the plague outbreak in neighbouring Maharashtra the outbreak in Surat was declared as pneumonic plague on 21 September 1994 (1, 8-12).

In February 2002, an outbreak of pneumonic plague (16 cases, 4 deaths) occurred in Hat Koti village, Shimla district, Himachal Pradesh. The outbreak is believed to have started after a person acquired the infection in the forest, which then spread to others through person - to - person contact. (5). Since 2002 there has been no

confirmed case of plage in India.

**Agent**

*Yersinia pestis* is a gram - negative coccobacillus. Yersinia was formerly classified in the family Pasteurellaceae, but has been now reclassified as members of the Enterobacteriaceae family. Though there are 11 species in the genus Yersinia, only three are considered important human pathogens. The bacteria is small (1.0 to 2.0 mcm x 0.5 mcm), pleomorphic and is seen as single cells or short chains in direct smears. They are nonmotile, nonsporulating, non-lactose fermenting facultative anaerobes (13-15).

**Vector**

*Yersinia pestis* is most commonly transmitted between animal reservoirs and to humans through the bites of infected fleas. There are more than 1,500 flea species, of which about 30 are known to be vectors for *Y pestis*. The major flea vectors include the following (15) :

(a) *Xenopsylla cheopis* (the oriental rat flea; nearly worldwide in moderate climates)

(b) *Oropsylla montanus* (United States)

(c) *Nosopsyllus fasciatus* (nearly worldwide in temperate climates)

(d) *Xenopsylla brasiliensis* (Africa, India, South America)

(e) *Xenopsylla astia* (Indonesia and Southeast Asia)

(f) *Xenopsylla vexabilis* (Pacific Islands)

To be an efficient plague vector, the flea must be able to ingest the *Yersinia pestis* with its blood meal. It must also live long enough for the pathogen to multiply in sufficiently large numbers. It must be able to transfer the pathogen to an animal or human host in sufficient concentrations to cause an infection. *Xenopsylla cheopis* is the most important vector of plague. A high incidence of plague infected *X. cheopis* in a given focus, greatly increases the risk of transmission to humans (1). *Pulex irritans*, the human flea may be responsible for human to human transmission of Plague (1, 16).

**Host**

More than 200 mammalian species have been known to be naturally infected with *Yersinia pestis*. However, plague is primarily a disease of rodents. The infection is maintained in natural foci of the disease in wild rodent colonies through transmission between rodents. The animal hosts of plague are classified as enzootic (maintenance) hosts and epizootic (amplification) hosts (1). Enzootic hosts are characterized by relatively mild illness, and low mortality rates. Voles and mice have been suggested as maintenance hosts. Epizootic rodents are associated with susceptibility and high mortality. Highly susceptible or epizootic plague hosts include various species of mice, rats, voles, gerbils, ground squirrels and marmots. Rats have historically been a primary carrier of plague (1, 15, 17-20)

**Transmission**

The most common mode of transmission of *Yersinia pestis* to humans is by the bite of infectious fleas. Other, less common modes of transmission include direct contact with infectious body fluids or tissues while handling an infected animal or inhaling infectious respiratory droplets (13). The mode of entry of the organism has marked clinical significance.

**Clinical Features**

Infection by *Yersinia pestis* causes a severe febrile illness characterized by headache, myalgia, malaise, shaking chills, prostration and gastrointestinal symptoms. The three commonest clinical presentations of plague are bubonic, septicemic and pneumonic (1, 13, 15). Less common forms of plague include pharyngeal and meningeal plague.

Bubonic Plague

For bubonic plague the mode of entry of the organism is by a flea bite. The infection spreads via the lymphatics to the regional lymph nodes causing inflammation and swelling in one or several nodes forming the classic buboes. Buboes may occur in any regional lymph node sites including inguinal, axillary, and supraclavicular. After an incubation period of 2 to 6 days, a patient experiences sudden onset of illness characterized by headache, chills, fever, malaise and pain in the affected regional lymph nodes. Progression of symptoms is usually rapid with the regional lymphadenitis becoming tender and painful. With specific treatment in uncomplicated cases, fever and general clinical symptoms usually resolve over 3 to 5 days.

Septicemic Plague

Septicemic plague occurs when *Yersinia pestis* invades and continues to multiply in the bloodstream. It can occur secondarily to bubonic plague or can develop without detectable lymphadenopathy. The host response may result in a wide spectrum of pathological events including disseminated intravascular coagulopathy, multiple organ failure and adult respiratory distress syndrome. Complications include plague pneumonia, plague meningitis and hepatic or splenic abscesses.

Pneumonic Plague

Pneumonic plague is the least common but most dangerous and fatal form of the disease. It can develop as a secondary complication of septicemic plague or result from inhalation of infectious droplets. The incubation period is usually varies from one to three days. There is sudden onset of chills, fever, headache, body pains, weakness and chest discomfort. This progresses rapidly to severe pneumonia accompanied by high fever, dyspnea, and often hemoptysis. If specific antibiotic therapy is not begun within 18 - 24 hours of onset, the patient is unlikely to survive. Pneumonic plague must be considered highly contagious, although person - to - person transmission is most likely in cold humid environments coupled with overcrowding. As the transmission occurs through infected droplets (and not airborne droplet nuclei), person - to - person transmission requires close contact.

Differential Diagnosis

Differential diagnosis of bubonic plague includes bacterial lymphadenitis, infectious mononucleosis, lymphatic filariasis, tick typhus, tularemia and other causes of acute lymphadenopathy. Involvement of intra - abdominal lymph nodes may mimic appendicitis or acute cholecystitis. Pneumonic plague may be confused with other causes of acute, severe community - acquired pneumonia, such as pneumococcal, streptococcal, or Haemophilus influenzae pneumonia (1).

## Diagnosis

Plague is diagnosed clinically based on exposure history and the symptoms of the patient. Presence of the classical buboes leads to suspicion of plague. Septicemic plague is resembles other gram - negative septicemias and is, therefore more difficult to diagnose on clinical grounds. Pneumonic plague can similarly be mistaken for other pneumonias. if possible, samples for confirmation of plague should be taken before treatment is begun. However, treatment should not be delayed by waiting for the laboratory results (15). Collection and transport of specimens is dealt with in detail in a separate chapter.

Routine blood tests show Leucocytosis with a predominance of neutrophils. Total WBC counts may be as high as 25,000/ml. The degree of leucocytosis is proportional to the severity of illness. Peripheral blood smear may show toxic granulations. Thrombocytopenia is common (21)

The laboratory diagnosis of plague is based on bacteriological and/or serological evidence. Diagnostic specimens for smear and culture include whole blood, sputum, aspirates from suspected buboes, pharyngeal swabs and cerebrospinal from suspected plague meningitis cases (1). Smears stained with Gram, Giemsa, Wright, or Wayson stain can provide supportive but not confirmatory evidence of a plague infection in the form of bipolar staining Gram - negative bacilli.

The diagnosis of plague is confirmed by the culture of *Y. pestis* from body fluids or tissues. *Y. pestis* grows on solid media as grey - white, translucent colonies, usually too small to be seen as individual colonies at 24 hours. After incubation at 37˚C for 48 hours, colonies are about 1 - 2 mm in diameter. After 48 - 72 hours of incubation colonies are raised and have an irregular appearance. Cultures are definitely identified as *Y. pestis* by specific phage lysis (1, 22).

Plague can be also be confirmed serologically by a four - fold or greater change in titre to the *Y. pestis* F1 antigen by passive haemagglutination testing of paired serum specimens. The specificity of a positive passive haemagglutination test can be confirmed by the F1 antigen haemagglutination - inhibition test. Some patients of plague seroconvert as early as 5 days after onset of symptoms, most seroconvert between 1 and 2 weeks after onset, while a few seroconvert 3 weeks or more after onset. Less than 5% do not seroconvert. After seroconversion, positive serological titres usually diminish gradually over months to years. Enzyme - linked immunosorbent assays (ELISAs) for detecting IgM and IgG antibodies may also be used for diagnosis. Detection of the F1 antigen in tissues or fluids by direct fluorescent antibody testing provides presumptive evidence of plague (1, 15)

In the recent past rapid diagnosis of plague has become available using the F1 antigen diagnostic assays based on dispsticks. These tests make a bedside diagnosis available within 15 minutes using bubo aspirate, serum and urine specimens (23).

A summary of laboratory diagnostic categories for human plague is as follows (From (1))

**Suspect plague**

(a) Compatible clinical and epidemiological features; and

(b) Suspicious organisms seen or isolated from clinical specimens.

**Presumptive plague**

(a) *Y. pestis* F1 antigen detected in clinical materials by direct fluorescent antibody testing, or by some other standardized antigen detection method; or

(b) Isolate from a clinical specimen demonstrates biochemical reactions consistent with *Y. pestis* or PCR positivity; or

(c) A single serum specimen is found positive for diagnostic levels of antibodies to *Y. pestis* F1 antigen, not explainable on the basis of prior infection or immunization.

**Confirmed plague**

(a) Isolate identified as *Y. pestis* by phage lysis of cultures; or

(b) A significant (4 - fold) change in antibody titre to the F1 antigen in paired serum specimens.

## Treatment

When a diagnosis of human plague is suspected, appropriate specimens for diagnosis should be taken immediately and the patient should be started on specific antibiotic treatment without waiting for laboratory confirmation. All patients suspected of having bubonic plague should be placed in isolation until 2 days after starting antibiotic treatment. Suspect plague patients with evidence of pneumonia should be placed in isolation and managed under respiratory droplet precautions.

Streptomycin is the drug of choice. The dose of streptomycin is 30 mg/kg/day (Not more than of 2 g/day) in divided doses given intramuscularly. Streptomycin must be given for a full course of 10 days or until 3 days after the temperature has returned to normal. Chloramphenicol is a suitable alternative. The dose of chloramphenicol is 50 mg/kg/day administered in divided doses either parenterally or orally for 10 days. Tetracyclines are effective in the primary treatment of patients with uncomplicated plague. An oral loading dose of 15 mg/kg tetracycline (not to exceed 1 g total) should

be followed by 25 - 50 mg/kg/day (up to a total of 2 g/day) for 10 days. Tetracyclines may also be used adjunctively with other antibiotics. Fluoroquinolones, such as ciprofloxacin are also effective (1, 15, 21)

### Prophylaxis

Close contacts of cases with pneumonic plague, or persons suspected to have had direct contact with body fluids or tissues of a *Y. pestis* - infected mammal, or exposed during a laboratory accident to known infectious materials should receive prophylactic antibiotics if the exposure was in the previous six days. Tetracycline and chloramphenicol are the antibiotics of choice for prophylaxis (1).

### Prevention and Control

Control of transmission is directed at controlling the rodent reservoirs and flea vectors of the disease. Trying to eliminate fleas and wild rodents from the natural environment in plague - infected areas are impractical. However, controlling rodents and their fleas around places where they are in close proximity of human beings is very important. Environmental sanitation and public health education are effective means of achieving these ends. Rodent and flea control measures are discussed in detail in the Chapters on Entomology and Rodents.

#### Surveillance

An effective surveillance system to provide early warning can abort epidemics. Effective plague prevention and control programmes require up - to - date information on the incidence and distribution of the disease. The surveillance programme must be designed to collect, analyse, and interpret clinical, epidemiological, and epizootiological data on plague. Surveillance should identify cases and epizootics as quickly as possible so that steps can be taken to control disease spread(1). Surveillance must include reporting of human cases, ecological and environmental observations, and surveillance of rodent populations. Readers may refer to the WHO Plague Manual (1) for details on human and rodent surveillance including precautions to be observed by health care workers.

#### Flea indices (from (1))

The most basic information obtained from flea and rodent surveys is the number of fleas of different species found on various species of hosts. This raw data can be used to calculate various indices. The important flea indices in use are :

**Total flea index** = Total number of fleas collected (regardless of species), divided by the total number of hosts of species examined

**Specific flea index** = Number of fleas of species A collected from host species divided by the number of individuals of host species examined (multiplication of this index by 100 gives the percentage index)

**Percentage of hosts infested** = Number of hosts of species infested with flea species divided by the total number of hosts of species examined, multiplied by 100.

**Burrow (or nest or house) index** = Number of fleas of species collected from burrows (or nest or house) of host species divided by the total number of burrows (or nest or house) of host species examined.

The specific flea index is the most widely used of the above indices. It has been reported that a specific flea index of greater than 1 for *X. cheopis* on rats represents a potentially dangerous situation with respect to increased plague risk for humans.

#### Vaccination

Plague vaccines were widely used in the past but have not proven effective in the control of plague. Both live attenuated and formalin - killed *Y. pestis* vaccines have been developed. The vaccines are variably immunogenic and moderately to highly reactogenic. They do not protect against primary pneumonic plague. Vaccination is of little use during human plague outbreaks, since a month or more is required to develop a protective immune response. Vaccines are, therefore, not recommended for immediate protection in outbreak situations. Vaccination is only recommended as a prophylactic measure for high - risk groups like laboratory personnel who are constantly exposed to the risk of contamination. (1, 16, 24)

The killed or inactivated plague vaccine is prepared from *Y. pestis* organisms grown in artificial media and then inactivated in formaldehyde. It is administered intramuscularly as a series of three primary doses. The initial dose of 1 ml is followed 1 to 3 months later by a 0.2ml dose. A third primary injection of 0.2 ml is given 5 to 6 months after the second. Two booster doses of 0.2ml are administered at 6 - month intervals, and additional boosters may be given every 1 to 2 years (15). Adverse reactions following injection of the first dose of plague vaccine generally are mild, but the frequency and severity of such events can increase with repeated doses.

Live *Y. pestis* vaccines composed of presumably avirulent strains also have been developed. However, none of these vaccines is commercially available, and their safety and

# Hazards due to Snakes

## Introduction

There are over 20 families of snakes in the world with above 3000 species. All the venomous snakes are however distributed across four families namely; Atractaspididae, Elapidae (including Hydrophiinae), Colubridae and Viperidae. A bite from a venomous snake can lead to disability or death. All snakes are carnivorous, eating animals smaller than it, including rodents, birds, eggs, insects and even snakes. Some have a venomous bite, used to incapacitate the prey before eating. Some snakes kill their prey by constriction and some swallow their prey live, as they cannot chew, so they have a flexible lower jaw (1).

A snake has always been associated with human symbolism. In Christianity the snake makes its infamous appearance in the Genesis in front of Adam and Eve. In India the snake is worshipped and associated with the Hindu Gods Shiva and Vishnu. Snakes are often associated with fertility and nagpanchami is celebrated every year. A snake is also one of the twelve celestial animals of the Chinese zodiac. The Nile Cobra adorning the crown of the Egyptian pharaoh and the depiction of Medusa in Greek mythology as having snakes instead of hair show the deep association of the reptile across human civilizations.

Serpents and medicine have also been symbolically associated. Snakes are seen in three medical symbols, namely the Rod of Asclepius (single snake), staff of Caduceus (two snakes entwined) and the Bowl of Hygea (symbolizing pharmacy). The Rod of Asclepius has been incorporated in the badge of the Army Medical Corps.

## Classification of Snakes

Study of snakes is called as ophiology. Dr Patrick Russell (1727 - 1805) is regarded as the father of Indian ophiology. Snakes now are classified morphologically by the arrangement of their scales (Lepidosis), dentition, osteology, mycology, sensory organs, the form of hemipenes and increasingly by sequence analysis of DNA encoding important mitochondrial and other enzymes (1). Snakes of medical importance primarily belong to four families only and are described in brief in the succeeding paragraphs (2). The common names of snakes of these families are listed in Table - 1.

## Venom Apparatus in Snakes

### Elapids

Generally found in tropical or sub - tropical regions of the world including Indian Sub - continent and the pacific. They are highly venomous and possess a set of hollow fixed fangs through which they inject venom.

### Viperadae

They are found all over the world except Australia and Madagascar. They have long hinged fangs, permitting deep injection of venom. When not in use the fangs fold back against the roof of the mouth and are enclosed in a membranous sheath. These snakes are highly venomous.

### Colubridae

It is a broad family including more than half the species of snakes of the world. A colubrid body is nearly fully covered in scales. Majority of the colubrids are harmless, non - venomous, but the ones listed in Table - 1 are venomous and have caused human fatalities. The colubrids are morphologically not a natural group and it is said that the family has been a dumping ground for snakes that do not fit anywhere.

### Atractaspididae

It is a family of venomous snakes found in Africa and Middle - east countries. This family includes many genera formerly classified in other families on the basis of dentition. Taxonomy of this family still is highly contentious.

## Snakes in India (3, 4)

Venom apparatus in Snakes

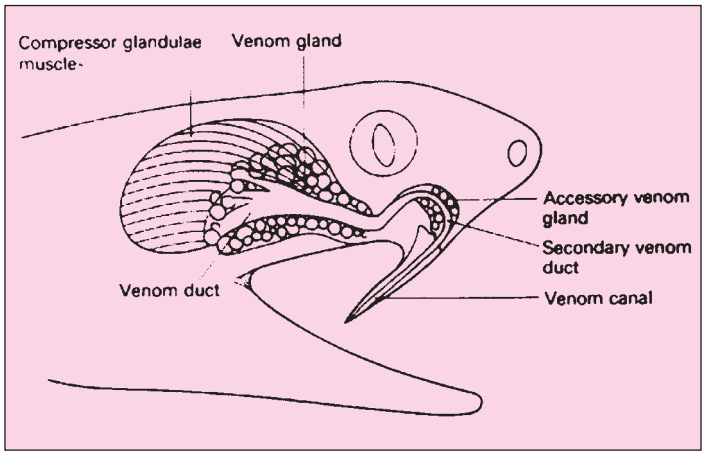

Table - 1 : Families of Venomous Snakes with common names

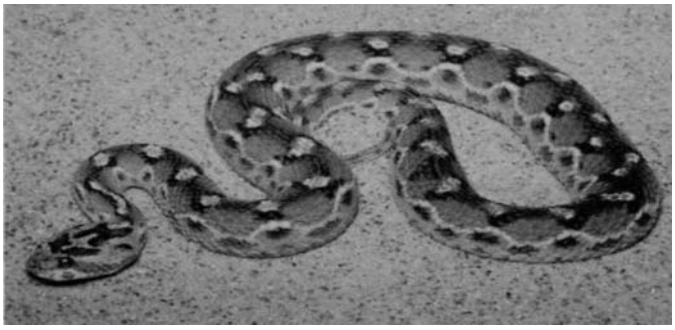
| Family | Common names |
|---|---|
| Elapids | Cobras, king cobras, krait, mamba, Australian copperheads, sea-snakes, coral snakes |
| Viperids | Russel viper, Saw-scaled viper, Hump nosed Pit Viper, Rattle snakes, Cottonmouths, Adders, Bushmasters |
| Colubrids | Boomslangs, Treesnakes, Vinesnakes, Mangrove snakes ( not all Colubrids are venomous) |

The Indian Cobra (*Naja naja*)

The Common Krait ( *Bungarus caeruleus*)

Russells Viper ( *Daboia russelli*)



The Saw Scaled Viper (*Echis carinatus*)

India has 216 species of snakes. For many decades the concept of the 'Big 4' snakes of medical importance in India have reflected a view that 4 species are responsible for Indian snake bite mortality - The Indian Cobra (*Naja naja*), Common Krait (*Bungarus caerulus*), Russells Viper (*Daboia russelli*) and the Saw - scaled Viper (*Echis carinatus*). The most recent discovery now has been the Hump - nosed Pit Viper (*Hypnale hypnale*), which till date was being confused with the Saw - scaled Viper. So now India is home to 5 main venomous snakes which cause mortality. The main features of the Indian snakes are given in Table - 2.

**Epidemiology of Snake Bite**

Snake bites take their toll the world over and India leads the race. It is said that India accounts for more than 50 % of the world's mortality due to snake bite. There are more than 2,00,000 bites per year across the country with over 35,000 deaths per year (2, 5). However no reliable database is available. In Maharashtra the highest incidence of snake bite is reported (70 bites per 1,00,000 population and mortality of 2.4 / 1,00,000 per year) (6). The other states in India which show high incidence include Tamil Nadu, Uttar Pradesh and Kerala (7). Personnel of the Armed Forces, especially Army, are very prone to snake bites during field exercises and maneuvers. Majority of bites in India occur in rural India (82%), where common places of occurrence is workers in fields and people sleeping outdoors at night (8). Snake bites have also shown a male preponderance, which suggests a special risk of outdoor activity (9, 10).

**Snake bite as an occupational hazard**

It is documented by the WHO that snake - bites across the world and especially in the SEARO is an occupational hazard. It mostly occurs due to access by humans to the snake's natural environment, occurring across various occupations. Some of the common occupations are:

(a) Farmers (especially paddy)

(b) Plantation workers (coffee, rubber)

Table - 2: Features of Indian Snakes (4)

| | Common Krait (*Bungarus caeruleus*) | Indian Cobra (*Naja naja*) | Russells Viper (*Daboia russelii*) | Saw Scaled Viper (*Echis carinatus*) |
|---|---|---|---|---|
| FEATURES | Medium sized, smooth, glossy scales, jet black, usual distinct white cross lines | Medium sized to large, smooth, shiny scales, wide head and neck, distinctive hood marking | Medium sized to large, strongly keeled scales, distinctive bright chain pattern, large triangular | Small, strongly keeled scales, head wider than neck, dull colour, cross mark on head distinctive |
| AVERAGE LENGTH | 1 m, At birth 25 cm, Max-1.75 m | 1m, At birth 25 cm, Max-2 m | 1m, At birth 25 cm, Max- 1.8 m | 30-50 cm, At birth 8 cm, Max- 80 cm |
| DESCRIPTION | Smooth glossy, bluish black, rounded head slightly different from neck. Adults have approx 40 thin white cross bands. The underside is white. | Smooth scaled snake, black eyes, wide neck and head and medium body. Colour varies from black to dark brown to yellowish white. Body has speckled patterns forming ragged bands | Heavy rough scaled snakes, vertical eye pupils, very bright pattern Colour is brown or yellowish with pattern of dark round spots edged with black and white. The spots are distinctly symmetrical. Underside is white and speckled. Short fat body abd with triangular shaped head | Rough scaled, large eyes, wider head than neck and stocky body. Colour brown, grayish or sandy, dark zigzag pattern and lance cross on head .Underside speckled white. Smallest venomous snake in India |
| DISTRIBUTION | Most of India, sea level up to 1700m, uncommon in Bengal, Assam Orissa where Banded Krait is common | Throughout India, sea level upto 2000 m | Hills and plains throughout India upto 3000 m | Through out India, upto 1500 m, plentiful in Maharashtra, Rajasthan, Punjab, Tamil Nadu & Andhra Pradesh. |
| HABITAT | Sandy soil, termite mounds, burrows, piles of bricks, rubble | More common in rice growing areas, due to availability of rodents. Granaries, termite mounds, earth dams and rock piles are favourite haunts. | Equally at home in the open areas of hilly country and plain scrub jungles bordering farmlands. Termite mounds, rock crevices are favourites. Also found in pandanus bushes (Kewda) and | Dry, sandy and rocky terrain. Not found in dense forests. Rest under rocks and dry plants. Areas of light scrub jungle are favourite. |
| HABITS | During day kraits hide, mostly nocturnal, territory consciousness present among males. They are short fanged snakes | Usually live in rat holes, near human habitat, shy in nature. Warning mechanism consists of spreading neck ribs (hood), hissing with sharp expulsion of air. | Looks sluggish, but capable of fast movements in short spurts. They hiss loudly and bite in defence. They are timid and less likely to be commensal with man | Nocturnal, also called 'Phoorsa,, rarely seen in daylight, active on humid / rainy nights, prefers warm roads and beated paths after dark. Produces hissing sound by rubbing |
| YOUNG | Lay 8-12 eggs in Mar- May which hatch in May-Jul. Female stays with eggs during incubation | Between May-Jul, female lays 12-30 eggs, stays during incubation (60 days) | May – Jul, females produce 6 -63 living young (Not eggs), they are viviparous-so the name vipers | 4-8 living young, Apr – Aug |
| FOOD | Other snakes, lizards and rodents. They are true cannibals | Insects, lizards, frogs, toads, rodents and other snakes. They maintain their grip till the prey becomes immobile | Young are cannibalistic, also eat lizards, rodents, scorpions and insects. Adults are predominantly rodent eaters. | Mice, Lizards, frogs , scorpions and other arthropods |
| STATUS | Very common and abundant. Thrive near human habitat | Hunted and killed for skins as also, worshipped and revered across the country | Major source of skin industry in South India, in some areas have been | Abundant, though collected in large numbers for skin |
| VENOM | Extremely neurotoxic. No local symptoms of envenomation seen | Neurotoxic venom, usually less than fatal amounts are injected | Bite is considered one of the most dangerous of all snakes, mainly due to amount of venom and vasculotoxicity | Cause largest number of bites, though bite rarely fatal. If fatal dose injected it takes days to die, generally treatment is available |

(c) Herdsmen
(d) Hunters
(e) Snake handlers
(f) Fishermen and fish farmers
(g) Army personnel (during field maneuvers)

### Determinants of severity of envenomation

Not all bites by venomous snakes are lethal and there are many factors which influence the severity of bite by a venomous snake. Some of the factors are:

(a) Dose dependency: Lethality depends upon the amount of venom injected by the snake.
(b) Species of snake
(c) Season and age of the snake
(d) Health, age, size and specific immunity of the victim (human).
(e) Nature and timing of First - Aid and subsequent treatment offered.

### Venom composition (2, 11)

Snakes have the most complex of all venoms. They contain more than 20 components. More than 90 % of dry weight is protein, comprising a rich variety of enzymes, non - enzyme polypeptide toxins and non toxic proteins such as nerve growth factor. Non-protein component includes carbohydrates and metals. The variation of venom occurs from species to species and within a single species throughout its geographical distribution, at different seasons of the year and also as result of the snake ageing. This is explained by the clinical diversity of the snake bite. Certain important venom constituents causing specific clinical problems are listed below:

(a) **Procoagulant Enzymes (viperidae)** : They stimulate blood clotting but result in incoagulable blood. The venom contains several procoagulants which activate different steps of the clotting cascade. The result is the formation of fibrin in the blood stream. Most of this is immediately broken down by the body's own fibrinolytic system. Eventually, depending on the dose of venom injected, the levels of clotting factors become so depleted that the blood will not clot (Consumption coagulopathy).
(b) **Haemmorrhagins (Zinc metalloproteinases)** : They damage endothelial lining of the blood vessel wall causing spontaneous systemic hemorrhage.
(c) **Cytolytic and Necrotic Toxins** : These digestive hydrolases (Proteolytic enzymes and Phospholipase A) and polypeptide toxins increase the permeability resulting in local swelling. They destroy cell membranes and tissues.
(d) **Hemolytic and Myolitic Phospholipase A2** : These enzymes damage cell membranes, endothelium, skeletal muscle, nerves and blood cells.
(e) **Presynaptic Neurotoxins** : (Elapidae and Viperadae) Phospholipase A2 that damages nerve endings, initially releasing acetylcholine transmitters, then subsequently, interfering with release.
(f) **Post Synaptic Neurotoxins** : They compete with acetylcholine for receptors at neuro - muscular junctions and lead to curare like paralysis.

### Identification of Venomous Snakes (4)

There is no simple rule for identifying a dangerous venomous snake. Many harmless snakes have evolved, and behave in a manner identical to a venomous snake. However some of the most venomous snakes can be recognized by their size, shape, colour, patterns and markings, their behavior when threatened. The defensive behavior of the cobra is well known: they rear up, spread a hood, hiss and make repeated strike towards the aggressor. The blowing hiss of a Russell's viper and the grating rasp of a Saw - scaled Viper are warning and identifying sounds. Vipers are also identified by their repeated and colourful dorsal pattern.

The identification of a dead snake by looking at the scales is not fool - proof and requires expertise. The criteria for species identification by external morphology of the dead snake is beyond the scope of the book, however reference can be made in "The Indian Field Snake Guide". It is also important that the identification should not form the basis of treatment which should solely be based on the clinical profile of the patient.

### Signs and symptoms of snake bite (1, 2)

#### When venom has not been injected

Many people are bitten by non - venomous snakes, or do not get injected by venom during a bite of venomous snake. There are some who imagine that they have been bitten, even with a mere contact of a snake. It has been documented that quite a sizeable number of such victims develop striking signs and symptoms, quite resembling envenomation. This is said to be a result of the understandable fear of consequences of a real venomous bite. Some common features seen are anxious tetany of the hands and feet, dizziness, vasovagal shock, bradycardia and collapse. Agitation and irrational behaviour are also seen.

Another source of resemblance of signs of envenomation is due to aggressive and wrong First - aid methods combined with traditional methods of treatment. Constricting bands and tourniquets may cause pain, swelling and congestion. Ingested remedies may produce vomit. Instillation of irritant plant juices in the eye may cause conjunctivitis. Forcible insufflations of oils in respiratory tract may cause aspiration, bronchospasm and pneumothorax. Local incision and cauterization may cause injuries.

#### When venom has been injected

Sometimes bites by venomous snakes, especially of kraits and sea snakes, may be virtually painless and cause negligible local reaction. A sleeping person may not even wake up and no detectable fang mark may be seen. However there are a plethora of signs and symptoms associated with envenomation, which may be clinically helpful to detect snakebite. Snake bite produces localized, generalized as well as species specific signs and

symptoms. Localized signs and symptoms are fang marks, local pain, local bleed, bruising, lymphangitis, lymph node enlargement, blistering, local infection, necrosis.

Generalized signs and symptoms

Some common signs and symptoms observed are nausea, vomit, malaise, abdominal pain, weakness, drowsiness and prostration.

Species specific symptomatology

Envenomation is known to be species specific and if carefully examined clinically, zeroing in on the species of the snake can be done based on clinical and laboratory findings. The specific signs and symptoms are mentioned against the alphabetical codes which can be compared from the table for the species in Table - 3.

**Alphabetical codes (Table - 3)**

**(A) Cardiovascular**

Dizziness, fainting, visual disturbances, collapse, shock, hypotension, cardiac arrhythmias, pulmonary oedema and conjunctival oedema.

Table - 3 : Species specific signs and symptoms

| Family and species | Code - Signs & symptoms |
|---|---|
| **Viperidae** | |
| Russells viper | A, B, C, D, E, F |
| Saw scaled viper | A, B, E |
| **Elapidae** | |
| Indian cobra | C |
| Common krait | C |
| Sea snakes | C, D, E |

**(B) Bleeding and clotting disorders**

Increased bleed from recent wounds (including fang marks and venepunctures) and from old partially healed wounds. Spontaneous systemic bleed from gums, epistaxis, hemoptysis, hematemesis, malena, hematuria, vaginal bleed, petechiae, purpurae and ecchymossis; conjunctival and mucosal bleeds, Intracranial bleeds, Sub Arachnoid bleeds, lateralizing signs and coma.

**(C) Neurological signs**

Drowsiness, parasthesiae, sensory abnormalities (especially taste and smell), ptosis, external ophthalmoplegia, cranial nerve palsies, aphonia, ascending paralysis, bulbar palsy, respiratory paralysis and generalized paralysis.

**(D) Skeletal muscle breakdown**

Generalised pain, stiffness, tenderness of muscles, trismus, myoglobinuria, hyperkalemia, cardiac arrest and acute renal failure.

**(E) Renal involvement**

Loin pain, hematuria, hemoglobinuria, myoglobinuria, oliguria, anuria and uremia.

**(F) Endocrine involvement**

Acute pituitary and adrenal insufficiency, hypoglycemia. Chronic phase (months to years after the bite) may lead to weakness, loss of secondary sexual hair, amenorrhoea, testicular atrophy and hypothyroidism.

Long term complications

At the site of bite; loss of tissue, sloughing, necrosis, chronic ulcers, infection, osteomyelitis, arthritis and even malignant transformation of ulcers are noted. Chronic Renal failure, chronic pan hypopituitarism and Diabetes insipidus especially after the bite of a Russell's viper are observed.

**Management of snake bite**

Prompt and proper management of a venomous snake bite is often the dividing line between life and death. Mortality due to snake bite is affected by many factors besides the envenomation itself. The important aspects to consider are

(a) First - Aid
(b) Transportation of the patient
(c) Rapid clinical assessment and resuscitation
(d) Laboratory support and investigations
(e) Antivenom treatment
(f) Supportive care and treatment

First - aid

This primarily aims at retarding the systemic absorption of venom, preserving life and preventing complications; before a patient can receive medical care. The following first - aid must be promptly offered:

(a) Reassure the patient and try to allay anxiety
(b) **Immobilize the limb** : Immediately immobilize the bitten limb with a makeshift splint / sling as any movement or muscular contractions will enhance the absorption of venom into the bloodstream and lymphatics.
(c) **Consider pressure immobilization**: (Especially Elapid bites) Ideally an elastic, stretchy crepe bandage approximately 10 cm wide and 4 m long. Otherwise any long strip of cloth can be used. The bandage is to be wound firmly around the bitten limb, starting distally around the fingers / toes and moving proximally to include a rigid splint (piece of wood, board, metal pipe etc). The bandage is bound as tight as would be for a sprained ankle, but not so tight so as to occlude peripheral pulses. Pressure immobilization is not recommended for viper bites due to its venom having local necrotic effects which may aggravate / enhance causation of local injury. Tight arterial torniquets are not recommended as they can cause more harm than benefit. They have often resulted in gangrenous limbs.

Transportation

It is of vital importance, as it decides the survivability of the victim. One should avoid undue movement of the bitten limb, with secure and proper splintage. Always attempt to carry the patient by whichever means available.

**Warning**

(i) Do not attempt to kill the snake as it may be dangerous

(ii) If the snake is dead, carry in a strong sealed box

(iii) Carefully handle a dead snake, never with bare

The victim should avoid walking on his own at all costs.

Antivenom (2)

**What is antivenom**

It is an immunoglobulin (usually the enzyme refined F (ab) 2 fragment of IgG) purified from the serum or plasma of an animal (usually horse) that has been immunized with the

**Rapid clinical management for envenomation**

(i) Try to identify snake as venomous or non - venomous but do not waste to much precious time in doing so.

(ii) See for rapid early extension of local swelling from site of bite.

(iii) See for early enlargement of local lymph nodes.

(iv) See for early systemic symptoms: Collapse, nausea, vomiting, diarrhoea, severe headache, drowsiness, heaviness of eyelids, ophthalmoplegia etc.

(v) See for signs of spontaneous systemic bleeding

(vi) See for ANAPHYLAXIS due to envenomation and treat expeditiously.

(vii) Establish good intravenous access. (Preferably two)

(viii) Secure airway if required

venoms of one or more species of snakes. The Antivenom production is based on the endemicity of the species of snake in the geographical area. If antivenom is for a single specific species, it is monovalent. Similarly bivalent and polyvalent antivenins are also made. In India, where predominantly 4 species are present across the length and breadth of the country, the Antivenom produced is polyvalent against the 'Big 4' mentioned in earlier paragraphs. Antibodies raised against the venom of one species may have a cross - neutralizing activity against other venoms, usually from closely related species. This is known as 'Paraspecific activity'. The Antivenom available in the Armed Forces is a PVMS supply of Section 2 of PVMS List having number 020001.

Indication for administering antivenom

Antivenom should only be administered on specific indications of envenoming, and not merely on the occurrence of snakebite. One important clinical method to accurately assess need for antivenom, especially in bites by vipers is the 20 Minute Whole Blood Clotting Test (see box) (12)

**Polyvalent antivenom production centres in india**

1. Central Research Institute, Kasauli (Himachal Pradesh)
2. Haffkine Biopharmaceutical Company Ltd, Acharya Doude Marg, Parel, Mumbai
3. Kings Institute of Preventive Medicine, Guindi, Chennai
4. Serum Institute of India Ltd, Hadapsar, Pune

How to administer antivenom

This is the most crucial part of management of snakebites. If indicated, Antivenom must be administered immediately. However, antivenom has proved effective even days after neurotoxic bites, while it can even be given

**20 WBCT**

1. Put 1 - 2 ml of blood in a new, clean glass test tube. Do not use a tube that has been washed since left - over detergent may prevent clotting of normal blood.
2. Leave alone for 20 minutes - do not agitate or keep picking up to inspect since this will alter rate of clotting.
3. After 20 minutes, invert once.
4. If the blood flows freely, and there is no clot, then the test is positive and Antivenom is indicated. The presence of even a small clot indicates that at least the clotting system is partially functioning and that there is a low risk of serious hemorrhage. Antivenom is therefore not indicated.
5. Positive tests : Repeat 6 hours after giving Antivenom. There is little point repeating before this time since it takes 6 hours for the liver to reconstitute the clotting system after neutralization of the venom components.
6. Negative test : Observe the patient carefully for other signs of envenoming and bleeding. Repeat

weeks after a viperine bite. The commonly used polyvalent ASV, available as a lyophilized powder, is reconstituted with sterile water. Frothing is avoided while reconstituting. The clear reconstituted fluid is further diluted in 250 – 500 ml of 5 % dextrose and given as a slow IV push over 20 - 30 minutes. Always keep a watch out for features of anaphylaxis as a result of antivenom. Antivenom is administered under supervision till all clinical and laboratory parameters indicate normalcy. Systemic envenomation may recur hours / days after initial favourable response due to continuous slow absorption of venom from site of bite. Hence it is important to keep constant supervision of the patient for 3-4 days. Neurotoxic envenomation may require ventilatory support. Reactions to antivenom may start 10 - 180 minutes after starting and use of steroids is beneficial.

**Prevention of snakebite in Armed Forces**

Snakes have been established to be shy creatures, which will bite only in some form of self defence, in case it feels threatened. Accidental contact with humans, across various occupations, which interfere and cut across the snakes natural ecosystem and habitat, are the most common causes of bite. The Armed Forces are regularly exposed to snakes during field exercises as also in

military cantonments, which offer a more favourable ecosystem for snakes to cohabit with humans. However, some measures, if religiously implemented, will markedly reduce the incidence of snakebites.

(a) Always be vigilant regarding the possibility of encountering a snake.

(b) Know about the local species of snake and its common habitat and take proactive measures in reducing such places.

(c) Educate troops and families about snakes, their habitat and First - aid measures for snake bite.

(d) Always carry a light / torch at night, especially sentries and patrols moving out at night.

(e) Encourage use of boots, especially with anklets, socks with long trousers, as the maximum incidence of snakebite is on the lower limb.

(f) Snakes if seen, should not be handled, attacked or disturbed.

(g) Avoid sleeping on ground.

(h) Instruct troops to:

(i) Dust and invert bedding/sleeping bag every time before lying down.

(ii) Invert and shake shoes / boots every time before wearing them.

(iii) Wear shoes / boots while moving in the dark and never walk barefoot.

(iv) Use mosquito nets, especially in camp sites, as it also prevents access of the snake near the human.

(j) Dig snake trenches - Trenches 60 cm deep and wide with vertical edges are a deterrent for the snake to enter inside a tent. This should be strictly implemented in campsites.

(k) Keep area of living clean, litter and rubble free, which will prevent rodent ingress and not attract snakes.

# Hazards due to Rodents

## Introduction

Rodents are characterised by two continuously growing incisors in the upper and lower jaws which must be kept short by gnawing.

Forty-percent of mammal species are rodents, and they are found in vast numbers on all continents. Common rodents include mice, rats, squirrels, chipmunks, gophers, porcupines, beavers, hamsters, gerbils, and guinea pigs. Rodents have sharp incisors that they use to gnaw wood, break into food, and bite predators. Most eat seeds or plants, though some have more varied diets. They have historically been pests, eating human seed stores and spreading disease. Rodents evolved some time around the end of the Cretaceous period, 65 million years ago.

Rodents are part of man's environment. Some of them live close to him. They are the reservoir and source of at least 20 percent of Zoonoses known up till now. They form more than one third of all the living species of mammals and exceed any other mammalian order in the number of individuals. All rodents are without canine teeth, but they have strongly developed incisors, which grow throughout the life of the animal, the front incisors covered with enamel are sharp and chisel like.

Family Muridae is the most extensive family of rodents. This is divided into several sub-families. Sub-family Murinae, which includes the Genus Mus (mice) and the Genus Rattus (rats); is the most important in human ecology and medicine. Mice can be distinguished from rats by their smaller size and the presence of a notch on the inner side of the upper incisors. There are many species of rats and mice. The different species of rats are identified by their colour, length of ears, body, tail, and hind feet; shape of the head; texture of pelage; number of mammae; and by the skull and teeth (1).

## Distribution

Most of them remain indigenous and local. *Mus musculus*, the common house mouse, *Rattus rattus*, the roof rat, and *Rattus norvegius*, the sewer rat follow man to all parts of the world. The genus Rattus has more than 250 species and several hundred sub-species, the principal populations of which are in Asia. *R. norvegicus* has spread throughout Europe and to practically every country and island in the world with human traffic, but *M. musculus* and *R. rattus* are generally limited to tropical and sub-tropical regions. There are approximately 110 species of rodents in India. These are broadly classified into two groups. The first group comprises domestic rodents which include *Rattus rattus* (the black rat), *Rattus norvegicus* (Norway rat) and *Mus musculus* or the common house mouse. The second group consists of wild rodents like *Tatera indica, Bandicota bengalensis, Bandicota indica,* and *Tatera meltada.* The commonest species in India are *Rattus rattus, Rattus norvegicus* and *Mus musculus* (2).

## Morphology

Brief description of commonest species is given below. For further studies standard works should be consulted.

(a) *Rattus norvegicus*

It is a brown rat of large size, with a blunt nose and small opaque ears which barely cover the eyes when laid forward. The tail is shorter than the length of the head and body together. The female has 12 mammae. It is essentially an outdoor rat frequenting sewers and the fields. When it enters houses, it usually invades only the ground floors. It feeds on sewer and house rubbish, garbage and other decaying material. It gnaws even the rusty iron sheets or bars.

(b) *Rattus rattus*

It is a more delicately built rat with slender body and pointed head. It is often black in colour, but reddish brown varieties are abundant in many parts of India. The ears are translucent and large, and reach beyond the middle of the eye when laid forward. The tail is more delicate and much longer than the length of the head and body. The female has 8 or 10 mammae. It is essentially a dweller in human habitations, and being a good climber it nests in roofs. It feeds mainly on man's food, garbage or swill. It gnaws fabrics, wiring, leather, woodwork and so on.

## Importance of rodents to human health and ecology

### Rodents and Disease

Rodents act as hosts to several ectoparasites and endoparasites causing human and animal diseases. The flea is the most important ectoparasite from medical point of view. Rodents also serve as hosts in the life cycle of ticks and mites. Rat louse helps migration of some endoparasite from rodent to rodent. *Yersinia pestis* causing bubonic plague is the most important, if not the commonest, of all the pathogenic organisms; *P. tularensis* and certain *salmonella* species are the other bacterial infections associated with rodents. The three species of Rickettsia, viz. *O. tsutsugamushi, typhi* and *R. rickettsia* causing scrub, endemic and tick typhus respectively; the three species of spirochaetes, viz. *Leptospira icterohaemorrhagica, Spirillum minus* and *Borrelia recurrentis* and *duttoni*, causing weils disease, rat bite fever and relapsing fever respectively; the viruses of lymphocytic choreomeningitis, haemorrhagic fever, encephalitis, and certain parasites causing leishmaniasis, chagas disease, histoplasmosis, and mellioidosis are other important infections. Rat is an intermediary host of *Trichinellla spiralis*, while *Hymenolepis diminuta* and amoebiasis can also be caused by it. Majority of these infections are transmitted through the ectoparasites. A dead rat is as dangerous as a living rat because the ectoparasites leave the cooling body and attack other animals and man, causing disease. *Spirillum minus* causing rat-bite fever is transmitted through rat bite. Tularaemia and mellioidosis occur by ingesting food

Table - 1 : Diseases Directly Transmitted by Rodents

| Disease | Agent | How does the Disease Spread | Where does the Disease Occur |
|---|---|---|---|
| Hemorrhagic fever with renal syndrome | Virus | Breathing in dust that is contaminated with rodent urine or droppings<br>Direct contact with rodents or their urine and droppings<br>Bite wounds, although this does not happen frequently<br>The disease may spread through direct contact from person to person, but it is extremely rare. | Primarily in eastern Asia, Russia, Korea, Scandinavia, western Europe, and the Balkans. |
| Leptospirosis | Bacteria | Eating food or drinking water contaminated with urine from infected animals<br>Contact through the skin or mucous membranes (such as inside the nose) with water or soil that is contaminated with the urine from infected animals | Worldwide |
| Lymphocytic Chorio-meningitis (LCM) | Virus | Breathing in dust that is contaminated with rodent urine or droppings<br>Direct contact with rodents or their urine and droppings<br>Bite wounds, although this does not happen frequently. | Worldwide |
| Plague | Bacteria | Bite of an infected flea<br>Direct contact with infected animal | Western US, S. America, Africa, Asia |
| Rat-Bite fever | Bacteria | Bite or scratch wound from an infected rodent, or contact with a dead rodent<br>Eating or drinking food or water that is contaminated by rat feces. | Worldwide; *Strepto-bacillus moniliformis* in North America and Europe; *Spirillum minus* in Asia and Africa. |
| Salmonellosis | Bacteria | Eating or drinking food or water that is contaminated by rat feces. | Worldwide |
| Tularemia | Bacteria | Handling infected animal carcasses<br>Being bitten by an infected tick, deerfly or other insect<br>Eating or drinking contaminated food or water<br>Breathing in the bacteria, *F. tularensis* | Worldwide |

Table - 2 : Diseases Indirectly Transmitted by Rodents

| Disease | Agent | Rodent(s) involved | Vectors | How the Disease Spreads |
|---|---|---|---|---|
| Babesiosis | Parasite | Deer mice and voles | Tick | Bite from an infected tick. |
| Colorado tick fever | Virus | Deer mouse, bushy-tailed woodrat, ground squirrel, porcupine, chipmunk | Tick | Bite from an infected tick. |
| Cutaneous leishmaniasis | Parasite | Wild woodrat | Sand fly | Bite from an infected sand fly. |
| Human granulocytic anaplasmosis | Bacteria | Deer mouse, dusky-footed woodrat, Mexican woodrat, white-footed mouse | Tick | Bite from an infected tick. |
| Lyme disease | Bacteria | Peromyscus spp. (white-footed mouse) in the northeastern and mid-western USA and other rodents (tree squirrel) in the western USA | Tick | Bite from an infected tick. |

Table - 2 (Contd.)

| Disease | Agent | Rodent(s) involved | Vectors | How the Disease Spreads |
|---|---|---|---|---|
| Murine typhus | Bacteria | Rats | Flea or mite | Bite from an infected flea or mite.<br>Contact of broken skin or wound with infected flea or mite or their droppings. |
| Scrub typhus | Bacteria | Rats | Mite | Bite from an infected mite. |
| Rickettsialpox | Bacteria | Mice | Mite | Bite from an infected mite. |
| Relapsing fever | Bacteria | Wild rodents | Tick | Bite from an infected tick. |
| Rocky Mountain spotted fever | Bacteria | Wild rodents | Tick | Bite from an infected tick. |
| Western equine encephalitis | Virus | Ground squirrel and snowshoe hare | Mosquito | Bite from an infected mosquito. |

contaminated by rats. Salmonellosis is transmitted mechanically through dropping by contamination of food. Similarly many disease of cattle and other animals of importance to human ecology are due to rats and their parasites (3).

### Rodents and Human Ecology

Rats are voracious consumers and great destroyers of food grains and standing crops; they spoil and render food grains unfit many times more than they consume. They are menace to eggs and poultry, which they eat and destroy more than all the other wild mammals. They burrow and cause damage to buildings, dams, embankments and other structures. They gnaw articles of clothing, furniture, leather, electric wire and even rusty iron pipes. The destruction of food, crops, household articles, property, masonry, buildings and merchandise caused by rodents is so great that this alone would justify active measures to exterminate them at any cost, even if rodent related human and animal diseases were to be controlled by alternative methods such as the control of ectoparasites and immunization. On the ships, they act not only as harassing menace, consumers and destroyers of food, damagers of structures and fitting of ships and personal belongings, and as health hazard to the ship's crew and passengers, but also constitute international conveyers of epidemic disease like plague. The great plague epidemics of the past were due to migration of infected rats on ships from China to India, Middle East and Europe and South America.

### Bionomics

#### Growth Potential

Reproduction occurs all the year round, but in some places there may be maximum births in spring and late autumn. The percentage females at a time varies between 18 to 40. The pregnancy rate per annum per female and the birth rate per pregnancy varies between four to eight. The weanling rate is about nine per females. The annual death rate among weanlings is about three per annual brood. Changes in rat population mainly depends upon death rates than upon the birth rates. The death rate is determined by competition among rats for food and harbourage available. Fierce fighting permits a few rats to dominate the others. These aggressive rats feed and reproduce inhibiting growth and reproduction of the inferior ones. Destruction by poisons, traps, cats and so on are rarely sufficiently intense and sustained to keep the population perpetually down. Actually, these procedures, as generally practiced, make room for other rats to grow up and reproduce. Even very intensive poisoning campaigns reduce the rat population only temporarily. They will rapidly increase to the level upto the capacity of the area to support them and then remain at that level.

#### Nesting Habits

When present along with *R. norvegicus*, which is a larger, more vicious and aggressive rat, the *R. rattus* usually nests in the upper parts of the building and in burrows, in dark and moist places over the false roof, in and behind cupboards, under wooden doors, and behind wall paneling. In tropical climates they also nest in trees. Although *R. norvegicus* prefer underground places, their nests may frequently be found inside the buildings, even in the upper parts where there is abundant harbourage. In temperate climates all the rodent species, including the mouse, infest the fields at considerable distance from buildings.

#### Locomotion

Norway rats are not as agile as the other species and are less expert climbers. In the open, rats have defective vision; by daylight they move slowly and uncertainly. In contact with the wall they run in great speed. This fact suggests that the vibrissae (whiskers) serve as feelers and that they are extremely sensitive.

#### Rat Runs

Rats prefer narrow places and overhead pipes and beams

as highways, and habitually follow the same course. These highways or 'runs' are useful in tracing their nesting and hiding places, in discovering defects that allow passage to such places, and are also available guides for placing traps and poisoned baits.

Feeding Habits

Rats are omnivorous but, as a group, grains are their food of choice. Roof rats prefer fruits and vegetables. Rats learn to eat the foods of the locality in which they live and will often ignore food selected by rats in other places. On the other hand, those of the same species and locality may show great divergence in their choice of foods. Most rats will take fresh meat, and dried meat which when mixed with grain is the best bait; dried coconut and pakoras also form good baits. Rats cannot vomit and hence poisons which have emetic effect on all other mammals e.g. red squill, can be used against them. They are however, very suspicious and any strange thing is shunned by them; even a strange smell deters them.

Migration

Rats, like other mammals, normally tend to remain within a limited area of home 'range' for long periods of time, provided enough food supply is constantly available and an undisturbed harbourage is ensured. They stay within 10 to 20 m, while house mice live within an area of only 4 to 5 m diameter for many months, unless there are radical conditions, denying nesting, feeding and breeding. In urban residential areas the diameter of the home range may be about 20 to 40 m. Overland mass migration of rats have been reported from country to country especially when food supplies are depleted. Ships and trains have been the commonest vehicles for migration. Movements of rats from houses and barns to the fields take place in the spring with the harvesting of crops, and there is a return during rains and winter months. Similar migrations occur from urban areas to rural areas. Rats liberated in a strange place may travel long distance in search of a new home, but after finding a suitable place they also remain within a circumscribed area for many months or until there is a change in the environment. Rats may enter vessels when they berth at docks and many of them are carried abroad in cargo. Now-a-days rat proofing is included as a standard requirement in building of new ships and vessels.

**Rodent control (4-6)**

The best way to prevent a rodent infestation and contact with rodents is to remove the food sources, water, and items that provide shelter for rodents.

The preventive and control measures can be summarized into the three following measurses:

**(a) Seal Up**

Seal up holes inside and outside the home to keep rodents out

**(b) Trap Up**

Trap rodents around the home to help reduce the population

**(c) Clean Up**

Avoid illness: Take precautions before and while cleaning rodent-infested areas

Before the various techniques, methods or strategies of controlling or managing rodents are described the general principles involved need to be discussed. An understanding of these principles by all those involved will assist in devising specific control strategies for a given situation. It will also help when explaining the need for certain activities to the staff actually executing the control work.

In Armed Forces rodents pose a continuous problem because of the climatic conditions, uninterrupted food supply and relatively open structures. Therefore the control of rodent pests should be approached as a management problem much more so than a simple and single poisoning action. For a control strategy to be effective staff responsible need to be trained and informed, their activities must be co-ordinated, responsibilities confirmed, inputs and equipment readily available and the entire action must be planned.

Control strategies should aim at preventing losses and thus require a pro-active rather than the more normal reactive approach. Once a large population of rodents has established itself in a store considerable losses, that cannot be retrieved, have already occurred and subsequent control action is expensive. It should be stressed that information from different sources should be incorporated into a control or management strategy and not just the techniques.

There are many more techniques and methods of controlling rats than are described here.

An important element of any rodent programme is monitoring. Usually it means surveillance for the presence of rodents. However it should also mean looking for features in the environment which would encourage rodents to migrate into it. Control of a rodent infestation is rarely completely successful; but if it is, it is usually only for a very short period. Therefore there is a need for continuous monitoring even after a successful control campaign regardless of the techniques and bait used.

If an area is made rat-free due to good management and/or effective control measures, rats from near-by areas will migrate into it. It is therefore more efficient if control campaigns are conducted in several adjacent areas simultaneously. In the case of a village, all households should be motivated and organised to control rats at the same time. While control in one household will still benefit the owner, benefits increase as the number of participating neighbors increases.

In the case of stores, large and small, surrounding areas including other stores should also be disinfested. This means that all the store keepers or managers involved should coordinate and synchronise their rodent control activities for maximum effect.

Rodent control measures can be broadly classified as:

**(a) Permanent Measures**

(i) Anti-rodent Engineering
(ii) Rodent Exclusion
(iii) Anti-rodent Hygiene

**(b) Temporary Measures**

(i) Trapping
(ii) Rodenticides
(iii) Biological Control

Permanent Measures

The rodent control is best achieved by denying them ingress; denying them nesting, breeding and hiding places; denying them food; and destroying them. Practical methods to achieve these measures are the anti-rodent engineering; anti-rodent hygiene; anti-rodent house keeping; and health education. Scientific and healthy town planning is essential to keep rats out of the blocks of human habitations. Good planning, designing and construction of buildings keep them out of dwelling, factories, shops, godowns and places like slaughterhouses, granaries and stores. Environmental tidiness, sanitation, high standard of living and good housekeeping are essential adjuncts to anti-rodent engineering. Education and civic sense are essential so that people take all these steps with understanding. Permanent rodent control in urban areas, can be achieved only by these methods, because rat destruction alone rarely reduces their population to an appreciably low level and it rapidly builds up to the original level. Furthermore, this still does not improve the living and sanitary conditions.

**Anti-rodent Engineering**

Rats enter through drainpipes left open; through doors and windows, especially from alleys; through basement windows and outside fittings; through the lower parts of the doors, ventilators, sky lights, unused chimney flues, down the electric wire casings and so on. The doors and windows should be tight fitting and reinforced with metal sheets to keep the rats from gnawing through the basement and upper windows; the other places of ingress such a ventilators, skylights, unused chimney flues, and opening around water, sewer, gas and steam pipes, and electric wires must be suitably protected. Screens to prevent rats wandering from one place to another in large group of buildings should be provided. Foundation walls laid without a break around the entire building, flush with the under surface on the floor above, and extending not less than 45 cm beneath the surface of the surrounding ground, prevents rats burrowing through. Floor joists should be embedded in the wall or the spaces between the joists filled in and completely closed up to the floor level. Floor should be concreted with a layer of at least 7 to 8 cm of thickness and finished with a soling surface of cement about 1 to15 cm thick or tiles. All water and drainpipes should be surrounded by concrete where they pierce the walls. If the lower portion of all the walls are made of glazed tiles or tinned with galvanized non-corrugated iron sheets, rats do not enter buildings.

**Rodent Exclusion**

(a) All openings greater than 1/4" should be sealed to exclude mice, but it may be impossible to seal all openings.
(b) All openings greater than 1/2" should be sealed to exclude rats.
(c) Likely access points for rodents are where utility lines come into walls, as well as openings around air conditioning, drain pipes and vents. Look for broken basement windows, warped doors, and unscreened vents as possible points of entry. All spaces beneath doors should be checked if the opening is too large and reduced if needed. Roofs should be checked to see that shingles are down tight and sheathing is complete. Also check roof ventilators, screen vents and wall vents.
(d) Hardware cloth may be used to seal openings such as attic vents. Install 1/4-inch wire mesh (hardware cloth) over attic, roof, and crawl space vents in order to prevent entry of birds, bats, squirrels, rodents, and other wildlife. Metal flashing may be used to seal up openings around the gutters
(e) Use Stuff It Copper Mesh around pipes and utility lines stuffing into the openings such as openings where pipes and wires enter the foundation and siding, e.g., around outdoor faucets, receptacles, gas meters, clothes dryer vents, and telephone/cable TV wires.

The chief sanctuaries for rats in cities are the provision houses, markets, warehouses, slaughterhouses, dairy farms, restaurants, bakery, shops, candy factories and human dwellings. In the rural areas, corn godowns, barns, granaries, cattle sheds, fodder rooms, piggeries, horse stables are the chief places which afford nesting, breeding and feeding sanctuaries for rats. The field rats in rural areas cannot be controlled by rat proofing for there is continual abundance of exterior food. Raising the flooring on piers 15 cm or more above the ground surface reduces rat harbourage under them. Rat burrows can be closed with a mixture of cement, sand and broken glass. Provision stores should be built in such a way that the height of each step is more than 25 cm. The tiles covering the steps should be jutting out. In urban and rural areas alike, the access of rats to places where they can secure nesting facilities, food or water should be barred.

**Anti-rodent Hygiene**

Rodents require food and shelter. Therefore it is most important to reduce the availability of these two key factors, which should be central in devising any kind of strategy. In the case of buildings the most effective method of rodent prevention is the improvement of hygiene or sanitation in and around them. Primarily this means sweeping the area and keeping both it and the

surrounding area neat and tidy, i.e. free from any objects such as empty containers, idle equipment or discarded building materials, which could provide cover or nesting places for rodents. Observations have shown over and again that these simple actions, even in the tropics, are the most effective preventative measures that can be taken.

(a) In a tidy store any infestation will be noticed at a very early stage, making other control measures far more effective. With reduced access to food and no places to hide, rats will not become established, that is live and breed, inside a building. Regular disturbance is something rats and mice avoid.

(b) Control procedures should take the life history and behaviour of species present into account. Rats avoid clear spaces. Therefore by keeping a strip of two or more metres around a building clear of vegetation will reduce the chance of rats entering the building.

(c) This should be augmented by keeping a strip of about one metre on the inside from the wall totally clear and swept. Branches overhanging the building should be lopped off to prevent climbing species to enter from above.

(d) All solid wastes must be disposed off hygienically. Slaughterhouse waste, in particular, should be incinerated. Very high standard of environmental sanitation, general neatness and tidiness in and about the houses, godowns, factories, provision stores, market places, slaughter houses deprives rats of places for nesting, breeding and resting.

(e) All rubbish piles and refuse must be eliminated and properly disposed.

(f) Landscaped areas need to be properly maintained with wood piles elevated off the ground.

(g) All garbage containers and dumpsters should have a tight fitting cover.

(h) Rodents can live on the spilled and surplus food from bird feeders and pet food.

(j) It is difficult to completely eliminate all food and shelter sources. However, the more food and shelter the mice have, the higher a mice population or infestation could occur. With the higher population, the harder it will be to control them. Rats require a lot more food and water. They also require more shelter. When there is a severe infestation of rats, it is usually indicative of a sanitation problem.

Temporary Control

Temporary measures are not as effective as the permanent control measures. These only bring down the rat population for a short period which soon builds up to the original level unless the permanent measures are also simultaneously adopted.

**Trapping**

It can reduce the population of domestic rats quickly, only if the traps are properly set and baited. Sewer rats or large population of house rats do not respond well to trapping. The proper method to attack is to use a large number of traps at the same time in an infested area; and when maximum results have been achieved, to shift the traps to a new area. The traps should be placed either near the burrows or along the rat runs. The break back traps can kill only one rat at a time but the catching trap can trap a number of them at the same time, without killing.

Another method of trapping is the use of lithographic varnish, 'ratsticker'. The varnish is spread on a board with a piece of cheese or other material as a bait on the center. On coming in contact with varnish, the rat becomes hopelessly entangled and its squeal attracts other rodents to the rescue so that they in turn become trapped.

Sticky or glue traps are another way of catching rats and mice. They are boards made of wood, hard- or cardboard covered with very sticky material. There are different types of glue available and they should be checked for suitability (stickiness, and usability in humid or dusty conditions) before large quantities are ordered. The boards are placed in the same way as traps, and normally there is no need for bait to attract rats. These traps should be checked daily, but are not regarded as very 'humane'.

Flushing rodents out of their burrows, with smoke or by flooding them with water, can be very effective and suitable in some situations. Ultrasonic devices are mentioned regularly, particularly by manufacturers of these devices, as a good repellent of rats and mice in buildings. However there is no scientific evidence of their effectiveness. It appears that rats become habituated to the sound or stay in 'sound shadows'

The most efficient bait for any locality is determined by trials. Dried meat, fish heads, coarse flour or ground grain, fresh vegetables, fruits, tomatoes, coconuts, pakoras are generally good baits.

**Rodenticides**

These are of two types i.e. acute or single dose and cumulative or multiple dose poisons. The former group are lethal to the rats after a single feeding, while the later, as the name suggests, require repeated feedings. The WHO Expert Committee in 1973 grouped the rodenticides as follows: -

**(a) Acute Rodenticides**

(i) Those requiring ordinary care such as Red squill, norbromide and zinc phosphide.

(ii) Those requiring maximal precautions-such as sodium fluoroacetate (1080), fluoroacetamide (1081) and strychnine.

(iii) Too dangerous for use such as arsenic-trioxide, phosphorus, thallium sulphate, ANTU and gophacide.

(iv) Calciferol : leaches calcium from bone into the blood.

**(b) Multiple Dose Rodenticides**

(i) Warfarin-Its dose varies from 250-500 ppm.
(ii) Diphacinone-Its dose varies from 50-250 ppm
(iii) Coumafuryl.
(iv) Pindone.
(v) Coumatetralyl

**(c) Bromadialone**

The latest acute anticoagulant which can be used in domestic areas.

**Choice of Rodenticide**

Among the many available rat poisons, red squill is favourite because its emetic action protects animals that can vomit; strychnine and thallium are used at times but are somewhat dangerous; zinc phosphide is seldom used because of erratic results and danger to human population; barium carbonate is used in Armed Forces, mainly due to its comparative safety, simplicity of use and availability. ANTU is specific for Norway rats but kills dogs and cats does not kill roof rats. Sodium fluoroacetate is a powerful poison but its use has been prohibited in many places because of human deaths. Warfarin is an anticoagulant that has a large safety margin because of the very low dosage (0.1 per cent) that is required to be given for four days to kill a rat. It keeps the rat population in area constantly low over a long period, provided it is used continuously. It is dangerous to household pets and is chiefly used on board the ships.

**Baiting Procedures**

The poisoning campaign should be carried out in three stages as follows: -

**(a) 'Trial baiting'**

It is the first step in the poisoning programme. Rats are usually accustomed to eat the 'bait base' of plain food such as bread crumbs or coarse atta. This should be placed along runways and at their visiting places for a day or two. Any other food commonly eaten by the local people may also be tried.

**(b) 'Pre-baiting'**

This should be carried out with the most acceptable materials without mixing the poison. The pre-baits are kept under supervision and replenished daily for 5 to 7 days.

**(c) 'Poison baits'**

These are prepared by adding poison to the bait base and are laid in the same manner and at the same places for the next one week or more.

The technique of pulsed baiting was introduced with the new single-dose anticoagulants, such as bromadiolone and brodifacoum. This contrasts with saturation baiting, in which bait is available to rats continuously over long periods until the population has declined to near zero. Pulse baiting is not necessarily more effective, but it is certainly cheaper, because the amount of labour and the quantity of bait required is much lower than in saturation baiting.

As mentioned earlier, death is delayed by three or more days after ingestion (depending on the species of rat and the type of rodenticide). This means that rats will continue to feed on bait even though they have received a lethal dose, which would be a waste of bait. In addition in some species (e.g. *R. norvegicus*), animals of lower hierarchal ranking cannot feed until 'higher' animals are removed from the population.

This behavioural characteristic is exploited by baiting in pulses. Poisoned bait is laid for 13 days (depending on the rodenticide) and discontinued for about a week, allowing the first batch of animals to die and thus be removed from the population. The next baiting pulse will remove another batch of rats. Normally three baiting pulses are sufficient to remove almost the entire population. The intensity of baiting periods (pulses) depends on the rat population in and around the building and the rate of immigration from neighbouring areas. In spite of the above, the intervals between and number of pulses has to be decided each time based on the results of monitoring.

The idea of perimeter baiting is to place bait in a circle around and outside the immediate area of interest and hopefully prevent rats from immigrating. However it is very difficult to give exact guidelines on the diameter of the circle, the distance between baiting points and the quantity of bait to use. The idea has its merits and an operator should experiment with this technique; for example, by placing baiting points between the store and places through which rodents might reasonably be expected to immigrate.

**Preparation of Baits**

**(a) Barium Carbonate**

It is mixed with three times the quantity of floor or bread mash, made from the grain which have been found to be readily consumed by the rats. Sufficient water is added to the mixture to make a fairly firm paste and rolled into pills weighing one gram each.

**(b) Zinc Phosphide**

It is usually not made into pills but mixed as a dry meal baited with 1/5th to 1/8th the quantity of the poison and left at the baiting stations in bait-boxes which are not approachable by children and pet animals. This is used on docks, warfs, godowns, granaries and such other places.

**(c) Warfarin**

It is similarly used in dry meal of bread crumbs, roasted grains or crushed chapatti in the proportion of 1:19 and left in bait trays or boxes. This is used mainly on board the ships and also in granaries where constant anti-rodent measures are very essential.

**(d) ANTU (Alphanaphthylthiourea)**

It is sprinkled in and around rat holes, rat runways and burrows. The rats lick their feet after running through it and can swallow enough poison to kill them. Poison may be sprinkled on and around the baits such as ground grain, sliced apples or melons, chopped meat, chicken or turkey heads and left in the evening in thin layers in each rat infested areas.

**(e) Coumatetralyl**

The compound is available as Racumin tracking powder(0.75%). The powder should be scattered into the rodent burrows and on rodent runways. Racumin ready made bait and wax blocks(0.0375%) are also available. For field rodents, Racumin oil concentrate(2.0%) is mixed with whole grains in 1:50 ratio. Any other food material can be mixed with racumin (1:19) for domestic use.

Fumigants

Fumigation may kill rats with certainty in any enclosed places, like ships, godowns, granaries and rodent burrows on embankments. Sulphur dioxide, carbon disulphide, calcium cyanide (cynogas or cymag) carbon monoxide and methyl bromide are usually used.

The control of rodents by fumigation can be very effective, but it may be expensive and dangerous. It should be remembered though that the gas must have access to burrows, if these are present in the building. That is the burrows should be open and the fumigant used must be heavier than air.

If the species concerned makes burrows which are easy to spot (e.g. *R. norvegicus, B. bengalensis* or *P. natalensis*), they can be fumigated directly. The simplest method is to use a powder which releases hydrogen cyanide, or aluminium (magnesium) phosphide tablets which release phosphine when placed into the burrows. The gases are generated when the powder or tablets come into contact with moisture in the soil. Alternatively, methyl bromide gas may be pumped into the burrow system.

As soon as the fumigant has been applied, all burrows must be closed by filling the entrance holes with earth. However, fumigants cannot be used in loose or sandy soils as too much gas escapes, and the treatment may not be effective. Occasionally, rats have been known to block tunnels and prevent complete distribution of the gas, so that some individuals survive.

All enclosed spaces are opened to allow penetration of the gases and exits are closed. The gases are then pumped in or mechanically released. Cyanogas has been extensively used in India for the fumigation of rats burrows. Aluminium phosphide tablets (3 gm/ rodent burrow) provide effective rodent control in peri domestic area and agricultural fields. The rodent burrows should be closed after bait placement with wet soil.

Only trained and properly qualified operators should be employed to use fumigants. They should be seen to be observing the following basic principles of fumigation:

(a) Two operators must always be present at a fumigation site
(b) Suitable respirators must be worn
(c) Operators should stand upwind when gassing
(d) Fumigants should not be used in strong winds or when it is raining
(e) Fumigants must not be used near buildings inhabited by man or animals as open burrows may be inside
(f) Operators should know about first aid and have appropriate first aid equipment with them.

**Precautions**

Clean hands and dishes are necessary to avoid imparting extraneous taste and odor to the baits as rats are very suspicious. The baits should be made fresh each day and unconsumed baits should be laid systematically and with great care so as to be beyond the reach of children or domestic animals. For initial baiting, 15-20 baits for a room of size of an I.P. tent are required and for subsequent baiting 5-10 baits may be enough. At the time of baiting all sources of food and water supply should be closed and baits should be placed near the places where food is normally stored, cooked, eaten or discarded and near washing places. Pre-baiting and baiting should be done during periods of clear and calm weather, as unsettled weather conditions interfere with the normal movement of rodents. Left over baits should be counted or measured and removed the next morning to prevent pets and live stock from eating it, and replaced in the evening. Prepared baits and water must be stored in places out of reach of human pets and domestic animals. Hands should be washed thoroughly with soap and water after handling powder or prepared bait.

**Standard safety precautions when handling poisons include:**

(a) Wearing protective clothing during operations
(b) Not eating, drinking or smoking during operations
(c) Not breathing in dust during operations (wear dust mask)
(d) Keeping baits out of reach of others, especially children and domestic animals
(e) Thoroughly washing the skin, clothing and equipment after operations (7).

The potential danger to non-targets of feeding on bait (primary poisoning) or animals feeding on poisoned rats (secondary poisoning)must always be kept in mind during the baiting process.

**The danger of unwanted poisoning can be virtually eliminated in buildings if some simple rules are adhered to:**

(a) Bait should be laid so that no other animals, including man, can have no access to it; in buildings this should be fairly simple
(b) The amount of bait laid out should be adapted to the anticipated population of rats, that is as little as necessary and placed in small quantities per station
(c) Application should be late in the afternoon, just before rats become active and as birds retire; in stores this is not so important
(d) Bait should be removed entirely after a control programme is terminated
(e) Dead rats, if found, should be buried or burnt
(f) Rodenticides should be under lock and key and empty containers should be disposed of properly

(8).

Biological Control

The natural enemies of the rats are the cats, larger hawks, eagles, vultures, owls, snakes, foxes, coyotes, weasels, mongoose, minks, dogs and ferrets. However, although some of these may be helping to keep down the rat population to some extent in nature, none of them is of practicable value in the rat control programme. There are also biological agents like *Salmonella typhimurium* and *enteriditis*. These are either impracticable or unsafe in the rat control programmes.

# Excremental Diseases

One of the main causes of sickness in an army in the field is excremental diseases. These, as explained in Oxford dictionary, refer to the diseases related to faeces. These are caused by infectious agents and commonly include diseases like diarrhoeas, dysenteries (amoebic and bacillary), food poisoning, cholera, enteric group of fevers, poliomyelitis, viral hepatitis A and so on.

All organisms causing excremental diseases are excreted through faeces of infected persons and ingested by mouth of the recipient. Disease transmission could be direct or indirect and is described as faeco-oral. Human beings are the reservoir in most of the cases but in a few infections like salmonellosis and the tapeworms the animals are the fundamental reservoir for human infection.

## Diarrhoea and Dysentery

Conventionally diarrhoeas and dysenteries are considered together because of their similarity with respect to their clinical features, their mode of spread and similar approaches for their prevention. However a differentiation can be made on the basis of presence of blood in stool in dysentery.

Diarrhoeal diseases commonly refer to frequent passage of loose, liquid or watery stools which may range from 4-5 times to more than 20 times per day. According to World Health organization (WHO) diarrhea is the passage of 3 or more loose or liquid stools per day, or more frequently than is normal for the individual (1). Acute diarrhea is an attack of sudden onset which usually lasts for 3 - 7 days, but may last up to 10 - 14 days (2). Diarrhea that starts as an acute episode and lasts at least 2 weeks is considered persistent or chronic (3, 4). This definition excludes specific conditions like celiac disease, tropical sprue, or other congenital, biochemical or metabolic disorders.

Dysentery (formerly known as the bloody flux or simply flux) is an illness involving severe diarrhea that is often associated with blood in the feces. It is one of the most dangerous types of diarrhoea. It is, usually, more severe and more likely to result in death than other forms of acute diarrhoea. Large scale outbreaks (epidemics) of dysentery are a particular threat to public health (5).

The term "bacillary dysentery" used to describe a diarrhoeal illness with fever, abdominal pain, and blood and pus in the stool, is often used as a synonym for diarrhea caused by *Shigella*. While epidemic dysentery is caused by *Shigella dysenteriae* type 1 (Sd1), endemic dysentery is caused by a range of organisms including *Shigella* (5, 6).

Pathophysiologically, diarrhoeal diseases are mainly of 2 types:

(a) Secretory noninvasive diarrhea : such as cholera, due to impairment of water absorption mechanisms in the small bowel and inducing watery stools and dehydration

(b) Enteroinvasive diarrhea : due to alteration of the colonic muco2sa, inducing dysentery. Most cases of infectious diarrhea are acute. Some pathogens, mainly parasites, can induce chronic diarrhea.

**Definitions**

**Dysentery** - Bloody diarrhea

**Epidemic dysentery** - Large-scale outbreaks of bloody diarrhoea, almost always caused by *Shigella dysenteriae* type 1 (Sd1)

**Endemic dysentery** - A normal incidence of bloody diarrhoea, caused by a range of organisms including *Shigella*.

*Shigella* : a genus of bacteria with four species - *Shigella dysenteriae, Shigella flexneri, Shigella boydii and Shigella sonnei. Shigella* causes the most serious episodes of bloody diarrhoea.

*Shigellosis* : infection caused by one of the *Shigella* species, often (but not always) associated with bloody diarrhoea.

**Source – (5)**

### Prevalence

Acute diarrhoeas are second only to respiratory infections as a cause of morbidity and mortality worldwide. In the United States, 1 episode per child per year is estimated to occur in children younger than 5 years, with about 10% of all hospital admissions for children in this age range. In developing countries, an average of 3 episodes per child per year in children younger than 5 years has been reported, but some areas have been reported to have 6-8 episodes per child per year. In these settings, malnutrition plays an additional and important negative role by exposing children to a higher risk of acute and prolonged diarrhea (7). According to a World Health Organization (WHO) estimate about 18% of all deaths each year among children under five years of age i. e. approximately 2 million children worldwide (almost entirely from developing countries) are because of diarrhoeal illness (8).

In India, during the year 2005, about 1.07 million cases of acute diarrhoea with 2040 deaths were reported; though the actual incidence may be manifold (9).

Epidemics of dysentery caused by Shigella had been the problem of military since long (6). Military is most often afflicted during mobilization. Diarrhoeal diseases and dysentery frequently become important disease problems among forces immediately following their induction, when insufficient attention is paid to environmental sanitation (10). The disease flourishes where the standard of hygiene is low. Carelessness in camp sanitation may result in epidemics of diarrhoea and dysenteries. Quite often, outbreaks of diarrhea and dysentery cause more

morbidity in a military campaign than the actual war injuries (11).

**Epidemiological determinants**

Agent factors

A number of infectious agents including virus, bacteria, protozoa and intestinal worms, have been incriminated in the causation of diarrhoeal diseases.

(a) **Virus :** Rotavirus and Norwalk virus are the commonest of the causes of viral diarrhoea. The other virus implicated include adenovirus, astrovirus, calcivirus and corona virus. Diarrhoeas due to viral infections usually have no fever or low grade fever and no accompanying abdominal pain.

(b) **Bacteria :** Common bacteria implicated in the causation of diarrhoea include *Campylobacter jejuni, Clostridium difficile, Clostridium perfringens, E coli, Salmonella sp, Shigella sp, Vibrio sp, Yersinia enterocolitica. Shigella dysenteriae* is most often the cause of an outbreak of bacillary dysentery. Identification of the causative infectious agent in the stool should be attempted wherever possible. In the past, it was only possible in 25% of the cases but now with newer techniques it is possible in 75% of the cases

(c) **Protozoa and others :** The common protozoans causing diarrhoeal diseases are Giardia sp, Cryptosporidium sp, and Entamoeba sp. Infection with *Entamoeba histolytica*, with or without clinical manifestations is known as Amoebiasis. Occasionally diarrhoeal diseases can also be caused by intestinal worms like *Trichuris trichura*.

Reservoir

Man is the principal reservoir of the infections. Mild cases which clinically recover in a few days without going to hospital, constitute one of the chief means by which the reservoir is maintained. Patients with acute amoebic dysentery pose only limited danger to others because of the fragility of trophozoites. Asymptomatic or mild cases excreting cystic forms of *E. histolytica* on the other hand are important reservoir of infection.

Host factors

Man has no natural immunity against the organisms of diarrhoea and dysentery. Both sexes are equally susceptible. Children and the aged suffer more. Transient immunity develops against the specific strain of Shigella. Although susceptibility to infection of *E. histolytica* is general; many persons harbouring the organism do not develop the disease. Host differences such as race and age have been described as affecting susceptibility of individuals to infection. Immunity to reinfection has not been clearly demonstrated.

Diarrhoeal diseases are most common during the first two years of life. Incidence is highest at the time of weaning i. e. between 6 - 11 months. This pattern reflects the combined effects of declining levels of maternally-acquired antibodies, the lack of active immunity in the infant, the introduction of food that may be contaminated with faecal bacteria, and direct contact with human or animal faeces when the infant starts to crawl. Most enteric infections, mainly beyond 2 years of age, are asymptomatic owing to the development of active immunity. Persons with asymptomatic infections play an important role in the spread of many enteric pathogens, especially as they are unaware of their infection, take no special hygienic precautions and move normally from place to place. Undernutrition, recent measles and immuno-suppression are associated with increased incidence, severity, or duration of diarrhoea (12).

Environmental factors

Diarrhoeal diseases follow a distinct seasonal pattern. In tropical areas, rotavirus diarrhoea tends to occur throughout the year, increasing in frequency during the drier, cool months, whereas bacterial diarrhoeas tend to peak during the warmer, rainy season. The incidence of persistent diarrhoea follows the same seasonal pattern as that of acute watery diarrhoea (12).

Mode of Transmission

Infection by all organisms of this group of diseases is invariably by ingestion in food or drink i. e. , faeco-oral route. Person to person transmission plays an important role in transmission. Individuals primarily responsible for transmission are those with poor personal hygiene and who fail to cleanse contaminated hands and carry organisms under their fingernails after defaecation. Contaminated water is believed to play a major role in the transmission of amoebiasis. The organisms of bacillary dysentery do not thrive in water and are readily killed by chlorination. But amoebic cysts are not killed by chlorine in amounts normally added for water disinfection. Water can be rendered free from cyst only by sand filtration. Milk and food are contaminated by infected water or by the hands of a carrier or case or more likely by flies & cockroaches which act as vehicles. Contamination of crockery, cutlery, kitchen utensils by food handlers or by dust containing cysts in case of *Entamoeba histolytica* is a possibility. Vegetable from fields irrigated with polluted water specially those cultivated with raw sewage as practiced in improper sewage farming are liable to carry infection.

Incubation period and Period of communicability

The incubation period varies from 1 to 2 days as in case of bacillary dysentery to 2 to 4 weeks, but can be prolonged to several months, as in case of amoebic dysentery. Diarrhoea and bacillary dysentery cases are most infective during the course of clinical illness and a short period thereafter. A case of amoebic dysentery is infective mostly during the non-clinical period between the remissions of clinical attack, because it is the cystic stage of amoeba which is infective and not the vegetative form.

Prevention and control

A constant maintenance of a high standard of waste disposal and environmental sanitation; personal hygiene including food hygiene and habits; wholesome water and milk supply; extermination of flies, and health education are the measures to be relied upon for preventing the infection in a unit. The following measures should be

| Key components in the prevention of diarrhoeal diseases |
|---|
| Safe drinking water |
| Safe disposal of human excreta |
| Food safety |
| Hand washing with soap |
| Breastfeeding |

Source - (13)

taken for controlling an outbreak

(a) Isolation

All serious cases should be admitted to hospital and isolated during acute illness with rigid personal precautions by attendants. Fluid and electrolyte replacement is important along with specific drugs. This will break the chain of transmission.

(b) Oral Rehydration Therapy (ORT)

The introduction of oral fluid by WHO has established the utility of Oral Rehydration Solution (ORS) as the single most important measure in the management of acute diarrhoea due to all aetiologies, in all age groups, and in all countries. The underlying principle is based on the observation that glucose given orally enhances the intestinal absorption of salt and water, and is capable of correcting the electrolyte and water deficit in mild to moderate cases. The aim of ORT is to prevent dehydration and reduce mortality.

However, because of its improved effectiveness, WHO and UNICEF are now recommending the use of reduced osmolarity ORS solution. UNICEF, since January 2004 and India, since June 2004 are procuring only this formulation for the management of diarrhoeal diseases.

The composition of reduced osmolarity ORS, as suggested by WHO, is as follows :

Packets of oral rehydration mixture are freely available.

| Composition of reduced osmolarity ORS | |
|---|---|
| Sodium chloride (table salt) | 2.6 g |
| Glucose, anhydrous | 13.5 g |
| Sodium bicarbonate (baking soda) | 2.5 g |
| Potassium chloride | 1.5 g |
| Trisodium citrate, dehydrate | 2.9 g |
| Total weight | 20.5 g |

Source : (14)

The contents of the packet are dissolved in 1 litre of drinking water. The prepared solution should be used within 24 h. It should not be boiled or sterilized otherwise. It alone can correct mild to moderate dehydration. The inclusion of tri-sodium citrate in place of sodium bicarbonate has made the product more stable. Besides, it also results in less stool output especially in high output diarrhoea (e.g. cholera), probably because of a direct effect of trisodium citrate in increasing intestinal absorption of sodium and water.

If these mixtures of salts are not available, a simple mixture - salt and sugar solution (SSS) - consisting of table salt 5 gm and sugar 20 gm dissolved in 1 litre of drinking water may safely be used until then. The general rule is that patients should be given as much ORS solution as they want, and that signs of dehydration should be checked until they subside. If the child's weight is known, the amount of ORS solutions required for rehydration during the first four hours may be calculated by setting the deficit at approx 75 ml/kg body weight. Intravenous infusion is usually required only for the initial rehydration of severely dehydrated patients who are in shock or unable to drink. Such patients are best transferred to the nearest hospital.

(c) Breastfeeding

Because of its protective qualities, breastfeeding must be continued for sick children (14).

(d) Safe drinking water

Water supplies should be scrutinized and superchlorinated.

(e) Food safety

Food hygiene should be made stricter. Adequate storage facility for storage of food (both cooked and uncooked) and adequate water for cleaning and cooking must be provided. All crockery and cutlery must be adequately cleaned before use. Milk should be boiled and the food habits of personnel should be improved.

(f) Concurrent Disinfection

All underclothings, soiled linen, bedding, and particularly the excreta should be treated by concurrent disinfection.

(g) Personal Hygiene

Thorough hand washing with soap before handling food must be stressed.

(h) Epidemiological Investigation

Epidemiological Investigation for the source of infection and modes of transmission should be carried out and appropriate control measures instituted.

(j) Control of Flies

Control and destruction of flies is the most important method of controlling an outbreak of dysentery. Persistent attention to exterminate breeding places by proper disposal of faeces and manure, ensuring good general sanitation, prohibiting indiscriminate defaecation and the use of insecticides lead to control of flies. Health education of all personnel is very important.

## Cholera

Definition A serious acute intestinal disease caused by *Vibrio cholerae* 01 (Classical or El Tor) and characterized by sudden onset, profuse, effortless watery stools, vomiting, rapid dehydration, muscular cramps, acidosis and circulatory collapse. Fatality rates in untreated cases may exceed 30-40 per cent; inapparent and wholly asymptomatic infections are many times more frequent

than clinically recognized cases, especially *Vibrio cholerae* biotype El Tor.

**Problem statement**

For centuries cholera has been one of the most feared diseases. The German poet Heinrich Heine, who lived in Paris when cholera first appeared there in the early 1830s, wrote home to tell his countrymen of the hatred shown towards people who had contracted the disease (15) : *"I saw one of these unfortunates when he was still breathing and the old hags were just pulling the wooden shoes from their feet and beating him on the head with them till he was dead. He was quite naked and bloody and mashed; they had torn off not only his clothes but his hair, his sex, his lips and his nose, and one ruffian tied a rope to the feet of the corpse and dragged it through the streets, shouting constantly, 'Voilà le cholera-morbus!'"*

Cholera remains a global threat to public health and one of the key indicators of social development. While the disease no longer poses a threat to countries where minimum standards of hygiene are met, it remains a challenge in those countries where access to safe water and adequate sanitation can not be guaranteed for all. Almost every developing country is facing either a cholera outbreak or the threat of an epidemic (16). The changing epidemiology of *V. cholerae* O1 and O139 infections has further aggravated the situation and needs regular monitoring (17).

In India, Cholera has been present since antiquity. In 1961, an unexpected situation arose. Cholera El tor which was localized in Sulawesi in Indonesia for many decades suddenly became widespread, starting the seventh pandemic. India became involved in 1964. It has since affected more than 80 countries in Asia, Africa & Europe. In India, cholera biotype El Tor has almost completely replaced the age old classical cholera. Currently the large endemic foci of cholera are found in Maharashtra, Tamil Nadu, Karnataka, Delhi, Gujarat & Kerala, which account for 80 percent of the reported incidence in the country.

During the year 2006, a total of 2472 cases and 28 deaths were reported from 6 Asian countries. The Indian subcontinent reported 78% of all cases notified from Asia, with India notifying a total of 1939 cases and 3 deaths (16).

**Epidemiological determinants**

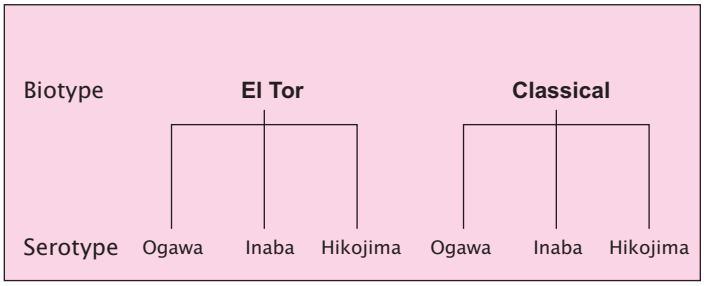
Agent factors

**(a) Agent**

The causative agent, *Vibrio cholerae* was first isolated in 1883 by Koch from the stools of patients with cholera. It is a small, curved, motile, aerobic gram - negative organism best identified by inoculating stool into taurocholate - tellurite - gelatin (TTG) agar or thiosulfate - citrate - bile salts - sucrose (TCBS) agar. *V. cholerae* colonies are relatively small on TTG agar after 24 hours and are translucent with a dark center and a cloudy zone surrounding the colonies. On TCBS agar *V. cholerae* are easily recognized as large yellow colonies on a blue - green medium. The species is identified on the basis of cultural and biochemical tests (18).

The antigenic classification of vibrios depends on the specific somatic (O) antigens. The flagellar antigen (H) is non specific and common to all. The group A vibrios which include both cholera and cholera like vibrios have been divided into six sub groups (I to VI) based on the antigenically different 'O' antigens. Cholera vibrios belong to serological O sub-group I of Gardner and Venkataraman and other serological Sub-group (II to VI) are NAG vibrios (non agglutinable to O group I antisera). The O subgroup I vibrios comprises of classical *V. Cholera* and *V. El Tor* biotype and they cannot be differentiated by serological or biochemical tests. But they can be differentiated by hemolytic property, sensitivity to lysis by Mukherjee's Group IV cholera phage, polymyxin B sensitivity and chicken red cell agglutination. Based on the O antigenic components, both classical *V cholerae* and biotype *El Tor* have been divided into 3 serotypes Ogawa, Inaba and Hikojima. The former two are common.

Classical vibrio cholerae can be distinguished from *El Tor* by the following tests :



**(b) Resistance**

Difference between Classical and El Tor Vibrio Cholerae

| Test | Classical V. cholerae | Biotype El tor |
|---|---|---|
| Chick erythrocyte agglutination | Negative | Positive |
| Polymyxin B sensitivity | Sensitive | Resistant |
| Cholera phage IV | Sensitive | Resistant |
| Haemolysis test | Negative | Positive |

Vibrio cholerae 01 can survive on a variety of foodstuffs for up to five days at ambient temperature and up to 10 days at 5-10 degrees Celsius. The organism can also survive freezing. Low temperatures, however, limit proliferation of the organism and thus may prevent the level of contamination from reaching an infective dose. The cholera vibrio is sensitive to acidity and drying, and commercially prepared acidic (pH 4. 5 or less) or dried foods are therefore without risk. Gamma irradiation and temperatures above 70°C also destroy the vibrio (19).

**(c) Toxin production**

Vibrios multiply in the lumen of small intestine and produce enterotoxins which act on adenyl cyclase - cyclic AMP system of mucosal cells and produce diarrhoea.

**(d) Reservoir of infection**

The only reservoir of infection is man, either a case or a carrier. The ratio of severe cases to mild or inapparent infections has been shown to be about 1 : 5 for classical cholera and 1 : 25 to 1 : 100 for El Tor cholera (20). Carriers in cholera are of four types viz. incubatory carriers, convalescent carriers, healthy carriers and contact carriers (21). Duration of carrier period is short, about 4 or 5 days. Chronic carriers who harbour the vibrio for more than 3 months are not many.

**(e) Infective material**

Stools and vomit of cases and carriers are infectious in nature. However, carriers excrete fewer vibrios as compared to cases.

**(f) Period of communicability**

A case of cholera is infectious for a period of 7 to 10 days. While convalescent carriers are infectious for 2 - 3 weeks, chronic carrier state may last from one month to 10 years or more.

Host Factors

Cholera usually affects persons belonging to the low socio-economic strata because of poor environmental sanitation. Their standard of personal hygiene is low. When cholera epidemic occurs in non-endemic areas, male adults are more affected. In contrast, in endemic areas, attack rate is equal in both the sexes and it is distinctly higher for children than for adults. This phenomenon is due to development of naturally acquired immunity with increasing age in the endemic areas.

Environmental factors

Contaminated water and food are the most important environmental factors in the causation of cholera. Unusually heavy rains, which have caused flooding, are blamed, at times, for the high incidence of the disease outbreak (15). Flies may carry *V. cholerae* but are not vectors of proven importance. Social factors responsible for the endemicity of the disease include poor literacy, poor personal hygiene, poor living standards and unhealthy habits in relation to water and food.

Mode of Transmission

Infection by *V. cholerae* is invariably by ingestion. Most important mode of transmission is through contaminated water. Disease may spread through food contaminated by food handlers and flies. Fruits and vegetables washed with contaminated water may transmit the infection. Person to person contact particularly in overcrowded dwellings without sanitary facilities is very important due to careless handling of human excreta under such conditions.

Incubation Period

It varies from a few hours upto 5 days, but commonly 1 to 2 days. Infectivity of cholera is high, but the disease rate is low; as a rule, although many members of family may be infected, usually one of them falls ill.

**Pathogenesis**

According to current concepts, the cholera vibrio gets through the mucus which overlies the intestinal epithelium. It probably secretes mucinase, which helps it move rapidly through the mucus. Then it gets attached or adhered to the intestinal epithelial cells, and this it probably does by an adherence factor on its surface. When the vibrio becomes adherent to the mucosa, it produces its enterotoxin which consists of 2 parts- the light or L toxin and the heavy or H toxin. The L toxin combines with substances in the epithelial cell membrane called gangliosides and this binds the vibrio to the cell wall. Binding is irreversible. The mode of action of H toxin is not fully clear. What we know is that there is a substance called "adenylcyclase" in the intestinal epithelial cells, and H toxin activates this substance. The activated adenyl cyclase causes a rise in cAMP. cAMP provides energy which drives fluid and ions into the lumen of the intestine. This fluid is isotonic and is secreted by all segments of small intestine. This increase in fluid is the cause of diarrhoea.

**Clinical features**

The severity of cholera is dependent on the rapidity and duration of fluid loss. Epidemiological studies have shown that more than 90 percent of El Tor cholera cases are mild and clinically indistinguishable from other acute diarrhoeas (22). However, a typical case of cholera shows 3 stages (23) :

(a) Stage of Evacuation

The onset is abrupt with profuse, painless, watery diarrhoea followed by vomiting. The patient may pass as many as 40 stools in a day. The stools may have a "rice water" appearance.

(b) Stage of collapse

The patient soon passes into a stage of collapse because of dehydration. The classical signs are : sunken eyes, hollow cheeks, scaphoid abdomen, sub-normal temperature, washerman's hands and feet, absent pulse, unrecordable blood pressure, loss of skin elasticity, shallow and quick respiration. The urinary output decreases and may ultimately cease. The patient becomes restless, and complains of intense thirst and cramps in legs and abdomen. Death may occur at this stage, due to dehydration and acidosis resulting from diarrhoea.

(c) Stage of recovery

If death does not occur, the patient begins to show signs of clinical improvement. The blood pressure begins to rise, the temperature returns to normal, and urine output is reestablished. If anuria persists, the patient may die of renal failure. The classical form of severe cholera occurs in only 5-10 percent of cases. In the rest, the disease tends to be mild characterised by diarrhoea with or without vomiting or marked dehydration. As a rule, mild cases recover in 1-3 days.

Epidemiologically, cholera due to *El Tor* biotype differs from *classical cholera* in the following respects :

(a) A higher incidence of mild and asymptomatic infection. This implies that the characteristic picture of rice-water stools and other signs of classical cholera described above may not be seen often.

(b) Fewer secondary cases in the affected families

(c) Occurrence of chronic carriers

(d) Since *El Tor* vibrios are more resistant than *classical cholera* vibrios, they survive longer in the extra intestinal environment.

**Laboratory diagnosis of Cholera**

The diagnosis of cholera can never be made with certainty on clinical grounds. Laboratory methods of diagnosis are required to confirm the diagnosis :

(a) Collection of Stools

A fresh specimen of stool should be collected for laboratory examination. Sample should be collected when the patient is having diarrhea, as soon after onset of illness as possible (preferably within 4 days of onset) and before antimicrobial treatment is started (24). Collection may be made generally in one of the following ways :

(i) **Rubber Catheter** : Collection by the catheter (26-28 size) is the best method but is complicated under field conditions. Soft rubber catheter sterilised by boiling should be used. The catheter is introduced (after lubrication with liquid paraffin) for at least 4-5 cm into the rectum. The specimen voided may be collected directly into a transport (holding) media. e. g. , Venkatraman-Ramakrishnan (VR) medium and alkaline peptone water.

(ii) **Rectal Swab** : Swabs consisting of 15-20 cm long wooden sticks, with one end wrapped with absorbent cotton, sterilized by autoclaving have been found to be satisfactory. Rectal swabs should be dipped into the holding medium before being introduced into the rectum. After collection, it should be sent to lab in a transport medium. If no transport medium is available, a cotton-tipped rectal swab should be soaked in the liquid stool, placed in a sterile plastic bag, tightly sealed and sent to the testing laboratory.

(iii) Stools from patients should be collected in clean containers without disinfectant or detergent residue and with tight-fitting, leak-proof lids. Specimens should not be collected from bedpans, as they may contain residual disinfectant or other contaminants. Unpreserved stool should be refrigerated if possible and processed within a maximum of 2 hours after collection. Specimens that cannot be cultured within 2 hours of collection should be placed in transport medium and refrigerated immediately (24).

(b) Vomitus

This is practically never used as the chances of isolating vibrios are much less and there is no advantage.

(c) Water

Samples containing 1-3 litres of suspect water should be collected in sterile bottles (for the filter method), or 9 volumes of the sample water added to 1 volume of 10 percent peptone water, and despatched to the laboratory by the quickest method of transport.

(d) Food Samples

Samples of food suspected to be contaminated with *V. cholerae* (or other enteric bacteria) amounting to 1-3 g are collected in transport media and sent to the laboratory.

(e) Transportation

(i) The stools should be transported in sterilized McCartney bottles, 30 ml capacity containing alkaline peptone water or VR medium should be used if larger stool specimens are collected. The specimen should be transported in alkaline peptone water or Cary-Blair medium if it is collected by a rectal swab. One gram or one ml of faeces in 10 ml of the holding medium will suffice. Rectal swabs should have their tops broken off so that caps of the containers can be replaced.

(ii) If suitable plating media are available (e. g. bile salt agar) at the bed-side, the stools should be streaked on to the media and forwarded to the laboratory with the transport media

(f) Direct Examination

If a microscope with a dark field illumination is available, it may be possible to diagnose about 80 percent of the cases within a few minutes, and more cases after 5-6 hours of incubation in alkaline peptone water. In the dark field, the vibrios evoke the image of many shooting stars in a dark sky. If motility ceases on mixing with polyvalent anti-cholera diagnostic serum, the organisms are presumed to be cholera vibrios. A presumptive diagnosis of cholera can thus be established.

(g) Culture Methods and Characterisation

On arrival at the laboratory, the specimen in holding fluid is shaken well, and about 0. 5 to 1. 0 ml of material is inoculated into Peptone Water Tellurite (PWT) medium for enrichment. After 4 to 6 hours incubation at 37°C, a loopful of the culture from the surface is subcultured on Bile Salt Agar medium (BSA, pH 8. 6). After overnight incubation, the plates are screened under oblique light illumination for vibro colonies. *V. cholerae* usually appear on bile salt agar (BSA) as translucent, moist, raised, smooth and easily emulsifiable colonies about 1 mm in diameter. The typical colonies are picked up and tested as follows :

(i) **Gram Stain and Motility** : Gram negative and curved rods with characteristic scintillating type of movement in hanging drop preparations are very characteristic of *V. cholerae.*

(ii) **Serological Test** : Slide agglutination test is done by picking up suspected colonies and making a homogeneous suspension in 0.85 percent sterile saline and adding one drop of polyvalent anti-cholera diagnostic serum. If agglutination is positive, the test is repeated with Inaba and Ogawa antisera, to determine the subtype.

(iii) **Biochemical Test** : Serologically positive colonies should be subcultured in one tube each of the sugar broths (mannose, sucrose, arabinose) and a tube of peptone water pH 7.2 for the cholera red reaction. Production of acid in sucrose and mannose, but not arabinose is characteristic of *V.*

*cholerae.*

(iv) **Further Characterisation** : Further characterisation of biotypes of *V. cholerae,* the following tests are carried out.

- The direct haemagglutination test with chicken or sheep red blood cells.
- Polymyxin B sensitivity test using 50 mcg discs.
- Sensitivity to cholera phage IV.
- V-P reaction.
- Haemolysis test.

Suspicious colonies that do not agglutinate with anticholera sera are tested further by the oxidase and string tests.

Recently developed dipsticks (sensitivity and specificity above 92 and 91%, respectively) for the rapid detection of Vibrio cholerae serotypes O1 and O139 from rectal swabs has been successfully used to diagnose cholera. This is likely to improve surveillance for cholera, especially in remote settings (25).

**Prevention & control**

Detailed guidelines on prevention and control of cholera, including management of cases, are given in the standard WHO text (26). Medical officers are advised to refer to the same.

(a) Control of cholera

Control of cholera depends on the improvement of environmental sanitation. Main aspects of environmental sanitation are adequately chlorinated and protected water supply, proper disposal of night soil/sewage and safe food supply. Food may be contaminated at the source, at different stages of processing, storing, serving and due to exposure to flies. Health education is important for improvement of personal hygiene.

(b) Immunization

The currently available saline suspension vaccines give protection in the range of 50-60 per cent and for a period of 3-6 months. Primary immunization consists of 2 equal doses of 0. 5 ml each in adults injected subcutaneously, at an interval of 4-6 weeks. If for any reasons, it cannot be carried out in 2 doses, a single 1 ml dose should be given. However in the vaccinated persons it does not reduce the severity of the illness or frequency of inapparent infection. As the efficiency of cholera vaccine is limited and duration of protection is short, it is essential that vaccine is used with discrimination and in proper time, that is anticipatory in selected place and population in face of epidemic.

Several mass vaccination campaigns using Oral Cholera Vaccines (OCV) have been performed with the support of WHO. Based on these, OCVs are now being considered as complements to traditional preventive measures (16).

The policy in the Armed Forces at present is not to give routine anti-cholera vaccination as at present it is not helpful in the prevention & control of cholera. At best they can be used as an adjunct to other preventive measures such as drug prophylaxis, proper sanitation and health education. Immunization against cholera is not regarded as an effective means of preventing the spread of cholera internationally. Cholera vaccination is not mandatory for international travel. However certain countries still insist on vaccination certificate against cholera. Before undertaking any travel one should consult the booklet issued by WHO every year "Vaccination Certificate Requirements for International Travel'.

(c) Action on Occurrence of the Disease

**(i) Isolation**

Even on the slightest of suspicion, the patient must be admitted immediately to the hospital where he must be strictly isolated in a special fly-proofed ward and diagnosis should be confirmed by identifying V cholerae 01 in the stool. Generally several cases occur at the same time; therefore, adequate arrangements for hospitalization of all cases are essential. In a large outbreak a separate hospital in the vicinity of the main hospital may have to be opened.

**(ii)Disinfection**

Soiled bedding and clothing, which cannot be sterilized, must be burnt. The floors of wards, huts and barracks must be thoroughly scrubbed with 5 per cent cresol (cresoli liquid). The place in which bed pans, urinals and soiled linen are stored should be fly-proofed or carefully covered with a sheet soaked in and kept moist with 5 per cent cresol. The stool and vomit should be poured into a receptacle containing an equal quantity of 5 per cent solution of cresol and left covered for 4 hours before its final disposal. Fresh WSP thoroughly mixed in the proportion of 1. 5 g to 1 lit of faeces/ vomitus may also be used as a disinfectant.

**(iii) Notification**

Previously, cholera was listed among the three communicable diseases - along with yellow fever and plague - whose notification to WHO was compulsory. Since 15 June 2005, the official notification of cholera is no longer mandatory but countries are required to inform WHO of public health events of international concern (16).

**(iv) Attendants**

They should be specially detailed and be isolated from the nursing staff of the main hospital. They should dip their hands in antiseptic solution after washing, after every contact with the patient, his bedding, objects or utensils. They should all be inoculated against cholera beforehand. The consumption of any food or drink by these attendants while in the cholera ward should be strictly prohibited. Gowns should always be worn while on duty.

**(v) Contacts**

They need not be isolated. All persons who are suspected of having partaken of the same infected food or drink as the patient, however remotely, should be kept under daily morning and evening surveillance for 5 days.

**(vi) Food and Drinks**

Control of food and drinks is the most important method of control of an outbreak. The following rules should be followed in the presence of an outbreak in the civilian community nearby :

- Drinking water should be super chlorinated. Washing and bathing water should be chlorinated. All rivers, ponds, wells etc. in the neighborhood should be put strictly 'out of bounds' to all troops other than authorized water duty personnel. Soda water and other drinks should be used only after the most careful investigation of their source of supply. Ice should not be used unless from an authorized source.
- Milk must be boiled. Cream and butter should be obtained only from reliable sources. Consumption of ice cream, unless its origin is absolutely beyond suspicion, should be strictly prohibited.
- Uncooked vegetables and fruits which are customarily eaten unpeeled should be avoided during epidemics. Others should always be washed and then soaked in a solution made by adding 3 scoopfuls or 6g WSP to a bucketful of water, before peeling. Cut fruits exposed for sale should not be eaten.
- All food must be protected against flies. Strict supervision of cookhouses and cooks are necessary to ensure that food is prepared, cooked stored and served under clean conditions. Golden rules for safe food preparation, as suggested by WHO (27) and given in the Box must be adhered to.

**What can I do to avoid cholera?**

By taking a few basic precautions cholera as well as most other food and water-borne diseases can easily be prevented. Main rule is : ***Always be aware of the quality of what you eat and drink when you are traveling.***

- **Drink only water that has been boiled or disinfected with chlorine.** Beverages such as hot tea or coffee, wine, beer, carbonated water or soft drinks, and bottled or packaged fruit juices are also usually safe to drink
- **Avoid ice, unless sure that it is made from safe water.**
- **Eat food that has been thoroughly cooked and is still hot when served.** Cooked food that has been held at room temperature for several hours and served without being reheated can be an important source of infection.
- **Avoid raw seafood and other raw foods**, except fruits and vegetables that you have peeled or shelled yourself. Remember : Cook it, peel it, or leave it.
- **Boil unpasteurized milk before drinking it.**
- **Ice cream from unreliable sources is frequently contaminated & can cause illness. If in doubt, avoid it.**
- **Be sure that meals bought from street vendors are**

**(vii) Mild cases**

A search for mild cases should be carried out by examination of the stools of all those who are suffering from diarrhoea. All diarrhoea cases, however, should be treated with suspicion until proved otherwise. Civilian labourers must be kept under strict supervision and given protective inoculation if considered necessary.

**(viii) 'Out of bound' places**

All villages and bazaars in the town in which a case of cholera has occurred must be placed 'out of bounds' to all troops until declared free from cholera. During an outbreak all eating and drinking places which are not absolutely above suspicion should also be placed 'out of bounds'

**(ix) Precautions**

All precautions, as given in the Box "What can I do to avoid cholera?" must be taken by all to protect oneself from cholera during an outbreak (28).

## Food poisoning

### Definition

Food poisoning is an acute gastro-enteritis caused by ingestion of food or drink contaminated with either living bacteria or their toxins or inorganic chemical substances and poisons derived from plants and animals. Food poisoning outbreaks are usually recognized by the sudden occurrences of an illness in a group of people who have consumed common food and have similar signs and symptoms. The food poisoning may occur as a result of eating any of the following :

(a) Substances containing specific poisons like eating fungi like *Amanita phylloides* instead of edible mushroom or eating sprouting potatoes which contains excess of alkaloid solanine.

(b) Food contaminated by poisons due to agricultural or industrial activities, fertilizers and pesticides in food or food contaminated with metallic poisons as a result of faulty cooking or storing such as use of cheap enamel dishes or galvanized pans.

(c) Foods infected with organisms mainly by three bacterial groups - Salmonella, Clostridium and Staphylococcus. This bacterial food poisoning is the commonest form and will be discussed in detail in subsequent paragraphs.

### Salmonella food poisoning

It is most common form of food poisoning. The causative organisms belong to Salmonella Group of which 50 are common out of over 1, 600 serotypes known. The species most commonly incriminated in human outbreaks is *Salmonella typhimurium*; others are *S. enteritidis, S. cholera-suis*. The organisms are natural commensals of rodents, pigs, cattle, poultry, ducks, eggs and also some healthy human carriers. Man acquires the infection from animals and poultry i. e. through contaminated meat, milk and milk products. Incubation period usually varies from 12 to 24 hours. On ingestion, the organism multiplies in the intestine and causes acute enteritis and colitis. The

WHO Golden rules for safe food preparation

**Cook raw foods thoroughly.** Under normal circumstances raw foodstuffs and water may become contaminated with pathogens, but in times of disaster the risk of contamination is even greater. Thorough cooking will kill the pathogens, which means the temperature of all parts of the food must reach at least 70 ˚C. Uncooked fruits or vegetables should not be eaten, unless they can be peeled. If milk has not been pasteurized, it should be boiled before use. Cooking will not necessarily destroy biotoxins.

**Eat cooked food immediately.** When cooked foods cool to room temperature, bacteria begin to grow. The longer the wait, the greater the risk. To be on the safe side, eat cooked foods as soon as they come off the heat.

**Prepare food for only one meal.** Foods should be prepared freshly and for one meal only, as far as possible. If foods have to be prepared in advance, or if there are leftovers, they should be stored cold, i. e. below 5 ˚C (in a refrigerator or in a cold box), or hot, i. e. above 60 ˚C. This rule is vitally important when it is planned to store food for more than 4-5 hours. Cooked foods that have been stored must be thoroughly reheated before eating, i. e. all parts reheated to at least 70 ˚C. Thorough reheating of foods is essential if refrigerators have ceased to operate for some hours due to power cuts.

**Avoid contact between raw foods and cooked foods.** Safely cooked food can become contaminated through even the slightest contact with raw food. This cross-contamination can be direct, e. g. when raw fish comes into contact with cooked foods. It can also be indirect. For example, preparing raw fish and then using the same unwashed cutting surface and knife to slice cooked food should be avoided, or all the potential risks of illness that were present before cooking may be reintroduced. Cross-contamination may also occur in a freezer when the power has been off for some time and this should be checked for. The juice of raw meat and poultry may drip onto other foods.

**Choose foods processed for safety.** Many foods, such as fruits and vegetables, are best in their natural state. However, in disasters and emergencies, they may not be safe and should be peeled before consumption if eaten raw. Foods that have been processed (e. g. canned food and packed dried food) and that have not been affected by the disaster may be safer. Dry rations may be easier to keep safe, as they do not need cold-storage, but they do need to be kept dry.

**Wash hands repeatedly.** Hands should be washed thoroughly before preparing, serving or eating food and after every interruption, especially after use of the toilet or latrine, changing a baby or touching animals. After preparing raw foods, especially those of animal origin, hands should be washed again before handling cooked or ready-to-eat foods.

**Keep all food preparation premises meticulously clean.** Since foods are so easily contaminated, any surface used for food preparation must be kept absolutely clean. Scraps of food and crumbs are potential reservoirs of germs and can attract insects and animals. The immediate surrounding of the temporary shelter, especially the kitchen and food storage areas, should be cleaned and sullage and solid kitchen waste should be disposed of properly. Food should be stored in closed containers to protect it from insects, rodents and other animals. Fly and rat traps should be used if necessary.

**Use safe water.** Safe water is just as important for food preparation as for drinking. If the supply of safe/potable water has been disrupted, the water intended for drinking or food preparation should be boiled. For example, condensed or powdered milk must be reconstituted with potable water only. Ice made from unsafe water will also be unsafe and may be a source of food contamination.

**Be cautious with foods purchased outside.** Sometimes food served in restaurants and by street food-vendors is not prepared under hygienic conditions. In times of disasters or emergencies, the risk that such foods are contaminated is greater. Therefore, caution must be exercised in the choice of food : only food that has been thoroughly cooked and is still hot when served should be eaten. Food bought from street food-vendors should be thoroughly cooked in the presence of the customer. Apart from fruits and vegetables that can be peeled, raw or undercooked foods should be avoided. Only water that has been boiled, or disinfected with chlorine or iodine, should be drunk. Beverages such as hot tea or coffee, wine, beer, carbonated water or soft drinks, packaged fruit juices and bottled water are usually safe to drink, if not damaged by the disaster. Avoid ice unless it is made from safe water.

**Breast-feed infants and young children.** Breast milk is the ideal source of nourishment for infants during their first months of life. It protects infants against diarrhoea through its anti-infective properties, and minimizes their exposure to foodborne pathogens. In times of epidemics and disaster situations, when foods may be contaminated or scarce, breast milk will ensure a safe and nutritionally adequate food for infants from birth up to the age of 4-6 months. Continued breast-feeding after this age can also contribute to the prevention of food-borne infections in older infants and

Source : (27)

onset is generally sudden with chills, fever, nausea, vomiting and profuse watery diarrhoea. The illness lasts for 2 to 3 days. Convalescent carriers are known to occur.

### Staphylococcal food poisoning

It is as common as food poisoning caused by salmonella. The causative organism is coagulase positive *Staphylococcus aureus* which causes the illness by production of heat stable entero-toxins. At least 5 different types of toxins have already been identified, and a sixth one is likely to exist (29). The toxin resists boiling for 30 minutes. Staphylococcus are ubiquitous in nature and are found in nose, throat and on the skin surface of human beings. They are common agents for pyogenic infections in man and animals. Cows suffering from mastitis have been responsible for the outbreaks. Tinned meat or fish inadequately processed, pickled meats, creams, milk, and milk products contaminated with staphylococcus have been incriminated in various outbreaks. The incubation period varies from 1 to 6 hours.

The disease manifests as sudden onset of vomiting with abdominal cramps and diarrhoea. In severe cases blood and mucous may appear. Fever is uncommon and so is mortality.

**Clostridium perfringens food poisoning**

*Clostridium perfringens (welchii)* is found in faeces of man and animals; and in soil, water and air. The spores of the organism are heat resistant and survive cooking, and if the cooked meat and poultry are not cooled enough, the spores germinate and produce a variety of toxins which cause the illness. The usual story is that the food is cooked 24 hours before consumption, allowed to cool down slowly and then heated just before the serving. The incubation period varies from 6 to 24 hours. The commonest symptom is diarrhoea with abdominal cramps. Fever and vomiting are usually absent. Illness is of short duration. Recovery is fast and mortality is rare.

**Botulism**

The food borne botulism (the others being wound botulism and infant botulism) is caused by *Clostridium botulinum* -a gram-negative, strict anaerobe, spore forming bacillus whose natural habitat is soil. It produces at least seven types of exotoxins of which type A, B and E are incriminated in food poisoning in humans. The foods most frequently responsible are home preserved foods such as smoked or pickled fish, home made cheese and similar low acid foods. The toxin is preformed in food under suitable anaerobic conditions and acts on parasympathetic nervous system. Incubation period is usually 12 to 36 hours. Clinical features include dysphagia, diplopia, ptosis, blurring of vision, dysarthria, muscular weakness and even quadriplegia. Gastrointestinal symptoms are very slight, fever is usually absent. Condition is frequently fatal - death occurring 4 to 8 days later due to respiratory or cardiac failure.

**Bacillus cereus food poisoning**

*Bacillus cereus* is an aerobic, spore bearing, motile, gram positive rod. It is ubiquitous in soil, and in raw, dried and processed foods. The spores survive cooking and germinate when the food is held at favourable temperature. It produces 2 types of entero-toxins - the emetic form with an incubation period of 1 to 6 hours, which produces upper gastrointestinal symptoms; and the diarrhoeal form with an incubation period of 12 to 24 hours, which produces lower intestinal tract symptoms. Recovery within 24 hours is usual.

**E. coli O157 food poisoning**

Food poisoning due to *E. coli* O157 has grown to prominence as an emerging public-health hazard since the first cases were reported in the early 1980s. Although far less common than *Salmonella* and *Campylobacter*, *E coli* O157 can survive for up to 6 months in mud and is far more likely to cause severe symptoms. While most food-poisoning events are short-lived and resolve without intervention, 2-7% of individuals (and up to 15% of children) infected with *E coli* O157 develop haemolytic uraemic syndrome, which leads to renal failure and potentially death (30).

Distinctive Features Of Common Food Poisonings

| Entity | Incubation period | H/o Fever | Vomiting | Diarrhoea |
|---|---|---|---|---|
| Staphylococcus | | 1-6 | - | |
| + | + | | | |
| Salmonella | 12-24 | + | + | + |

**Food poisoning Vs Cholera**

Majority of the food poisoning cases present with diarrhoea and, at times, it becomes difficult to differentiate it from cholera. But, while most of the food poisoning cases recover on their own, cases of cholera need active management, failing which the case may end fatally. Hence, there is a need to differentiate the two conditions. The distinctive features are given in the Table - 1

**Prevention and control of epidemics of food poisining**

The common measures recommended for the prevention and control of epidemics of food poisoning in Armed Forces include the following :

(a) **Meat and Meat Products** : Animals should be slaughtered in a hygienic, rat proof, vermin free butchery. Strict supervision should be kept on the whole cycle of meat processing.

(b) **Milk and Milk Products** : Milk should be pasteurized or boiled and every care should be taken against subsequent contamination.

(c) **Protection of Foods** : Adequate precautions should be taken against contamination of food during storage or during processing. The food items should not be left overnight in warm pantries and those not eaten immediately should be kept in cold storage to prevent bacterial multiplication and toxin production.

(d) **Food Handlers :** They should be periodically examined and those suffering from boils, ulcers, throat or eye infections and with history of having suffered from enteric fever or diarrhoea in recent past should not be employed as food handlers. A high standard of personal hygiene among food handlers must be maintained. Food handlers should be educated in matters of clean habits and personal hygiene.

(e) **Hazard Appraisal and Critical Control Point (HACCP) evaluation** - A simple and effective method for preventing food borne illnesses is by undertaking a detailed analysis of the steps in which food items are procured / prepared / stored / served, followed by identification of critical points where hygiene and sanitation can be breached / contamination can be introduced and finally making a check list of these critical control, points for taking acton for control / preventive action. The system has been recommended by the WHO. The golden rules for food safety issued by WHO are shown in the box on previous page

Table - 1 : Differences between food poisoning and cholera

| | Cholera | Food poisoning |
|---|---|---|
| Epidemiology | Occurs often in epidemic form associated with other cases in the neighbourhood. Secondary cases occur. | Often single group of persons who shared common meal are affected No secondary cases. |
| Incubation period | From few hours to 5 days | 1 to 24 h |
| Onset | With purging | With vomiting |
| Nausea and retching | None | Present |
| Vomiting | Projectile, effortless, watery & continuous | Often single severe vomit, mucus & blood soaked |
| Stools | Copious, rice watery & in -offensive | Frequent, may contain mucus blood |
| Tenesmus | None | Present |
| Abdominal tenderness | None | Present |
| Dehydration | Very marked | Distinct |
| Muscular cramps | Constant and severe | Less constant |
| Surface temperature | Subnormal | 100-102°F |
| Headache | None | Often present |
| Urine | Suppressed | Seldom suppressed |
| Blood | Leucocytosis | Normal |

## Enteric Group of Fevers

### Definition

This is a group of clinically similar, but immunologically distinct fevers, characterized by typical continuous fever for 3-4 weeks, relative bradycardia, with involvement of lymphoid tissues and considerable constitutional symptoms. The disease vary in severity, and many mild cases occur. The term 'enteric fever' includes both the typhoid and paratyphoid fevers.

### Geographical Distribution

Enteric fever occurs in all parts of the world, but the incidence of the disease has declined greatly with the provision of clean water and good sewage systems in Europe and the USA since the early 20th century, but the disease remains a serious public - health problem in developing countries (31). *S. paratyphi* is becoming predominant in some provinces in China and increasing numbers of cases are reported from Pakistan (32).

### Incidence

Few established surveillance systems for typhoid exist in the developing world, especially in community settings, so the true burden is difficult to estimate. According to an estimate of US Centers for Disease Control and Prevention there are 21. 6 million typhoid cases annually, with the annual incidence varying from 100 to 1000 cases per 100 000 population. The incidence is highest in the age group of 5 - 19 years but population based studies from South Asia suggest that the incidence is highest in children aged less than 5 years, with higher rates of complications and hospitalization (33). The overall ratio of disease caused by *S typhi* to that caused by *S paratyphi* is about 10 to 1 (33) to 4 to 1 (34). Enteric fevers are not notifiable diseases throughout India and hence the correct incidence is not known. Limited studies in the country reveal more than three lac cases and more than 650 deaths (approx) annually in our country. In Armed Forces, due to better hygiene and sanitation, safe water supply and systematic immunization, the incidence is low.

### Epidemiological determinants

Agent factors

**(a) Agent**

Typhoid fever is caused by Salmonella enterica serovar Typhi (*S. typhi*), a Gram negative bacterium. Paratyphoid

fever - a similar but often less severe disease - is caused by *S paratyphi A* and, less commonly, by *S paratyphi B* (Schotmulleri) and *S paratyphi C* (Hirschfeldii) (33). They are readily killed by heating at 60ºC, drying, pasteurization and common disinfectants.

**(b) Reservoir**

Man is the only reservoir of infection. The case may be mild, moderate or severe and is infectious as long as the bacilli are excreted in stool or urine. The carriers (or chronic) are more important. Convalescent carriers excrete the bacilli for 6 - 8 weeks. Chronic carriers are those who excrete the bacilli for more than one year after clinical attack. A chronic carrier may excrete the bacilli for several years, either continuously or intermittently. *S. typhi* once lodged in human carrier may persist for 20-50 years. Faecal carriers are commoner than urinary carriers. The carrier state is commoner in middle aged persons; females predominating over males. The famous case of "Typhoid Mary" who gave rise to more than 1, 300 cases is a good example of a chronic carrier. She is said to have spent the last 15 years of her life in quarantine in a New York hospital (35) Urinary carriers, though less common, are more dangerous to the community than faecal carriers because of greater chances of contamination of hands during micturition. Detection of carriers is by isolation of organisms from faeces or urine of suspects, agglutination tests are much less reliable.

**(c) Source of Infection**

The sole source of infection is the faeces or urine of cases and carriers. The bacilli are excreted for varying periods in faeces and urine.

Host factors

**(a) Age**

Enteric fever can occur at any age. Highest incidence of this disease occurs in the 5-19 years of age group but population based studies from South Asia suggest that the incidence is highest in children aged less than 5 years, with higher rates of complications and hospitalization (33).

**(b) Sex**

More cases are reported among males probably as a result of increased exposure to infection but carrier rates are more common in females.

**(c) Immunity**

An attack of the disease gives lasting immunity; second attacks however are not uncommon. The Armed Forces personnel, due to routine inoculation, constitute a relatively immune population.

**(d) Genetic factors**

Involvement of host genetic factors has also been implicated in the pathogenesis of typhoid fever. HLA-DRB1*12 is associated with protection against complicated typhoid fever (36).

Environmental factors

Enteric fevers are observed all through the year. The peak incidence is reported during July-September. This period coincides with the rainy season and an increase in fly population. Outside the human body, the bacilli are found in water, ice, food, milk and soil for varying periods of time. Typhoid bacilli do not multiply in water; many of them perish within 48 hours, but some may survive for about 7 days. They may survive for over a month in ice and ice-cream and up to 70 days in soil irrigated with sewage under moist winter conditions. Food being a bad conductor of heat, provides shelter to the bacilli in which they may multiply and survive for sometime. Typhoid bacilli grow rapidly in milk without altering its taste or appearance in anyway. Vegetables grown in sewage farms or washed in contaminated water are a positive health hazard. These factors are compounded by such social factors as pollution of drinking water supplies, open air defecation and urination, low standards of food and personal hygiene and health ignorance. Typhoid fever may therefore be regarded as an index of general sanitation in any country.

Incubation period and period of communicability

It is usually 10-14 days but in many cases it may well be outside the range. When the disease is water-borne, the incubation period tends to be longer. The incubation period for paratyphoid is 4 to 5 days. The case is infectious during the later part of incubation period and for a variable period thereafter.

Mode of Transmission

Enteric fever is spread chiefly through the medium of contaminated water, food, milk and vegetables. Flies constitute an important subsidiary vehicle for sporadic incidence. A small proportion of cases may occur due to direct transmission of infection from an actual case / carrier through contamination of hands, while handling patients or their excreta. The mode of transmission for explosive outbreaks of any considerable size, is, however water, milk or milk products adulterated by contaminated water or handling by carriers.

**Prevention**

The fundamental preventive measures are

(a) Provision of protected, clarified and chlorinated water supply
(b) Efficient pasteurization or boiling of milk
(c) Proper sanitary disposal of night soil
(d) Strict anti-fly measures
(e) Protection and cleanliness of fruits and vegetables
(f) High standard of food handlers' hygiene
(g) Personal hygiene and food habits
(h) Protective inoculation

Immunization

(a) **TA Vaccine** : Out of all the vaccines available, the rigidly carried out protective immunization with TA vaccine of all ranks has proved the most important and effective single preventive

measure. The immunization state of every unit at any time must be 100 percent. The records must be scrutinized every month. Those who are due or are likely to be away when next due, must be immunized immediately. Families of Armed Forces personnel and civilians employed in the Armed Forces must be similarly protected.

(b) **Vi polysaccharide vaccine :** This vaccine is licensed for use in individuals older than 2 years and is given in a single subcutaneous or intramuscular dose. The vaccine is moderately effective for about 3 years after vaccination (37). Revaccination is recommended every 3 years. The Vi vaccine can be given simultaneously with other vaccines relevant for international travellers such as yellow fever and hepatitis A.

(c) **Live Oral Vaccine :** This live oral vaccine available in enteric-coated or liquid formulation is approved for use in people 6 years of age and older. The liquid formulation for younger children is currently marketed in only a few countries. Three doses are recommended each given 2 days apart. Antimicrobials should be avoided for 7 days before or after vaccination. The vaccine is moderately effective for up to about 3 years after vaccination (38). A booster dose is recommended every 3 years in endemic areas and travellers should be revaccinated annually. The vaccine can be given simultaneously with other vaccines and with antimalarial prophylaxis. The vaccine is still under consideration for introduction in the Armed Forces.

(d) **Managing outbreak :** On the occurrence of an outbreak or increasing incidence all the preventive measures must be tightened. A search for carriers and missed cases, by stool and urine culture, blood culture and serological methods may be made within the unit, particularly among the cooks, mess waiters and other food handlers. Restaurants, cafes and other such places should be placed "out of bound' to all ranks. If only few cases have occurred the chances of tracing the source are good. Immunization is the most important measure in arresting the progress of an outbreak. The occurrence of a case in the unit warrants scrutiny of the inoculation state of the unit followed by immediate protection of those who are due within the next quarter and of all doubtful cases. Inoculation may not prevent the disease in those who are incubating the infection, but it will do them no harm and definitely arrests the outbreak.

#### Action on occurrence of a case

(a) **Hospitalization** : The patient should be admitted immediately to hospital and treated in a fly proof ward. The food handlers should be discharged from hospital when their stool and urine culture show negative result.

(b) **Disinfection** : Concurrent and terminal disinfection should be done. Faeces and urine can be disposed of directly into sewer without preliminary disinfection where adequate sewage disposal systems are available.

(c) **Notification** : It should be carried out as per existing order.

(d) **Personal Hygiene/Protection** : Attendants should be protected by TA vaccine, wear gowns and wash hands scrupulously whenever they handle the patients.

(e) **Close Contacts** : They should be kept under daily medical surveillance for 21 days.

## Viral Hepatitis

#### Introduction

Viral hepatitis is defined as an infection of the liver caused by hepatotropic virus and is clinically characterized by an acute or sub acute febrile illness associated with nausea, anorexia, abdominal discomfort, dark coloured urine, light coloured stools and appearance of jaundice in sclera or skin.

The known hepatotropic viruses commonly include hepatitis viruses A, B, C, D, E and G. However, the term hepatotropic is itself a misnomer. Infections with hepatitis viruses, especially hepatitis virus B and C, have been associated with a wide variety of extrahepatic manifestations. Infrequent causes of viral hepatitis include adenovirus, cytomegalovirus, Epstein-Barr virus, and, rarely, herpes simplex virus infection.

Hepatitis A virus (HAV); hepatitis B virus (HBV); hepatitis C virus (HCV); hepatitis D virus (HDV), which requires coexisting HBV infection; and hepatitis E virus (HEV) cause approximately 95% of cases of acute viral hepatitis. Whether hepatitis G virus (HGV) is pathogenic in humans remains unclear.

Among these the most common types are viral hepatitis A and viral hepatitis B. Distinguishing features between the two is given in Table - 2.

#### Geographical Distribution

HAV has a world wide distribution. The risk of infection is inversely proportional to levels of sanitation and personal hygiene (39). In developing countries with poor environmental hygienic conditions, nearly all children are infected with HAV before the age of 9. There is substantial underestimation of hepatitis A cases in these areas, because HAV infections for young children are mostly asymptomatic and therefore unrecognized. As sanitary conditions improve, transmission shifts to older age groups and the incidence of symptomatic disease increases. In most developed countries, endemic HAV transmission is unlikely. Epidemics of hepatitis A often evolve slowly, involve wide geographic areas and last many months, but common source epidemics (e. g. faecal contamination of drinking water) may evolve explosively.

HBV also has world wide distribution where 66 percent of the world's population is living in areas where there are high levels of infection. More than 2 billion people world

Table - 2 : Difference between Hepatitis A and B

| Character | Viral Hepatitis A | Viral Hepatitis B |
|---|---|---|
| Incubation period | 15 to 50 days | 50-180 days |
| Type of onset | Acute | Insidious |
| Fever over 100. 4°F | Common | Uncommon |
| Age preference | Children & young adults | Any age |
| Virus in stools demonstrated | Found in acute phase | Not |
| Route of infection (usual) | Faeco-oral (usual) parenteral (uncommon) | Parenteral |
| **Duration of Carrier State** | | |
| Blood | Unknown | May be as long as 5 yrs |
| Faeces demonstrable | Atleast 4 weeks | Not |

wide have evidence of past or current HBV infection and 350 million are chronic carriers of the virus, which is harboured in the liver. The virus causes 60-80 per cent of all primary liver cancer, which is one of the three common causes of cancer related death in East and SEAR, the Pacific Basin and Sub-Saharan Africa. Infection with HBV is a major cause of morbidity and mortality in the SEAR. More than one-third of the population has been infected with HBV, and it is estimated that there are 80 million HBV carriers (about 6% of the total population). Many are life long carriers, although not all are infectious, and some will clear the virus after intervals varying from many months to years. Transmission of HBV infection by blood transfusion and in other medical interventions in both modern and traditional health practices is also common in the Region (40). In India, the carrier rate of HBsAg in hospital staff has been found to be higher than in voluntary blood donors and in the general population. Sero-epidemiologic studies from Armed Forces also suggest that hepatitis carrier state is an important issue (41).

HCV is prevalent in 0. 5-2% of populations in nations around the world. It has been shown to be the major cause of parenterally transmitted non-A, non-B (PT-NANB) hepatitis. Approximately 170 million individuals are chronic carriers and are at risk of developing liver cirrhosis or liver cancer.

Hepatitis D or Delta hepatitis is also widespread and the infection always occurs in association with Hepatitis B. HDV is believed to infect approximately 5% of the world's 300 million HBsAg carriers. The sharing of contaminated needles in intravenous drug use is thought to be the most common means of transmitting HDV. Persons who use intravenous drugs and are also positive for HBsAg, have been found to have HDV prevalence rates ranging from 17-90%. Sexual and perinatal transmissions are also described.

HEV is transmitted via the fecal-oral route. HEV appears to be endemic in some parts of the lesser-developed countries. Anti-HEV antibodies are observed in as many as 60% of Indian children younger than 5 years. Sporadic infections are observed in persons traveling from western countries to these regions.

HGV can be transmitted by blood transfusion. HGV co-infection is observed in 6% of chronic HBV infections and in 10% of chronic HCV infections. However, whether HGV is actually pathogenic in humans remains unclear.

### Incidence

In peace time the incidence of the HAV & HEV disease which have a faeco-oral route of transmission is low but in war time and field service with the movement of troops into endemic areas and lowering of standards of sanitation, there is often a local high incidence. HBV, HCV & HDV which have a parenteral route of spread have a high incidence in a set up where proper sterilization is not maintained in surgical procedures or in injection rooms or in blood transfusion banks.

### Agent factors

Agent

**(a) HAV**

HAV, first identified in 1973, is a nonenveloped, spherical, positive stranded RNA virus with a diameter of 27-32 nm, classified within the genus hepatovirus of the picornavirus family (42). HAV strains recovered from widely separated regions of the world are antigenically similar. In humans, a single serotype of HAV exists. The virus is fairly resistant to heat and chemicals. It withstands heating to 60º C for one hour and is not affected by chlorine in dose of 1 ppm usually employed for chlorination of water.

**(b) HBV**

Discovered by Blumberg in 1963, Hepatitis B virus is a 42 nm double stranded DNA virus of the Hepadnaviridae family. It is present in human blood of patients and carriers. Antigenically it is very complex and has at least 3 separate antigen- surface antigen (HbsAg), core antigen (HbcAg) and antigen (HbeAg). The virus has not yet been grown in the organ culture system. It is killed by heat sterilization in an autoclave for 30 to 60 min or easily destroyed by sodium hypochlorite.

**(c) HCV**

HCV is a Flavivirus with a diameter of 55 nm. It has one serotype and multiple genotypes. At least 6 major genotypes and more than 80 subtypes are described. The genetic variability of HCV hampers the efforts of scientists to design an effective anti-HCV vaccine.

**(d) HDV**

HDV is also called the 'Delta Agent' / 'Defective Virus'/'Dane Particle' It is a single-stranded RNA virus with a diameter of 36 nm and contains HDAg and the RNA

strand. It uses HBsAg as its envelope protein. Thus, HBV co-infection is necessary for the packaging and release of HDV virions from infected hepatocytes.

**(e) HEV**

HEV is a Calicivirus. It is 27-34 nm long non-enveloped RNA virus

Reservoir of Infection

Man is the reservoir for all the viruses. However non human primates may also serve as reservoir of hepatitis A virus (chimpanzees and marmoset monkeys) but this reservoir is epidemiologically not of much relevance.

**Host factors**

HAV

HAV infection, usually, is commoner and milder in children than in adults. However any age group can be affected, if susceptible. Degree and duration of homologous immunity after attack are unknown but presumed to be long lasting.

HBV

Though infection can be contracted in any age, acute hepatitis occurs in approximately 1% of perinatal, 10% of early childhood and about 30% in those above 5 years of age. Development of chronic hepatitis is inversely related to age and occurs in about 95% of persons infected perinatally. Certain occupational categories have been identified as associated with an excess risk of hepatitis B infection. The categories include dentists, nurses, laboratory technicians and the work areas include haemodialysis units, blood banks, surgical intensive care units. Higher mortality rate has been reported in hepatitis B developing after blood transfusion.

While the host factors for HCV and HDV are similar to those of HBV, the host factors for HEV are similar to those of HAV. However HEV has a propensity to induce acute fulminating form of disease in pregnant women with a mortality that may reach about 80%.

**Environmental factors**

The tendency of viral hepatitis A&E to occur among children in endemic areas with poor environmental sanitation but amongst adults with better sanitation standards and of a socio-economically higher class has been observed. Sporadic cases occur from person to person through intimate contact evenly spread all round the year with seasonal upsurge in the fly breeding season. Explosive outbreaks as experienced in Delhi during 1955-56, may occur due to massive pollution of water supplies with sewage or of milk through milk handlers or water used for adulteration.

Hepatitis B, C & D cases have been traced to clinics among patients who have received parenteral inoculations from contaminated and inadequately sterilized syringes and needles.

**Communicability period**

Maximum infectivity for hepatitis A & E is during the later half of incubation period continuing through early acute phase of infection during the first 1-2 weeks or longer.

In hepatitis B, C & D blood remains infective many weeks before the onset of symptoms, through the acute clinical course of the disease and during the chronic carrier state.

**Mode of transmission**

Typical patterns of virus transmission are as follows, with + symbols indicating the frequency of transmission (more + symbols indicated increased frequency) :

**Fecal-oral transmission**

HAV (+++), HEV (+++)

**Parenteral transmission**

HBV (+++), HCV (+++), HDV (++), HGV (++), HAV (+)

**Sexual transmission**

HBV (+++), HDV (++), HCV (+)

**Perinatal transmission**

HBV (+++), HCV (+), HDV (+)

**Sporadic (unknown) transmission**

HBV (+), HCV (+)

**Source : (43)**

**Incubation period**

The average incubation period for various viruses :

| Type of virus | Incubation period (IP) |
|---|---|
| HAV | 15 to 45 days; usually 25 to 30 days |
| HBV | 45 to 180 days; usually less than 100 |
| HCV | 8 weeks (Approx) |
| HDV | Co-infection with HBV |
| HEV | 2 to 9 weeks |

Many persons may be carriers without having experienced a clinically recognized attack.

**Prevention and control**

HAV (& HEV)

As almost all HAV infections are spread by the faecal - oral route, good personal hygiene, high quality standards for public water supplies and proper disposal of sanitary waste are the mainstay of prevention and control of infective hepatitis.

(a) The patient should be admitted to hospital. He can be kept in sub-acute medical ward provided flies do not get access to faeces, urine and sputum ;

(b) Concurrent and terminal disinfection as for any other excremental diseases should be ensured;

(c) Notification of the disease is essential ;

(d) Attendants should take all precautions;

(e) Immunisation

(i) **Passive Immunisation :** Contacts may be given normal human immunoglobulin (16 % solution) at 0.02 to 0.12 ml per kg of body weight intramuscularly as soon as possible after exposure to prevent or attenuate clinical illness.

(ii) **Active Immunization** : Several inactivated or live attenuated vaccines or a combination vaccines containing inactivated hepatitis A are licensed but not in use in the Armed Forces as of now.

(f) Water supply should be safeguarded against faecal contamination. Even superchlorination may not kill the virus, unless water is very efficiently chlorinated and a half an hour contact period is ensured. Water should be preferably boiled during an outbreak. For small bodies of troops or on individual basis, especially during ops and similar situations, use of out fit water sterilizing must be ensured.

(g) Sanitation should be kept at a very high level. Methods of proper disposal of human wastes and strict anti-fly measures should be reinforced.

(h) Personal hygiene must be maintained at an extremely high level. All ranks must be persuaded to wash their hands with soap and water after defaecation and before handling or consuming food, particularly so in case of cooks and food handlers.

HBV (& HCV & HDV)

Preventive measures for HBV infection include the following :

(a) Immunization

(i) **The plasma derived vaccine** : It is a formalin inactivated sub-unit viral vaccine for intramuscular injection. It is given in 3 doses of 1 ml each at 0, 1 & 6 months. It gives 95 percent protection up to 3-5 year after which booster doses may be given.

(ii) **The RDNA :** Yeast derived vaccine is as effective in protection but more cost effective than the above vaccine. The schedule is 0, 1 & 6 months. Protection is up to 15 year and based on current scientific evidence, life long (44).

(b) Needles and syringes used for routine immunization must be autoclaved for twenty minutes or boiled for 30 min.

(c) It is mandatory that all blood donors and blood products be screened for HBV and HCV infection and those found positive should be rejected. Voluntary blood donation should be encouraged because purchased blood has shown a higher risk of post-transfusion hepatitis.

(d) Carriers should be told

(i) Should not share razors or tooth brushes

(ii) Use barrier methods of contraception

(iii) Should not donate blood.

## Poliomyelitis

### Definition

Poliomyelitis (polio) is a highly infectious disease caused by a virus which invades the nervous system, and can cause total paralysis in a matter of hours. The disease is characterized by fever, fatigue, headache, vomiting, stiffness in the neck and pain in the limbs which may be followed by irreversible paralysis (usually in the legs) in one in 200 cases.

### Problem statement

In the pre-vaccination era, poliomyelitis was found in all countries of the world. In 1988, the forty-first World Health Assembly adopted a resolution for the worldwide eradication of polio. Four agencies i. e. World Health Organization, Rotary International, the United Nations Children's Fund (UNICEF) and the United States Centers for Disease Control and Prevention (CDC) formed the core of the "polio partnership" (45). Overall, in the 17 years since the Global Polio Eradication Initiative was launched, the number of cases has fallen by over 99%, from an estimated more than 350 000 cases in 1988 to 1951 reported cases in 2005. In 2006, only four countries in the world i. e. Nigeria, India, Pakistan and Afghanistan, remain polio-endemic, down from more than 125 in 1988. Despite these achievements, the Global Polio Eradication Initiative faces an increase in global cases in 2006, due to an ongoing outbreak in northern Nigeria, and a new outbreak in western Uttar Pradesh, India (46). Uttar Pradesh State in western India remains one of the world's hotbeds of poliomyelitis. Nearly all of the 297 reported cases in India during 2006 were in Uttar Pradesh (India had 66 cases in 2005) (47).

### Prevalence

In developing countries such as India where the polio endemicity is stable, virtually all cases of polio have an onset before the fifth year of life. The most accurate technique to measure the prevalence of polio in a community therefore is a house to house survey of lameness and muscle wasting due to polio in children aged 5-10 years. Alternatively, surveys of school children may be taken up, less accurate though they may be. It has been found that surveys based on identifying lameness of the leg as a sole criterion for diagnosis of paralytic polio will identify about 80 per cent of cases. The total prevalence of residual paralysis due to poliomyelitis could be estimated by multiplying the prevalence of lameness due to polio by 1.25 and reported as cases per 1,000, usually in children older than 5 years. This prevalence rate represents the sum of all cases, almost all of which occurred from 0-4 years of age.

### Incidence

The prevalence rate of residual paralysis can be used to estimate annual incidence of paralytic cases. For example, if a prevalence rate of 10 cases per 1,000 is found in a cohort of children 5-10 years of age, correction for those

cases not involving the lower extremities is done by multiplying the prevalence rate by 1.25 which gives a prevalence rate of 12.5 per 1,000. This can be translated into average annual incidence by dividing the prevalence rate (12. 5) by the number of years at risk (i. e. five), giving an average annual incidence of 2. 5 per 1, 000 in the age

| | | |
|---|---|---|
| Annual incidence per 1000 in total population | = | Annual incidence in the age group 0-4 years **X** Distribution of 0-4 year age group in general population |

group 0-4 years.

If the 0-4 year population is known (usually 20%) the annual incidence of polio for the whole population can be determined as follows :

Continuing the above example, if the 0-4 year-old population makes up 20 per cent of the population, the annual incidence is 2.5 x 0.2 = 0.5 per 1,000 population or 50 per 100,000 population. An estimate of all cases of paralytic poliomyelitis can be made by multiplying annual incidence by 1.33 to correct for those cases that completely recovered or died after onset of disease (48).

### Epidemiological determinants

Agent factors

**(a) Agent**

The causal organism is a filterable neurotropic virus with three immunological types - Polio virus types 1, 2 and 3. All types can cause paralysis but type 1 has been most commonly involved. Polio viruses are resistant to freezing and drying. They are easily killed by heat at 55ºC for 30 min, potassium permanganate, ultraviolet rays and chlorine. In a cold environment, it can live in water for 4 months and in faeces for 6 months. It is therefore well adapted for the faeco-oral route of transmission.

**(b) Reservoir**

Man is the only reservoir. Persons with inapparent infection, especially children constitute the main reservoir. It is estimated that for every clinical case there may be 1000 subclinical cases in children and 75 in adults.

**(c) Source of Infection**

Persons with inapparent infection, in early clinical period; generally prior to paralysis, serve to keep infection going in a community through their faeces or pharyngeal secretions. However the silver lining is that there are no chronic carriers.

Host factors

**(a) Age**

Poliomyelitis is essentially a disease of childhood. Adults are usually spared because of acquired immunity. In India 50% of polio cases occur during infancy. The most vulnerable age is 6 months to 3 years.

**(b) Sex**

Male sex stands at a disadvantage - being affected 3 times more often than females.

**(c) Risk factors**

Certain factors which precipitate attack of paralytic polio have been identified. These include fatigue, trauma, intramuscular injections and operative procedures such as tonsillectomy especially during a polio epidemic.

**(d) Immunity**

Immunity following infection is fairly solid. However re-infection can occur with a different serotype as infection with one serotype does not protect completely against the other two types of viruses.

### Environmental factors

Polio spreads particularly in large and densely packed populations with poor sanitation and less than optimum routine immunization. The disease is more likely to occur during rainy season. The environmental sources of infection include contaminated water, food and flies.

### Mode of Transmission

Poliomyelitis (polio) is a highly infectious viral disease, which mainly affects young children. The common mode of disease transmission is faeco - oral. The virus is transmitted through contaminated food and water, and multiplies in the intestine, from where it can invade the nervous system. Many infected people have no symptoms, but do excrete the virus in their faeces, hence transmitting infection to others. Mouth to mouth spread by droplets can also occur.

### Incubation period

Usually 7 to 14 days, though it can range from 3 days to 35 days.

### Clinical features

Clinical features of the disease varies from inapparant or sub-clinical infection to paralytic poliomyelitis. Initial symptoms are fever, fatigue, headache, vomiting, stiffness in the neck and pain in the limbs. One in 200 infections leads to irreversible paralysis (usually in the legs). Among those paralyzed, 5%-10% die when their breathing muscles become immobilized.

Affection of the central nervous system is more a rarity than a rule, but such cases are more obvious than the non-paralytic cases and also cause socio-economic hardships later. This makes the disease more recognizable by its nervous involvement. The anterior horns in the spinal cord and motor neurons of cranial nerves are affected in such cases, resulting in a lower motor neuron type of flaccid muscular paralysis mainly in the limbs and specially the lower limbs. The case fatality rate in paralytic cases is 2 to 3 per cent and in the bulbar type it is 5 to 6 per cent. The paralysis starts with varying degrees, initially more extensive but gradually reducing down to a lesser residual paralysis. Patients with paralysis represent a small minority of clinical cases.

### Prevention

(a) A high standard of hygiene and sanitation should be maintained with arrangements for proper disposal of faeces, safe water supply and proper food hygiene.

(b) Active immunization of all infants / children should be carried out with oral polio vaccine. The Armed Forces have joined the nation in the attempt to eradicate polio from the country. They are active participants of the Pulse Polio Immunization Programme.

**Acute Flaccid Paralysis (AFP) surveillance**

Polio confirmed and Polio compatible cases : Poliomyelitis cases are confirmed only when poliovirus is identified in the stools of a patient with acute flaccid paralysis (AFP). However, it is impossible to collect stool samples from all such patients, which satisfy the stringent conditions to be labelled as adequate. When an AFP patient without an adequate stool sample has residual paralysis beyond 60 days from the date of onset, detailed clinical, laboratory, and epidemiological investigations are done, and the evidence is submitted to the National Expert Review Committee. The committee sifts through the available evidence and diagnoses any poliomyelitis cases; these are classified as "polio-compatible" cases (49).

While dealing with polio eradication, we are interested in polio confirmed cases rather than polio compatible cases. Hence there is a need to reduce the number of compatible cases. Since AFP surveillance is an important strategy to eradicate polio, surveillance quality will affect the eradication process. India has made great progress towards polio eradication and the National Polio

# Helminthiasis

## Definition

Traditionally helminthic infections include infections by diverse group of worms such as filarial worms. schistosomes, trematodes, in addition to cestodes and nematodes. This section deals with the later two, being important public health problems in our country. All over the globe, particularly in developing countries, Helminthic infections lead to considerable morbidity, suffering, reduction in work efficiency and economic loss.

The prevalence in the Armed Forces follows that in the civil population. Recruits hailing from high endemic areas may be about 80 to 100 per cent infested. As a result of treatment and comparative freedom from re-infection these rates naturally fall very considerably after enrolment. Some personnel are however re-infested when they spend their leave in their homes in rural areas. Helminthiasis in the past accounted for 4-6 per cent of total morbidity in the Armed Forces of which Round worm and Hook worm formed the major portion of helminthiasis about 80 per cent. However the overall incidence is far reduced now and is (per 1000 troops) 0. 03 for Army, 0. 02 for Navy and 0. 02 for Air Force in 2006.

## Classification

Helminths can be classified into Phylum Nemathelminthes, Class Nematoda or round worms and Platyhelminthes, Class Cestoda or tape worms and Class Trematoda or flukes. They can be grouped according to their mode of transmission such as soil (Geo), food and animal borne. In this chapter only those helminths which are of importance in the Armed Forces in India are described (Table - 1).

### Geo Helminths

These are intestinal nematodes, part of the development of which takes place outside the body – in the soil. These nematodes are usually found as multiple infections. Without soil life they cannot become infective. They may be divided into three types according to their life cycle.

#### Type 1 : Direct

Embryonated eggs are passed; they hatch and reinfect within 2-3 hours by being carried from the anal margin to the mouth and either do not reach the soil or, if they do, do not require a period of development there. This group includes *Enterobius vermicularis* (thread worm)and

Table - 1 : Classification of Helminths

| | Nematodes | Cestodes | Trematodes |
|---|---|---|---|
| Geo-helminths<br>(Soil trasmitted)<br>(a)Direct<br>(b)Modified direct<br>(c) Penetration of the skin | *Enterobius Vermicularis*<br>*Trichuris trichiura*<br>*Ascaris lumbricoides*<br>*Toxocara canis*<br>*Ancylostoma duodenale*<br>*Necator americanus*<br>*Strongyloides stercoralis* | | |
| Contagious (Faecal borne) | *Enterobius vermicularis* | *Taenia, Echinococcus*<br>*Hymenolepis nana* | |
| Arthropod transmitted | *W. bancrofti, B. malayi,*<br>*Onchocerca volvulus* | | |
| Snail & Cyclops transmitted | *Dracunculus medinensis* | | *Schistosoma haematobium*<br>*Schistosoma japonicum*<br>*Schistosoma mansoni*<br>*Fasciola hepatica*<br>*Fasciolopsis buski*<br>*Paragonimus westermani*<br>*Clonorchis sinensis* |
| Food & animal transmitted | *Trichinella spiralis* | *Taenia solium, Taenia saginata,*<br>*Diphyllobothrium latum* | |

*Trichuris trichiura.*

**Type 2 : Modified direct**

Eggs are passed out in the stool and undergo a period of development in the soil before being ingested, where they hatch, releasing larvae which penetrate the mucous membrane of the stomach and enter the circulation to reach the lungs, passing up the respiratory tract to enter the oesophagus, reaching the intestine where they become adult. These include *Ascaris lumbricoides* (roundworm) and *Toxocara canis.*

**Type 3 : Penetration of the skin**

In this group eggs are passed in the stools to the soil, where they hatch into larvae which undergo further development before they are ready to penetrate the skin and reach the circulation and lungs, which they penetrate to enter the respiratory tract; they move up to enter the oesophagus and reach the small intestine, where they become adult. *Ankylostoma* (hookworm) and *Strongyloides stercoralis* belong to this group. *Strongyloides*, however, differ in that larvae are passed in the stool and auto infection can occur at the anal margin, or independent development takes place in soil, where the can exist in the absence of any further cycle through man.

**TYPE 1 : Direct**

## Enterobiasis (Threadworm, Pinworm, Oxyuriasis)

Distribution : Worm is distributed worldwide.

### Aetiology

The adult worms are small and white with the skin transversely striated. The female (9-12mm) has a long, pointed tail and a slit like vulva in the anterior quarter of the body. The male which is much smaller (2. 5mm) has a posteriorly curved third and a blunt caudal extremity. The egg has a characteristic shape, flattened on one side. It is almost colourless, with a bean-shaped double contour shell containing a fully formed embryo.

### Life cycle

There is no multiplication inside the body of the human host. The mature female has a life duration of 35 to 90 days and when the ovary is full of eggs she migrates down to the anus, from which she emerges to lay the eggs on the peri-anal skin and on the perineum. The eggs, which are ingested in the faecal material lodged under the finger nails, hatch in the stomach and larvae emerge which rapidly pass along the intestine to caecum and appendix, where they mature. The whole cycle takes 2-4 weeks.

### Transmission

There are four possible methods of transmission. The most common is by direct transmission from peri-anal region to the mouth by contaminated finger nails or soiled night clothes. A second way is by exposure to viable eggs on objects in the environment. A third way is via the mouth or nose from contaminated dust. The fourth way is by retro-infection in which eggs hatch on the anal mucosa and larvae migrate up the bowel. Ectopic lesions have occasionally been found in the female genital organs, abdominal cavity and even ear & nose.

### Symptoms and Signs

Pruritis ani is the main symptom, varying from mild itch to severe pain, which mainly occurs at night. General symptoms are insomnia and restlessness, and a number of children have loss of appetite, weight-loss, irritability and enuresis. There is usually no eosinophilia or anemia.

### Diagnosis

The diagnosis is made by finding the characteristic eggs in the faeces (5% only), peri-anal scraping with Scotch tape or by finding the adult worms around the anus, usually at night.

### Prevention and Control

The whole must be treated to avoid re-infection. Chemotherapy must be combined with education, and personal hygiene aimed at preventing auto-infection. Although it is simple to effect a temporary cure, eradication may be difficult because of re-infection from the contaminated environment or from asymptomatic members of the household. During treatment the child must sleep in clean clothes and gloves. The finger nails must be cut short and scrubbed.

## Trichuriasis (Whipworm)

### Distribution

*Trichuris trichiura* occurs worldwide. The annual global mortality is estimated to be around 60 000.

### Aetiology

*Trichuris trichiura* is a greyish-white worm, often slightly pink, which lives in the caecum and the appendix. The male (30-45mm long) has an attenuated anterior portion which is half as long as the thicker posterior portion. The caudal extremity is curved through 360 degrees with a single spicule in the sheath which is studded with spines. The female (30-35 mm long) has the posterior half occupied by a stout uterus packed with eggs. The egg is brown with a characteristic barrel shape with a plug at each end; it contains a single embryo.

### Life cycle

The worms live in the caecum, embedded in the mucus between the intestinal villi. The egg is laid unsegmented, and embryonation takes at least 21 days. It can withstand low temperatures but not desiccation. Infection is direct from stale faeces. The egg hatches after being swallowed in the intestine, where the shell is digested by intestinal juices and the larva emerges in the small intestine. It penetrates the villi and develops for a week until it re-emerges and passes to the caecum and colo-rectum, where it attaches itself to the mucosa and becomes adult.

### Transmission

Transmission is direct from mature eggs to the mouth via fingers contaminated from infected soil.

### Symptoms and signs

The prepatent period from ingestion of eggs to appearance of eggs in the stool is 60 days. In light infections, there are no symptoms. Epigastric pain, vomiting, distension, flatulence, anorexia and weight loss may occur. Pain in epigastrium and iliac fossa is common. Co- infection with *E hystolitica, E coli* or *Shigella* causes

aggravated symptoms of dysentery. Anemia is seen when associated with amoebic infection. Eosinophilia, if present, denotes concurrent *Toxocara* infection. In severe infantile trichuriasis digital clubbing, hypo-protonaemia and growth retardation may be seen.

Diagnosis

The diagnosis is made by finding the characteristic eggs in the stool by direct smear or by concentration method. Proctoscopy in cases of dysentery will show numerous worms attached to the mucosa.

Prevention and control

Trichuris is common in areas of high rainfall, high humidity, dense shade and poor sanitation and contaminated soil. *T trichiura* is primary a human infection but *T suis* is indistinguishable and thus an increased incidence is seen in people handling pigs. The greatest prevalence is in children of primary school age who pollute the soil around the house and develop heavy worm burden. Avoidance of soil pollution is the key to control which can be combined with mass chemotherapy. Susceptibility to albendazole may vary in different regions and it is prudent to evaluate sensitivity when planning mass chemotherapy.

**Type 2 : Modified direct**

## Ascariasis (Roundworms)

Distribution

It is one of the most widespread human infections. Distribution is world wide. Infestation is most common in moist, hot tropical countries, where hygienic disposal of faeces is inadequate, and the soil is of clay type. The infestation is very heavy in rural India and in insanitary urbanised areas. Permanent habitat of the adult worm is the small intestine of man. No natural or induced immunity exists.

The high atmospheric and terrestrial moisture and temperature favour development of the infective stage of the eggs. Children are more frequently and more heavily infected than adults. This is more likely to occur in those localities where defaecation and faecal contamination occur indiscriminately near the dwellings.

Aetiology

Adult worms are 25-40 cm in length. When freshly passed they are light brown or pink in colour. They are cylindrical in shape tapering at both ends; the anterior end is thinner than the posterior. The sexes are separate. The male is smaller in size and coiled posteriorly. The life span of the adult worm in the human host is from 6 months to a year.

Life cycle (Fig - 1)

Permanent habitat of the adult worm is the small intestine of man. Fertilized egg is round or oval, mammillated, bile stained and brownish in colour, 60-75 microns in length by 40-50 microns in breadth. It contains a large conspicuous unsegmented ovum and floats in a saturated solution of common salt. The female is capable of liberating eggs even if not fertilized. Unfertilized egg is narrower and more elliptical in shape with thinner shell containing a small atrophied ovum and does not float in salt solution. Fertilisation takes place in small intestine and are passed out as immature ova. . Embryo develops in the damp soil in2-4 months (at the optimum of 25 degrees C in 3 weeks). It remains coiled up in the egg and undergoes one moult before being hatched as the infective second stage rhabditiform larva in the small intestine when the egg is swallowed. Here the rhabditiform larva penetrates the mucous membrane and enters the blood stream, reaching the lungs via the right heart. As it can not pass through the lung capillaries, it burrows through the alveolar wall to enter the respiratory tract. From here it is carried up the trachea to the larynx, where it moves over the epiglottis and enters the oesophagus, and is swallowed a second time to reach the small intestine. The whole process takes 10 – 14 days, during which time the larva again moults twice. In man the period from infection to the first passage of ova in the stool (prepatent period) is 60 – 70 days.

Transmission

Reservoir is an infested person discharging eggs in and about houses where facilities for proper faecal disposal are lacking. The adhesive nature of the egg probably results in gradual contamination of most of the objects in houses and public places as well as food, particularly vegetables grown in soil where faeces are used as manure.

Clinical Features

**(a) Larval Phase (Larval Ascariasis)**

Clinical manifestations may first appear in relation to pulmonary migration of the larvae. They range from a mild dry cough to severe dyspnoea, cyanosis, whooping type of cough and haemoptysis. There may be urticarial rashes, eosinophilia, asthmatic attacks and mottled lung infiltration noticed in chest radiograph. This syndrome is called Loeffler's syndrome which may turn out to be fatal. The nature and severity of symptoms depend upon the number of invading organisms and on the degree of the sensitivity of the host. Eosinophilia is quite a common feature at this stage and also later.

**(b) Adult stage (Intestinal Ascariasis)**

Presence of a large number of worms in the intestine increases the abdominal contour producing a protuberant abdomen and lumbar lordosis. They rob the host of his nutrition and give rise to colicky pain. They may produce appendicular, biliary and intestinal obstruction. They may migrate into the peritoneal cavity through a perforated intestinal ulcer.

Diagnosis

Stool examination for evidence of eggs is the commonest laboratory method. The presence of worms can be demonstrated by radiography with a barium meal, which on being ingested by the worm within 4-6 hours, casts an opaque shadow. The confirmation of diagnosis is by finding the adult worm in stool or vomit with or without an antihelminthic administration.

Prevention and Control

**(a) Primary Prevention**

Methods based on primary prevention are the most effective in interrupting transmission. Health education

on these aspects, taking into consideration the life cycle of the parasite and the peculiar ecological, social and cultural circumstances that prevail in a community are the ultimate keys to the control of ascariasis. These are :

(i) Sanitary disposal of human excreta to prevent or reduce faecal contamination of the soil. Mothers should be educated regarding dangers of indiscriminate defaecation by children. Open air defaecation in general, should be prohibited. On the other hand effective and acceptable sanitary facilities should be provided.

(ii) Safe drinking water from a safe source, after proper treatment including filtration should be provided. Water hygiene discipline in homes should be strictly followed where again, education of mothers is important.

(iii) Food hygiene by way of thorough washing of vegetables to be consumed should be insisted upon.

(iv) Personal hygiene- viz washing hands before taking any meal and after ablution should be practiced, biting of nails or sucking of thumb/fingers should not be practiced.

**(b) Secondary Prevention**

The safe and effective ascaricides such as mebendazole, pyrantel and Levamisole are available. Early diagnosis and treatment are important tools in prevention and control of transmission in low endemic areas. Even in hyper endemic areas they form a part of mass treatment and thereby a useful and important option. However mass treatment will not interrupt transmission of the disease but merely reduce the worm load.

### Toxocariasis (Dog roundworm)

#### Distribution

*Toxocara* canis infection in dogs is worldwide. Its manifestations in humans such as *Visceral* larva migrans and ocular toxocariasis also have been detected in Americas, Africa and Europe.

#### Aetiology

*T canis* has morphology like that of *A lumbricoides* though its eggs are larger with superficial pitting.

#### Life cycle

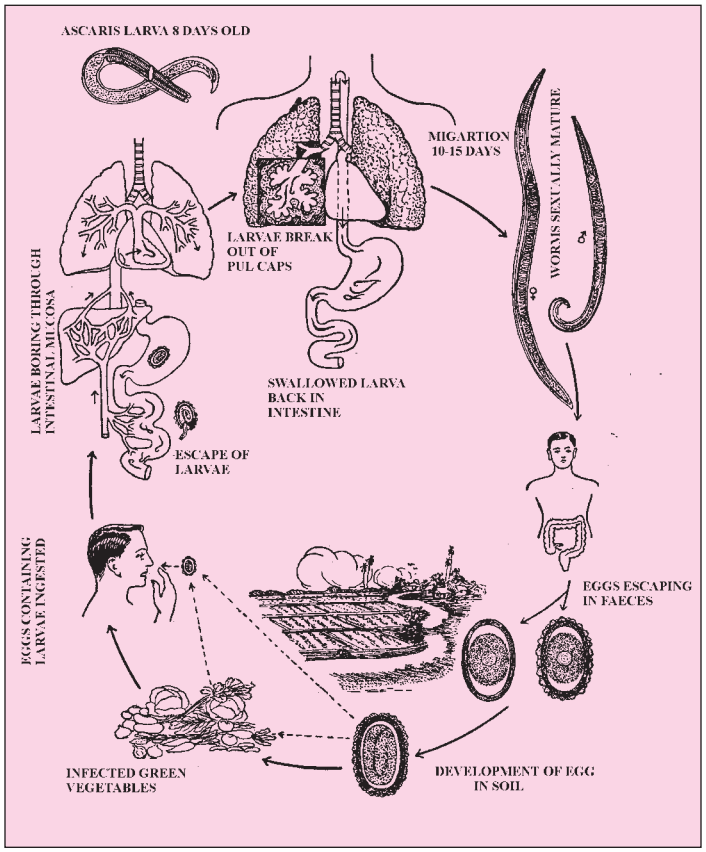
In the dog the life cycle is similar to of *Ascaris* in man except that transplacental infection of puppies takes place and the whole cycle may be maintained in a small flat without any access to the outside.

In man, who is not the normal host, the eggs hatch in the stomach and the second stage larvae penetrate the mucosa to enter mesenteric vessels, reaching viscera and liver where they are held up in the capillaries but may pass to lungs and brain through general circulation. There they are destroyed by granulomatous reaction. The larvae do not grow or moult in man but can remain alive for up to 10 years.

#### Transmission

The main source of infection is puppies, which excrete

Fig - 1 : Life cycle of ascaris lumbricoides.



large number of eggs. Infection is acquired from contaminated soil, Direct infection from handling puppies is not considered a risk because embryonation of excreted *Toxocara* ova requires a minimum of 2 weeks.

#### Clinical Features

Unless the infection is heavy and the VLM syndrome is produced, most cases remain asymptomatic. VLM can be self-limiting or cause death. Lesions in the eye can produce loss of vision where it may closely resemble retinoblastoma.

#### Diagnosis

Serology of IgG, IgH and anti-A isohaemagglutinin are consistent laboratory findings.

#### Prevention and control

Control rests upon control of infection in dogs. Regular treatment of dogs, bitches as well as puppies with anthelmintics is essential when there are children in house as the mean age of infection is 2 to 5 years. Dogs should be denied access to children's play areas.

**Type 3 : Penetration of the Skin**

### Ankylostomiasis (Hookworm disease)

#### Introduction

Hookworm is caused by two hookworms *Ankylostoma duodenale*, the old world hookworm and the very closely allied species *Necator americanus*, the new world hook worm. The intestinal infestation is commonly termed

'ankylostomiasis' and the clinical syndrome of anemia is usually called the 'hook worm disease'.

### Geographical Distribution

It is widely distributed in all the tropical and subtropical countries where hygienic disposal of faeces is inadequate, the soil is loamy and moisture retaining, high moisture and temperature favouring development of infective larvae. The geographical distribution lies in the tropical and subtropical zones between 45° N and 30° S (15). *Ancylostoma duodenale* is widespread throughout India, but the really heavy infestation is in the sub Himalayan division of Northern India from Uttar Pradesh to Assam (tea gardens), Prevalence is low in the drier parts of Rajasthan and Gujrat. In the southern and eastern parts of India, *Necator americanus* is predominant. In other parts a mixture of both exists.

### Endemicity Index

Morbidity & mortality due to this worm depends much on the worm load. Chandler's Index is still used in epidemiological studies to assess worm load and also the effect of mass treatment in different populations.

### Aetiology

The adult worm is cylindrical, greyish white and about one cm long. The anterior end of the worm is bent slightly to form a hook. In *A. duodenale* the buccal capsule is provided with six cutting teeth; four hook like triangular plates on the ventral surface and two knob-like on the dorsal surface. *Necator americanus* has got four chitinous plates instead of six cutting teeth, two on the ventral surface and two on the dorsal surface; hence they are less

Assessment of worm load

| Average number of eggs per gram of stools | |
|---|---|
| Below 200 | Hookworm is not of much significance |
| 200-250 | May be regarded as potential danger |
| 250. 300 | Minor public health problem |

invasive and less effective blood suckers. Sexes are separate. The male is smaller and its posterior end is expanded in an umbrella fashioned copulatory bursa, whereas in the female it is tapering. The eggs are colourless (not bile stained) with a thin egg-shell containing segmented ovum usually with four blastomeres and a clear space between the egg shell and the ovum.

### Life cycle (Fig - 2)

The eggs with fertilized ovum are passed in the faeces of the human host into the soil. From each egg a rhabditiform larva (250 microns) hatches out in the soil. It moults twice and develops into filariform larva (500 microns-600 microns) which is the infective stage of the parasite. The time taken for development from egg to filariform larva is on an average 8-10 days. The optimum temperature required for development is between 28ºC to 32ºC for *N. americans* and 5ºC to 8ºC lower than that for the A. *duodenale.* Direct dessication kills larva quickly; hence moisture, is essential for its survival. This is usually supplied to the soil by frequent light showers of rain. Sandy or loamy soil is most suitable for hookworm larvae but not clay. Under favourable condition these larvae can remain infective for two months. Gaining entrance into a new human host through the bare skin, the infective filariform larvae cast off their sheaths and penetrate the skin deeper. Farming practices in which raw manure infested with larvae is used and when hands have to be used for harrowing the earth as in potato farming carry the risk. The custom of walking barefoot in the polluted fields and in deep mining, where defaecation is indiscriminate also carries risk of infection. *Ancylostoma* may at times, utilize the oral source of entry. On reaching the subcutaneous tissue, the larvae enter the venous circulation and then via the right heart into the pulmonary capillaries, breaking through the capillary wall and entering into the alveolar spaces. They then migrate upto the bronchi, trachea, larynx and crawl over the epiglottis to the pharynx and they are ultimately swallowed. During migration a third moulting takes place and a buccal capsule is formed. It takes about 10 days for migration from skin to the small intestine. The growing larvae settle down in the small intestine, undergo a fourth moulting and develop into adolescent worms. In 3-4 weeks time they are sexually matured and the fertilized females begin to lay eggs. The adult worm anchors to the mucousa of the small intestine particularly the jejunum, less often of the duodenum, and sucks blood. Eggs are passed in the faeces. The cycle is then repeated. The interval between the time of skin penetration and the first appearance of eggs in the faeces is about six weeks.

### Transmission

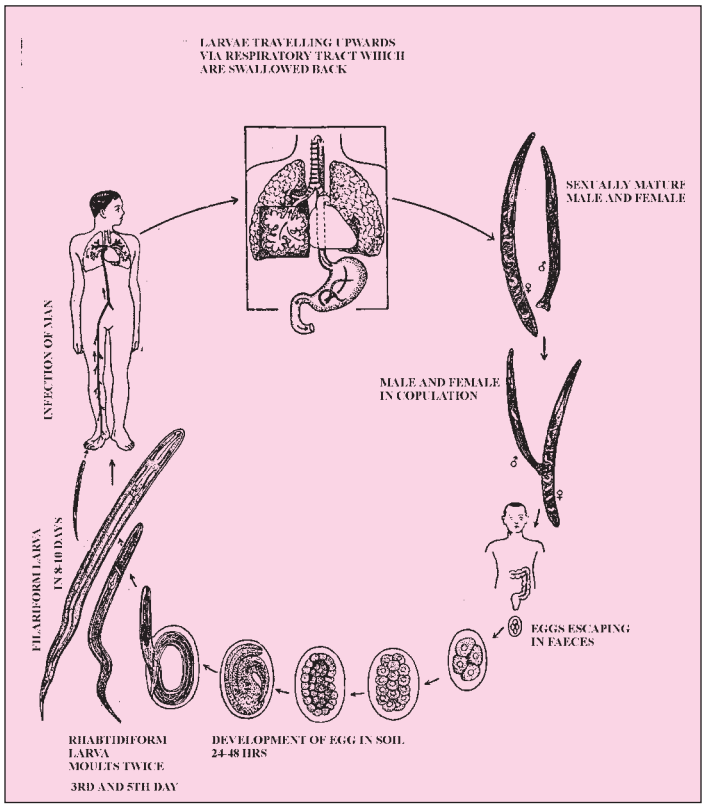
Infection is normally acquired via the skin from filariform larvae in the soil contaminated by human faeces; or orally via the ingestion of contaminated food.

### Clinical Features

The interval between the time of skin penetration and the first appearance of eggs in the faeces is about six weeks. At the site of entry of infective larvae there is a 'ground itch', which consists of an irritating vesicular rash on exposed portions of body like hands or feet. Symptoms may take a few weeks, months or even years to appear, depending upon the intensity of infection, state of nutrition and general condition of the host, or may not appear at all. However, they remain potential source of infection as long as they are infected and continue to pollute the soil. The average daily blood loss for *A duodenale* is about 0. 15 to 0. 2 ml while for *N americanus* it is 0. 03 ml per worm. With a worm load of 500-1000significant blood loss and anemia will result, even in the presence of adequate iron intake.

In some patients taste may be perverted with some of them exhibiting an unnatural craving for such things as mud or lime (pica or geophagy). In children features include *diarrhea*, melaena, vomiting and massive

Fig - 2 : Life cycle ***A duodenale***



haemorrhage. The mortality is up to 12%.

More frequently the disease is chronic, ebbing and flowing, slowly progressing over a number of years.

Diagnosis

Occult blood is always present in stools. Diagnosis of ancylostomiasis is made by stool examination for ova or adult forms. The 'hook worm disease' is assessed by taking a complete haemogram which shows anemia of iron deficiency. Intradermal test using antigen prepared from adult worms may sometimes be used for epidemiological surveys. In the laboratory the faeces is examined for the ova by the following methods :

**(a) Direct Method**

After making a saline suspension on a glass slide and covering the suspension with a cover slip.

**(b) Concentration Method**

A moderately dense suspension of faeces is made in a small bottle with a wide mouth, such as an empty penicillin vial, using saturated solution of common salt. The bottle is then filled to the brim with a salt solution. A microscope slide is put carefully on the top of the bottle, so that the fluid is in contact with the slide. It is left undisturbed for 20 min. Then the slide is removed vertically up and turned upside down, so that adherent fluid is upper most. A cover slip is put and examined.

Eggs float in saturated solution of common salt. It is oval or elliptical in shape, measuring 65 microns in length by 45 microns in breadth.

Reservoir and Source of Infection

Reservoir is an infested person discharging eggs in the faeces. The usual immediate source of infection is soil contaminated with infective larvae.

Prevention and control

The sheet anchor is to prevent contamination of soil. To prevent development of the infective stage of the parasite or exposure to it, the following measures should be adopted :

**(a) Sanitary Measures**

Provision of proper latrines, proper disposal of faeces and prohibition of indiscriminate defecation are the trio of first importance. Shallow trench latrines are dangerous; deep trench latrines and bore hole latrines are better; trenching of stool is inferior to composting; septic tank or sewage disposal plants are the best disposal systems.

**(b) Health Education**

It is very important because the provision of latrine is one thing and its use is another thing. Farmers should be educated not to walk bare footed and to wear sandals in the neighbourhood of latrines and not to use human manure before two months of its maturation.

**(c) Mass Deworming**

Several effective drugs viz Albendazole, Mebendazole, Levamisole & Pyrantel are available for treatment. Mass treatment should be carried out with caution as there are toxic side effects. Further, treatment of anaemia is important in individual cases of hookworm disease.

## Food and animal-transmitted Helminths

In these helminths the infective stage develops in animals whose flesh is an important item of food for man. They are the cestodes-- *Taenia saginata* (beef tape worm), *Taenia solium* (pork tapeworm), *Diphyllobothrium latum* (fish tapeworm); and a nematode -- *Trichinella spiralis*.

## Taenia saginata and Taenia solium (Taeniasis)

*T. solium* is the pork tape worm, the 'armed ' tape worm of man and *T. saginata* is the beef tape worm, the 'unarmed' tape worm of man. Adults of both tapeworms infest the small intestines of man and this infestation is commonly termed "Taeniasis". The larval stages infect the porcine and bovine muscles; the larva of *T. solium* (Cysticercus cellulosae) may infect man also.

Geographical Distribution

The infection is common in countries where sanitation is poor and where these animals are allowed to graze in the neighbourhood of human habitation. *T. Saginata* infestation is prevalent among the beef eating population and *T. Solium* is common among pork eaters.

Aetiology

Adult tape worms are white, semitransparent, 5-10 m in length and consists of head(scolex) neck and segments (proglottides). Scolex in *T. saginata* measures 1-2 mm in diameter, quadrate in outline and has four lateral circular suckers but no rostellum and hooklets. The neck is thin and tapering behind the scolex. Scolex in *T. solium* is 2-3 mm long and has a short rostellum and is provided with a double row of 20 to 50 hooklets. The number of segments

varies from 1000-2000 in T. saginata and 800-900 in *T. solium.* The segments near the scolex are immature, in the middle portion they are mature showing both the sex organs and at the tail-end are seen gravid segments. The uterus in the gravid segment consists of a central longitudinal stem with lateral dichotomous branches which are 5 to 10 in *T. solium* and 15 to 30 in *T. saginata*. Eggs are liberated by the rupture of gravid proglottides. The eggs are spherical and brown due to bile stain, 30-40 microns in diameter with thick radially striated wall containing hexacanth (3 pairs of hooklets) embryo. They do not float in saturated salt solution. They may remain viable for 8 weeks. Eggs of *T. saginata* are infective to cattle only and those of *T. solium* are infective to pigs and man.

Life Cycle (Fig - 3 & Fig - 4)

Man is the sole definitive host, the adult tapeworm inhabits man's intestinal canal. The gravid segments of the worm containing eggs are passed in faeces. The cow/pig acquires infection by eating grass or drinking water which has been contaminated by human faeces. Having reached the stomach of the cow/pig the eggs release the contained larvae which pierce the gut wall and are carried via the blood stream to the muscles and other organs where they encyst. This stage is known as Cysticercus bovis (measly beef in cattle) and Cysticercus cellulosae in pigs (measly pork) . The cysts resemble small mistletoe berries. For their further development the encysted larvae must be consumed by man while they are in a viable stage and this occurs when man eats underdone beef or pork. Encysted larvae are released in man's stomach, pass into the intestine and then develop into adult tapeworms. The important difference in infestation by these two tape worms is that while for *T. saginata* man never acts an intermediary host, he may do so for *T. solium* when he swallows eggs through contaminated water or food, or by regurgitation of a gravid segment from his intestine to his stomach. The cysticerci developing in the muscles or brain give rise to various syndromes. Man may thus harbour both adult *T. solium* and its larval form. After the larvae are ingested it takes 8 to 10 weeks for the worm to develop, become sexually mature and produce eggs.

Transmission

The life cycle of these is maintained between humans, who are the only definitive host for them, and pigs for *T solium* and cattle for *T saginata*. The humans are able to harbor both the types of adult worms without much ill effect and thus act as chronic carriers. Cattle and pigs become infected by eating grass or garbage and the hexacanth embryo is librated in their intestines. The embryo penetrates the mucosa and reaches brain, muscles and other tissues. At these sites, larvae loose their hookletes, enlarge and develop into fluid filled cysts. On consumption of inadequately cooked flesh with cysticerci by man, these are digested free of muscles and protoscolex attaches itself to the intestines of man to develop into adult worm. Occasionally, in case of *T solium*,

Fig - 3 : Life cycle of **Taenia saginata**

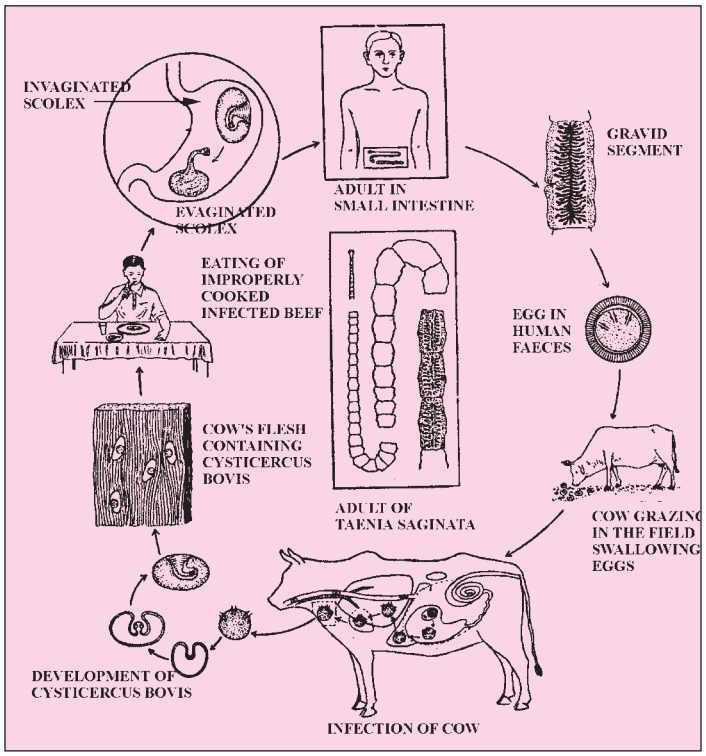


Fig - 4 : Life cycle of **Taenia solium**

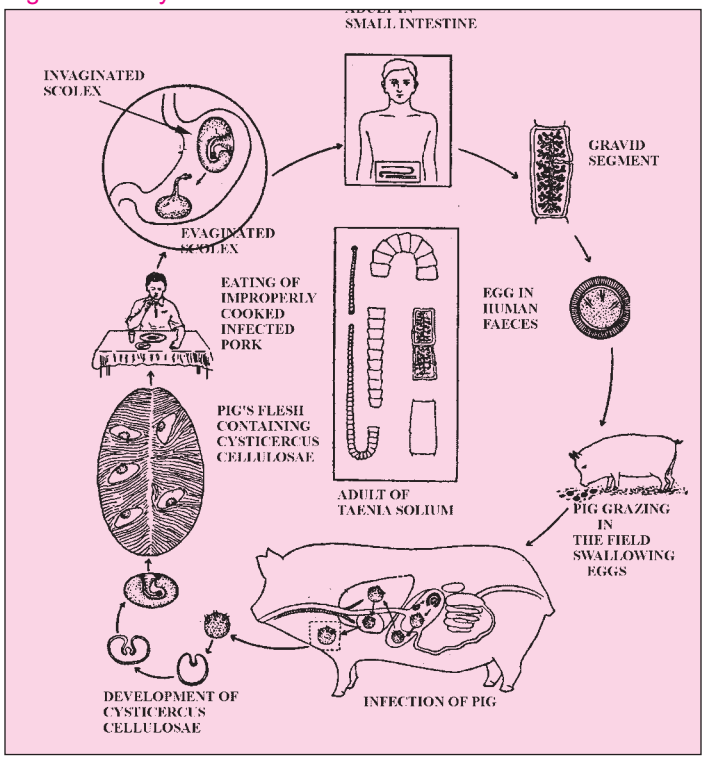


man can get infected like the pig by consuming food or water contaminated with the eggs, leading to development of cystecercosis in man.

Diagnosis

Presence of gravid segments on naked eye examination of stools is an evidence of tape worm infestation. These should be collected for further microscopic examination for determining the type of worm and demonstration of eggs. The sample of faeces after antihelminthic treatment should be screened and examined for the presence of scolex to confirm cure. Cysticercus cellulosae can be diagnosed by biopsy examination and radiological examination revealing calcified cysts.

Reservoir

Reservoir is an infested person discharging eggs in faeces. Immediate source of infection is the flesh of the infested animal. Person harbouring *T. solium* can, however, become a source of infection to another person or to himself. Man remains a source of infection for 10 years or even 30 to 40 years. Susceptibility is universal and there is no acquired immunity.

Pathogenicity and Clinical Features

Adult worm living in the intestine usually does not give rise to any symptoms. It may sometimes give rise to vague abdominal discomfort, chronic indigestion, diarrhoea alternating with constipation, anaemia, anorexia, loss of weight, nervousness and insomnia. Cysticercus cellulosae may give rise to symptoms referable to the particular organ affected; thus it may produce epilepsy if the brain is the seat. While *adult T solium* infection is acquired by man by eating under-cooked pork containing cysticerci, however, human cysticercosis is a *faceo*-oral *infecton* acquired by ingestimg eggs excreted in the faeces of a human infested with adult tape worm. Individuals harbouring an adult *T solium* are at a higher risk of suffering from cysticercosis, probably through *faceo*-oral auto-infection. It has long been hypothesized that internal auto-infection might also occur as a result of reverse peristalsis, thereby allowing *Tinea solium* eggs to travel from small bowel to the stomach and these become activated and invasive; little evidence, however, has emerged to support this view.

Prevention and Control

(a) Proper animal husbandry and hygienic feeding of cattle and pigs and avoidance of eating underdone beef or pork are the most important measures for prevention and control. Adequate meat inspection and health education of the consumer supplement these measures.

(b) Proper sewage disposal, prohibition of indiscriminate defaecation, health education of the people are the long term control measures.

(c) Treatment of all cases with effective drugs like praziquantel & niclosamide, reduces the infective quantum. Praziquantel is given in the dose 10-20 mg/kg as single dose. Adult dose of niclosamide is 2 gm. Personal hygiene and hygiene of all the food handlers is important to prevent likelihood of ingestion of eggs of T. solium through auto infection and infection from others.

(d) Those harbouring the adult worms infect the cows and pigs and hence should be treated until the scolex is excreted. The patient of T. solium infestation should be isolated and treated with the same precautions as a case of enteric fever. He should be warned of the danger of auto-infestation and hence must practice scrupulous personal hygiene. Stools should preferably be destroyed by burning.

## Echinococcus granulosus

(Cystic echinococcosis, Hydatid disease)

Introduction

This is an infestation of the small intestine of a dog with a tape worm, *Echinococcus granulosus*. It constitutes a zoonosis as the larval form of the worm produces the hydatid disease in human beings as well as in sheep and cattle.

Distribution

Although the hydatid disease is world wide in distribution, it is most commonly found in those countries where sheep and cattle raising is an important industry resulting in close association between man, sheep and dog. The disease is more prevalent in the subtropics and in temperate climate than in the tropics.

Aetiology

Adult worm is 3 to 6 mm long. It has a scolex, neck and strobila consisting of 3 to 4 segments. The first segment is immature, the second one is mature and the next are gravid. The head bears four suckers and a rostellum with two circular rows of hooks. The neck is short and thick. Eggs resemble those of other taenia.

Life Cycle (Fig - 5)

In the duodenum the hexacanth embroys hatch out and they bore their way though the intestinal wall and are carried though radicals of the portal vein to the liver which acts as a first filter. Some of the embryos may pass through the hepatic capillaries, enter the pulmonary circulation and filter out in the lungs. A few of the embryos may pass the pulmonary capillaries, enter the general blood stream and invade any other organ. However, they are most commonly found in the liver and lungs. Wherever the embryo settles, it forms the hydatid cyst. From the inner layer of the cyst, 'brood capsule' with a number of scolices develops. A fully developed scolex is the sign of complete biological development of the hydatid cyst. When ingested by the definitive host, the scolices are capable of developing into adult worms in about 6 to 7 weeks time. Thus the cycle is repeated usually between dog and sheep. As the dogs have no access to the hydatid cysts developed in the viscera of man, the human infestation is a blind alley. Life span of the adult worm is a few months in contrast to the life span of the larval from which may continue to develop for many years.

Hydatid Cyst

The larval form causes hydatid cyst in man. The cyst wall consist of the ectocyst which is the outer chitinous laminated hyaline membrane about 1 mm. thick and the endocyst which is the inner germinal layer. This is a cellular vital layer of the cyst giving rise to brood capsule

with scolices and the hydatid fluid. The host reacts by forming a fibrous layer known as pericyst around the growing embryo. The parasite derives its nourishment through it. When an old cyst becomes sclerosed or calcified, the parasite within it dies due to lack of nutrition. Hydatid fluid is antigenic and highly toxic. If it is allowed to stand, the granular deposit which settles at the bottom consists of liberated brood capsule, free scolices and loose hooklets.

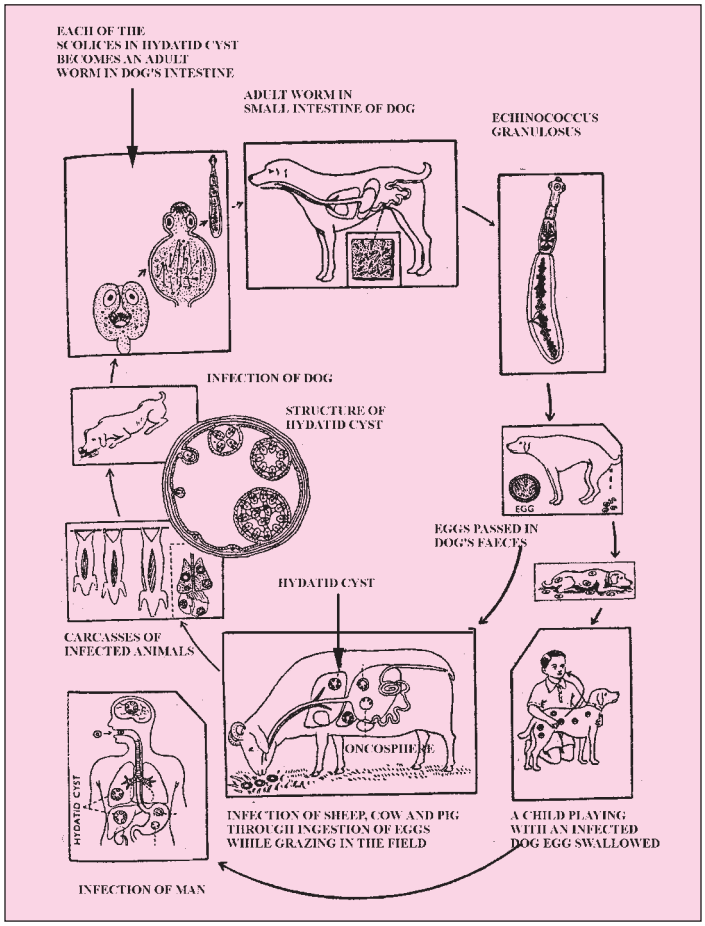
### Transmission, Reservoir and Source

The reservoirs are the carnivorous animals like dogs, wolves, jackals and foxes who are the definitive hosts harbouring the adult worm. Out of these animals, dog is the most important animal as far as the hydatid disease in man is concerned. The sheep is the most suitable intermediate host but cattle can also act as such. The eggs discharged in the faeces of these definitive hosts are swallowed by the intermediate hosts, while grazing in the field. Man gets the infestation by handling and fondling of the dogs.

### Clinical features

The condition remains asymptomatic throughout the life in majority of cases. In symptomatic cases, the clinical manifestations are highly variable and depend on the following :

Fig - 5 : Life cycle of **Echinococcus granulosus, E. multilocularis**



(a) Organ involved

(b) Size of the cyst

(c) Interaction between the expanding cyst and surrounding organ

(d) Complications caused by the rupture of cysts.

The cysts located in vital organs interfere with the functions of the organ and may cause fatality in certain cases.

Occasionally, due to trauma or surgery, the cysts may rupture. A ruptured cyst presents two risks;

(a) Hydatid fluid when absorbed into circulation produces fatal anaphylactic shock

(b) Secondly, it may lead to formation of secondary echinococcois in other parts of the body due to spread of scolices in circulation.

### Diagnosis

Diagnosis is made by precipitin, complement fixation and haemagglutination test and intradermal Casoni's test. Microscopic examination for hooklets, scolices and cyst membrane in sputum, vomitus, urine or faeces after rupture of cysts or in discharge from a sinus also aids in diagnosis. Confirmation is by examination of tissues obtained surgically or at autopsy. Eosinophilia is present. Radiological examination for hydatid is often helpful. Detection of antigen excreted in urine by CIEP or Co-A is the most recent approach which may also be used to evaluate success of treatment.

### Prevention and Control

(a) Prevention of infection in dogs by rigid control of slaughter-houses so that dogs do not have access to them.

(b) Deworming of infested dogs with specific antihelminthics.

(c) Health education of people for understanding the nature of the disease, precautions to be taken, need for personal prophylaxis (cleaning of hand before eating) and controlled slaughtering of animals, should be emphasized. General household hygiene must be improved.

(d) There is no specific treatment excepting surgical removal of cysts which is not without considerable risk in as much as the accidental penetration of one of the cysts can lead to anaphylactic shock which may prove fatal. Mebendazole has been tried and may well become drug of choice.

## Mechanism of Air-borne Infections

The central aspect of the spread of infectious disease is the transmission of infection, or the various mechanisms by which disease agents reach and infect the human host. This involves escape of the agent from the source, conveyance to the susceptible host , and entry into that host. Transmission may be direct or indirect, the classification is as follows

Classification of the mechanism of transmission is as follows

| Direct transmission | Indirect transmission |
|---|---|
| Direct contact | Airborne |
| Droplet infection | Vehicleborne |
| | Vectorborne |

Since the Stone Age and before, man and his ancestors have sought refuge from the elements by taking shelter within caves, tents and wooden structures. Little aware that the common protection they obtained also fostered the exchange and proliferation of airborne pathogens, which would in the coming years form of one of the most dreaded group of organism.

Airborne infection is defined as "A mechanism of transmission of an infectious agent by particles, dust, or droplet nuclei suspended in the air."

Two types of particles are implicated in the airborne kind of spread

(a) Droplet nuclei

(b) Dust

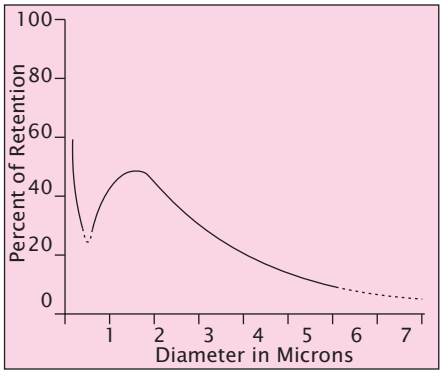
**Dust**

Dust are particles of varying size that result from resuspension of particles that have settled on floors or bedding. A variety of infectious agents ( bacterias, viruses and fungal spores) have been found in the dust of hospital wards and living rooms, these agents survive for varying periods as per optimum condition of temperature and humidity. These particles become airborne due to the act of sweeping, dusting or bed-making or from the soil by the wind.

**Droplet nuclei**

Droplet nuclei are tiny particles (1-10 microns) that represents the dried residue of droplets. Smaller particles that are less than 3 to 5 microns in diameter may contain one or two micro-organism fail to settle out of gravity & remain suspended in the atmosphere for long periods of time. These infectious aero-sols are small enough to bypass host defenses in the upper respiratory tract and airways. More particles are deposited in small bronchioles and alveoli as particle size decreases below 5 micron . One such inhaled particle may be sufficient to reach the alveolus and initiate infection. Typical pulmonary infections acquired due inhalation of infectious aerosols include Tuberculosis, Influenza, Legionellosis, Histoplasmosis, Q fever etc. Fig - 1 Shows the relationship between particle size and retention in the alveoli.

Fig - 1



These droplet nuclei may be formed in several ways which are

(a) Evaporation of droplets that have been coughed or sneezed into the air.

(b) Aeroliztion of infective material in the course of laboratory procedures

(c) Processes for rendering animals in slaughter houses.

**General Prevention and Control measures**

Ventilation

Since organisms transmissible through the air can be widely dispersed, specific air ventilation is required to manage their dispersion thus control outbreaks of airborne infections. If resources are available then (especially in healthcare facility) techniques such as the use of monitored negative airflow ventilation with at least six air changes per hour and filtration of direct exhaust to the outside should be used. In routine areas of work and stay adequacy of ventilation at all times is ensured by provision of at least 2 windows/ room with an area of about 10 percent of the floor space and arranged so as to provide cross ventilation.

Respiratory protection devices

Surgical masks that cover the mouth and nose should be worn by healthcare staff in hospitals and by the patient themselves also. (CDC-recommends N95 respirator / surgical mask made by 3M.)

Overcrowding

Other important measure, for preventing airborne infections is prevention of overcrowding. The minimum floor area should be 6 $m^2$ per person. Beds must be spaced with an interval of at least 2 m between the centres of the two adjacent beds, the greater the interval, the better it is.

# Small Pox : A Historical Introspection

## Introduction

Smallpox (variola) represents both the zenith and nadir of human achievement. It is the only disease that has been eradicated through a concerted and extensive effort that transcended political and ideological boundaries. Because of these efforts, not one documented naturally occurring case of this infection, which once caused high mortality rates, has occurred since October 26, 1977. (The last naturally occurring case involved an unvaccinated hospital cook in Somalia. ) Smallpox officially was declared eradicated by the World Health Organization (WHO) in 1980. Later two accidental laboratory infections were reported in Birmingham, England in 1978 (1, 2). Smallpox also represents one of the most devastating potential biological weapons ever conceived (3). In 1976, there were 76 laboratories through out the world that officially kept stocks of Smallpox virus. By 1980, the number was reduced to six laboratories. In 1983, the number was down to two; the US Laboratory in Atlanta, Georgia, and the Research Centre of Virology, Koltsovo, Russia, both WHO collaborating centers(4).

## Eradication of the disease

Small Pox eradication has been possible due to the following reasons (5) :

(a) No known animal reservoir.

(b) No long-term carrier of the virus.

(c) Life long immunity, after recovery from the disease.

(d) The detection of cases is comparatively simple because the rash was so characteristic and occurred in visible parts of the body.

(e) Persons with sub clinical infection did not transmit the disease.

(f) Presence of a highly effective vaccine which was easily administered, stable and conferred long term protection.

(g) International Co-operation.

## The looming threat of smallpox

Smallpox is classified as a Category A agent by the Centers for Disease Control and Prevention. Category A agents are believed to pose the greatest potential threat for adverse public health impact and have a moderate to high potential for large-scale dissemination. Other Category A agents are anthrax, plague, botulism, tularemia, and viral hemorrhagic fevers. Smallpox might find mankind across the whole world a fertile medium to spread, given that most of us have no immunity against it. The WHO has at its disposal some 200 million doses of the smallpox vaccine, but most of them are old and have been kept frozen for many years, and hence their effectiveness on human beings remains untested(6).

## Vaccine current status

Stockpiled vaccine has been used only for laboratory researchers working on orthopoxviruses. In the event of a known bioterrorist release of smallpox virus, vaccine would be administered to exposed individuals. If vaccine is given within 3 to 4 days of exposure, immunity can develop before the disease occurs, and this would be expected to prevent or ameliorate the severity of disease. Post exposure immunization is recommended for persons who have had face-to-face, household contact with or have been in proximity to a person who has active smallpox skin lesions, persons who have been involved in the care of such an individual, and persons exposed in any way to laboratory specimens or bedding from an infected patient. The rationale for a policy based on the so-called RING VACCINATION strategy recommended by the Centers for Disease Control and Prevention, in which cases of smallpox are rapidly identified, infected individuals are isolated, and contacts of the infected individuals as well as their contacts are immunized immediately(7). The ring strategy is based on the knowledge that vaccination can prevent or ameliorate disease severity if given within 3 to 4 days of initial exposure and can decrease symptoms if given within the first week of exposure.

New Vaccine

On September 01, 2007, the U. S. Food and Drug Administration (FDA) licensed a new vaccine ACAM2000 against smallpox which can be produced quickly upon need. Centers for Disease Control and Prevention has stockpiled 192. 5 million doses of the new vaccine (derived from the old Dryvax, and made using a pox virus vaccinia).

## Antiviral Drugs

Cidofovir (Vistide)

In vitro studies demonstrated cidofovir to inhibit poxvirus replication and cell lysis. This drug must be used under an FDA Investigational New Drug (IND) protocol because it is not licensed for use as a treatment for smallpox. Cidofovir is a nucleoside analog DNA polymerase inhibitor; if administered within 48 h of exposure may attenuate or avoid infection; adefovir, cidofovir, and ribavirin are under investigation for use in smallpox. Ribavirin as an aerosol treatment for paediatric respiratory syncytial virus is under investigation. **Adult Dose** of cidfovir is 5 mg/kg IV over 1h.

## Monkey pox

Isolated cases of a vesiculopustular disease resembling smallpox have occurred in West Africa and Zaire after smallpox transmission has been interrupted in the area. The virus isolated is identical with monkey pox, a member of the variola vaccinia group of viruses. Serological surveys of wild monkeys have shown that monkey pox is an uncommon infection in the wild non-human primates (8).

## Small Pox

- Caused by variola virus
- Only disease that has been eradicated in medical history in recent times
- Last indigenous case in India occurred in 17 May 1975 in Bihar
- The world's last case occurred in Somalia on 26 Oct 1977
- On 08 May 1980 WHO declared eradication of Small Pox
- Strategy for eradication : Surveillance and containment
- Classified as Category A agent by CDC as a bioweapon
- Recommended strategy for control:

## Rash in small pox

**Distribution**

- palms and soles frequently involved
- axilla usually free
- rash predominant on extensor surface and bony prominences

**Characterstics of rash**

- deep seated
- vesicles multilocular and umblicated
- only one stage of rash may be seen at one time
- No area of inflammation is seen around vesicles

**Evolution**

- Evolution of rash is slow, deliberate and majestic passing through definite, stages of macule, papule, vesicle and pustule
- Scab begins to form 10-14 days after the rash appears
- Fever subsides with the appearance of rash

## Small Pox Vaccine

| | |
|---|---|
| **Vaccine Name** | Vaccinia virus vaccine (Dryvax) -- Vaccine contains live vaccinia virus but does not contain variola virus, which causes smallpox. Following inoculation, vaccine induces an immune reaction that serves to protect against smallpox. |
| **Adult Dose** | Using biohazard precautions, pick up a droplet of vaccine using bifurcated (eg, two-pronged) needle (supplied with vaccine) and deposit on skin on upper arm; with same needle, prick skin percutaneously over droplet site 2-3 punctures for primary vaccination (15 punctures for revaccination) within a few seconds to allow vaccine to penetrate; wipe off any remaining vaccine from skin with sterile gauze and dispose in biohazard waste container; administration will create a sore and cause 1-2 droplets of blood to form |
| **Pediatric Dose** | Administer as in adults |
| **Contraindications** | Documented hypersensitivity; eczema or atopic dermatitis and other acute, chronic, or exfoliative skin conditions; diseases, drugs, or conditions that cause immunodeficiency or immunosuppression; pregnancy and household contacts of pregnant women; infants <1 y; Note: No contraindications exist if patient was exposed to smallpox; contraindications exist only when vaccinating those without exposure |
| **Interactions** | None reported |
| **Pregnancy** | Usually safe but benefits must outweigh the risks. |
| **Precautions** | Do not administer IM, IV, or SC; may cause rash (rare), fever, myalgias, or headache; soreness may occur at injection site; rare severe reactions include eczema vaccinatum, progressive vaccinia, or postvaccinal encephalitis; based on past experience, deaths due to severe reactions are estimated to occur in 1 person per million following primary vaccination and 1 person per 4 million for revaccination; vaccinia immune globulin IV is available from the CDC to treat extensive lesions following implantation, vaccinia necrosum, ocular exposure, eczema vaccinatum, and generalized vaccinia |

# Measles

## Introduction

An acute highly infectious disease of childhood caused by a specific virus of the group myxoviruses. It is associated with high mortality and morbidity in developing countries (1).

### History

The first scientific description of the disease and its distinction from smallpox is attributed to the Persian physician Ibn Razi (Rhazes) 860-932 who published a book entitled "Smallpox and Measles". In 1954, the virus causing the disease was isolated from an 11-year old boy from the US, David Edmonston, and adapted and propagated on chick embryo tissue culture(2). To date, 21 strains of the Measles virus have been identified (3). Licensed vaccines to prevent the disease became available in 1963.

## Burden of the disease

### World

While Measles is now rare in many industrialized countries, it remains a common illness in many developing countries. More than 20 million people are affected each year by Measles. In 2005, it was estimated that there were 345 000 Measles deaths globally : this translates to about 945 deaths every day; 39 people die every hour from Measles. The primary reason for continuing high childhood Measles morbidity and mortality is the failure to deliver at least one dose of Measles vaccine to all infants. According to the World Health Organization (WHO), Measles is a leading cause of vaccine preventable childhood mortality. It is virtually endemic in all parts of the world. Before the vaccine became available in the 1960s, Measles killed between 7-8 million children in a year and caused an estimated 135 million cases (4). Today it still kills about 1million children of the estimated 30 million who get Measles. Africa and Southeast Asia continue to experience endemic transmission and high mortality rates, despite a global mortality reduction of 39% between 1999 and 2003(5).

### India

Table - 1 : Estimated Measles deaths by World Health Organization (WHO) region, 2005

| WHO Region | Cases |
|---|---|
| Africa | 126000 |
| Americas | <1000 |
| Eastern Mediterranean | 39000 |
| European | <1000 |
| South East Asia | 174000 |
| Western Pacific | 5000 |
| **Total** | **345000** |

In India Measles is a major cause of morbidity and a significant contributor to childhood mortality. However with the increase in immunization coverage levels, the intervals between cyclical peaks have increased and the intensity of peaks minimized. After the implementation of UIP, the numbers of cases have come down from 2. 47 lakhs to 51700 during the year 2001(6). Out of the 51546 cases reported of Measles in 2004, 140 had died in the country.

## Armed Forces

Hospital admission due to Measles as a percentage of total admission (less members of MNS) in 2005 and 2006 was 0. 09% and 0. 06 % respectively (7).

There has been an overall decrease in hospital admission due to Measles (Rate per 1000) in combined cadets and recruits.

## Epidemiology

Measles is one of the most contagious infectious diseases. The epidemiology of Measles is markedly affected by population size, density, movement and social behaviour. In the absence of vaccination the disease infects essentially everyone at some time during life except in some isolated populations (8). Mathematical models suggest that in a totally susceptible population the average case of Measles may result in transmission of Measles to 12-18 persons (9). Thus it is estimated that the immunity level needed to interrupt transmission is on the order of 94 percent or higher.

### Agent

Measles virus (MV) is an enveloped, nonsegmented negative-stranded RNA virus of the Paramyxoviridae family (10). It is very sensitive to acid conditions, drying and light but can survive well in aerosolised droplets. Three membrane proteins appear to play a critical role in the pathogenesis. The hemaagglutinin protein (H), which projects from the virion, attaches to cell surfaces. The fusion (F) protein allows cell to cell spread. Finally the Matrix M protein, associated with inner surface of viral envelope, appears to be important for successful generation of viral particles. Abnormalities in the synthesis of these proteins have been postulated to play an important role in the pathogenesis of SSPE (11).

Source of infection is a case and a subclinical case (1). Period of communicability is appoximately 4 days before and 5 days after the appearance of rash.

### Host

Children in the age group 6 months to 3 years of age in developing countries and over five years in developed countries are commonly affected. One attack of Measles confers life long immunity. A review of the community based studies of published Measles outbreak investigations found a median case-fatality ratio of 3. 7% (range 0 to 23. 9%). (12).

### Envionmental Factors

Although the reasons for the severity of infection in the developing world are still debated, two possible reasons stand out (13) :

**Overcrowding**

Measles is very contagious; up to 90% of non immune people who come in contact with a case will be infected. Transmission rates are therefore high in areas of overcrowding. Secondary cases resulting from household contact are also more severe- in one epidemic, case fatality was 23% for secondary cases Vs 1% for the first household case; 85 % of the deaths were due to secondary household infections.

**Malnutrition**

Cellular immunity is very important for the host's response to the Measles virus. Since this is impaired in the severly malnourished child, poverty and malnutrition predispose to severe and persistent infections.

**Transmission**

The Measles virus is a highly contagious airborne pathogen which spreads primarily via the respiratory system. The virus is transmitted in respiratory secretions, and can be passed from person to person via aerosol droplets containing virus particles, such as those produced by a coughing patient. Once transmission occurs, the virus infects the epithelial cells of its new host, and may also replicate in the urinary tract, lymphatic system, conjunctivae, blood vessels, and central nervous system (14).

**Pathogenesis**

The virus infects and lyses epithelial cells of the respiratory and GI tracts, leading to secondary bacterial pneumonia and enteropathy that further produces malnutrition. It also attacks and depreses the immune system encouraging the secondary infections and reactivation of dormant pathogens. Death occurs from chest and CNS complications.

**Clinical features**

Incubation period is commonly 10 days from exposure to onset of fever, and 14 days to onset of rash. The classical symptoms of Measles include a fever for at least three days, and the three Cs-Cough, coryza (runny nose) and conjunctivitis (red eyes). The fever may reach up to 104˚ Fahrenheit/ 40˚ Celsius. Koplik's spots seen inside the mouth are pathognomonic (diagnostic) for Measles but are not often seen, even in real cases of Measles, because they are transient and may disappear within a day of arising. **Koplik's spots** are small, irregular, red spots with a minute bluish white speck in the center of each seen on the buccal mucosa and lingual mucosa (mucous membrane of the inside of the cheek and tongue) and are pathognomonic of early stage Measles. They are named after Henry Koplik (1858-1927), an American pediatrician who first described them in 1896. The characteristic Measles rash is classically described as a generalized, maculopapular, erythematous rash. It starts on the head before spreading to cover most of the body, often causing itching. The rash is said to "stain", changing colour from red to dark brown, before disappearing. Measles infection during pregnancy is asssociated with spontaneous abortion and with delivery of low birth weight infants(14). Time course of Measles infection is described as under(13) :

**Complications**

(a) Pneumonia most common cause of death. Caused by Measles virus or secondary bacterial infections (16).
(b) Otitis media
(c) Laryngitis both secondary bacterial and viral
(d) Sore mouth- decreases feeding in infant
(e) Corneal ulceration and Keratomalacia (secondary HS infection) leading to blindness (exacerbated by Vitamin A deficiency)
(f) Diarrhea(+/- tenesmus, blood) leading to dehydration and malnutrition
(g) Hemorrhagic Measles with purpuric rash and mucosal hemorrhage (rare but fatal)

CNS Complications

Febrile convulsions are the most common. Encephalitis occurs in three forms :

(a) Acute post infectious Measles encephalitis
(b) Acute progressive encephalitis
(c) Subacute Sclerosing panencephalitis is a rare complication. Slow progressive disease over months with subtle changes in personality and intellect due to continuing infection; later myoclonic jerks, chorioathetosis, ataxia, coma, focal retinitis. There is no specific treatment.

**Diagnosis**

Clinical diagnosis of Measles requires a history of fever of at least three days together with at least one of the three Cs. Observation of Koplik's spots is also diagnostic of Measles. Alternatively, laboratory diagnosis of Measles can be done with confirmation of positive Measles IgM antibodies or isolation of Measles virus RNA from respiratory specimens. In cases of Measles infection following secondary vaccine failure IgM antibody may not be present. In these cases serological confirmation may be made by showing IgG antibody rises by Enzyme immunoassay or complement fixation. Positive contact with other patients known to have Measles adds strong epidemiological evidence to the diagnosis. Histologically, a unique cell can be found in the paracortical region of hyperplastic lymph nodes in patients affected with this condition. This cell, known as the Warthin - Finkeldey cell, is a multinucleated giant with eosinophilic cytoplasmic and nuclear inclusions.

**Management**

(a) Give Vit A 200, 000IU immediately and repeat on next day. There is evidence that vitamin A supplementation in children is associated with a reduction of 23% to 30% in mortality risk and

attenuation in the severity of Measles and diarrhoea (17).

(b) Give topical antibiotics

(c) Chloramphenicol eye drops 6 hourly

(d) Symptomatic hydration and nutrition

(e) Secondary infections can be prevented by antibiotics. It decreases mortality in an epidemic

**Hospital admission**

| | Degree of severity of infection | | | |
|---|---|---|---|---|
| | Severe | Mod/Sev | Moderate | Mild |
| **Oral lesions** | | | | |
| Buccal mucosa | + | + | + | + |
| Gingiva | + | + | +/- | - |
| Tongue/palate | + | + | - | - |
| Haemorrhagic | + | - | - | - |
| **Rash** | | | | |
| Haemorrhagic | + | - | - | - |
| Confluent | + | + | - | - |
| Desqumating | + | +/- | - | - |
| Widespread | - | - | + | - |
| Scattered | - | - | - | + |
| **Systemic upset** | | | | |
| Bronchopneumonia | + | + | - | - |
| Cough | + | + | + | - |
| Coryza | + | + | + | + |
| Diarrhoea | + | + | + | - |
| Bloody diarrhoea | + | - | - | - |
| | | | | |

During an epidemic, decide which clinical signs should determine whether a patient is ill enough to warrant admitting to hospital. The following criteria were used by Lamb in a Gambian epidemic to grade severity of illness (18).

Other signs that may warrant admission include :

(a) Severe mouth or skin ulceration

(b) Corneal ulceration

(c) Convulsions/LOC

(d) Laryngeal obstruction

(e) Marked dehydration

If the child is malnourished or underweight, these signs should be considered with greater seriousness.

**Prevention**

Measles vaccination

A number of live, attenuated Measles vaccines are available, either as single-antigen vaccines or in combination with either rubella or mumps and rubella vaccines. When the combined MR or MMR vaccines are used, the protective immune response to each of the components remains unchanged. A killed Measles vaccine was licensed in 1963, but was withdrawn after a few years because of frequent association with high fever and severe atypical pneumonia following subsequent exposure to Measles virus (19).

**Measles vaccine strains**

Most of the live, attenuated Measles vaccines used now originate from the Edmonston strain of Measles virus isolated by Enders and Peebles in 1954.

**Age at immunization**

The recommended age for Measles vaccination depends on the local Measles epidemiology as well as on programmatic considerations. In most developing countries, high attack rates and serious disease among infants necessitate early vaccination, usually at 9 months of age, despite the relatively low (80 - 85%) seroconversion rates following vaccination in this age group. HIV-infected infants should receive Measles vaccine at 6 months of age, followed by an additional dose at 9 months. Asymptomatic HIV infection is an indication, not a contraindication, for Measles vaccination. In most industrialized countries, Measles vaccination may be deferred until a child is 12-15 months old, when seroconversion rates in excess of 90% may be expected. To ensure optimum population immunity, all children should be given a second opportunity for Measles immunization. Although generally administered at school entry (age 4-6 years), the second dose may be given as early as one month following the first dose, depending on the local programmatic and epidemiological situation.

In countries with Measles elimination goals, a one-time only Measles Supplemental Immunization Activities (SIA) (20, 21, 22, 23) should be considered, targeting all children aged 9 months to 14 years, regardless of disease history or previous vaccination status. Efforts are also needed to target specific groups of young adults who may be at increased risk for Measles infection, including military recruits, university students, health care workers, refugees and international travellers to Measles endemic areas. Efforts to eliminate Measles require careful surveillance, including the capacity for laboratory confirmation of suspected Measles cases.

**Vaccine characteristics**

The vaccine is very sensitive to sunlight, hence the need to keep it in coloured glass vials; following reconstitution, the vaccine must be stored in the dark at 2-8°C and used within 6 hours. Measles vaccine is generally injected subcutaneously but is also effective when administered intramuscularly. Each dose of 0. 5 ml contains at least 1000 infective units of the vaccine virus; this is also true when it is combined with mumps and/or rubella vaccines.

**Immunity**

The vaccine induces both humoral and cellular immune responses comparable to those following natural infection, although the serological titres are usually lower. IgM, IgG and IgA antibodies may be detected in both serum and nasal secretions, and IgG persists for many years. The concentration and persistence of maternal antibodies differ in infants of women vaccinated against Measles versus infants of naturally immune women (24).

**Adverse reactions**

Slight pain and tenderness at the site of injection may occur within 24 hours, sometimes followed by mild fever and local lymphadenopathy. About 7-12 days after vaccination, up to 5% of Measles vaccine recipients may experience fever of at least 39. 4 ˚C for 12 days. Thrombocytopenia purpura occurs in approximately 1 in 30 000 vaccinated individuals. Toxic shock syndrome (TSS) occurs when Measles vaccine is contaminated or the same vial is used for more than one session on the same day or next day.

**Combined vaccine**

Measles vaccine can be combined with other live attenuated vaccines such as mumps, and rubella vaccines (MMR vaccine) and such combinations are also highly effective.

Immunoglobulin

Measles may be prevented by administration of immunoglobulin (human) early in the incubation period. The dose recommended by WHO is 0. 25 ml per kg of body weight. It should be given within 3-4 days of exposure. The person passively immunized should be given live Measles vaccine 8-12 weeks later. The need for immunoglobulin is now much reduced because of the availability of an effective live attenuated vaccine.

**Public Health aspects**

Measles, in spite of available vaccination, remains a heavy public health burden worldwide especially in developing countries. Of the deaths attributable to Measles, 98 per cent occur in developing countries (25). The recent Measles outbreak in UK (London)(26), Australia (Victoria)(27), Japan (Tsu)(28), India (Orissa, Chandigarh) (29) and other places highlights the worldwide rise in Measles infection and the challenge to meet the goal of Atlanta Declaration for reducing the disease and disease associated mortality by half by the year 2005. To achieve the goal of Measles elimination vaccination coverage must be increased (30, 31). Availability of health workers can be a major constraining factor on vaccination coverage in developing countries (32). However, great progress in Measles control has been made in resource-poor countries through accelerated vaccination (33). Interepidemic period, which corresponds to the interval between major epidemics of Measles, increases as the vaccination ratio increases(34). The global elimination of Measles has been debated since Measles vaccines were first licensed in the 1960's, and this debate is likely to be renewed if polio virus is eradicated (35).

**Current status of implementation of Measles control strategies in India**

Under the Universal Immunization Programme started in 1985, all States in the country give a dose of Measles containing vaccine to children aged 9-12 months. The coverage is variable between states and within the states even in the good performing states there are districts which have medium to low coverage. The absolute number of children dropping out between BCG and Measles is 6. 26 million (12).

Plan of action 2005-2010

The Multi year strategic plan of the government of India addresses the issue of reducing the Measles mortality by two-thirds by 2010, compared to 2000 estimates. The plan emphasizes on achieving at least 90% coverage in 80% of the districts of the country by 2009 and collection and use of good quality epidemiological data from active surveillance and outbreak investigation to guide further action.

Key Strategies

(a) Achieving high routine Measles vaccination coverage of infants at 9-12 months of age; provide Measles vaccine to the children over 1 year if not vaccinated earlier at the earliest contact.

(b) Effective Measles surveillance that provides information at a minimum; about number of cases and deaths by month. This is supported by good quality outbreak investigation confirmed through laboratory investigations & which capture parameters like age and vaccination status of cases and deaths.

(c) Improving management of Measles cases, including vitamin A supplementation and adequate treatment of cases.

(d) Based on evaluated Measles immunization coverage and surveillance data, providing a second opportunity for Measles immunization to appropriate age groups of children through either a second routine dose of Measles vaccine or through supplemental immunization activities.

**Vaccination strategy in developed nations**

In developed countries, most children are immunized against Measles at the age of 18 months, generally as part of a three-part MMR vaccine (Measles, mumps, and rubella). The vaccination is generally not given earlier than this because children younger than 18 months usually retain anti-Measles immunoglobulins (antibodies) transmitted from the mother during pregnancy. A "booster" vaccine is then given between the ages of four and five. Vaccination rates have been high enough to make Measles relatively uncommon.

**Measles and Millennium Development Goals**

Combining Measles immunization with other health interventions is a contribution to the achievement of Millennium Development Goal Number 4 : a two-thirds reduction in child deaths between 1990 and 2015.

**Action during disasters**

During disaster management disturbed social conditions are present and a large number of children with low

nutritional status who were either partially immunized or not immunised lived together in close contact at the camp setting (36). In a high-risk situation prevailing at the camp site with children residing in close contact to each other, immunization of children even between 6 and 9 months of age is also recommended (37). The general principle for managing outbreak of respiratory group of diseases is to isolate the cases and keep the contacts under surveillance till the longest incubation period of the disease.

**Exanthema**

- Measles (1st disease)
- Scarlet fever (2nd disease)
- Rubella (3rd disease)
- Duke's disease (4th disease)
- Slap cheek (5th disease)

# Rubella

## Introduction

Rubella, commonly known as German measles, is a contagious infectious disease caused by an RNA togavirus of the genus Rubivirus (1). It is usually a mild and self limiting illness which has assumed importance because of its ability to induce congenital defects in infants of women who acquire rubella during pregnancy.

### History

All the physicians (Friedrich Hoffmann, de Bergen, Orlow, George de Maton, who carried out initial work on rubella were German, and the disease was known medically as Rötheln (from the German name Röteln), hence the common name of German measles was given(2, 3). Norman McAllister Gregg found 78 cases of congenital cataracts in infants and 68 of them were born to mothers who had caught rubella in early pregnancy(4, 5).

### Occurrence

In temperate climates, rubella is endemic year-round, with a regular seasonal peak during springtime. In tropical areas, rubella is widespread. Before the advent of rubella vaccination, major epidemics of rubella tended to occur at 6 to 9 year intervals (6). Despite the marked drop in incidence, it is estimated that upto 15 percent of adolescents and young adults remain susceptible. Transmission of rubella has continued to occur in the postpubertal population, with more than half of all cases occurring among persons 20 years of age or older in recent years.

## Transmission

Humans are the only known reservoir. Rubella is highly communicable but less so than measles or varicella. Virus is transmitted by the respiratory route, and infection usually occurs as a result of contact with nasopharyngeal secretions of infected persons by droplet spread. Primary rubella infection induces lifelong immunity.

## Clinical Characteristics (7)

### Postnatal Infection

Rubella is an acute, mild disease in children and young adults. The first symptoms occur after an incubation period ranging from 14 to 21 days. Communicability begins about 7 days before the onset of rash and persists at least 4 days after rash onset. Infectivity is greatest when the rash is erupting (8). The cardinal manifestations of the disease are a nonspecific maculopapular rash lasting 3 days or less (hence the term "3 day measles") and generalized lymphadenopathy, particularly of the postauricular, suboccipital, and posterior cervical lymph nodes. However, asymtomatic infections are common : upto 50 percent of infections occur without rash (6), and cases without enlargement of lymph nodes have been documented (9). Rash which is often the first sign of illness, appears first on the face and then spreads downward rapidly to the neck, arms, trunk and extremities; pruritus is not unusual. In adolescents or adults, the rash may be preceded by a 1 to 5 day prodrome of low-grade fever, headache, malaise, anorexia, mild conjunctivitis, coryza, sore throat, and lymphadenopathy. The manifestations rapidly subside after the first day of the rash. Exanthems comparable to that observed with rubella infection have been described in infections with echovirus and coxsackie virus, fifth disease (parvovirus), other enteroviral infections, and mild measles; these infections, however, are not commonly associated with postauricular or suboccipital adenopathy.

### Prenatal Infection

The major disease burden of rubella virus is congenital infection. Primary rubella infection during pregnancy, whether clinical or subclinical, carries a significant risk of fetal infection. Congenital rubella syndrome is often associated with a disseminated and chronic infection that may persist throughout fetal life and for many months after birth. Spontaneous abortion, stillbirth, or CRS can result from chronic infection and inhibition of cell multiplication in the developing fetus. Delayed and deranged organogenesis and hypoplastic organ development lead to the characteristic structural defects. Transplacental infection is not always reflected by immediately apparent disease; upto 50 to 70 percent of infants with congenital rubella infection may appear normal at birth. Deafness is commonly diagnosed later when it is the sole manifestation.

Congenital infection is not inevitable, however, and the fetal response to infection is not uniform; the **gestational age** of the conceptus at the time of primary maternal infection is the principal factor influencing the outcome of pregnancy. The risk of CRS as a consequence of maternal infection in the first trimester may be as high as 85 percent(7) but the risk decreases sharply after the eighth week and is absent after the twentieth week of gestation.

## Complications

Although rubella is a mild disease in children, it may be more significant with complications in adults. Arthralgia and arthritis may occur in adults, particulary women, at a reported rate as high as 70 percent. Joint involvement usually occurs after the rash fades and typically lasts 5 to 10 days. Rare complications include optic neuritis, thrombocytopenic purpura, and myocarditis. Postinfectious encephalitis of short duration may occur 1 to 6 days after the appearance of rash; its incidence rate is estimated at 1 in 5, 000 to 16, 000 cases.

## Diagnosis

Clinical diagnosis is often unreliable, because symptoms (including rash) are absent in up to one-half of persons infected with rubella. A history of exposure to rubella may be helpful in the absence of the full complement of clinical signs and symptoms. Culture of virus is difficult and not widely available. Serologic confirmation remains the definitive means of diagnosing rubella. Antibodies to the virus (initially, both IgM and IgG) appear after the onset of illness. IgM antibodies generally do not persist more than 4 to 5 weeks after the onset of illness, whereas IgG

antibodies usually persist for the lifetime of the patient. Many rubella antibody assay methods are available, such as enzyme-linked immunosorbent assay (EIA), latex agglutination (LA), and fluorescent immunoassay (FIA). Approximately 90 percent of all neonates with congenital rubella infection have virus in most of their accessible extravascular fluids (e. g, cerebrospinal fluid, tears, urine) and in the posterior portion of the oropharynx. Because IgM antibody normally does not cross the placenta, the presence of rubella-specific IgM antibody in cord blood is evidence of congenital infection. The presence and persistence of rubella-specific IgG postpartum at higher levels than expected (the half-life of maternal antibodies is one month) are also suggestive of intrauterine infection.

**Congenital rubella Syndrome (CRS)**

Congenital rubella infection and CRS are caused by infection in early pregnancy. From just before conception and during the first 8-10 weeks of gestation, rubella infection may result in multiple fetal defects in up to 90% of cases, and often results in miscarriage or stillbirth. The risk subsequently declines. Fetal defects are rarely associated with maternal rubella after the 16th week of pregnancy, although sensorineural hearing deficit may occasionally occur up to 20 weeks. Studies indicate that in India 40% of the women of child bearing age are susceptible to rubella (10).

**Manifestations of congenital rubella infection**

(a) Spontaneous abortions
(b) Stillbirths
(c) Bone lesions
(d) Cardiac defects
  (i) Patent ductus arteriosus
  (ii) Pulmonary stenosis and coarctation
  (iii) Myocardial necrosis
(e) CNS defects
  (i) Encephalitis
  (ii) Mental retardation
  (iii) Microcephaly
  (iv) Progressive panencephalitis
  (v) Psychomotor retardation
  (vi) Spastic quadriparesis
(f) Hearing impairment (deafness)
(g) Endocrinopathies
  (i) Adrenal disorders
  (ii) Diabetes mellitus
  (iii) Precocious puberty
  (iv) Growth retardation
  (v) Growth hormone deficiency
(h) Eye defects
  (i) Cataracts
  (ii) Glaucoma
  (iii) Microphthalmos
  (iv) Retinopathy
(j) Genitourinary defects
(k) Hematologic disorders
  (i) Anaemia
  (ii) Thrombocytopenia
  (iii) Immunodeficiencies
(l) Hepatitis
(m) Interstitial pneumonitis
(n) Psychiatric disorders

**Prevention**

The primary purpose of rubella vaccination is to prevent the occurrence of congenital rubella infection including CRS. Two approaches are recommended (11) :

(a) Prevention of CRS only, through immunization of adolescent girls and/or women of childbearing age; or
(b) elimination of rubella as well as CRS through universal vaccination of infants and young children (with/ without mass campaigns), surveillance, and assuring immunity in women of childbearing age. The currently licensed rubella vaccines in wide international use are based on the live attenuated RA 27/3 strain of the virus. The 27/3 vaccines are propagated in human diploid cells and have proven to be safe and efficacious. Rubella vaccines are commercially available in a monovalent form, a bivalent combination with measles vaccine or mumps vaccine, or as trivalent measles-mumps-rubella vaccine (MMR).

When immunization is targeted at adolescent girls or women of childbearing age, the epidemiology of rubella is largely unaffected since most infections occur before the age at immunization. With such an approach, the incidence of CRS declines linearly with the level of coverage. However, elimination of CRS cannot be achieved with this strategy, in part because it would require every susceptible woman to be effectively immunized.

Childhood immunization of both sexes reduces the number of infections and extends the interepidemic interval by reducing the circulation of rubella virus in the community. Hence, one consequence of a childhood-only immunization programme may be an increase in the proportion of susceptibles in the adult population. The higher the vaccination coverage, the more apparent this effect will be. This shift in the proportion of susceptibles in older age groups can result in more cases of CRS than in the prevaccination period.

Countries undertaking measles elimination should consider taking the opportunity to eliminate rubella as well, through use of MR or MMR vaccine in their childhood immunization programmes, and also in measles campaigns. All countries undertaking rubella elimination should ensure that women of childbearing age are immune and that routine coverage in children is sustained >80%.

If the health care system cannot reach a substantial

proportion of women of child bearing age, initial emphasis might be placed on interrupting transmission while attempting to reach as many of the risk population as possible (12).

MMR Vaccine

It's a live attenuated vaccine

**Contents :** each 0. 5 ml contains Measles (100 TCID) 50, Schwartz strain) Mumps (5000 TCID 50, Urabe AM-9), Rubella (1000 TCID 50, Winsrar RA/3M) cultured on human diploid cells.

**Dose and route :** 0. 5ml S/C single dose, upper arm or thigh.

**Age :** 15-18 months. If not given at this age, all girls should be immunized at any age.

**Storage :** 2-8 $^{0}$C.

**Adverse effects :**

(a) Mild fever in 5-15%

(b) Rash 5% (5-7 days after vaccination)

(c) Lymphadenopathy.

(d) Arthralgia/arthritis-10-21 days after vaccination. Occurs uncommonly in children but more frequently in post-pubertal females with a frequency of 25% and 10% respectively.

(e) Transient peripheral paresthesia and pain in the arms and legs-rarely.

**Complications** due to measles are very rare; SSPE, toxic shock syndrome and convulsions.

Efficacy induces Ab in 99% of recipients and has protective efficacy in 90%

**Contraindictions :**

(a) Pregnancy (women vaccinated with MMR should avoid pregnancy for 3 months)

(b) Allergy to a vaccine component

(c) Immunodeficiency

(d) Moderate or severe acute illness with or without fever

(e) Recent immune globulin administration

### Rubella

- Rubella is an infection caused by a virus.
- Rubella is normally a mild childhood disease, but women who get rubella early in pregnancy can pass the virus on to their fetuses. This is called congenital rubella syndrome (CRS).
- A rash is the most prominent symptom of rubella, especially in children. Complications from rubella are rare. But complications from CRS are more serious and include deafness, cataracts, and mental retardation. Rubella vaccines are safe and effective. But because conditions vary greatly from country to country, there is no universal recommendation on the use of vaccines.
- If countries immunize against rubella, they generally use a combination vaccine that also guards against measles (MR) or measles and mumps (MMR).
- It is important to ensure that coverage in infants is sustained at over 80% to avoid the shifting of rubella

### Rubella Vaccine

- Type of vaccine - Live attenuated viral
- Number of doses - One dose
- Schedule - Generally 12-15 months
- Booster - A second opportunity for immunization is recommended ( routine or campaign )
- Contraindications - Severe reaction to previous dose; pregnancy; congenital or acquired immune disorders (not HIV infection). Although it is not recommended to administer the vaccine during pregnancy, there has never been any evidence of damage to the fetus from vaccinating the mother during pregnancy
- Adverse reactions - Same as measles vaccine, plus cases of arthritis in adolescent females for rubella-containing vaccine and parotitis; rarely aseptic meningitis with mumps- containing vaccines may occur
- Special precautions - None
- Dosage - 0.5ml
- Injection site - Outer mid-thigh/upper arm depending on the age
- Injection type - Subcutaneous

# Diphtheria

## Introduction (1)

Diphtheria is an acute infectious disease caused by toxigenic strains of Cornybacterium diphtheria. The bacilli multiply locally and elaborate a powerful exotoxin which is responsible for

(a) Formation of a grayish yellow membrane ("false membrane") commonly over tonsils, pharynx or larynx (or at the site of implantation) with well defined edges and the membrane cannot be wiped away.

(b) Marked congestion, edema and local tissue destruction.

(c) Enlargement of lymph nodes.

(d) Signs and symptoms of toxemia.

The infection is typically that of upper respiratory tract; the sites most commonly affected are fauces, nasal mucosa, pharynx and larynx; but it may occur in any tissue. The second important though less common site is the skin (2).

| Causes of Sore Throat (3) |
|---|
| Streptococcus pyogens (rheumatic heart disease and glomerulonephritis) |
| Mild viral infections |
| Corynebacterium diptheriae |
| Epstein Barr virus |
| Neisseria gonorrhoeae |
| Secondary syphilis |

### History

The word diphtheria means pair of leather scrolls , Aretaeus, the Cappodocian in second century, described the Egyptian or Syriac ulcer, which most medical historians agree can be identified as diphtheria (4). The disease was first recognized as a clinical entity by Bretonneau who called it 'diphtherite'. The name is derived from the tough, leathery pseudomembrane formed in the disease (diphtheros, meaning leather). It is also known by the name of strangling angel of children (5). The diphtheria bacillus was first discovered by Klebs(1883), but was cultivated by Loeffler(1884)(6,7). It is hence known as Klebs- Loefler bacillus.

### Geographical Distribution

Diphtheria occurs in all parts of the world, but it is mainly a disease of temperate climate (8). Diphtheria is endemic in many parts of the world, including countries of the Caribbean and Latin America. During the last 10 years, large epidemics of diphtheria have occurred in the former Soviet Union, where formerly, diphtheria had been well controlled. The largest outbreak of diphtheria in the developed world occurred from 1990-1995 throughout the states of the former Soviet Union. Since 1994, with the initiation of aggressive immunization efforts, the number of reported cases has decreased. A feature of these epidemics concerns the age group; most cases have occurred among adolescents and adults, rather than children.

| 2005 Global figures |
|---|
| 8,229 reported cases |
| 5000 estimated deaths |
| 78% estimated DPT3 coverage |
| 29% of countries reached >=80% DPT3 coverage in all |

### India

The reported incidence of diphtheria in the country during 1987 was about 12,952 whereas during the year 1999, there were only 2,725 cases showing a decline of about 79 %( 9). It is still endemic in our country (1). The last decade has seen resurgence of diphtheria in both developed and developing countries where it was previously well controlled (10). Low or declining routine immunization coverage, as well as naturally waning of immunity against diphtheria are major factors for endemicity or even resurgence of diphtheria. This is a matter of concerned for all public health professionals. It occurs more in cities than in the rural areas, and more in dry areas than wet. Several studies carried out over last 30 years at different places in this country also reported that diphtheria occur more frequently during the month of August to November (11-14).

### Armed Forces

Diphtheria is not an important cause of sick wastage in the Armed Forces and the incidence is low.

### Epidemiology

The causative organism, Corynebacterium diphtheria, is a gram positive, non-motile organism. Three types of diphtheria bacilli are differentiated-gravis, mitis and intermedius. There are both virulent & avirulent strains of diphtheria bacilli. The avirulent strains do not produce exotoxin. The toxin, which is a protein, has been isolated in crystalline form. The virulence of C. diphtheria is conditioned by the presence of one or more bacteriophages(15). Man is the only reservoir of infection (1).

### Carrier State

Diphtheria carriers are the usual cause of clinical cases. They may be temporary or chronic carriers; nasal or throat carriers. The nasal carriers are particularly dangerous as source of infection since they shed more organisms into the environment than do throat carriers. The temporary carrier state may last for about a month, but the chronic carrier state may persist for a year or so.

### Source

A case of clinical diphtheria is highly infectious, but being usually isolated in hospital (or at home) becomes a less important means of spreading the disease. Sub-clinical cases, which are frequently missed, are an important source of infection. The healthy 'carrier' is, however, a particularly important cause of outbreaks in close communities such as the Armed Forces units, schools and other residential institutions. In schools a 'carrier epidemic' often precedes the clinical epidemic.

### Mode of Transmission

The mode of transmission may be droplets, direct contact or indirect contact. The droplet route is the most important mode of spread of diphtheria in the Armed Forces. The greater the overcrowding in barracks the higher is the probability for infection of a susceptible individual. Among children direct contact as in kissing or close fondling is an important route of transmission of infection from adult carriers. Quite commonly older children bring the infection home from their schools and transmit it to younger ones. Indirect transmission, especially by putting in their mouths, toys or pencils which may have been sucked by a 'carrier' child, also plays an important part. Outbreaks have also been recorded from milk infected by a 'carrier' or a mild case.

### Host

Diphtheria is primarily a disease of children. Infants born of immune mothers derive maternal antibodies which protect them during the first few months of life against diphtheria. Recovery from clinical attack is not always followed by lasting immunity. Immunity is often acquired through an in apparent infection. Schick test surveys in India have revealed that 70 per cent of children over the age of 3 years, and 99 percent over the age of 5 years are already immune to diphtheria.

#### Incubation Period

The incubation period is usually 2 to 6 days, occasionally may be longer.

#### Communicability Period

The period of communicability is variable. It is usually two weeks or less but seldom more than 4 weeks; carriers may remain infective much longer.

### Clinical features

#### Tonsils and pharynx

Tonsillar and pharyngeal diphtheria are most common; symptoms begin with a sore throat, usually in the absence of systemic complaints. Fever, if it occurs, is usually lower than 102°F, and malaise, dysphagia, and headache are not prominent features.

(a) In individuals with diphtheria infection who are not immune, membrane formation begins after the 2-5 day incubation period and grows to involve the pharyngeal walls, tonsils, uvula, and soft palate. The membrane may extend to the larynx and trachea, causing airway obstruction and eventual suffocation.

(b) Underlying tissue of the throat and neck becomes edematous, and lymphadenopathy develops. Marked edema of the neck may lead to a bull-neck appearance with a distinct collar of swelling; the patient throws the head back to relieve pressure on the throat and larynx. Erasure edema associated with pharyngeal diphtheria obliterates the angle of the jaw, the borders of the sternocleidomastoid muscle, and the medial border of the clavicles. Swallowing may be made difficult by unilateral or bilateral paralysis of the muscles of the palate.

(c) If toxin production is unopposed by antitoxin and severe disease occurs, early localized signs and symptoms give way to circulatory collapse, respiratory failure, stupor, coma, and death.

(d) **Larynx:** In a minority of patients, the larynx is the initial site of infection, with initial presenting symptoms similar to laryngotracheobronchitis from other causes. Initial hoarseness may progress to loss of voice and severe respiratory tract obstruction. Initially, nasal diphtheria may present as a common viral upper respiratory tract infection. A foul odor may develop. This form of diphtheria is most common in infants.

(e) **Skin:** Cutaneous diphtheria may occur at one or more sites, usually localized to areas of previous mild trauma or bruising. It is more common in tropical climates, but outbreaks have occurred in the United States. Pain, tenderness, and erythema at the site of infection progress to ulceration with sharply defined borders and formation of a brownish gray membrane. Local disease may persist for weeks to months.

(f) **Other sites:** Additional sites of infection have included the external ear, the eye (usually the palpebral conjunctivae), and the genital mucosa. Rare sporadic cases of endocarditis have been reported, usually due to nontoxigenic strains. Septicemia caused by C diphtheriae is rare but universally fatal.

### Complications

Respiratory tract obstruction occurs due to swelling and sloughing of pseudomembrane. Myocarditis (dysrhythmias, conduction disturbances and cardiomyopathy) is seen in almost one quarter of hospitalized patients; those who die usually do so within 4 or 5 days. Polyneuropathy occurs 3-5 weeks after diphtheria and follows an indolent course. Pneumonia develops in more than half of patients who succumb to diphtheria (16).

### Diagnosis

An appropriate microbiological diagnosis is crucial and is always regarded as being complementary to clinical diagnosis (17). Diagnostic tests used to confirm infection combine isolation of C diphtheriae on cultures with toxigenicity testing. Bacteriologic culturing is essential to confirm the diagnosis of diphtheria.

#### Schick test

The intracutaneous skin test introduced by Schick in 1913 that enables us to distinguish between individuals who are susceptible and those who are resistant (i.e., immune) to diphtheria toxin and to test for sensitivity to toxoid details in Table - 1. The test is based on the following empirical findings:

(a) Intracutaneous injection of 1/50 MLD (minimal lethal dose) (for a guinea pig) of diphtheria toxin produces a strong, but tolerable, reaction in individuals having no antitoxin.

(b) Individuals having 1/30 unit or more of antitoxin per ml of blood neutralize this test dose and show no reaction. Such individuals are also usually resistant to diphtheria.

The Schick test is a simple screening device helpful in the assessment of immunocompetence (18).

**Treatment**

The CDC recommends either:

(a) Erythromycin (orally or by injection) for 14 days (40 mg/kg per day with a maximum of 2 g/d), or

(b) Procaine penicillin G given intramuscularly for 14 days (300,000 U/d for patients weighing <10 kg and 600,000 U/d for those weighing >10 kg). Patients with allergies to penicillin G or erythromycin can use rifampicin or clindamycin.

**Preventive Measures**

The control of diphtheria is based on the following three measures.

(a) Primary prevention of disease by ensuring high population immunity through immunization.

(b) Secondary prevention of spread by the rapid investigation of close contacts, to ensure their proper treatment.

(c) Tertiary prevention of complications and deaths by early diagnosis and proper management.

Avoidance of overcrowding, spacing of beds, adequate ventilation in all barracks, rooms, huts and tents and protection from cold should be ensured. Issue of charpoy and use of mosquito net augments these measures. A routine adult immunisation is not considered necessary in the Armed Forces. The most important single primary prophylactic measure in children of Armed Forces personnel is their routine immunisation by administration of triple antigen (DPT) in infancy, besides health education of families to ensure ventilation and adequate spacing in bed rooms.

Table - 1 : Reactions to schick test

| Skin response | Toxin | | Toxoid | | Interpretation |
|---|---|---|---|---|---|
| | 36 h | 120 h | 36 h | 120 h | |
| Positive reaction | - | + | - | - | Nonimmune, nonsensitive |
| Negative reaction | - | - | - | - | Immune, nonsensitive |
| Pseudo reaction | + | - | + | - | Immune, sensitive |

**WHO-recommended surveillance standard of diphtheria**

Rationale for surveillance

Diphtheria is a widespread severe infectious disease that has the potential for epidemics. Surveillance data can be used to monitor levels of coverage (target > 90%) and disease as a measure of the impact of control programmes. Recent epidemics have highlighted the need for adequate surveillance and epidemic preparedness

Recommended case definition

An illness characterised by laryngitis **or** pharyngitis **or** tonsillitis, **and** an adherent membrane of the tonsils, pharynx and/or nose

Recommended types of surveillance

(a) Routine monthly reporting of aggregated data of probable or confirmed cases is recommended from peripheral level to intermediate and central levels

(b) Designated reporting sites at all levels should report at a specified frequency (e.g. weekly or monthly) even if there are zero cases (often referred to as "zero reporting")

(c) All outbreaks should be investigated immediately and case-based data collected

(d) In countries achieving low incidence (usually where coverage is > 85-90%) immediate reporting of case-based data of probable or confirmed cases is recommended from peripheral level to intermediate and central levels

**Control action on occurrence of a case**

(a) Isolation

It should be continued until 2 cultures, taken not less than 24 hours apart (after cessation of antimicrobial therapy) from throat and nose, fail to show diphtheria bacilli; where culture is impractical, isolation may be ended after 14 days with fair degree of safety.

(b) Concurrent Disinfection

It should be carried out for naso-pharyngeal discharges, linen and cutlery used by patient and local terminal disinfection as described in Chapter 82.

(c) Notification

It should be carried out immediately including to the local heath authorities.

(d) Attendants

They should be proved Schick test negative otherwise active immunisation should be carried out.

(e) Surveillance of Contacts

(i) All intimate contacts should be segregated until nose or throat cultures are negative. All carriers should be treated with antibiotics.

(ii) Contacts who are intimately exposed and

not previously immunised with toxoid should be given first dose of toxoid and 1000-2000 units of diphtheria antitoxin as well as an appropriate antibiotic (Penicillin or erythromycin) if culture is positive. Persons previously immunised should have a booster dose of toxoid.

(iii) The contacts should be thoroughly investigated by repeated swabbing to detect any atypical cases among intimate contacts. They should be isolated and treated.

(f) Epidemic Measures

Immediate action should be taken to immunise the population group involved with emphasis on protection of infants and pre-school children. If cases continue to occur in the unit, Schick test and examination of throat swab should be carried out. The results of the throat swab and Schick test should be analysed and action as under should be taken.

(g) High incidence among school children

When incidence among children in a locality is high, all children below the age of 10 years should be immunised without any preliminary Schick test, children upto 5 years of age with triple vaccine and children over 5 years of age, with the combined diphtheria-tetanus vaccine. However, PTAP or PTAH alone can also be used if immunisation against tetanus is not required. A preliminary Schick test should be carried out when dealing with children above the age of 10 years and adults. TAF is a safer agent than PTAP or PTAH among adults.

(h) Contacts among school children

In case of contacts among school children, specially in residential schools, the following procedures are adopted :-

(i) Throat swabs of all contacts are taken and all are given 5000 units of antitoxin in one arm after sensitivity test has been carried out; the first dose of PTAP is given in the other arm.

(ii) Those showing positive swabs are segregated until virulence test shows them non-virulent. Then they are returned to the hostel / school and given the rest of the active immunisation.

(iii) Those with virulent bacilli are treated with topical and systemic antibiotics. They are returned to the hostel/ school when three consecutive swabs with interval of 3 days between each show negative result or after 14 days of the 2nd doses of antigen is given to the rest of the community, whichever is earlier. Alternatively the procedure in subpara (f) is carried out.

DPT Vaccine

- **Type of vaccine:** Diphtheria and Tetanus as toxoids. Pertussis as killed whole-cell bacterium
- **Number of doses:** At least three primary doses
- **Schedule:** 6, 10, 14 weeks of age
- **Booster:** 18 months
- **Contraindications:** Anaphylactic reaction to previous dose or to any constituent
- **Adverse reactions:** Mild local or systemic reactions are common
- **Special precautions:** DPT not usually given over 6 years of age
- **Dosage:** 0.5ml
- **Injection site:** Outer mid-thigh in infants/outer upper arm if older
- **Injection type:** Intramuscular
- **Storage:** Store between 2˚C - 8˚C. DPT vaccine should never be frozen

**DTP vaccine**

Diphtheria-tetanus-pertussis vaccine is made from diphtheria toxoid, tetanus toxoid, and pertussis vaccine. It is a liquid vaccine. If a vial of DTP vaccine stands for a long time, fine particles may separate from the liquid. They look like fine sand at the bottom of the vial. Before giving the vaccine shake the vial to mix the vaccine and liquid. DTP vaccine should never be frozen. The "Shake test" will determine if the vaccine has been damaged by freezing. If the vaccine fails the shake test you must discard it.

Usually, reactions to DTP vaccine are mild. The side-effects include:

Fever

Up to half of the children who receive DTP vaccine may have a fever in the evening after receiving the injection. The fever should disappear within a day. Note that a fever that begins more than 24 hours after a DTP injection is not likely to be a reaction to the vaccine. Administering paracetamol or any appropriate antipyretic at the time and at four and eight hours after immunization decreases the subsequent incidence of febrile and local reactions.

Diphtheria

- Diphtheria is spread from person to person in airborne droplets.
- Symptoms of the disease include sore throat, loss of appetite, and a slight fever.
- Patients with the disease can experience complications such as abnormal heartbeats and inflammation of the heart muscle and valves.
- Children with diphtheria should be treated with diphtheria antitoxin and antibiotics.

### Soreness

Up to half of the children may have pain, redness, or swelling at the injection site.

### Crying

Crying for more than three hours, mostly because of pain, can be observed in up to 1% of infants.

More severe reactions reported include convulsions (usually related to fever, one case in 12 500 doses administered) and hypotonichypo responsive episodes (one case in 1750 doses administered). Anaphylactic reactions are extremely rare. There is no evidence that the vaccine causes any serious neurological disorder such as encephalopathy.

# Varicella

## Introduction

Varicella (Chicken pox) and Herpes Zoster (shingles) are two distinct diseases caused by Varicella Zoster Virus (VZV). Varicella is the clinical manifestation of the primary infection caused by VZV, which like other herpes viruses is capable of maintaining latency in the human body and reactivating to result in secondary or latent infection known as herpes zoster (1) It is world wide in distribution and occurs both in epidemic and endemic forms (2).

### Armed Forces

Chicken pox is the 10th leading cause of hospital admission in Armed forces. It forms 2. 26 percent of the total hospital admissions. Chicken pox has overall showed a decline in incidence in 2006 as compared to 2005 (3).

### History

There are many explanations offered for the origin of the name chickenpox :

(a) Samuel Johnson suggested that the disease was "no very great danger", thus a "chicken" version of the pox

(b) The specks that appear looked as though the skin was pecked by chickens

(c) The disease was named after chick peas, from a supposed similarity to size of the seed with the lesions

(d) The term reflects a corruption of the Old English word “giccin”, which meant itching.

As "pox" also means curse, in medieval times some believed it was a plague brought on to curse children by the use of black magic.

## Etiology

VZV is a DNA virus also known as human herpes virus 3 (HHV-3), one of the eight herpes viruses known to affect humans and is member of the herpes virus group (4).

## Pathogenesis

VZV enters through the respiratory tract and conjunctiva. The virus is believed to replicate at the site of entry in the nasopharynx and in regional lymph nodes. A primary viremia occurs 46 days after infection and disseminates the virus to other organs, such as the liver, spleen, and sensory ganglia. Further replication occurs in the viscera, followed by a secondary viremia, with viral infection of the skin.

## Transmission

Chickenpox is a highly contagious disease that spreads from person to person by direct contact or through the air from an infected person's coughing or sneezing. Touching the fluid from a chickenpox blister can also spread the disease. It takes from 7-21 days after contact with an infected person for someone to develop chickenpox (5). The incubation period may be prolonged in immunocompromised patients and those who have received post exposure treatment with a varicella antibody containing product.

## Clinical Features

A mild prodrome may precede the onset of a rash. Adults may have 1 to 2 days of fever and malaise prior to rash onset, but in children the rash is often the first sign of disease. The rash is generalized and pruritic and progresses rapidly from macules to papules to vesicular lesions before crusting. Rash evolves into noninfectious dried crusts over a 5 to 6 days period (6). A thin-walled, clear vesicle (dew drop) develops on top of the area of redness. This "dew drop on a rose petal" lesion is very characteristic for chickenpox. The rash usually appears first on the head, then on the trunk, and then the extremities; the highest concentration of lesions is on the trunk **(centripetal distribution).** Lesions also can occur on mucous membranes of the oropharynx, respiratory tract, vagina, conjunctiva, and the cornea. Lesions are usually 14 mm in diameter. The vesicles are superficial and delicate and contain clear fluid on an erythematous base. Successive crops appear over several days, with lesions present in several stages of development. The clinical course in healthy children is generally mild, with malaise, pruritis, and temperature up to 102˚F for 23 days. Adults may have more severe disease and have a higher incidence of complications. Respiratory and gastrointestinal symptoms are absent. Children infected with human immunodeficiency virus also may have severe, prolonged illness. Although immunity following varicella infection is considered to be long lasting, second cases of varicella do occur rarely among immunologically normal persons (7).

### Complications

Varicella severity and complications are increased among immunocompromised persons, neonates, children less than 1 year of age, and adults(8, 9). However, healthy children and adults may also develop serious complications and even die from varicella (9, 10, 11, 12). Secondary bacterial infections of skin lesions with Staphylococcus or Streptococcus are the most common cause of hospitalization and outpatient medical visits. Central nervous system manifestations of varicella range from aseptic meningitis to encephalitis. Involvement of the cerebellum, with resulting cerebellar ataxia which is the most common complication. **Reye's syndrome** is an unusual complication of varicella and occurs almost exclusively in children who take aspirin during the acute illness. The etiology of Reye's syndrome is unknown.

## Communicability

The period of communicability extends from 1 to 2 days before the onset of rash through the first 4 to 5 days, or until lesions have formed crusts. Immunocompromised patients with varicella are probably contagious during the entire period when new lesions are appearing. The virus has not been isolated from crusted lesions. It is less contagious than measles, but more so than mumps and rubella. Secondary attack rates among susceptible household contacts of persons with varicella are as high as 90% (i.e. 9 of 10 susceptible household contacts of

persons with varicella will become infected).

### Congenital VZV Infection

Primary maternal varicella infection in the first 20 weeks of gestation is occasionally associated with a variety of abnormalities in the newborn, including low birth weight, hypoplasia of an extremity, skin scarring, localized muscular atrophy, encephalitis, cortical atrophy, chorioretinitis, and microcephaly. This constellation of abnormalities, collectively known as **congenital varicella syndrome**, was first recognized in 1947.

### Laboratory diagnosis

The clinical features of the disease are generally clearcut and laboratory diagnosis is not required. However the laboratory criteria for diagnosis is

(a) Positive serologic test for varicella - zoster immunoglobulin M (IgM) antibody.

(b) Isolation of varicella-zoster virus (VZV), demonstration of VZV antigen by direct fluorescent antibody (DFA) or by polymerase chain reaction (PCR) tests from a clinical specimen

(c) Significant rise in serum varicella immunoglobulin G (IgG) antibody level by any standard serological assay

However examination of vesicle fluid under direct microscope will show multinucleated giant cells, covered by Giemsa stain. The direct fluorescent antibody (DFA) test is the method of choice for rapid clinical diagnosis.

## Recurrent Disease (Herpes Zoster)

Herpes zoster, or shingles, occurs when latent VZV reactivates and causes recurrent disease. The immunologic mechanism that controls latency of VZV is not well understood. However, factors associated with recurrent disease include aging, immunosuppression, intrauterine exposure to VZV, and having had varicella at a young age (younger than 18 months). The vesicular eruption of zoster generally occurs unilaterally in the distribution of a sensory nerve. Most often, this involves the trunk or the fifth cranial nerve. Two to four days prior to the eruption, there may be pain and paresthesia in the involved area. There are few systemic symptoms (13).

## Vaccination

Vaccine effectiveness has been found most commonly in the range of 70%-86% for prevention of all disease with several lower estimates (40%-59%) and > 95% for severe disease (15). Varicella vaccine may be used either at an individual level to protect susceptible adolescents and adults, or at a population level, to cover all children as part of a national immunization programme. Vaccination of adolescents and adults will protect at-risk individuals, but will not have a significant impact on the epidemiology of the disease on a population basis. On the other hand, extensive use as a routine vaccine in children will have a significant impact on the epidemiology of the disease. If sustained high coverage can be achieved, the disease may virtually disappear. If only partial coverage can be obtained, the epidemiology may shift, leading to an increase in the number of cases in older children and adults.

The recommendations by WHO for varicella vaccine are :

(a) Most developing countries have other vaccine-preventable diseases that cause significantly greater morbidity and mortality, and varicella vaccine is not a high priority for routine introduction into their national immunization programmes.

(b) Routine childhood immunization against varicella may be considered in countries where this disease is a relatively important public health and socioeconomic problem, where the vaccine is affordable, and where high (85% - 90%) and sustained vaccine coverage can be achieved. (Childhood immunization with lower coverage could theoretically shift the epidemiology of the disease and increase the number of severe cases in older children and adults. )

(c) Additionally, the vaccine may be offered in any country to individual adolescents and adults without a history of varicella, in particular to those at increased risk of contracting or spreading the infection. This use in adolescents and adults entails no risk of an epidemiological shift, as childhood exposure to VZV remains unaffected.

Varicella vaccine (14)

| Type of vaccine | Live attenuated virus, Oka strain |
|---|---|
| **Number of doses** | One dose for persons aged under 13 years; two doses in adolescents and adults four to eight weeks apart, |
| **Schedule** | subcutaneous 1224 months of age for early childhood immunization |
| **Contraindications** | Pregnancy; reaction to previous dose (including reaction to a component such as gelatin); any advanced immune disorder or cellular immune deficiency; symptomatic HIV |

### MMRV Vaccine

MMRV vaccine is indicated for vaccination against measles, mumps, rubella and varicella in children 12 months to 12yrs of age. Persons 13 yrs of age and older should not receive MMRV. MMRV may be used for both the first and second doses of MMR and varicella in children younger than 13 years. The minimum interval between doses of MMRV is 3 months.

### Herpes Zoster Vaccine

Zoster vaccine is approved by FDA for persons 60 years and older. A single dose of zoster vaccine is recommended for adults 60 years of age and older whether or not they report a prior episode of herpes

zoster. Persons with a chronic medical condition may be vaccinated unless a contraindication or precaution exists for the condition.

**Post exposure Prophylaxis**

It is recommended to use varicella vaccine for susceptible persons following exposure to varicella and for outbreak control. If administered within 72 hours and possibly up to 120 hours following varicella exposure, varicella vaccine may prevent or significantly modify disease (16, 17, 18).

**Varicella Zoster Immune Globulin**

Varicella Zoster Immune Globulin (VZIG) is recommended for post-exposure prophylaxis of susceptible persons who are at high risk for developing severe disease and when varicella vaccine is contraindicated (12). VZIG is most effective in preventing varicella infection when given within 96 hours of varicella exposure.

## Steps for investigation and control of varicella outbreaks

**(a) Confirm outbreak, investigate all persons exposed in the outbreak, and determine varicella susceptibility.**

(i) Define cases and confirm outbreak.

(ii) Screen outbreak cohort for susceptibility to varicella.

- Use history of disease and vaccination
- Use serologic testing.

(iii) Investigate cases to characterize illness including onset, severity, duration, pre-existing medical conditions and medications, and complications.

**(b) Initiate outbreak control & treat cases (if appropriate)**

(i) Isolate or cohort infective cases.

(ii) Exclude non-vaccinated persons without history of disease.

(iii) Recommend treatment of active cases with antiviral therapy (adolescents and adults only).

(iv) Offer vaccine to susceptible persons.

(v) Offer VZIG to exposed, susceptible persons at high risk of severe disease.

**(c) Establish surveillance for :**

(i) Additional varicella cases

(ii) Vaccine-associated adverse events.

**(d) Analyze collected data.**

(i) Describe cases and transmission (date of rash onset, age, sex, severity, etc. ).

(ii) Describe serological status (if serology testing performed).

(iii) Evaluate outbreak control efforts.

### Chicken Pox (Varicella)

- Caused by varicella Zoster virus
- Transmitted from person to person by droplet infection and droplet nuclei
- Incubation period 7-21 days
- Latent infection produces Herpes zoster
- Action in an outbreak; Cases isolate, contacts surveillance and vaccination
- Complications vary by age
- During the disease aspirin should be avoided for fear

### Differential Diagnosis of Fever with Rash (19)

- Centrally distributed maculopapular eruptions (e.g. Measles & Rubella)
- Peripheral eruptions (e.g, Rocky Mountain spotted fever, secondary syphilis)
- Confluent desquamative erythemas (e.g Toxic shock syndrome)
- Vesiculobullous eruptions (e.g Varicella, Smallpox, Rickettsialpox)
- Urticarial eruptions : Hypersensitivity reactions are usually not associated with fever. The presence of fever suggests serum sickness, connective-tissue disease or infection (Hepatitis B, Enteroviral or Parasitic infection)
- Nodular eruptions (e.g disseminated candidiasis, Cryptococcosis, Erythema Nodosum, Sweet's Syndrome)
- Purpuric eruptions (e.g, Acute Meningococcemia,

# Mumps

## Introduction

The name comes from the British word "to mump", that is grimace or grin. This results from the appearance of the patient as a result of parotid gland swelling. Mumps is a viral infection primarily affecting the salivary glands. In most instances mumps is a mild childhood disease. However, the mumps virus may also affect adults, among whom complications such as meningitis and orchitis are relatively common. Encephalitis and permanent neurological sequelae are rare complications of mumps. In most parts of the world, the annual incidence of mumps is in the range of 100 to1 000 per 100 000 population, with epidemic peaks every two to five years. Peak incidence is found among children five to nine years of age. (1)

## Epidemiology

The mumps virus belongs to the genus rubulavirus and is a part of the paramyxoviridae family. It is an enveloped, non-segmented, negative-sense RNA virus with helical symmetry. It has two major surface glycoproteins : the hemagglutinin-neuraminidase and the fusion protein. Mumps virus is sensitive to heat and ultraviolet light. Only one serotype is known. (2)

Mumps is endemic worldwide. In areas without childhood vaccination against mumps, epidemics occur every two to five years. (3). Before the 1960s, mumps was a common infectious disease in all parts of the world, with annual incidences usually ranging from approximately 0. 1% to1%, and up to 6% in certain populations. In hot climates the disease is endemic throughout the year, whereas in temperate climates incidence peaks in winter and spring. (1)

## Transmission

Humans are the only known natural host for mumps virus. The virus is spread via direct contact or by airborne droplets from the upper respiratory tract and requires more intimate contact for transmission than measles or chicken pox. Rarely, transmission can be fomite borne through articles freshly contaminated with saliva. Overcrowding resulting in close contact such as school classrooms, cinema halls, army barracks facilitates transmission. Persons with mumps are infective from about 2 days before the onset of swelling of the salivary glands up to 9 days after the onset of swelling.

## Pathogenesis

The primary site of viral replication is the upper respiratory tract or the gastrointestinal tract. The virus spreads rapidly to the local lymphoid tissue and a primary viraemia ensues following which the virus spreads to distant sites in the body. The parotid gland is most commonly involved. However the testis, epididymis, pancreas, ovary and CNS may also be involved. A few days after the onset of illness, virus can again be isolated from the blood, indicating that virus multiplication in target organs leads to a secondary viraemia. The virus is excreted in the urine in infectious form during the two weeks following the onset of clinical illness. Natural infection usually results in life long immunity.

## Clinical Features

The incubation time averages 16 to18 days with a range of 2 to 4 weeks. (1) With an overall mortality of only 1 per 10 000 cases, mumps is generally a mild, self limiting disease. (1). A prodromal illness of headache, malaise, myalgia and low grade fever occurs for one or two days before the onset of parotid enlargement. Cases of classic mumps develop enlargement of one parotid gland, followed a few days later by enlargement of the contralateral gland. The patient complains of pain and tenderness in the area of the gland. The sub-mandibular and sublingual glands may occasionally be involved. Parotid swelling develops in 95% of those with clinical illness. Up to 30% of patients may have no or very mild symptoms (sub-clinical cases). Most infections in children below two years of age are subclinical. In a small proportion of patients, the symptoms may resemble mild URTI. The parotid swelling starts to subside after 4 to 7 days and complete recovery usually takes another three days.

## Complications

Although the disease is usually mild, up to 10% of patients can develop aseptic meningitis. Encephalitis which can result in death or disability is a less common complication. Permanent deafness, orchitis, and pancreatitis are other untoward effects of mumps.

### Epididymo-orchitis

Epididymo-orchitis occurs in about 25% of postpubertal men who contract mumps. (4) Testicular atrophy occurs in about one-third of patients with mumps orchitis, but sterility is rare. Mumps orchitis appears to be a risk factor for testicular cancer, though not a major one (5). Oophoritis can occur in postpubertal; one study found mastitis in 31% of women over 14 years of age (6). Among women who acquire mumps during the first 12 weeks of pregnancy, more than a quarter suffer spontaneous abortion (7). Maternal mumps is not associated with congenital anomalies. (8, 9).

### Aseptic meningitis

Aseptic meningitis occurs in 10% of patients with mumps but as many as 50% show abnormalities in the CSF. (10, 11). The symptoms are similar to other types of aseptic meningitis and can start one week before parotid swelling to 3 weeks after it. The virus can be isolated from the CSF during the first 2 to 3 days after onset. Later, specific antibodies can be demonstrated in the CSF. Symptoms of meningitis subside three to 10 days after onset and recovery is usually complete. Encephalitis is a rare complication of mumps. The incidence of encephalitis is

around 1 in 6000 cases of mumps. (12, 13). Clinical features suggesting encephalitis are convulsions, focal neurological signs, movement disorder and changes in sensory perception.

Deafness

Deafness is a well-recognized complication of mumps. (14, 15). Before vaccinations, mumps used to be one of the leading causes of hearing loss in children and young adults. In most cases, the hearing loss is transient but permanent dysfunction may occur. Hearing problems did not correlate with meningitis and appears to be due to direct damage to the cochlea. The incidence of hearing loss is estimated to be in the region of 1 per 15, 000 cases.

Pancreatitis

The exact incidence of pancreatitis is hard to determine but is thought to be as high as 4%. 16). There is evidence suggesting that mumps virus can infect human pancreatic beta cells, and may trigger the onset of insulin-dependent diabetes mellitus in some individuals (17).

Arthralgia

Arthralgia affecting a large joint may develop 2 weeks after parotitis. They are more frequent in young male adults. Myocarditis can usually only be found on ECG examination in 10 - 15% of patients. Rarely, congestive heart failure and deaths have been reported. Transient renal dysfunction is a frequent complication of clinical mumps. Cases of symptomatic nephritis following mumps are unusual.

**Diagnosis**

Cases are commonly diagnosed based on history and clinical presentation and laboratory tests are unnecessary. For specific diagnosis, it is possible to isolate the virus from throat swabs, saliva, urine, and CSF. An assay for the detection of mumps-specific immunoglobulin M antibodies in serum and oral fluid specimens is commercially available. Diagnosis can also be made by significant rise between acute and convalescent phase titers in serum mumps IgG antibody level using any standard serologic assay or positive serologic test for mumps IgM antibody. Interpretation of titer rise may have limitations because of mumps cross-reaction with parainfluenza viruses. (1, 2). Mumps virus replicates in a variety of cell cultures as well as in embryonated hens eggs. For primary isolation in routine diagnostic virology, monkey kidney, human embryonic kidney or HeLa cell cultures are used. The presence of mumps virus in a cell culture may be detected by the hemadsorption inhibition (HAI) test. (1).

**Management**

Mumps is a mild, self limited disease. No specific anti – viral therapy is indicated. Treatment is conservative. Analgesics may be given for severe headaches or discomfort due to parotitis. In orchitis, stronger analgesics may be needed. Bed rest is recommended for a faster recovery.

**Prevention**

Deaths due to mumps are rare. However, the fact that in unvaccinated communities almost every person may get infected and infections are associated with a number of complications imposes a substantial economic burden on society (1). Effective vaccines against mumps and high vaccination coverage reduce the incidence of mumps to insignificant levels.

The first vaccine developed against mumps was a killed vaccine which was used in the United States between 1950 and 1978. This vaccine offered low efficacy and short term effectiveness. Since then, live attenuated mumps virus vaccines have been developed based on several different strains. The common ones are the Jeryl-Lynn strains, RIT 4385 strains, Leningrad-3 strains, L-Zagreb strains, Urabe strains & the Rubini strains. (1).

The recommended use is the form of a single dose schedule, given at age 12-18 months. This is because persistent maternal antibody to mumps virus from previous infection or vaccination interferes with the response to mumps vaccines in young infants. Mumps vaccines are available as monovalent, bivalent measles-mumps (MM) and trivalent measles-mumps-rubella (MMR) vaccines. Most of these vaccines contain more than 1 000 cell-CCID50 of attenuated mumps virus per dose. The trivalent MMR vaccine is given as 0. 5 ml subcutaneously in the outer aspect of upper arm between 12 to 15 months of age. In India the MMR vaccine is manufactured by the Serum Institute of India. The strains used are L Zagreb for mumps, Edmonston Zagreb for measlesa and Plotkins RA 27/3 for rubella. Being live vaccines, these have exacting storage requirements. They should be protected from heat and light both before and after reconstitution. Reconstituted vaccine must be discarded if not used within 6 hours.

There are very few contraindications to mumps vaccination. Like all other live vaccines the mumps vaccine should not be administered to immunocompromised individuals. MMR vaccine can be given to individuals infected with human immunodeficiency virus (HIV) and who are not severely immunocompromised (35). Though the vaccine has no known teratogenic effects, the mumps vaccine should not be administered to pregnant women and pregnancy should be avoided for three months after vaccination (18).

The mumps vaccine has proven to be extremely safe, adverse effects are rare and mild. The most common adverse reactions following mumps vaccination are parotitis and low-grade fever. Aseptic meningitis following vaccination has been reported at widely varying frequencies. Vaccine-associated meningitis usually resolves spontaneously in less than a week without any sequelae. Orchitis and sensory-neural deafness have been reported following mumps vaccination.

Immunoglobulin has not been demonstrated to be of established value in post exposure prophylaxis and is not recommended.

**Control**

The World Health Organization (WHO) believes that

mumps can be controlled through high routine coverage with mumps vaccine administered at age 12-18 months. Coverage rates below 70%-80% may result in an epidemiological shift, as reduced (but not interrupted) circulation of mumps virus in the community may result in an increased number of cases in adults without immunity from natural infection. It considers the addition of mumps vaccine to the measles and rubella vaccination programmes using the MMR combined vaccine as logistically sound, encourages the use of MMR

# Meningococcal Meningitis

## Introduction

Meningitis, or inflammation of the meninges, can be caused by several different bacterial pathogens. By far, the most important of these pathogens is *Neisseria meningitidis* because of its potential to cause epidemics (1). Meningococcal meningitis occurs worldwide in both endemic and epidemic forms. It is estimated to be responsible for over 500, 000 cases and about 135, 000 deaths annually (2). First isolated in 1887, *Neisseria meningitidis*, is an exclusive human pathogen with the mucosal surfaces of the human nasopharynx being its natural habitat and reservoir (3). In most cases colonization of the human nasopharynx is asymptomatic. However, blood stream invasion by *Neisseria meningitidis* can lead to meningitis and septicaemia with serious consequences. Even with adequate chemotherapy, meningococcal meningitis has a fatality rate of about 10% and about 15% of the survivors have residual central nervous system (CNS) damage (4). The disease has special significance for the Armed Forces since outbreaks frequently occur among persons living in close proximity such as military barracks.

## Agent

*Neisseria meningitidis* are bean shaped, gram negative, aerobic diplococci. The bacteria are surrounded by an outer membrane of lipids, membrane proteins and lipopolysaccharides. Pathogenic meningococci are enveloped by a polysaccharide capsule (5). The capsular polysaccharide provides the basis for their classification into serogroups (6). They differ in their agglutination reactions to sera directed against polysaccharide antigens. At least 13 serogroups have been described : A, B, C, D, E, H, I, K, L, W-135, X, Y and Z. Almost all meningococcal infections are caused by five serogroups A, B, C, 29E or W-135 (7).

## Host Factors

Maternal antibodies offer protection against invasive disease till the age of six months. Susceptibility peaks at age 6-12 months and decreases again after colonization of closely related nonpathogenic bacteria. Subsequent colonization with *Neisseria meningitidis* induces antibodies to the infecting strain, thus reinforcing natural immunity. Invasive disease occurs if no protective bactericidal antibodies are mounted against the infecting strain (7). Those infected with the human immunodeficiency virus are probably also at increased risk for sporadic meningococcal disease (8).

Incidence rates are highest between the age of six months and two years (8). The disease is rarely reported in individuals over 50 years of age. There appears to be no gender predilection, though males account for slightly more than half the reported cases (7). Smoking, both active and passive, antecedent upper respiratory tract infection, underlying chronic illnesses are all associated with increased risk of meningococcal disease (8). Low socioeconomic status with its attendant attributes of poor housing, overcrowding, and inadequate ventilation have been consistently found to be associated with higher risk for meningococcal disease (9, 10).

## Environmental Factors

Individuals acquire the infection if they are exposed to virulent bacteria and have no protective bactericidal antibodies. Smoking and concurrent viral infection of the upper respiratory tract diminish the integrity of the respiratory mucosa and increase the likelihood of invasive disease. Crowded living conditions also facilitate disease spread, since individuals from different areas have different strains of meningococci. The risk of invasive disease is higher in the first few days after exposure to a new strain.

## Epidemiology

Worldwide serogroups A, B and C account for most cases of meningococcal disease The predominant serogroups in Asia and Africa are A and C while serogroups B and C are responsible for the majority of cases in Europe and the Americas (8, 11-13). Recent outbreaks among Haj pilgrims have been attributed to serogroup W135 (8). Epidemic rates of meningococcal disease varies from <1-3/100,000 in many developed nations to 10-25/100,000 in some developing countries.

The highest level of meningococcal disease occurs in the 'African meningitis belt', which stretches across sub-Saharan Africa from Senegal in the west, to Ethiopia in the east. During epidemics this region has a disease incidence rate of >1,000 cases per 10,000 population (14). The largest recorded outbreak of meningococcal disease in history occurred in Africa in 1996 where 250,000 cases including 25,000 deaths were reported to the WHO.

Major epidemics of menincococcal meningitis have been reported from Asia over the past 35 years. China, Vietnam, Mongolia, Bhutan, and Nepal have all reported large outbreaks with Serogroup B being implicated most often (8).

Isolated cases of meningococcal meningitis have been reported from many Indian states including Haryana, Uttar Pradesh, Rajasthan, Sikkim, Gujarat, Jammu & Kashmir, West Bengal, Chandigarh, Kerala and Orissa (8). Serogroup A has been associated with all the repeated outbreaks of meningitis, although serogroup B and C have been detected in a few sporadic cases (15, 16). Several outbreaks of meningococcal meningitis have been reported from Delhi in 1966, 1985 and 2005 (8).

## Transmission

The main modes of transmission are direct contact and respiratory droplets. Respiratory droplets produced by coughing and sneezing can be transmitted to non immune hosts within a distance of one meter. Close contact like kissing, living in close quarters (like military dormitories) and sharing of utensils enhance the risk of transmission

(1).

The average incubation period is 3 – 4 days with a range of 2 to 10 days (1). This is also the period of communicability. The bacteria are rapidly eliminated from the nasopharynx after starting antibiotics, usually within 24 hours. Humans are the only reservoir. Both cases and carriers serve as the source of infection. 5 – 10% adults are asymptomatic nasopharyngeal carriers during inter-epidemic periods. This figure can, however, rise to 60 – 80% in closed populations like military recruits in camps (7).

### Pathophysiology

For invasive disease to occur, a susceptible host must be exposed to a pathogenic strain, be colonized by the pathogenic strain on the naso-oropharyngeal mucosa followed by invasion by the bacteria. Invasion can be subdivided into mucosal penetration followed by invasion of blood stream and finally, invasion of meninges (8). Meningococci overcome host defenses and attach to the microvillous surface of nonciliated columnar mucosal cells of the nasopharynx, where they multiply. Binding stimulates engulfment of the meningococci by epithelial cells, which may then traverse the mucosal epithelium. In most persons coloniozation of the nasopharynx is an immunizing process, resulting in a systemic protective antibody response. In a small proportion of those infected, *N. meningitidis* penetrates the mucosa and gains access to the bloodstream, causing systemic disease (6). Systemic disease appears with the development of meningococcemia and usually precedes meningitis by 24 to 48 hours. This can lead to systemic infection in the form of bacteremia, involvement of the meninges or severe systemic infection with circulatory collapse and disseminated intravascular coagulation. Meningococcemia leads to diffuse vascular injury (7).

### Clinical Features

The most common symptoms are acute onset of intense headache, high fever, nausea, vomiting, sensitivity to light (photophobia), and stiff neck. These symptoms can develop over several hours, or they may take 1-2 days. Most adult patients have an altered mental state with clinical signs of nuchal rigidity. Less commonly reported symptoms include stupor or coma, which carries a poorer prognosis. A more severe form of meningococcal disease is meningococcal septicaemia which is characterized by a haemorrhagic rash which usually indicates disease progression and rapid circulatory collapse.

In Infants and young children bacterial meningitis usually presents as a subacute infection that progresses over several days. There is a slower onset of signs and symptoms with nonspecific symptoms and neck stiffness may be absent. Irritability and projectile vomiting may be the presenting features in this age group. Seizures occur in 40% of children with meningitis. The Waterhouse-Friderichsen syndrome may develop in 10-20% of children with meningococcal infection. This syndrome is characterized by large petechial hemorrhages in the skin & mucous membranes, fever, septic shock & DIC (7).

Even when the disease is diagnosed early and adequate therapy instituted, 5% to 10% of patients die, typically within 24-48 hours of onset of symptoms. Bacterial meningitis may result in brain damage, hearing loss, or learning disability in 10 to 20% of survivors (1)

### Diagnosis

The diagnosis of meningococcal meningitis is suspected by the clinical presentation and a lumbar puncture showing a purulent spinal fluid. Typical CSF abnormalities in meningitis include the increased pressure (>180 mm water), WBC counts between 10 and 10, 000 cells/μL, (predominantly neutrophils), decreased glucose concentration (<45 mg/dL), and increased protein concentration (>45 mg/dL) (7).

Bacteriological diagnosis in patients with meningococcal disease can be done by Gram staining, direct antigen detection using latex agglutination, or culture. Blood cultures may not be always revealing and only CSF samples are generally positive. Molecular diagnosis using polymerase chain reaction (PCR) has also been used. As soon as the CSF has been collected, it should be transported to the microbiology laboratory, where it should be examined within one hour from the time of collection. In case, delay of several hours is anticipated, the sample may be incubated at 35°C in a 5% $CO_2$ atmosphere.

Gram staining of cerebrospinal fluid is still considered an important method for rapid detection of *N meningitides*. However, definitive diagnosis of meningococcal disease has relied on bacteriologic culture. Gram stain is positive in 70-90% of untreated cases, and culture results are positive in as many as 80% of cases (7). However, the sensitivity of culture may be low, especially when performed after the initiation of antibiotic treatment. However culture from skin biopsy specimens or antigen detection or PCR in blood or CSF are not affected by prior antibiotic administration (8, 17-20).

Commercially available kits to detect polysaccharide antigen in cerebrospinal fluid, have been used to enhance the laboratory diagnosis. These methods are rapid and specific and can provide a serogroup-specific diagnosis, but false negative results are common (20). Polymerase-chain-reaction (PCR) analysis offers the advantages of detecting serogroup-specific *N meningitidis* DNA and of not requiring live organisms for a positive result.

### Management

Meningococcal disease is potentially fatal and should always be viewed as a medical emergency. Management of meningococcal disease requires early recognition of the disease, prompt initial parentral antibiotic therapy and close monitoring with frequent repeated prognostic evaluations. Admission to a hospital centre is essential. Isolation of the patient is not necessary. Antimicrobial therapy must be commenced as soon as possible after the lumbar puncture has been carried out. Several antibiotics can be used for treatment including penicillin, ampicillin, chloramphenicol, and ceftriaxone (1). A single intramuscular dose of an oily suspension of

chloramphenicol has been shown to be as effective as a five-day course of crystalline penicillin in the treatment of meningococcal meningitis. During epidemics, this may offer a practical alternative to penicellin or ceftriaxone which require multiple injections (21).

Because of the risks of severe illness and death effective antibiotics should be promptly administered in patients suspected of having meningococcal disease. Standard empirical therapy varies according to age. In infants younger than 4 weeks, it consists of ampicillin plus cefotaxime or an aminoglycoside. Infants aged 4 to12 weeks should be treated with ampicillin plus a third-generation cephalosporin. In children aged 12 weeks to 18 years, a third-generation cephalosporin or ampicillin plus chloramphenicol is an appropriate combination. Adults should be treated with a third-generation cephalosporin, while individuals older than 50 years should be treated with ampicillin plus a third-generation cephalosporin. Once the accurate diagnosis of meningococcal meningitis is established, appropriate changes can be made. Currently, penicillin is the drug of choice for the treatment of meningococcal meningitis and septicemia (7).

The adult dose of penicillin is 4 million units IV four times a day. The paediatric dose is 250,000 Units/kg/day given intravenously in divided doses. For Ceftriaxone the adult dose is four gram IV per day divided into two doses. Paediatric dose is 50 mg/kg IV divided into two doses (not to exceed 4 g/d).

The use of corticosteroids has not been shown to be effective for meningococcal meningitis and its use remains controversial.

### Prevention and Control

#### Chemoprophylaxis

Chemoprophylaxis is the preferred means of prevention of disease among close contacts of sporadic cases. Household contacts, contacts at day care centers and anyone else directly exposed to an infected patient's oral secretions should be administered chemoprophylaxis as soon as possible (ideally within 24 hours). Chemoprophylaxis has probably limited or no benefit if given more than 14 days after the onset of disease. Antibiotics that can be used for chemoprophylaxis are rifampin, ciprofloxacin, ceftriaxone, minocycline, ofloxacin, and spiramycin. Ciprofloxacin single oral dose of 500 mg, rifampicin 600 mg 12 hourly for two days, or ceftriaxone 250 mg IM single dose are the options for adults. Rifampicin should be avoided during pregnancy. The choices for children include rifampicin 10 mg/Kg 12 hourly for two days (5mg/Kg for infants), or injection ceftriaxone 125 mg IM single dose (22, 23).

Chemoprophylaxis is not recommended during epidemics because of multiple sources of exposure and prolonged risk of exposure. Logistic problems and high cost also make this an impractical alternative for mass use. It is not an effective means of interrupting transmission during an epidemic.

Chemoprophylaxis may prevent secondary cases among close contacts but, since secondary cases comprise less than 2% of all meningococcal disease, chemoprophylaxis is of little value for the control of most endemic and epidemic disease. As almost 15% of children and young adults carry meningococci in the nasopharynx, control of meningococcal disease based on chemotherapeutic elimination of nasopharyngeal carriage is practically impossible except in small communities. Immunization using safe and effective vaccines is the only rational approach to the control of meningococcal disease (24).

### Meningococcal Vaccines

Invasive disease occurs only in patients without specific bactericidal or opsonizing antibodies and therefore, can be prevented by inducing these antibodies. Of the five common serotypes responsible for more than 90% of meningococcal disease, vaccines are available for group A, C, Y and W-135. At present two types of meningococcal vaccines are licensed; meningococcal polysaccharide vaccines (bivalent and quadrivalent) and meningococcal conjugated polysaccharide vaccine.

#### Polysaccharide Vaccines

Bilvalent polysaccharide vaccines provide protection against serogroups A and C, while the quadrivalent polysaccharide vaccines provide protection against serogroups A, C, Y and W-135. The vaccines are purified, heat-stable, lyophilized capsular polysaccharides from meningococci of the respective serogroups. The recommended single dose of the reconstituted vaccine contains 50 µg of each of the individual polysaccharides. The dose for primary vaccination for both adults and children older than two years is a single 0. 5-mL subcutaneous injection. The vaccine can be administered at the same time as other vaccines but should be given at a different anatomic site. The antibody responses to each of the four polysaccharides in the quadrivalent vaccine are serogroup-specific and independent. Protective levels of antibody are usually achieved within 7-10 days of vaccination. These unconjugated polysaccharide vaccines confer protection in complement deficient persons also. The serogroup A and C vaccines have good immunogenicity, with clinical efficacy rates of 85% to 100% among children five years of age or older and adults. Serogroup Y and W-135 polysaccharides are safe and immunogenic in older children and adults. Vaccination does not reduce the transfer of bacteria to non-vaccinated persons and carrier status is unaffected. Vaccination has been highly effective in the control of community outbreaks and epidemics in military centers (8, 23, 24).

The vaccine is extremely safe. Adverse effects are mild, the most frequent reaction being pain and redness at the site of injection, lasting for a couple of days. Severe reactions to polysaccharide meningococcal vaccine are uncommon. The major drawback of the presently available vaccines is the absence of activity against group B meningococci (8, 23, 24).

#### Conjugated polysaccharide vaccine

A quadrivalent A, C, Y and W-135 conjugate vaccine has been licensed since January 2005. This vaccine contains 4 µg each of A, C, Y and W-135 polysaccharide conjugated to

48 µg of diphtheria toxoid. The meningococcal conjugate vaccines induce a T-cell-dependent response, resulting in an improved immune response in infants, priming immunologic memory and leading to a booster response to subsequent doses. These vaccines provide long-lasting immunity even when given as a series in infancy and thus induce herd immunity through protection from nasopharyngeal carriage. Nasopharnygeal carriage rates may also be decreased by use of the conjugate vaccine, reducing bacterial transmission. The conjugated polysaccharide vaccine is contraindicated in patients with a known hypersensitivity to any component of the vaccine, including diphtheria toxoid and in patients with a history of a severe reaction to any other vaccine containing similar components (23, 24)

Recommendations for use of meningococcal vaccine

Routine childhood vaccination with the meningococcal polysaccharide vaccine is not recommended because of its relative ineffectiveness in young children below two years of age. Large scale coverage with current vaccines does not provide sufficient "herd immunity". Consequently, WHO does not currently recommend meningococcal polysaccharide vaccine as part or routine infant immunization (24).

Routine vaccination with the vaccine is recommended for certain high-risk groups, including persons who have terminal complement component deficiencies and those who have anatomic or functional asplenia. Laboratory personnel and healthcare workers who are exposed routinely to *Neisseria meningitidis* in solutions that may be aerosolized should also be considered for vaccination (23).

Vaccination with a single dose of polysaccharide vaccine is recommended for travelers above 18 months of age going to an area experiencing an epidemic of meningococcal disease or to areas with a high rate of endemic meningococcal disease. Since the epidemic of meningococcal disease that occurred in 1987 during the Hajj in Mecca, proof of vaccination against meningococcus has been required for the pilgrims to the Hajj or Umra, at their entry in Saudi Arabia. More information concerning geographic areas for which vaccination is recommended can be obtained from internet (http : //www. cdc. gov/travel/).

Revaccination may be indicated for persons at high risk for infection (living in endemic areas) particularly for children who were first vaccinated when they were less than four years of age; such children should be considered for revaccination after 2-3 years if they remain at high risk

# Tuberculosis

## Introduction

Tuberculosis (TB) is one the biggest public health challenges facing the world today. It is one of the oldest diseases known to mankind. Its causative organism *Mycobacterium tuberculosis* was one of the first bacterial pathogens to be identified. The etiopathogenesis of the disease is clearly understood. A vaccine against tuberculosis has been available for close a century. Effective treatment against the disease has been available for over sixty years. Yet the disease is close to its highest levels ever and the World Health Organization declared TB as a global public health emergency in 1993. It remains a potentially fatal disease which is transmitted by droplet nuclei after close contact with a person who has infectious disease. Treatment requires prolonged multidrug therapy which increases the potential risk of nonadherence by patients. Tuberculosis is a true indicator for social development. An overwhelming majority of cases and practically all deaths due to tuberculosis take place in developing countries (1 - 4).

Tuberculosis is currently second only to AIDS as an infectious cause of death worldwide. The World Health Organization estimates that the disease killed 1.7 million people in 2006 (1). The silver lining is that the number of new cases per capita appears to have been falling globally since 2003 (1).

The organism can infect practically any organ of the body. However, pulmonary tuberculosis accounts for over eighty per cent of the total cases suffering from tuberculosis. The other common forms of tuberculosis are meningeal, bone and joint, renal, genital, abdominal or mesenteric and tubercular lymphaedenopathy (1, 2). Tuberculosis is the commonest opportunistic infection in patients suffering from AIDS in large parts of the world. The association with HIV infection has refocused global attention on tuberculosis.

## History

Tuberculosis has been known by a number of names through history. The ancient Greeks called it phthisis (to waste). The swollen glands of the neck due to tuberculosis were called scrofula. TB of the skin was known as lupus vulgaris. TB of the bone is known as Pott's disease with characteristic vertebral fusion and deformity of the spine. The most familiar term for TB was consumption, which means to consume or wear away. Among all these names, perhaps the most fitting is 'Captain of the Men of Death'.

*Mycobacterium tuberculosis* has been present in the human population since antiquity. There is evidence of the disease in fragments of the spinal column from Egyptian mummies from 2400 B.C. which show definite pathological signs of tubercular decay (5). Around 460 B.C. , Hippocrates identified phthisis as the most widespread disease of the times, and noted that it was almost always fatal. Sylvius was the first to identify actual tubercles in the lungs and other areas of consumptive patients in 1679. He also described their progression to abscesses and cavities. In 1882, Robert Koch discovered a staining technique that enabled him to see *Mycobacterium tuberculosis* (6).

## Epidemiology

### World

Tuberculosis has been controlled almost completely in the developed world. Almost all the case and practically all deaths due to tuberculosis take place in developing countries. Though the absolute numbers of cases and deaths are the largest in Asia, the rates of disease and deaths are the highest in Africa.

The latest WHO report on Tuberculosis states that the disease is a major cause of illness and death worldwide, especially in Asia and Africa. A total of 9.2 million new cases (139 per 1,00,000 population) and 1.7 million deaths from TB occurred in 2006, of which 0.7 million cases and 0.2 million deaths were in HIV - positive people. 44% of the new cases were smear positive (1). The increase in the number of cases as compared to the previous year (2005) is attributed to population growth. India, China, Indonesia, South Africa and Nigeria rank first to fifth respectively in terms of absolute numbers of cases. The African Region has the highest incidence rate per capita (363 per 1,00,000 population).

The 2007 estimate is that 8.8 million new TB cases occurred of which 7.4 million occurred in Asia and Sub-Saharan Africa with 1.6 million deaths (7). In 1993, tuberculosis was declared a global public health emergency (2, 8). In Aug 2005 the WHO declared a tuberculosis emergency in Africa (9). One - third of the world's population is already infected with TB. Over the centuries, TB has taken over 1 billion lives. Deaths due to tuberculosis comprise 25% of all avoidable deaths in developing countries. 95% of TB cases and 98% of TB deaths are in developing countries. 75% of TB cases in developing countries are in the economically productive age group of 15 - 50 years (1).

The largest number of cases occur in South East Asia which accounts for 34% of incident cases globally. In 2007 there were an estimated 5.7 million cases in the region. Every year, 3 million people develop active TB in the region and more than 50,000 die. 80% of the patients are in the age group 15 - 54 years. Bangladesh, India, Indonesia, Myanmar and Thailand account for 95% cases (7). However, the estimated incidence per capita in Sub - Saharan Africa is nearly twice that of South East Asia at 350 cases per 1,00,000 population (2). As with cases of disease, the highest number of estimated deaths due to tuberculosis is in the South - East Asia Region, but the highest mortality per capita is in the Africa Region, where

HIV has led to rapid increases in the incidence of TB and increases the likelihood of dying from TB (1, 2, 7).

Despite these high numbers of cases and deaths the WHO believes that the global incidence of TB per capita peaked around 2003 and appears to have stabilized or begun to decline. Incidence per 1,00,000 population is falling in almost all parts of the world except Eastern Europe where it is stable. The downward trend is most pronounced in Latin America and the Caribbean ( 3.4% per year, 2001 - 2006). However, the slow decline in incidence is more than offset by the global population growth. This resulted in an increase in the number of new cases from 9.1 million in 2005 to 9.2 million in 2006. While there has been a tremendous decrease in tuberculosis cases in developed countries in the last forty years, there has been an increase in the absolute number of tuberculosis cases in developing countries (1).

It is estimated that between 2002 and 2020, approximately 1 billion people will be newly infected, over 150 million will get sick, and 36 million will die of TB, if control is not further strengthened (2).

India

Tuberculosis is the biggest public health problem in the country. With 1.8 million cases occurring annually, India accounts for a fifth of the world's new TB cases and 2/3rd of the cases in South - East Asia. This makes India the highest TB burden country in the world. It has been estimated that for the year 2000 there were about 3.8 million bacteriologically positive TB cases in the country (10). Overall prevalence of infection in India is estimated to be 30% while the annual incidence of infection is estimated to be 1 - 2 %. The prevalence of disease is thought to be 4 per 1000 and the incidence of disease 1.5 per 1000. The prevalence of infection has been found to be increasing with age. The peak age for males is 45 - 54 years and that for females is 35 years. No rural - urban differences in rate have been found.

TB kills more adults than any other infectious disease in India. Because it affects adults, tuberculosis causes enormous social and economic disruption. Prior to 2000, the annual number of deaths due to tuberculosis was estimated to be 5,00,000. This has been revised downwards to 3,70,000 as per WHO estimates in 2004 (mortality rate 30 per 1,00,000 persons). More than 80% of the burden of tuberculosis is due to premature death, as measured in terms of disability adjusted life years (DALYs) lost. In India, over 70% of the cases occur in the economically productive age group (15 - 54 years). TB causes huge economic loss with about 17 crore workdays lost due to the disease. The annual economic cost of tuberculosis to the Indian economy is at least US$ 3 billion (more than Rs 13,000 crore) (10). The burden of TB is enormous but is hidden by stigma. TB kills more women in India than any other infectious disease. Women with tuberculosis are often severely stigmatized.

**Armed Forces**

In the Armed Forces the prevalence has been much lower owing to the initial selective recruitment, much better living standards, better general nutrition, and comparative seclusion from the general population. The prevalence fluctuates between 1 and 3 per 1000 population (11, 12).

**Agent**

Human tuberculosis is caused by *Mycobacterium tuberculosis* which belongs to the genus *Mycobacterium*, family *Mycobacteriaceae* and Order *Actinomycetales*. *Mycobacterium tuberculosis* is Gram positive, non - motile, non - sporing, pleomorphic rod. The bacilli are obligate aerobes growing most successfully in tissues having the highest partial pressure of oxygen, such as lung apices. They are facultative intracellular pathogens, slow - growing with a generation time of 12 to 18 hours. Hence, lesions typically evolve in a sub - acute to chronic course. They are classified as acid - fast bacilli (AFB) because they retain the carbol - fuchsin red dye after washing with acid, alcohol, or both (3, 4).

*Mycobacterium bovis* is the etiologic agent of TB in cows and rarely in humans. Both cows and humans can serve as reservoirs. Humans can also be infected by the consumption of unpasteurized milk. *Mycobacteriun africanum* can be a rare cause of tuberculosis. Other human pathogens belonging to the *Mycobacterium* genus include *Mycobacterium avium* which causes a TB - like disease especially prevalent in AIDS patients, and *Mycobacterium leprae*, the causative agent of leprosy.

**Host**

Tuberculosis can occur at any age. In India disease prevalence is more in the older age groups. It occurs in both the sexes and it is not a hereditary disease. Man has no inherited immunity against tuberculosis. It is now known that both delayed hypersensitivity and acquired resistance to tuberculosis are cell mediated immune responses. Persons who are undernourished and suffering from silicosis, diabetes, myxoedema, HIV infection or under immuno - suppressive drugs are more susceptible (3, 4). Tuberculosis has often been described as a barometer of social welfare. It strikes poor people and those who do not have access to health care. The highest burden of tuberculosis is in the most impoverished countries. Poor housing and overcrowding are closely associated with transmission of infection.

**Mode of Transmission**

The source of infection is an open case (sputum positive) of pulmonary tuberculosis. *Mycobacterium tuberculosis* is spread by airborne particles, known as droplet nuclei that can be generated when persons with pulmonary or laryngeal TB sneeze, cough, speak, or sing. It has been estimated that a cough can generate 3000 droplet nuclei. The same number is generated by a person talking for five minutes (13). Persons who share the same airspace with persons with infectious TB disease are at greatest risk for infection. Infection occurs when a susceptible person inhales droplet nuclei containing tubercle bacilli and these bacilli become established in the alveoli of the lungs and

spread throughout the body. Prolonged household contact with an open case may lead to infection. Fomites do not play any role in transmission of the disease. Ingestion of unpasteurized milk or dairy products may lead to infection by *M bovis*. Direct inoculation though the skin can also lead to infection. However both these modes of transmission probably cause a very small number of cases (3, 7).

### Pathogenesis of TB

Primary infection occurs on first exposure to tubercle bacilli. Inhaled droplet nuclei are so small that they avoid the muco - ciliary defenses of the bronchi and lodge in the terminal alveoli of the lungs. Infection begins with multiplication of tubercle bacilli in the lungs. This is the Ghon focus. Lymphatics drain the bacilli to the hilar lymph nodes. The Ghon focus and related hilar lymphadenopathy form the primary complex. Bacilli may spread in the blood from the primary complex throughout the body. The immune response (delayed hypersensitivity and cellular immunity) develops about 4 - 6 weeks after the primary infection. The size of the infecting dose of bacilli and the strength of the immune response determine the course following primary infection. In most cases, the immune response stops the multiplication of bacilli. However, a few dormant bacilli may persist. A positive tuberculin skin test would be the only evidence of infection. The immune response in a few cases is not strong enough to prevent multiplication of bacilli and disease occurs within a few months (14).

#### Post - primary TB

Post - primary TB occurs after a latent period of months or years after primary infection. It may occur either by reactivation or by reinfection. Reactivation means that dormant bacilli persisting in tissues for months or years after primary infection start to multiply. This may be in response to a trigger, such as weakening of the immune system by HIV infection. Reinfection means a repeat infection in a person who has already previously had a primary infection. Post - primary TB usually affects the lungs but can involve any part of the body. The characteristic features of post - primary PTB are extensive lung destruction with cavitation, positive sputum smear, upper lobe involvement with usually no intrathoracic lymphadenopathy (14). Extra - pulmonary TB can affect the lymph nodes, pleura, bones and joints, the genito - urinary tract, the nervous system (meningitis), intestines etc. If untreated, TB leads to death within 2 - 3 years in at least half the patients (15).

### Management

Diagnosis and treatment of cases of tuberculosis is carried out in accordance with the guidelines issued by the Revised National Tuberculosis Control Programme. The following have been extracted from the Technical and Operational Guidelines for Tuberculosis Control issued by Central TB Division, Directorate General of Health Services, Ministry of Health and Family Welfare, Nirman Bhavan, New Delhi in October 2005 (15).

### Diagnosis

#### Identification of tuberculosis suspects

Most patients with TB visit health facilities promptly after symptoms occur. Hence, every adult patient with respiratory symptoms attending the health facility must be asked about symptoms suggestive of tuberculosis. The most common symptom of pulmonary TB is a persistent cough for 3 weeks or more, usually with expectoration. It may be accompanied by one or more of the following symptoms such as weight loss, chest pain, tiredness, shortness of breath, fever, particularly with rise of temperature in the evening. In some cases there will be blood in the sputum, loss of appetite and night sweats. About 2 - 3% of new adult outpatients in a general health facility are expected to have cough for 3 weeks or more and on an average 10% of the suspects are expected to have sputum positive pulmonary TB.

#### Case finding tools

The main tools for diagnosing pulmonary TB are sputum smear microscopy, chest X-ray, and culture of *Mycobacterium tuberculosis* bacilli.

#### Sputum smear microscopy

This is the primary tool for diagnosing TB as it is easy to perform at the peripheral laboratories, not expensive and specific with low inter and intra reader variation. It is simple and requires minimum training and can be used for diagnosis, monitoring and defining cure. Therefore, this is the key diagnostic tool used for case detection in RNTCP. If good diagnostic practices are followed, it is expected that at least 50% of the new pulmonary TB patients diagnosed will be smear - positive.

#### Chest X - ray

X - ray as a diagnostic tool is sensitive but less specific with large inter and intra reader variations. No shadow is typical of TB. 10 - 15% culture - positive cases remain undiagnosed and 40% patients diagnosed as having TB by X - ray alone may not have active TB disease. It is supportive to microscopy.

#### Culture

Culture of *Mycobacterium tuberculosis* bacilli is very sensitive and specific but is expensive as it requires a specialized laboratory set - up and results are available only after several weeks. If available, culture of tubercle bacilli may be helpful, although in sputum - negative cases a clinical decision to treat for TB based on X - ray findings and lack of response to broad - spectrum antibiotics would be more practical and also ensure prompt treatment. Culture and sensitivity testing is valuable for diagnosis and management of drug resistant tuberculosis, besides epidemiological surveillance and planning.

#### Tuberculin test

Tuberculin test may be useful as an additional tool for diagnosing pediatric TB, in whom a positive test is more likely to reflect recent infection with TB and indicates a much higher risk of developing disease. However, the tuberculin test has no role in diagnosing adult pulmonary TB disease in India.

### Diagnosis by Sputum Microscopy

Microscopic examination of sputum is, as a rule, the only way by which the diagnosis of pulmonary TB can be confirmed. Whenever TB is suspected, at least 3 specimens of sputum should be collected over 2 consecutive days and examined by microscopy. Only one laboratory form needs to be filled for all the three specimens of the patient. The smears are fixed by drying or heating and stained with the Ziehl - Neelsen (ZN) stain & examined under the oil immersion lens of a microscope. The interpretation of the slides is as given in Table - 1.

Table - 1: Reporting of Smears

| Examination finding | Result Recorded | Grading | No. of fields examined |
|---|---|---|---|
| > 10 AFB per oil immersion field | Positive | 3+ | 20 |
| 1 - 10 AFB per oil immersion field | Positive | 2+ | 50 |
| 10 - 99 AFB per 100 oil immersion fields | Positive | 1+ | 100 |
| 1 - 9 AFB per 100 oil immersion fields | Positive | Scanty | 100 |
| No AFB in 100 oil immersion fields | Negative | Negative | 100 |

### Classification of tuberculosis cases

The treatment of tuberculosis under the RNTCP is standardized into different categories. It is important to classify a patient into the correct category so that he may receive the correct combination of drugs and duration of treatment. Classification of pulmonary cases should be based on at least 3 sputum smear examinations. Sputum should also be examined for cases of suspected extra - pulmonary TB if pulmonary symptoms are present.

Pulmonary tuberculosis

#### Smear - positive patient

A patient with at least 2 initial sputum smear examinations (direct smear microscopy) positive for acid - fast bacilli (AFB) OR A patient with one sputum examination positive for AFB and radiographic abnormalities consistent with active pulmonary TB as determined by the treating Medical Officer (MO) OR A patient with one sputum specimen positive for AFB and culture positive for *M. tuberculosis.*

#### Smear - negative patient

A patient having symptoms suggestive of TB with at least 3 sputum examinations negative for AFB, and radiographic abnormalities consistent with active pulmonary TB as determined by the treating MO, followed by a decision to treat the patient with a full course of anti - TB therapy OR A patient whose diagnosis is based on culture positive for *M. tuberculosis* but sputum smear examinations negative for AFB.

#### Extra - pulmonary tuberculosis

Extra - pulmonary tuberculosis (EPTB) is tuberculosis of organs other than the lungs, such as the pleura (pleurisy), lymph nodes, intestines, genito - urinary tract, skin, joints and bones, and meninges of the brain. Diagnosis should be based on one culture - positive specimen from an extra - pulmonary site, or histological or radiological, or strong clinical evidence consistent with active extra - pulmonary TB followed by the treating MO's decision to treat with a full course of anti - TB therapy. Pleurisy is classified as extra - pulmonary TB. A patient diagnosed with both sputum smear positive pulmonary TB and extrapulmonary TB should be classified as a case of pulmonary TB.

Diagnostic algorithm of RNTCP

Patients with at least two positive smear results are diagnosed by the physician as a case of smear positive TB. They are further classified as new or old cases based on their treatment history, and appropriate therapy is prescribed.

For patients with only one sputum positive result on smear examination, chest X - ray is taken. If findings of the X - ray are consistent with pulmonary tuberculosis patient is diagnosed by the physician as a case of sputum positive pulmonary TB.

Patients in whom all 3 samples are negative on sputum smear examination are prescribed symptomatic treatment and broad spectrum antibiotics (such as cotrimoxazole, doxycycline, amoxycillin) for 10 - 14 days. In such cases antibiotics such as fluoroquinolones (ciprofloxacin, ofloxacin, etc.), rifampicin or streptomycin, which are active against tuberculosis, are not to be used. Most patients are likely to improve with antibiotics if they are not suffering from TB. If the symptoms persist after a course of broad spectrum antibiotics, repeat sputum smear examination (3 samples) must be done for such patients.

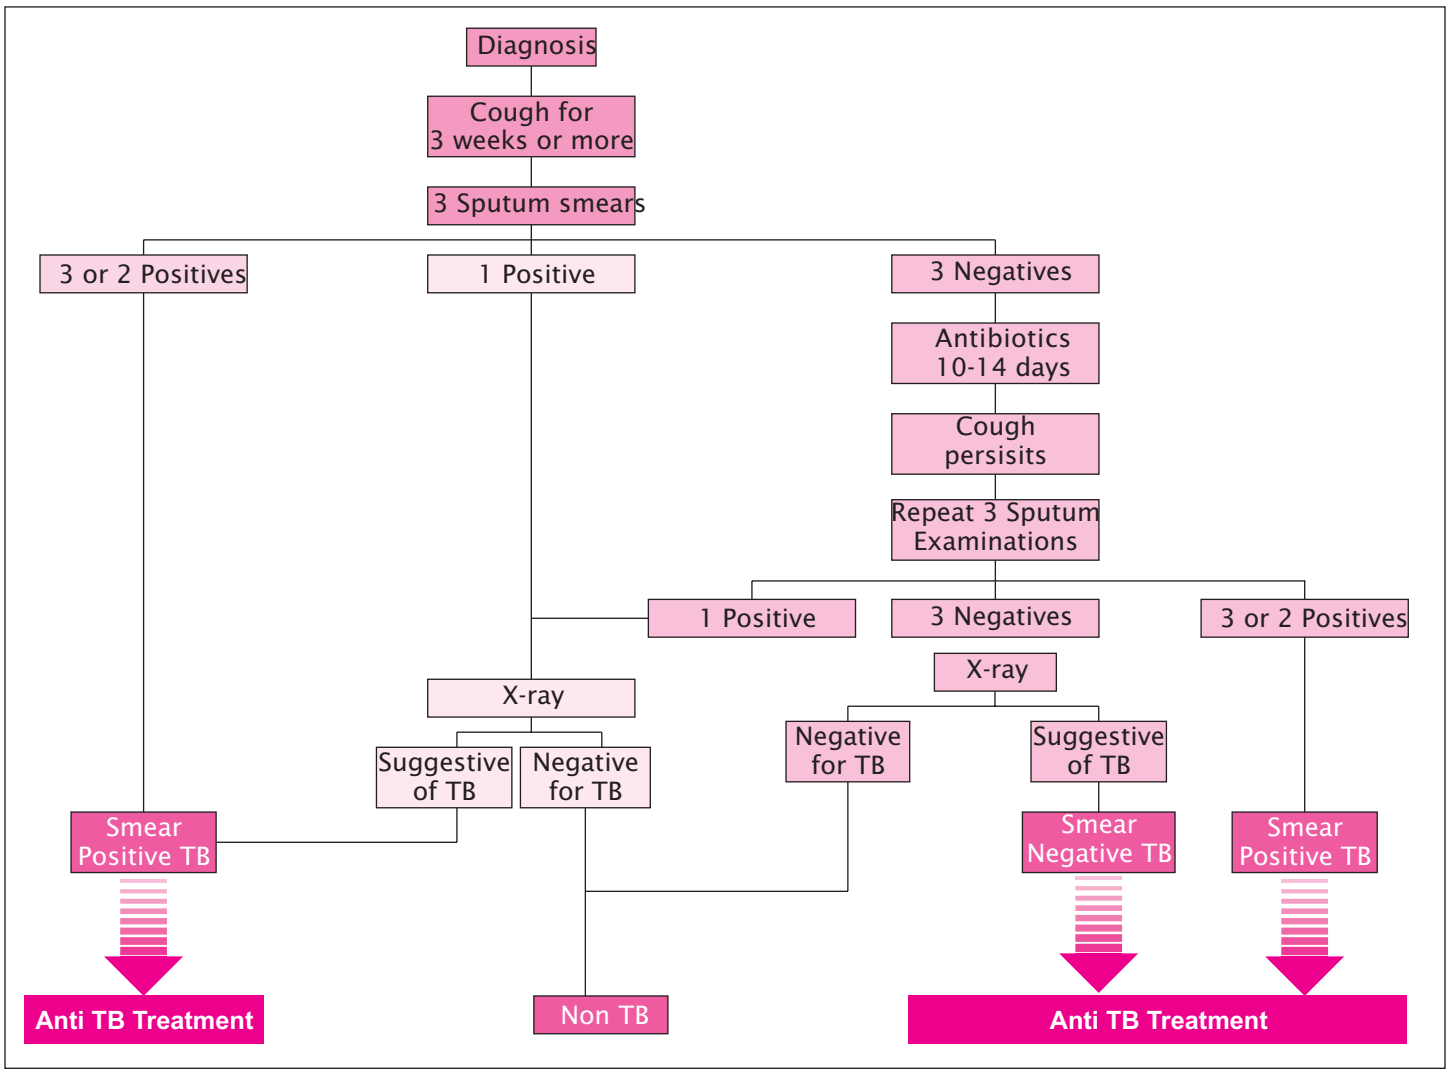
If two or more smears are positive, the patient is diagnosed as having smear positive pulmonary TB. If only one sputum sample is positive, chest X - ray is taken. If findings of the X - ray are consistent with pulmonary tuberculosis, patient is diagnosed by the physician as a case of sputum positive pulmonary TB. If the results for all the three sputum samples of repeat examination are found negative then a chest X - Ray is taken. If findings of the X - ray are consistent with pulmonary tuberculosis, patient is diagnosed by the physician as a case of sputum negative pulmonary TB. The Diagnostic Algorithm is given in Fig - 1.

Patients with EPTB who also have cough of any duration, should have 3 sputum samples examined. If the smear result is positive, the patient is classified as pulmonary TB and his/her treatment regimen will be that of a case of smear positive pulmonary TB.

### Treatment

Under the RNTCP, the objectives of tuberculosis treatment are to decrease mortality and morbidity by ensuring cure, minimizing relapses and preventing development of drug

Fig 1 : Diagnostic algorithm



resistance; to decrease infections and break the chain of transmission of infection; and to achieve the above whilst minimizing side effects due to drugs. These objectives are achieved in RNTCP through intermittent (thrice weekly) treatment regimens given under direct observation for both pulmonary and extra - pulmonary tuberculosis patients. Treatment regimens for tuberculosis have emerged as a result of controlled clinical trials in India and other parts of the world. It has been proven that thrice-a-week (intermittent) treatment is as effective as daily treatment and produces lesser side effects.

RNTCP provides standardized anti - TB treatment in three categories. Once the patient has been diagnosed as having TB, may be pulmonary or extra - pulmonary, his treatment regimen is decide based on the results of sputum Smear examination, history of previous anti - TB treatment, disease classification (pulmonary/ extra - pulmonary), and severity of illness.

Definition of types of cases

**New :** A TB patient who has never had treatment for tuberculosis or has taken antituberculosis drugs for less than one month.

**Relapse** : A TB patient who was declared cured or treatment completed by a physician, but who reports back to the health service and is now found to be sputum smear - positive.

**Transferred in** : A TB patient who has been received for treatment in a Tuberculosis Unit, after starting treatment in another unit where she/he has been registered.

**Treatment after default** : A TB patient who received anti - tuberculosis treatment for one month or more from any source and returns to treatment after having defaulted, i.e., not taken anti - TB drugs consecutively for two months or more, and is found to be sputum smear - positive.

**Failure** : Any TB patient who is smear - positive at 5 months or more after starting treatment. Failure also includes a patient who was treated with Category III regimen but who becomes smear - positive during treatment.

**Chronic** : A TB patient who remains smear - positive after completing a re - treatment regimen.

**Others** : TB patients who do not fit into the above

mentioned types. Reasons for putting a patient in this type must be specified.

Treatment regimens

Standardized treatment is given to patients based on their treatment category. The details of treatment are given in Table - 2. The most important drugs used in the treatment of TB are isoniazid (H), rifampicin (R), pyrazinamide (Z), streptomycin (S) and ethambutol (E). The dosage of the drugs is shown in Table - 3. Drugs are supplied in patient - wise boxes (PWB) containing the full course of treatment, and packaged in blister packs. The PWB have a color code indicating the category (Red for CAT I, Blue for CAT II and Green for CAT III). In each PWB, there are two pouches one for intensive phase (A) and one for continuation phase (B). For the intensive phase, each blister pack contains medicines for one dose. For the continuation phase, each blister pack contains one week's supply of medication. The drugs for extension of the intensive phase (prolongation pouches) are supplied separately. For adults, drugs will be given in the recommended number of pills/capsules irrespective of body weight. However, for patients weighing more than 60 kilograms an additional capsule of rifampicin 150 mg will be added to the treatment regimen. Patients who are more than 50 years old receive streptomycin 500mg and patients who weigh less than 30 Kg receive drugs as per body weight. For children, the drugs will be given according to body weight. Patient wise boxes for children is being developed, however until these are available the drugs are given to children as per body weight.

Table - 2 : Treatment

| Category of Treatment | Type of Patient | Regimen* |
|---|---|---|
| Category I | New sputum smear-positive<br>Seriously ill** new sputum smear-negative<br>Seriously ill** new extra-pulmonary | 2 $H_3R_3Z_3E_3$ / 4 $H_3R_3$ |
| Category II | Sputum smear-positive Relapse<br>Sputum smear-positive Failure<br>Sputum smear-positive | 2 $H_3R_3Z_3E_3S_3$ / 1 $H_3R_3Z_3E_3$ / 5 $H_3R_3E_3$ |
| Category III | New Sputum smear-negative, not seriously ill<br>New Extra-pulmonary, not seriously ill | 2 $H_3R_3Z_3$ / 4 $H_3R_3$ |

* The number before the letters refers to the number of months of treatment. The subscript after the letters refers to the number of doses per week. The dosage strengths are as follows: H: Isoniazid (600 mg), R: Rifampicin (450 mg), Z: Pyrazinamide (1500 mg), E: Ethambutol (1200 mg), S: Streptomycin (750 mg). Patients who weigh 60 kg or more receive additional rifampicin 150 mg. Patients who are more than 50 years old receive streptomycin 500 mg. Patients who weigh less than 30 kg, receive drugs as per body weight. Patients in Categories I & II who have a positive sputum smear at the end of the initial intensive phase receive an additional month of intensive phase treatment.

Table - 3 : Dosage of Drugs

| Medication | Dose (thrice a week) |
|---|---|
| Isoniazid | 600 mg |
| Rifampicin | 450 mg |
| Pyrazinamide | 1500 mg |
| Ethambutol | 1200 mg |
| Streptomycin | 0.75 g |

** Seriously ill also includes, any patient, pulmonary or extra-pulmonary who is HIV positive & declares his serostatus to the categorizing/treating medical officer. For the purpose of categorization, HIV testing should not be done

*** In rare & exceptional cases, patients who are sputum smear - negative or who have extra-pulmonary disease can have Relapse or Failure. This diagnosis in all such cases should always be made by an MO & should be supported by culture or histological evidence of current, active TB. In these cases, patient should be categorized as 'Others' & given Category II treatment.

**Monitoring of patients**

Sputum smear microscopy is much more informative than radiology in monitoring the progress of chemotherapy. Hence, the patient should be referred for follow - up sputum examinations at the prescribed intervals. Other investigations like ESR, antibody detection etc. are unreliable and have no role in diagnosing and / or evaluating the progress or results of treatment.

Follow up Smear examination

**New smear - positive patients**

Two smears are examined each time during follow - up. The first follow - up sputum examination is done at the end of 2 months of intensive phase. On the 22nd dose in intensive phase, the patient is given a sputum container and instructed to bring the early morning sample. The patient brings the sputum sample when he comes for the 23rd dose in the intensive phase when a spot sample is also collected. The results of both the smear examinations will be available at the next visit of the patient. If both smears are negative, the patient will be put on the continuation phase. If either of the smears is positive, the intensive phase will be extended by one more month, and sputum examination will be repeated at the end of the third month. Thereafter, the patient is put on the continuation phase regardless of his/her sputum status at the end of the extended intensive phase. Subsequent follow - up smear examinations are done after 2 months into continuation phase and if found positive the patient is declared as a treatment failure, re - registered and started on the re - treatment regimen afresh. If the follow - up sputum is negative, the continuation phase is completed and smear examination repeated at the end of treatment. The sputum should generally be collected at the time of collection of the 16th blister so that the results are available at the time of supply of the last week's blister pack. Results of end of treatment sputum should be available not later than one week of completion of treatment.

**Re - treatment patients**

The first sputum smear examination is done at 3 months after beginning of the intensive phase. On the 34th dose of the intensive phase the patient is given a sputum container and instructed to bring the early morning sample. The patient brings the sputum sample when he comes for 35th dose in the intensive phase when a spot sample is also collected. The results of both the smear examinations will be available at the next visit of the patient. If both smears are negative, the patient will be put on the continuation phase. If either of the samples is positive, the intensive phase of treatment will be extended by one more month, and another smear examination will be done at the end of the fourth month of treatment. Thereafter, the patient is put on the continuation phase regardless of his sputum status at the end of 4 months of the intensive phase. Subsequent follow - up sputum examinations are done after 2 months into continuation phase. Irrespective of the results of the follow - up smear examinations, the patient continues and completes the treatment when a final follow - up sputum smear is done. The sputum should generally be collected at the time of collection of the 20th blister so that the results are available at the time of supply of the last week's blister pack.

**Smear - negative patients**

Two smears are examined during the follow - up visit at the end of 2 months of the intensive phase and again at the end of treatment. If the patient becomes sputum smear - positive at the end of IP or at the end of treatment, his outcome is 'failure' and is started on re - treatment Cat II regimen after registration.

### Management of Pediatric Tuberculosis under RNTCP

Childhood TB is a reflection of the prevalence of sputum smear - positive pulmonary tuberculosis (PTB) and the extent of transmission of TB infection in the community. Children are likely to suffer from more serious forms of TB and are more likely to die if not treated properly. Reliable data on disease incidence and prevalence is however not available due to the difficulties in diagnosis of pediatric TB under field conditions.

TB should be suspected among children presenting with fever and / or cough for more than 3 weeks, with or without weight loss or no weight gain; and history of contact with a suspected or diagnosed case of active TB disease within the last 2 years. Diagnosis should be based on a combination of clinical presentation, sputum examination wherever possible, Chest X ray (PA view), Mantoux test (1 TU PPD RT23 with Tween 80, positive if induration >10mm after 48 - 72 hours) and history of contact. Diagnosis should be made by a Medical Officer and the existing RNTCP case definitions be used for all cases diagnosed. Children showing neurological symptoms like irritability, refusal to feed, headache, vomiting or altered sensorium may be suspected to have TB meningitis. Use of currently available scoring systems is not recommended for the diagnosis of TB among children. Where diagnostic difficulties are faced, the child should be referred to a pediatrician for further management. DOTS is the recommended strategy for treatment of TB and all pediatric TB patients should be registered under RNTCP. Intermittent short course chemotherapy given under direct observation should be used in children, as in adults.

Recent infection with tubercle bacilli is one of the risk factors for disease development. The younger the child, the higher is the risk of breakdown of infection into disease. Therefore, household contacts of smear - positive TB cases, especially those below 6 years of age, must be screened for symptoms of tuberculosis. In case of symptoms being present, the diagnostic algorithm for pediatric TB should be followed and the child should be given a full course of anti TB treatment if He / she is diagnosed as a TB case. For asymptomatic children under 6 years, chemoprophylaxis with isoniazid (5 mg per kg body wt) should be administered daily for a period of six months. This is regardless of the BCG vaccination status.

### Management of Extra - Pulmonary Tuberculosis

Extra - pulmonary TB (EPTB) comprises about 10% to 15% of all new TB cases in our country. Among them, 75% have lymph node or pleural TB. A person with extra - pulmonary TB may have symptoms related to the organs affected, such as, swelling of lymph nodes, occasionally with discharge of pus; pain and swelling of the joints; headache, fever, stiffness of the neck and mental confusion when the brain or meninges are involved. In addition, the following general symptoms like weight loss, fever, particularly with rise of temperature in the evening and night sweats may be present. Patients with suspected EPTB should be referred to a competent medical practitioner for expert opinion. Diagnosis of such patients may be made by using appropriate diagnostic procedures (such as FNAC/Biopsy/culture from the site of disease) as well as clinical methods. Patients with EPTB who also have cough of any duration, should have 3 sputum samples examined. If the smear result is positive, the patient is classified as pulmonary TB. Intermittent short course chemotherapy regimens of 6 - 9 months are recommended internationally for all forms of extra - pulmonary TB. In cases of Tubercular Meningitis (TBM), initial hospitalization is recommended. In TBM, ethambutol should be replaced by streptomycin in the intensive phase and continuation phase of the treatment is for 6-7 months. Adjunctive steroids may be useful in pericardial & meningeal TB.

### Management of Patients with HIV Infection and Tuberculosis

People co - infected with HIV and TB have a higher risk of developing TB disease. Irrespective of HIV status RNTCP diagnostic algorithm should be followed for all TB suspects. Anti - TB treatment is the same for HIV - infected persons as it is for HIV negative TB patients. Hence they should be treated with RNTCP regimens. All new TB cases known to be HIV positive are classified as seriously ill and treated with Category I regimen. The re - treatment cases are to be treated with Category II regimen. It is important to maintain confidentiality regarding HIV status of individuals including TB suspects and patients, in order to prevent stigmatization and discrimination. TB patients

should be encouraged to voluntarily share their HIV status with the treating physician for the purpose of taking clinical decisions like categorization for treatment of TB, treatment of other opportunistic infections and provision of ART. The HIV - positive status should not be disclosed by the treating physician to any other staff involved in RNTCP. In addition, the HIV - positive status should not be mentioned in any RNTCP records. TB patients who have other HIV - associated opportunistic infections, or report risk behaviour for HIV, should be offered referral to the nearest Voluntary Counseling and Testing Centre (VCTC) for voluntary counseling and HIV testing. Routine HIV testing of all TB suspects/patients is not the national policy.

**Drug Resistance**

Drug resistance is more common among patients who show poor compliance, develop TB disease again, after having taken anti tubercular treatment in the past, or come from areas where drug - resistant TB is common (16).

MDR - TB

(Multidrug Resistant TB) describes strains of tuberculosis that are resistant to at least the two main first - line TB drugs - isoniazid and rifampicin. Two thirds of all cases of MDR are found in China, India and the Russian Federation. In 2007, the estimated number of cases of MDR-TB were 4,24,000 and the estimated number of deaths due to MDR-TB were 1,16,000 (17). In India MDR-TB estimates are placed at less than 3.5% of new cases and 12% of retreatment cases. RNTCP advocates using a standardised treatment regimen comprising of six drugs (kanamycin, ofloxacin, ethionamide, pyrazinamide, ethambutol and cycloserine) during 6 - 9 months of the Intensive Phase and 4 drugs (ofloxacin, ethionamide, ethambutol and cycloserine) during the 18 months of the Continuation Phase for cases of MDR-TB (18).

XDR - TB

Extensive Drug Resistant is MDR - TB that is also resistant to three or more of the six classes of second - line drugs. In 2007 the estimated number of cases were 27,000 and the estimated number of deaths due to XDR TB were 16,000 ( 1 7 ) . 28 countries have published cases of XDR - TB and/or reported cases to WHO.

**Prevention and Control of Tuberculosis**

Early diagnosis and treatment, particularly of sputum smear positive cases is the cornerstone of tuberculosis control. The Revised National Tuberculosis Control Programme has focused on achieving high cure rates. The protective efficacy of BCG has ranged between 0 to 80% in different studies. Details on the vaccine are given in the chapter on Immunization.

The Stop TB Strategy has six major components: DOTS expansion and enhancement; addressing TB/HIV, MDR - TB and other challenges; contributing to health system strengthening; engaging all care providers; empowering patients and communities; and enabling and promoting research (1).

Action on Occurrence of a Case (Armed Forces) (11, 12)

In case a diagnosis of tuberculosis is arrived at in a serving person, the individual is promptly transferred to one of the referral centres for tuberculosis for further management. However, in the event that tuberculosis is detected amongst ex - servicemen or the family members / dependents of serving personnel, they are given domiciliary treatment from dependent hospitals preferably with DOTS. The various referral hospitals for treatment of tuberculosis cases amongst services are:

(a) MH (CTC) Pune for:
  (i) Officers / Nursing Officers / Cadets of the three services.
  (ii) Multi - drug resistant TB
  (iii) Cases requiring chest surgery
  (iv) TB patients from all fmn except Eastern Command zone and UP Area

(b) MH Namkum for all cases from Eastern Command zone

(c) MH Dehradun for cases from UP Area

(d) INHS Asvini

(e) Comd Hosp (AF) Bangalore

**Research**

It is evident that new tools are urgently needed to improve treatment, detection and prevention of TB. The Stop TB Partnership of WHO has created three specific research working groups devoted to new drugs, diagnosis, and vaccine development, respectively. The need for new rapid and inexpensive diagnostics for diagnosing tuberculosis and drug resistance is obvious. An effective

# Avian Influenza

### Introduction

Avian influenza is an infectious disease of birds caused by type A strains of the influenza virus. The disease, which was first identified in Italy more than 100 years ago, occurs worldwide. All birds are thought to be susceptible to infection with avian influenza, though some species are more resistant to infection than others. Migratory waterfowl – most notably wild ducks – are the natural reservoir of avian influenza viruses. Avian influenza viruses do not normally infect species other than birds and pigs. Of the 15 avian influenza virus subtypes, H5N1 is of particular concern for several reasons. H5N1 mutates rapidly and has a documented propensity to acquire genes from viruses infecting other animal species (1, 2)

### Current Avian Influenza Outbreak

Some time prior to 1997, the H5N1 strain of avian influenza virus began circulating in the poultry populations of parts of Asia, quietly establishing itself. The virus first erupted in its highly pathogenic form in 1997, but did not appear again. Then, towards the end of 2003, H5N1 suddenly became highly and widely visible. Infection by the H5N1 strain has now been documented in either domestic poultry or migratory birds in over twenty countries spread across Asia and Europe. Over a 140 million birds have been destroyed worldwide in efforts to control the spread of this virus (3).

The ability of the H5N1 strain to cause severe disease in humans has now been documented on at least two occasions. The first documented infection of humans with an avian influenza virus occurred in Hong Kong in 1997, when the H5N1 strain caused severe respiratory disease in 18 humans, of whom 6 died (4). In its second documented outbreak, since December 2003, the H5N1 strain has infected at least 340 people and killed 208 in 13 countries, mostly in South East Asia (5).

### Lessons from History

An influenza pandemic is a rare but recurrent event. Three pandemics occurred in the previous century: "Spanish influenza" in 1918, "Asian influenza" in 1957, and "Hong Kong influenza" in 1968. The 1918 pandemic killed an estimated 40–50 million people worldwide. That pandemic, which was exceptional, is considered one of the deadliest disease events in human history. Subsequent pandemics were much milder, with an estimated 2 million deaths in 1957 and 1 million deaths in 1968. . Experts agree that another influenza pandemic is inevitable and possibly imminent. Striking similarities exist between the 1918 virus and the H5N1 strain. The 1918 pandemic is believed by many experts to have begun following adaptive mutation of an avian virus which acquired, following stepwise changes during subsequent human infections, the adaptations needed to sustain efficient human-to-human transmission. Recent publications have suggested other similarities between H5N1 and the 1918 virus in the severity of disease, its concentration in the young and healthy, and the occurrence of primary viral pneumonia in the absence of secondary bacterial infection (6, 7).

## Mode of Transmission

### Bird to Bird Transmission

Transmission among birds: Infected birds shed the virus in oculonasal discharges and feces, and contaminated drinking water is commonly implicated as the source of infection among birds. Once introduced into a flock, infected birds, contaminated equipment, insects, rodents, and personnel have all been implicated in the spread of the virus. When birds are in close proximity and air movement is conducive, airborne transmission can occur (7).

### Transmission form Birds to Humans

Direct contact with infected poultry, or surfaces and objects contaminated by their faeces, is presently considered the main route of human infection. To date, most human cases have occurred in rural or periurban areas where many households keep small poultry flocks, which often roam freely, sometimes entering homes or sharing outdoor areas where children play. Moreover, because many households in Asia depend on poultry for income and food, many families sell or slaughter and consume birds when signs of illness appear in a flock, and this practice has proved difficult to change. Exposure is considered most likely during slaughter, defeathering, butchering, and preparation of poultry for cooking. There is no evidence that properly cooked poultry or eggs can be a source of infection (7).

### Human to Human Transmission

There is no definite evidence of human to human transmission in the current episode. A new virus adapted for efficient human-to-human transmission would spread very rapidly. The respiratory tract is the most likely route of entry.

### People at risk of contracting Avian Influenza (8)

(a) Workers handling poultry in farms, markets & involved in culling activity, veterinary workers and health workers are at higher risk of acquiring the infection. Even the family members of these workers are at higher risk.

(b) Any type of Influenza tends to be more serious in children, elderly persons above 65 years of age and the chronically sick persons.

### Spread from one Country to another

The disease can spread from country to country through international trade in live poultry. Migratory birds, including wild waterfowl, sea birds, and shore birds, can carry the virus for long distances and have, in the past, been implicated in the international spread of highly pathogenic avian influenza. Migratory waterfowl – most notably wild ducks – are the natural reservoir of bird flu viruses, and these birds are also the most resistant to

infection. They can carry the virus over great distances, and excrete it in their droppings, yet develop only mild and short-lived illness.

## Clinical course

The incubation time for influenza ranges from 1 – 5 days with an average of 2 days. In most cases, virus is found in specimens from the respiratory tract from 1 – 2 days before to 4 – 5 days after onset of disease, corresponding to the period of communicability. There is no chronic carrier state, but in young children viral shedding tends to last longer than in adults. Clinical onset is characterized by abrupt fever, headache, malaise and myalgias. Systemic symptoms usually last for 3 days. Sore throat, rhinitis and non-productive cough may continue for several days after the systemic symptoms have ceased. Influenza may be misdiagnosed clinically: several infectious agents including respiratory syncytial virus may cause outbreaks of influenza-like disease, illustrating the importance of laboratory based confirmation of the clinical diagnosis (9).

The incubation period of influenza A(H5N1) is currently uncertain. Based on limited experience from 6 cases in Viet Nam, the median time between exposure and onset of illness is 3 days (range 2–4 days). Cases have been characterized by high fever (above 38 °C), cough and shortness of breath. Lower respiratory symptoms or signs developed early and include dyspnoea and auscultatory signs. Clinically apparent pneumonia with chest X-ray changes was seen in all patients, although the X-ray changes were nonspecific and included diffuse, multifocal or patchy infiltrates, interstitial infiltrates, and segmental or lobular consolidation with air bronchograms. The illness rapidly progressed to respiratory distress and subsequent respiratory failure within 1 week of the onset of symptoms. Most cases have died in spite of ventilatory support. Common laboratory findings were lymphopenia ($<1 \times 10^9$/litre) and slightly or moderately raised alanine aminotransferase and aspartate transaminase (10).

## Laboratory Diagnosis (11)

The optimal specimen for influenza A virus detection is a nasopharyngeal aspirate obtained within 3 days of the onset of symptoms, although nasopharyngeal swabs and other specimens can also be used. The WHO recommended procedure for collection and dispatch of human and animal specimens is given as Appx 'A' and Appx 'B' respectively. WHO guidelines for storage and transport of specimens are given as Appx 'C'. Assays available for the diagnosis of influenza A virus infections include:

**(a) Rapid antigen detection :** Results can be obtained in 15–30 minutes.

(i) Near-patient tests for influenza. These tests are commercially available

(ii) Immunofluorescence assay. A widely used, sensitive method for diagnosis of influenza A, B virus infections and other clinically important respiratory viruses.

(iii) Enzyme immunoassay. For influenza A nucleoprotein (NP).

**(b) Virus culture :** Provides results in 2–10 days. Both shell-vial and standard cell-culture methods may be used to detect clinically important respiratory viruses. Positive influenza cultures may or may not exhibit cytopathic effects but virus identification by immunofluorescence of cell cultures or haemagglutination-inhibition (HI) assay of cell culture medium (supernatant) is required.

**(c) Polymerase chain reaction and Real-time PCR assays** : Primer sets specific for the haemagglutinin (HA) gene of currently circulating influenza A/H1, A/H3 and B viruses are becoming more widely used. Results can be available within a few hours from either clinical swabs or infected cell cultures.

Any specimen with a positive result using the above approaches for influenza A virus and suspected of avian influenza infection should be further tested and verified by a designated WHO H5 Reference Laboratory. Laboratories that lack the capacity to perform specific influenza A subtype identification procedures are requested to forward specimens or virus isolates to a National Influenza Centre or to a WHO H5 Reference Laboratory for further identification or characterization. For the Indian Armed Forces, all specimens from suspected human cases or of animal origin should be forwarded in accordance with the guidelines, through courier, to Head, Department of PSM, Armed Forces Medical College, Pune 411040. In case of extreme urgency human specimens can be forwarded directly to National Institute of Virology, Pune under intimation to Department of PSM, AFMC. In similar situations animal specimens may be forwarded directly to High Security Animal Diseases Laboratory Bhopal. Contact details of these two laboratories are given in Appx 'D'.

## Treatment

Two drugs (in the neuraminidase inhibitors class), oseltamivir (commercially known as Tamiflu) and zanamivir (commercially known as Relenza) can reduce the severity and duration of illness caused by seasonal influenza. The efficacy of the neuraminidase inhibitors depends on their administration within 48 hours after symptom onset. For cases of human infection with H5N1, the drugs may improve prospects of survival, if administered early, but clinical data are limited. The H5N1 virus is expected to be susceptible to the neuraminidase inhibitors. An older class of antiviral drugs, the M2 inhibitors amantadine and rimantadine, could potentially be used against pandemic influenza, but resistance to these drugs can develop rapidly and this could significantly limit their effectiveness against pandemic influenza. Some currently circulating H5N1 strains are fully resistant to these the M2 inhibitors. However, should a new virus emerge through reassortment, the M2 inhibitors might be effective. Guidelines for management of suspected case of H5N1 influenza are given as Appx "E" to this document.

## Prevention and control strategies (12)

Vaccination and the use of antiviral drugs are two of the most important response measures for reducing morbidity and mortality during a pandemic. On present trends, neither of these interventions will be available in adequate quantities or equitably distributed at the start of a pandemic and for many months thereafter. In such a situation surveillance to provide early warning and health education to reduce human exposure are the most important control measures.

**Surveillance (13)**

(a) Surveillance is the cornerstone of pandemic preparedness and response. The following events need to be reported to local, state or National health authorities on priority :

(i) Individuals with, and clusters of, acute respiratory illness on or during admission;

(ii) Unexplained deaths due to acute respiratory illness in the community;

(iii) Unexplained deaths due to acute respiratory illness in health care facilities;

(iv) Monitoring sales of antiviral drugs for influenza A viral infection, antimicrobials commonly used for the treatment of acute respiratory infections, decongestant drugs, or antitussive drugs.

(b) For countries and territories where influenza A/H5 viruses have not been identified as a cause of illness in human or animal populations since 1 October 2003, like India, the WHO recommends that the decision on whether to test for influenza A/H5 viruses should be the result of a risk assessment that considers both geographical proximity to countries or territories where HPAI outbreaks are reported in animal populations and the following case-based factors: (Case definitions are given as Appx 'F' to this document):

(i) Clinical presentation, including death due to unexplained acute respiratory illness

(ii) Occupational exposure; (At-risk occupations such as a domestic fowl or swine farm worker, domestic fowl processing plant worker, domestic fowl culler (catching, bagging, or transporting birds, disposing of dead birds), worker in live animal market, chef working with live or recently killed domestic fowl, dealer or trader in pet birds, worker in a laboratory where specimens are tested for influenza A/H5 viruses, health care worker.

(iii) Living in an area in which there are rumours of deaths of domestic fowl;(Domestic fowl are birds that are commonly reared for their flesh, eggs, or feathers and are kept in a yard or similar enclosure, including chickens, ducks, geese, turkeys, guinea-fowl)

(iv) History of travel, during the 7 days before the onset of symptoms, to a country or territory with reported HPAI outbreaks due to influenza A (H5N1) in the animal populations AND one or more of the following:

- contact (within 1 metre) with live or dead domestic fowl, wild birds, or swine in any setting;
- exposure to settings in which domestic fowl or swine were or had been confined in the previous 6 weeks;
- Contact (within touching or speaking distance) with a confirmed human case of influenza A/H5 infection;
- contact (within touching or speaking distance) with a person with an unexplained acute respiratory illness that later resulted in death;
- positive laboratory result for influenza A.

**Vaccination**

Vaccines are universally regarded as the most important medical intervention for preventing influenza and reducing its health consequences during a pandemic. In the past, however, vaccines have never been available early enough and in sufficient quantities to have an impact on morbidity and mortality during a pandemic. Past problems, related to the special nature of pandemic vaccines and the inadequacy of manufacturing capacity, have endured. Several companies are trying to make an effective vaccine against H5N1. While initial testing of an avian flu vaccine shows promise and trials should be completed by the end of 2005, questions remain about the vaccine's ability to protect large numbers of people. Potential problems include a high initial dose, the requirement of two doses, and requirement of about six weeks for effective immunity to develop. Another major concern is the inability to produce adequate number of doses, once the vaccine is approved (14-15).

**Chemoprophylaxis**

The current recommendation for chemoprophylaxis against H5N1 influenza is one oseltamivir phosphate 75 mg tablet each day for at least 7 days beginning as soon as possible after exposure. Antiviral prophylaxis should begin immediately or at least within 2 days of exposure and may continue for up to 6 weeks (15).

**Non Medical Measures**

In resource-poor settings, non-medical interventions may be the main line of defence throughout the first wave of a pandemic. Health education to inform the general public especially small poultry farmers is essential to reduce exposure risk. Key advice for the general public as well as biosafety measures for poultry farm workers is given as Appx 'G'. Stringent sanitary measures and appropriate bio-security practices should be applied, including the control of human traffic and introduction of birds of unknown disease status into the flock. Carcasses of suspected and confirmed poultry case of Influenza should preferably be incinerated or buried deep using lime and soil in the ratio of 1:3.

The H5N1 avian influenza virus is not transmitted to humans through properly cooked food. The virus is sensitive to heat. Normal temperatures used for cooking (so that food reaches 70°C in all parts) will kill the virus. To date, no evidence indicates that any person has become infected with the H5N1 virus following the

consumption of properly cooked poultry or poultry products, even in cases where the food item contained the virus prior to cooking. Poultry and poultry products from areas free of the disease can be prepared and consumed as usual, with no fear of acquiring infection with the H5N1 virus. As a standard precaution, WHO recommends that poultry and poultry products should always be prepared following good hygienic practices, and that poultry meat should be properly cooked. This recommendation protects consumers from some well-known and common

## Appendix 'A'

### WHO guidelines for the collection of human specimens for laboratory diagnosis of Avian Influenza infection

General information

Respiratory virus diagnosis depends on the collection of high-quality specimens, their rapid transport to the laboratory and appropriate storage before laboratory testing. Virus is best detected in specimens containing infected cells and secretions. Specimens for the direct detection of viral antigens or nucleic acids and virus isolation in cell cultures should be taken preferably during the first 3 days after onset of clinical symptoms.

**Type of specimens**

A variety of specimens are suitable for the diagnosis of virus infections of the upper respiratory tract:

- Nasal swab
- Nasopharyngeal swab
- Nasopharyngeal aspirate
- Nasal wash
- Throat swab.

In addition to swabs from the upper respiratory tract, invasive procedures can be performed for the diagnosis of virus infections of the lower respiratory tract where clinically indicated:

- Transtracheal aspirate
- Bronchoalveolar lavage
- Lung biopsy
- Post-mortem lung or tracheal tissue.

Specimens for the laboratory diagnosis of avian influenza A should be collected in the following order of priority:

- Nasopharyngeal aspirate
- Acute serum
- Convalescent serum.

Specimens for direct detection of viral antigens by immunofluorescence staining of infected cells should be refrigerated and processed within 1–2 hours. Specimens for use with commercial near-patient tests should be stored in accordance with the manufacturer's instructions. Specimens for virus isolation should be refrigerated immediately after collection and inoculated into susceptible cell cultures as soon as possible. If specimens cannot be processed within 48–72 hours, they should be kept frozen at or below –70 °C. Respiratory specimens should be collected and transported in virus transport media. A number of media that are satisfactory for the recovery of a wide variety of viruses are commercially available.

Procedures for specimen collection

**Nasal swab**

A dry polyester swab is inserted into the nostril, parallel to the palate, and left in place for a few seconds. It is then slowly withdrawn with a rotating motion. Specimens from both nostrils are obtained with the same swab. The tip of the swab is put into a plastic vial containing 2–3 ml of virus transport medium and the applicator stick is broken off.

**Nasopharyngeal swab**

A flexible, fine-shafted polyester swab is inserted into the nostril and back to the nasopharynx and left in place for a few seconds. It is then slowly withdrawn with a rotating motion. A second swab should be used for the second nostril. The tip of the swab is put into a vial containing 2–3 ml of virus transport medium and the shaft cut.

**Nasopharyngeal aspirate**

Nasopharyngeal secretions are aspirated through a catheter connected to a mucus trap and fitted to a vacuum source. The catheter is inserted into the nostril parallel to the palate. The vacuum is applied and the catheter is slowly withdrawn with a rotating motion. Mucus from the other nostril is collected with the same catheter in a similar manner. After mucus has been collected from both nostrils, the catheter is flushed with 3 ml of transport medium.

**Nasal wash**

The patient sits in a comfortable position with the head slightly tilted backward and is advised to keep the pharynx closed by saying "K" while the washing fluid (usually physiological saline) is applied to the nostril. With a transfer pipette, 1–1.5 ml of washing fluid is instilled into one nostril at a time. The patient then tilts the head forward and lets the washing fluid flow into a specimen cup or a Petri dish. The process is repeated with alternate nostrils until a total of 10–15 ml of washing fluid has been used. Dilute approximately 3 ml of washing fluid 1:2 in transport medium.

**Throat swab**

Both tonsils and the posterior pharynx are swabbed vigorously, and the swab is placed in transport medium as described above.

**Sera collection for influenza diagnosis**

An acute-phase serum specimen (3–5 ml of whole blood) should be taken soon after onset of clinical symptoms and not later than 7 days after onset. A convalescent-phase serum specimen should be collected 14 days after the onset of symptoms. Where patients are near death, a second ante-mortem specimen should be collected. Although single serum specimens may not provide conclusive evidence in support of an individual diagnosis, when taken more than 2 weeks after the onset of symptoms they can be useful for detecting antibodies against avian influenza viruses in a neutralization test.

## Appendix 'B'

### WHO laboratory guidelines for the collection of animal specimens for diagnosis of influenza infection

General information

The success of virus diagnosis depends largely on the quality of the specimen and the conditions under which the specimen is transported and stored before it is processed in the laboratory. Specimens for isolation of respiratory viruses in cell cultures or embryonated chicken eggs and for the direct detection of viral antigen or nucleic acids should generally be taken during the first 3 days after onset of clinical symptoms of influenza. In mammals, including humans, pigs and horses, influenza is primarily a respiratory tract infection while in avian species it can be an infection of both the respiratory tract and the large intestinal tract.

Type of specimens

A variety of specimens from animals and birds are suitable for the diagnosis of virus infections of the upper respiratory tract:

- Nasal swab
- Throat swab
- Tracheal swab

In addition to swabs from the upper respiratory tract, sampling of avian species for influenza infection should include:

- Cloacal swab
- Faecal specimen

Whenever possible, cloacal swabs should be collected from live or freshly killed birds. Faecal specimens collected from cages or from the environment are often the only specimens that are available and cannot be assigned with total certainty to the species of origin. If dead animals are found as part of the investigation, highly pathogenic avian influenza virus should be suspected, and representative internal organs, including brain, spleen, heart, lung, pancreas, liver and kidney, should be sampled together with sampling of the respiratory and intestinal tracts.

Specimens for the laboratory diagnosis of influenza infection should be collected in the following order of priority:

- From live animals
  - Tracheal
  - Throat/nasal
  - Cloacal
  - Faecal (environmental)
- Drinking-water
- From dead animals
  - Lung lavage
  - Pooled tissue (including trachea and lung)
  - Faecal (environmental)
  - Cloacal
- Drinking-water

**Procedures for specimen collection**

Virus transport medium

**Transport medium 199**

- Tissue culture medium 199 containing 0.5% bovine serum albumin (BSA)

To 1 litre of 0.5% BSA add:

- Benzylpenicillin (2 x $10^6$ IU/litre)
- Streptomycin (200 mg/litre)
- Polymyxin B (2 x $10^6$ IU/litre)
- Gentamicin (250 mg/litre)
- Nystatin (0.5 x $10^6$ IU/litre)
- Ofloxacin hydrochloride (60 mg/litre)
- Sulfamethoxazole (0.2 g/litre)

- Sterilize by filtration and distribute in 1.0–2.0-ml volumes in screw-capped tubes.

- OR -

Glycerol transport medium

| | |
|---|---|
| NaCl | 8 g |
| KCl | 0.2 g |
| $Na_2HPO_4$ | 1.15 g |
| $KH_2PO_4$ | 0.2 g |

**Phosphate-buffered saline (PBS):**

- Autoclave PBS and mix 1:1 with sterile glycerol to make 1 litre
- To 1 litre PBS / glycerol add:
  - Benzylpenicillin (2 x $10^6$ IU/litre)
  - Streptomycin (200 mg/litre)
  - Polymyxin B (2 x $10^6$ IU/litre)
  - Gentamicin (250 mg/litre)
  - Nystatin (0.5 x $10^6$ IU/litre)
  - Ofloxacin hydrochloride (60 mg/litre)
  - Sulfamethoxazole (0.2 g/litre).

Preparing specimen collection vials

To sterile plastic screw-cap vials dispense 1.0–2.0 ml of transport medium. It is preferable to store these vials at 20 °C until use. However, they can be stored at 4°C for 48-96 hours (optimally less than 48 hours) or at room temperature for short periods of 1–2 days.

**Preparing to collect specimens**

The following information should be recorded: type of animal sampled, species, type of specimen, date of collection, and geographical location of specimen collection, etc.

Tissue culture medium (A) is widely used for collection and transport of clinical specimens from all species. The glycerol-based medium (B) provides longer-term stability of specimens where cooling is not immediately possible; it is suitable for egg inoculation but not suited for tissue culture inoculation.

Clinical specimens should be collected as described below and added to transport medium. All specimens should be kept on ice or at 4 °C.

Standard precautions should always be followed, and barrier protections applied whenever samples are obtained from patients.

**Nasal swab**

A dry polyester swab is inserted into the nostril, parallel to the palate, and left in place for a few seconds. It is then slowly withdrawn, with a rotating motion, down the inside of the nose. Specimens from both nostrils are obtained with the same swab. The tip of the swab is put into a vial containing 2–3 ml of transport medium and the applicator stick is broken off.

**Throat swab**

The posterior pharynx is swabbed vigorously, and the swab is placed in transport medium as described above.

**Tracheal swab**

The trachea of live birds is swabbed by inserting a polyester swab into the trachea and gently swabbing the wall. The swab is then placed in transport medium as described above.

Tracheal swabs from dead animals, including pigs at slaughterhouses, can be taken after removal of the lungs and trachea from the carcass. The trachea is held in a gloved hand and the swab inserted to its maximal length with vigorous swabbing of the wall. The swab is then placed in transport medium as above.

**Cloacal swab**

A cloacal swab from a live bird is taken by inserting a swab deeply into the vent and vigorously swabbing the wall. The swab should be deeply stained with faecal material. The swab is then placed in transport medium as above.

**Faecal specimens**

Faecal specimens from the cages of live poultry in bird markets or from wild birds in the field are collected from freshly deposited wet faeces; the swab should be heavily coated with faeces. The swab is then placed in transport medium as above.

Sera collection for influenza diagnosis and surveillance

**Tissue specimens**

Tissue specimens should ideally be frozen immediately, without transport medium, and later ground in transport medium before inoculation of eggs or tissue culture.

For diagnosis, an acute-phase serum specimen (3–5 ml of whole blood) should be taken soon after onset of clinical symptoms, and not later than 7 days after onset. A convalescent-phase serum specimen should be collected 2–4 weeks later. In serological surveillance studies at slaughterhouses or of free-flying wild birds that are bled and released, a single sample of serum is collected. The blood is allowed to clot then centrifuged at 2500 rpm for 15 minutes to separate red blood cells and serum. The serum should be pipetted off, and the red cells may be discarded. Serum samples are stored at –20 °C.

## Appendix 'C'

**WHO guidelines for the storage and transport of human and animal specimens for laboratory diagnosis of suspected Avian Influenza A infection**

Specimen storage

Specimens in viral transport medium for viral isolation should be kept at 4 °C and transported to the laboratory promptly. If specimens are transported to the laboratory within 2 days, they may be kept at 4 °C; otherwise they should be frozen at or below –70 °C until they can be transported to the laboratory. Repeated freezing and thawing must be avoided to prevent loss of infectivity. Sera may be stored at 4 °C for approximately one week, but thereafter should be frozen at –20 °C. Specimens should be collected and transported in a suitable transport medium on ice or in liquid nitrogen. Standard precautions should always be followed, and barrier protections applied whenever samples are obtained from patients. Specimens for influenza should not be stored or shipped in dry ice (solid carbon dioxide) unless they are sealed in glass or sealed, taped and double plastic-bagged. Carbon dioxide can rapidly inactivate influenza viruses if it gains access to the specimens through shrinkage of tubes during freezing.

Specimen transport

Transport of specimens should comply with the WHO guidelines for the safe transport of infectious substances and diagnostic specimens (WHO, 1997). The receiving laboratory should be notified before shipment of specimens in order to arrange for an import license for the specimens. Transport of specimens within national borders should comply with the procedures detailed within each country's regulations. International air transport of human specimens known or suspected to contain the avian influenza agent or of specimens from avian influenza infected animals must follow the current edition of the International Air Transport Association (IATA) Dangerous Goods Regulations.

Packaging shall be constructed and closed so as to prevent any loss of contents that might be caused under normal conditions of transport, by vibration or by changes in temperature, humidity or pressure. Primary receptacles shall be packed in secondary packaging in such a way that, under normal conditions of transport, they cannot break, be punctured or leak their contents into the secondary packaging. Secondary packaging shall be placed in a final outer package with suitable cushioning material. Any leakage of the contents shall not substantially impair the protective properties of the cushioning material or of the outer packaging.

For liquids
