This book is dedicated to our families. There are no substitutes for their patience, encouragement, love, and support.

To
Helen, Ally, and Eric Pass

Gloria Mitchell

Beverly and Mary-Michael Johnson

Kathy, Richard, Casey, Harmon, Katie, Carolyn, and, mostly, little Emilia Turrisi

And the family of John Minna

The inspiration for this endeavor came from our patients, students, and residents, as well as from our colleagues and mentors. These sources of incredible wisdom and diversity forced us to grapple with our limitations, and help us to recognize how we can best utilize our strengths.

PREFACE

It is now three years since we wrote that "lung cancer is the leading cause of cancer-related deaths in North America and Europe, and its incidence is rising elsewhere," ensuring an increasing number of lung cancer deaths worldwide. Unfortunately, we can substitute "remains the leading cause" for "is the leading cause." In 1997 alone, 178,100 new lung cancer patients were diagnosed in the United States. Lung cancer is rising at an exponential rate in women and in under-served populations. Children and young adults continue to smoke in alarming proportions. That's the bad news.

The encouraging news is that lung cancer and tobacco abuse are getting the attention necessary to actually open pocket books for related clinical and benchwork research. Advocacy groups for lung cancer, virtually unheard of in 1996, are taking a more proactive stance in the education of patients, families, and primary care physicians. An unprecedented resurgence in early detection, screening, and lung cancer prevention is gaining momentum, which could eventually translate into stage migration. New imaging techniques are being validated for increased sensitivity that may even change surgical staging practices. Aggressive multimodality therapy is moving into clinical trials for patients with earlier stages. Even the staging system (biologic staging) is different! Scientists are beginning to lay out an evolutionary molecular model of airway carcinogenesis. This model may predict or describe either the earliest event that could signal the development of lung cancer, or the event in the spectrum that is the latest, but reversible, so that it would be possible to indicate who will move on to neoplasia.

The task for all of us involved in the management of lung cancer is to look critically at past, present, and novel therapies for lung cancer. After this survey, we must assess the reasons for their failure, and study new therapies in ways that will delivers answers, hopefully at an unprecedented pace.

This, the second edition of *Lung Cancer: Principles and Practice,* retains the specifications that were made for its predecessor. It contains contributions from clinicians in *ali* relevant disciplines=msurgery, radiation oncology, medical oncology, pathology, and pulmonology. Also, it includes contributions from basic scientists working in the field. We have attempted to blend clinical reality with benchwork dreams in a manner that assumed nothing regarding the reader's basic knowledge of lung cancer. Additionally, we have retained a similar format, starting with the biology of the disease. This concept extends to the clinical disciplines, with discussions of basic principles regarding surgery, radiotherapy, and chemotherapy. After the groundwork is laid, indepth discussions of innovative or aggressive treatments are outlined by authors who offer original detailed descriptions. This book alludes to the advantages, limits, and results of a multidisciplinary approach throughout, while making a concerted effort to unite concepts regarding this disease, such that the reader is armed with a greater understanding of the natural history, biology, and treatment options for lung cancer.

This second edition is meant to serve as a *comprehensive reference* for any individual interested in lung cancer; one that would appeal to scientists with very basic information of lung cancer, clinicians, and serve to broaden the knowledge base of medical students, primary care physicians, and cancer specialists.

Although the format may look similar, this edition has changed in accordance with the changes that occurred in the world of lung cancer. The book is bigger, and this reflects the increasing fund of clinical and benchwork knowledge that occurred since 1996. Newer aspects of the molecular genetics and biology of lung cancer are found in contributions concerning *FHIT,* telomerase, and *erbB*-2, as well as the intricacies of the cell cycle and angiogenesis. Lung cancer immunology and gene therapy are completely updated, and the newest elements of genetic susceptibility are included as a separate chapter. Technical changes, even in processing material for molecular evaluation are discussed, as is the use of these techniques in defining preneoplasia at the chromosomalPIshgenetic level. Obviously, this requires that both biologic staging and morphologic/pathologic staging be discussed separately. There is a greater emphasis on screening and prevention for early disease, as well as the management of the elderly with lung cancer. The explosion of new cytotoxic agents for lung cancer and their interaction with radiation therapy is given a prominent role in this edition. Palliation is discussed again as a separate section, but a new discussion of cost-effectiveness of lung-cancer therapies reminds us of the economic realities of this problem.

The editors cannot emphasize enough the attention to detail and the cooperation shown by the contributing authors. All are experts who have made contributions to the study of lung cancer and the care of the lung cancer patient.

The editors would also like to express their gratitude to Lippincott Williams & Wilkins, specifically Stuart Freeman, who was always supportive of this effort, and Tanya Lazar, whose skillful coordination between contributors, editors, and Lippincott kept the project moving without incident.

Lung Cancer: Principles and Practice is intended to provide both the practitioner and the trainee with a reference source that will be useful in those moments of frustration in dealing with this disease. The editors' most profound wish is that the material presented will stimulate other investigators to join in the fight against lung cancer, so that future editions will describe therapies that will move the survival curves upward and towards the right.

GENERAL CONCEPTS OF MOLECULAR BIOLOGY RELATED TO LUNG CANCER

MARY J. MULLIGAN-KEHOE
ANGELO RUSSO

Molecular biology has assumed a preeminent role in biomedical research. The rapid ascension of molecular biology has occurred because it provides a solid framework for explaining and extending biological phenomena that were previously only observable. Certainly there continues to be a descriptive approach to biology, but more and more these descriptions are fashioned in molecular terms. Furthermore, molecular biology extends into so many fields of study because the methods employed are relatively straightforward, easily learned, and rapidly applied. Upon opening any biological or medical journal one quickly sees that molecular biology methods are being applied to all biological sciences. Minuscule quantities of potentially short-lived biomaterials can be amplified, isolated, studied, and subsequently perturbed and reevaluated. Within this chapter we emphasize the molecular biology of gene regulation and expression because we fundamentally believe that lung cancer occurs as a result of deregulation of normal gene expression. We also provide a compendium that defines and explains frequently used terms and illustrates the common methods employed by those who apply molecular biology to the study of lung cancer.

DNA STRUCTURE

Cellular function and structure are predetermined by the genetic profile of the cell. Although viruses are capable of archiving genetic information as ribonucleic acid (RNA), single-stranded (ss) deoxyribonucleic acid (DNA), or double-stranded (ds) DNA, prokaryotic (nonnucleated) and eukaryotic (nucleated) cells store genetic information within dsDNA.[1] Upon isolation and purification of DNA, one finds that it is formed from two purine nucleotides, adenine (A) and guanine (G), and two pyrimidine nucleotides, thymidine (T) and cytosine (C) (Figure 1.1).[2] Single-stranded DNA is a linear biopolymer resulting from covalent phosphate diester bonds between the deoxyribose sugars of the nucleotides. The hydrogen bonding between two ssDNA molecules results from individual As of one chain bonding with Ts of the other chain, likewise for the Gs with Cs (Figure 1.2). Consequently, in dsDNA the percentage of A always equals T, and likewise G equals C. Each nucleotide of the individual single strand inclines approximately at a right angle to the axis of the deoxyribose backbone. As the nucleotides project toward one another and wind about the axis of the backbone, they overlap to greater or lesser degrees, and as such there is an additional stability to the structure that results from Van der Waal's stacking forces. Approximately ten nucleotides form each 360-degree turn of the biopolymer. The hydrophilic phospho-sugars within the backbone establish major contact with the water environment of the cell, and the pendent nucleotides bind the two chains together and create a more hydrophobic interior. The macromolecular structure formed from such an arranged paired of ssDNA molecules, running in opposite directions, is a right-handed, antiparallel, double helix (Figure 1.3).[3,4 and 5] As is seen in Figure 1.3, in addition to the above structural characteristics, the double helix has a major and a minor groove.

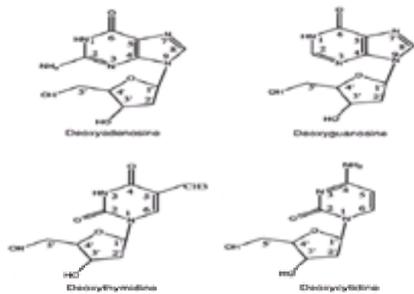

FIGURE 1.1. The four nucleotides that form DNA. Note the formal nomenclature for the deoxynucleotides. In common usage these are referred to as adenosine, guanosine, thymidine, and cytidine. These nucleotides are composed of nucleoside bases and deoxyribose sugars.
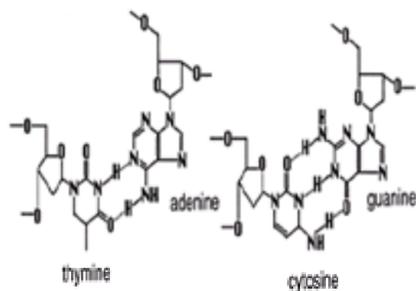

FIGURE 1.2. The nucleotides are shown to demonstrate the hydrogen bonding between nucleotides. Note that adenine and thymine share two hydrogen bonds, whereas guanine and cytosine share three hydrogen bonds.
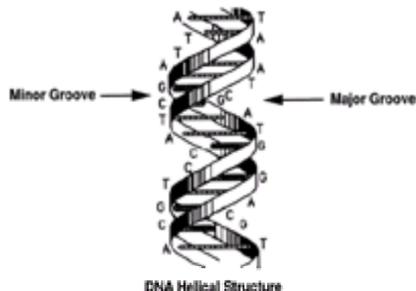

FIGURE 1.3. Double-stranded DNA is presented in its double helical form. The horizontal lines represent hydrogen bonding between the nucleotides within each single-stranded DNA molecule. The major and minor grooves of the helix are depicted with arrows.

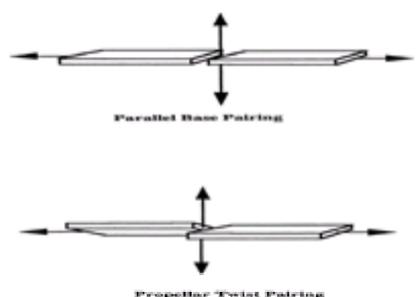
One might assume that the double helix is a monotonous set of deoxyribonucleotides winding about a central axis, and the information stored within this string of nucleotidyl bases is but a simple alphabetic display which can be represented by a long piece of thin tape having an extensive display of doublets of As and Ts or Gs and Cs. This is not the case. The helix is conformationally flexible or polymorphic as a result of the local nucleotide sequences. The actual twist and bend of the helical structure may change as a function, for instance, of the A to T ratio. A homopolymer of A/T has a twist of approximately 36 degrees per base step or ten bases per turn of the helix, that is, the helix is overwound relative to an average of 34 degrees per base found in random-sequence DNA. [6] Moreover, if one considers the actual nucleotide sequence, for instance A:T pairs that are binding from the individual ssDNA through two hydrogen bonds, then there is, when compared to G:C pairs that have three hydrogen bonds, a greater chance that the individual A and T will be slightly twisted relative to the right-angle plane of the axis of the helix (Figure 1.4). The result of A and T being potentially positioned slightly out of the plane is local distortion and/or stress in the helical structure. If nucleotide sequences repeat at a frequency corresponding to the helical periodicity, that is, approximately every ten bases, it becomes even more apparent that local structure can function to exert bending forces on the helical structure. [7] The nucleotide sequences can and do influence the depth and width of the major or minor grooves, and the depth and width of the grooves may determine if or how effectively a protein binds DNA. Therefore a DNA-binding protein may not recognize just a linear sequence of bases, but local environment as well. This means that not only do nucleotides code for specific amino acids, but also that the sequence of nucleotides encodes local topological information that may have profound implications on DNA-protein interactions or intracellular conduction of transduced signals or may simply the ease by which DNA unwinds, which in itself may affect recombination or replication or transcription.


FIGURE 1.4. In (A) the nucleotide bases within DNA are represented schematically as two parallel bases. In (B) the bases are slightly twisted and consequently they are no longer parallel.

The double-helical DNA contains all the cell's genetic information, that is the genome. A bacterium's genome is composed of one linear dsDNA structure (chromosome) and is measured in the millions of nucleotides; whereas eukaryotic genomic dsDNA is composed, for the most part, of many individual chromosomes, each composed of 10^7 to greater than 10^8 nucleotides. In bacteria there are no DNA-binding histone complexes. The DNA is not compacted; it is spread generally throughout the central aspect of the cell in a structure which contains no nuclear membrane and is referred to as a nucleoid shape. [8] In contrast, eukaryotic chromosomal DNA is within a nuclear envelope and, for the most part, is highly compacted around histone protein complexes that are further compressed. [9] A consequence of this fundamental difference in storage of information is that bacteria are more readily able to access DNA either to duplicate or to decode genetic information than are eukaryotes. The genome of a eukaryotic cell can therefore be viewed as an encrypted genetic archive made of sequences of linear arrayed nucleotides existing in a double helix, and the helix is further structured by virtue of bends and torsions and by winding around histone core protein complexes that are capable of assuming yet higher organizational structures.

TRANSCRIPTION

The array of nucleotides contains specific signals that allow proteins access to sites to start genomic duplication (origin of replication) [10,11] or gene transcription.[12,13 and 14] Transcription—copying DNA in an RNA form—of a gene is always started at the 5' portion of the gene. In bacteria the nucleotide sequences containing information for gene transcription are streamlined. The nucleotide sequence coding for a specific gene product (a polypeptide or RNA) is composed of a promoter region followed immediately by a gene. In some cases the gene is transcribed as a single unit of RNA. In other cases the promoter is followed by a sequence that results in transcription of multiple, juxtaposed, metabolically related genes. [15] The gene(s) in the DNA is transcribed into an exact complementary single strand of RNA that is usually translated into a polypeptide. This is the operon model of gene expression that is used by prokaryotes. [16,17] It is simple and exceedingly efficient. As messenger RNA (mRNA) destined to be translated into protein is being synthesized, it is immediately tethered to a ribosome, [18,19,20 and 21] wherein triplets of nucleotides (codons) of the mRNA sequences[22] are translated by aligning with a triplet nucleotide structure (anticodon) within an amino acid carrier molecule, transfer RNA (tRNA), which is positioned in the ribosomal structure. Rapidly thereafter the amino acid charged tRNA transfers its specific amino acid to a growing polypeptide chain. Each successive codon is translated by positioning another tRNA, until the stop codon is reached, whereupon the process of translating RNA into protein is completed. In the bacteria translation begins while the mRNA is being synthesized. [23] In fact, the amino terminal portion of a protein—that which corresponds to the 5' segment of the gene—is frequently being synthesized while the 3' segment of the gene is being transcribed. For bacteria, speed of gene expression is facilitated by

such an efficient means of protein synthesis.

Prokaryote Transcription

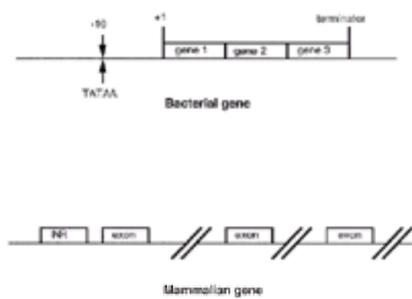
In bacteria, a rather simple promoter sequence is the DNA determinant for the site of initiation of gene expression. The promoter is always in front (5') of the gene. It usually has a TATA-box lying ten nucleotides 5' of the start of transcription, that is, −10 nucleotides form the transcriptional initiation start site (Figure 1.5). Usually directly upstream of the TATA-box is the region where proteins can bind to DNA to either repress or stimulate synthesis. [24,25] Transcription begins when an open TATA-box or promoter element is recognized by one of a set of alternative protein transcriptional factors, s, that binds to a multi-subunit RNA polymerase core enzyme (E)—composed of bb'a$_2$—to form the transcriptional complex holoenzyme (Es). [26] The structure of bb'a$_2$ is triangular, with bb' forming the two sides and a$_2$ the base. [27,28] s-factor fits in the middle of the triangle and makes contact with the TATA-box element. E without a s-factor has the characteristics of nonspecific binding to DNA and has the capability of synthesizing long pieces of RNA from nicked DNA or single-stranded DNA. When a s factor binds to the core enzyme it effects a conformational change in E. [29] With this conformational change, Es no longer binds DNA nonspecifically but rather recognizes specific promoter sites and initiates transcription from the start site, that is, s changes E to an initiation-specific RNA polymerase. The s-factor appears more than just to change the conformation of the core enzyme in order to allow it to bind the −10 TATA-box site, it also allows the holoenzyme to interact with the DNA approximately two turns more 3' or 5' to the −10 site, that is, in the vicinity of −35 relative to the initiation origin. Once Es binds to the promoter region at the TATA-box, the closed complex is formed in which the RNA polymerase is bound to the DNA, but the DNA has not started to unwind. Since hydroxyl radicals are highly reactive species that will damage any exposed DNA, they have been used to demonstrate that in the closed-complex state, RNA polymerase protein complex protects the DNA from hydroxyl radical-induced base damage on one side of the helix by virtue of partially enwrapping the DNA. In the open complex it appears as if the DNA is completely enwrapped and both sides of it are protected. [30,31] This implies that in the closed complex, the initiation complex rests on only one side of the DNA, whereas in the open complex the DNA is surrounded by the initiation complex. As the DNA unwinds there is separation of the two strands to form a "bubble," [32,33] and thereby to allow Es to align incoming ribonucleotides with the corresponding coding strand of DNA and to start synthesis of a complementary nucleotide polymer in an RNA format; that is, transcription begins. When the RNA polymerase complex proceeds past the initiation site—approximately ten nucleotides beyond the start site—the s detaches from the core enzyme structure, and elongation of RNA commences and continues until, and beyond, the gene or operon terminus, whereupon E dissociates from the DNA, and the mRNA continues to be translated. [34,35,36 and 37] The selection of individual promoters to be transcribed is determined by the concentration of individual s-factors which are in competition with one another. The s[70]-factor is the most abundant of the s-factors in *Escherichia coli* (*E. coli*). In general, s[70] recognizes the most commonly employed promoter element in bacteria; the TATA-box sequence. As s[70] concentration decreases, there is greater utilization of other promoter-specific s-factors, which in turn results in transcriptional selection of more specific genes. [38,39] In general, transcriptional regulation of housekeeping genes is controlled by the concentration of a specific s. Most recently, another aspect of s concentration regulation has been found in which anti-s-factors bind specifically to specific s-factors to regulate the available concentration of s-factors available to initiate transcription. [40] In bacteria, once the mRNA is synthesized, its lifetime is measured in minutes, usually being degraded immediately after being translated. This is not necessarily the case for eukaryotic mRNA.


FIGURE 1.5. Contrast the construction of a bacterial gene containing three tandem genes with that of a mammalian gene which has an initiation element (INR), exons, and intervening introns.

It should be recognized that a bacterium is a single-cell organism that sustains itself, for the most part, by multiplying at a faster rate than its competitors. Therefore, rapid doubling times demand ready access to the DNA for duplication and transcription. Regulation of transcription is essentially minimalistic, with on and off switches being controlled by accessibility to the promoter by the transcriptional complex containing RNA polymerase. Models of prokaryotic transcription envision the RNA polymerase complex being bound to dispersed DNA awaiting a signal to permit synthesis. Gram-negative *E. coli*'s cytoplasm is surrounded by an envelope composed of two membranes having an intermediate zone called the periplasmic space. The bacterium must therefore direct proteins to the cytoplasm, the inner or outer membrane, and the periplasmic space and react to its environment by quickly transducing messages directly to the DNA. Consequently, bacteria have trafficking signals (amino acid sequences that direct a protein to a specific site) and have specific pores for entry of substrates that will be metabolized by or interact with macromolecules. The bacterium must utilize nutrients efficiently and therefore be able to activate quickly a set of proteins that metabolize a specific substrate (gene arrangement in an operon facilitates such an existence) and subsequently suppress the synthesis of unnecessary proteins. It is the rule that repressed on/off promoters remain so until they are needed or until s-factors are produced or activated as a result of adaptive stress. The entire life process in molecular biologic terms is efficiently fast because life depends on the ability to take advantage of the environment by multiplying and thereby replicating and producing proteins and other needed metabolic products faster than competing rivals.

Eukaryote Transcription

Although eukaryotes have comparable macromolecular structure to the bacterium, the higher eukaryotic cells for the most part are much more elaborate than bacteria by virtue of cellular structure and function. In eukaryotic cells, rapid multiplication is not usually the life-sustaining issue; controlled growth in concert with other cells is paramount. Deviation from concerted growth patterns results in unfavorable consequences. Stated differently, loss of regulatory control of any cell within a multicellular organism may have untoward effects, such as death of the cell or worse, and more threatening to the entire organism is development of cancer and subsequent death of the entire organism. Consequently, a universal theme in the molecular biology of higher eukaryotic cells is regulation that depends upon skillfully arranging elaborate networks to modulate an individual cellular function.

Chromatin Structure

For mammalian cells the important cellular function of transcribing information from DNA becomes much more complex than that described for prokaryotes. In fact, the entire genome is larger and more elaborate and more regulatory controls are manifest in both the DNA interacting proteins as well as, or maybe because of, the DNA structure itself. As noted above, the bacterial genome is, for the most part, set for rapid access and utility; whereas the mammalian genome, for the most part, is compacted into defined structures that may be bound to the nuclear membrane and other intranuclear matrix filamentous structure. Before a sequence of DNA (gene) can be transcribed, it must be exposed. The chromatin structure of eukaryotic cells is composed of a basic structure, the nucleosome. [41] Core nucleosomes contain approximately 146 base pairs wrapped twice around a core octameric histone protein complex (Figure 1.6). The core of the histone octamer is constructed from a central tetramer composed of two H3 and two H4 histones in continuity on each side with two heterodimers of histone H2A and H2B. This fundamental nucleosomal structure has a 7-nm diameter and when viewed by electron microscopy has the appearance of beads that are linked to one another by threads of nonnucleosomal DNA. In higher eukaryotic cells the core nucleosomes can then associate with H1 histone, which can then result in a more elaborate compacted display in which the individual nucleosomes are wound together in a structure that results in further compression of the chromatin into a 30 nm structure. The 30 nm fibers can then be further organized into a more compact structure by interacting with nonhistone proteins to result in a highly compressed genome. [9,42,43,44 and 45] As would be expected from the nucleosomal structure, there would be limited access to an embedded mammalian gene within the highly compressed chromatin structure. Even in the state where the chromatin has been decompressed to the individual nucleosomal complex, the face of the DNA that is in contact with the internal histone octamer is not accessible to activator proteins. Stated differently, proteins that do interact with the nucleosomal DNA must do so by interacting with only the outer surface of the DNA. Initiation sites that are enwrapped within the nucleosome cannot be accessed by, nor accommodate a transcriptional complex. One can only conclude that the very structure of chromatin is acting in a regulatory sense as a suppressor. Experimental proof of chromatin repression is difficult, yet Straka and Horz were able to show just that. [46] In yeast, a lower eukaryotic cell which does not have H1 histone but does form nucleosomes, there is chromatin structure made of histones that are

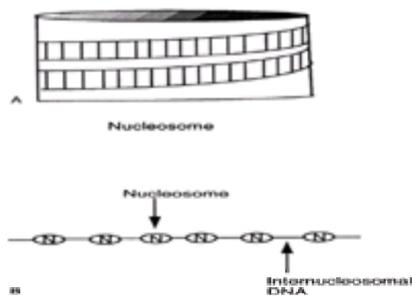
highly homologous to that in higher eukaryotes. Expression utilizing PHO5, a yeast gene that remains suppressed until there are low phosphate levels in the medium, is known to be highly responsive to the phosphate status of the environment. The activator response elements are structured from two upstream activating sites (UAS) which are the equivalent of enhancer elements in higher eukaryotes. *In vivo* basal expression of PHO5 is negligible until it is induced. The UAS and promoter elements are thought to be embedded in nucleosomal structure. A mutant having the H4 gene deleted from both chromosomes and a galactose conditional episomal (not part of the genomic DNA) copy of H4 was constructed. When galactose is the food source, H4 is induced in ample quantities; however, when glucose is substituted for galactose, H4 synthesis immediately stops. Glucose-fed cells do not assemble new nucleosomes as they go through the DNA replicative or synthesis phase (S-phase). As a result of not having new nucleosomes and therefore having PHO5 in a spread out or accessible state, PHO5 expression increased dramatically in the absence of any specific induction—a clear example that demonstrates that the nucleosomal structure functions as a suppressor element.


FIGURE 1.6. A: the core nucleosome, which is 7 nm in diameter, composed of a tetramer of histones with two loops of the DNA strand wrapped around the outermost aspect of the histone tetramer. **B:** the "beads on a string" arrangement of nucleosomal DNA.

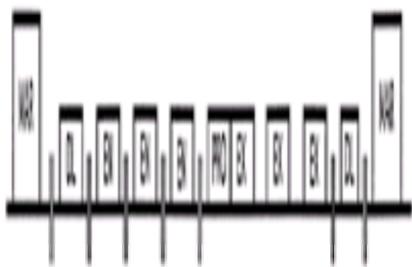
DNase I hypersensitivity assays[47] show that chromatin structure is loosened when there is active gene synthesis. Furthermore, data acquired from transfection experiments with the b.-globin gene show that a DNA locus control region (LCR) that resides greater than 50 kilobases upstream of the transcriptional start site is the primary regulator that institutes relaxation of heterochromatin structure within the domain that contains the globin gene cluster and exposes the region to DNase hypersensitivity.[48,49] When the LCR is deleted, the domain becomes DNase I resistant and gene expression is down-regulated. The chromatin is tethered to the nuclear matrix attachment sites (MAR)[50] at both the 5'- and 3'-ends of the domain that contains the gene or gene cluster (Figure 1.7). These domains, moreover, may have certain DNA sequences which limit the effect of accession by activators or conformational changes that would result from LCR-like elements. In *Drosophila melanogaster,* the heat shock genes are clustered in a domain that has demarcating sequences ranging in size from 200 to 350 bases called specialized chromatin structures[51,52 and 53] that function to limit the spreading of chromatin conformational changes to adjoining genes, that is, loosening and DNase hypersensitivity, that occur when a gene is activated.


FIGURE 1.7. A portion of chromosomal DNA is represented by a line structure. The hashed marks denote varying lengths of DNA. The matrix attachment region (MAR) in a DNA sequence is associated with increased levels of AT and is also attached to the nuclear matrix. DL denotes a delimiting sequence that stops propagation of transcription; EN denotes enhancer elements; PRO is the core promoter; and EX is the abbreviation form of exon.

Such observations demonstrate that unlike bacteria, mammalian cell promoter construction is not simply an "on/off" switch composed of a few tens of nucleotides positioned immediately before the gene to be synthesized. The very definition of promoter becomes one that has to encompass a sequence structure that may be composed of multiple different enhancer or repressor elements (nucleotide sequences that interact with protein or in some manner change the structure of the DNA) that can be vast distances in front of or behind or, for that matter, within the gene to be transcribed. There are specific sets of intranuclear proteins whose function is to acetylate histones within the nucleosomal structures. The acetylated histones allow greater access to DNA-binding proteins. In general, histone structure without acetylated groups results in compaction of DNA structure; whereas acetylated histones loosen up DNA structure for access by protein complexes to the DNA so that the myriad of events that are requires for transcription and replication and repair may occur. [54]

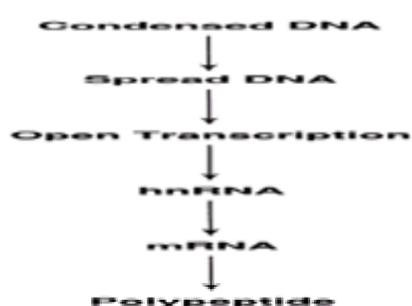
The picture that develops from such a paradigm of gene construction is one which shows that gene regulation begins by a set of commands that controls opening and shutting of entry to heterochromatin (Figure 1.8). Such a view would further allow one to appreciate that the complexity resulting from the presence of many regulatory elements built into the promoter can provide numerous places for concerted control of gene expression. If the repressor or enhancer proteins that bind to specific elements within the DNA or DNA sequences themselves acting as structural elements are thought of as keys that either lock or unlock embedded DNA sequences, then an expanded view of the eukaryotic promoter construction would be considered necessary to provide insight into how access to and transcription of the gene is selectively accomplished. Therefore, the potential of having to open heterochromatin in response to stimulatory signals in a eukaryote would be expected to be relatively slow, but speed is sacrificed for control. Furthermore, if a segment of DNA is opened or partially opened by a set of response elements, then, in a eukaryotic cell, DNA accessibility could be thought of as being preset by a cascade of DNA-interacting proteins, such as hypermobility group (HMG) proteins, [55] without there necessarily being an immediate gene expression response or, for that matter, expression at all unless subsequent signals are received.


FIGURE 1.8. Denotes the cascade of events that starts at condensed heterochromatin and ends with synthesis of the gene product: the polypeptide.

Once the DNA is loosened, there is a requirement that different sets of proteins must interact with the DNA before transcription begins. Unlike in bacteria, eukaryotes do not utilize one RNA polymerase core enzyme complex for synthesis of all genes; rather there are three specific RNA polymerases which, as a consequence of their order of elution from a chromatography column, are designated RNA polymerase I, II, and III. RNA polymerase I is responsible for the transcription of ribosomal preRNA 45S,[56] RNA polymerase III transcribes all tRNA and 5S RNA and like genes,[57] and RNA polymerase II transcribes, among other genes, all genes responsible for proteins that are made in the cell. The RNA polymerases can be distinguished biochemically on the basis of their inhibition by a-amanitin (RNA polymerase I is not sensitive, II is sensitive, and III may or may not be inhibitable, depending on the species). Type II genes are those genes that are transcribed by RNA polymerase II.

Promoter Region

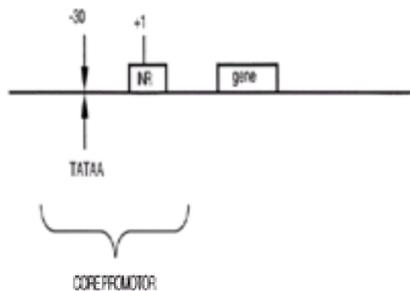
Expression of type II genes is highly regulated at all levels, but the greatest degree of regulation occurs at the transcriptional level. It follows naturally that the construction of the promoter sequence and the enhancer or inhibitory elements associated with the promoter are of primary importance in regulation of gene expression. A core or minimal promoter may, then, be defined as one that does not contain binding sites for sequence specific factors; rather it contains elements that interact with general transcriptional factors (GTF) and transcriptional-associated factors that are required for basal transcription (Figure 1.9).[58,59 and 60] The core or minimal promoter in higher eukaryotes has at least one of two distinct elements that affect transcription: the initiation (Inr) element [61] which encompasses the site of transcriptional initiation and, at −30 relative to the start site, an AT-rich element of which the TATA box is the cognate or consensus sequence. [25,62,63] All promoters examined to date have at least one of these two elements. In referring to a promoter and its related gene, +1 is the start site for transcription, those nucleotides that follow the start site are—reading left to right—consecutively numbered +2, +3, . . ., + *N,* and those nucleotides that precede the initiation site are numbered from right to left, −1, −2, . . ., −*N.* There is no zero.


FIGURE 1.9. The core promoter is depicted by curled brackets. The horizontal line denotes double-stranded DNA having a TATAA box, transcriptional initiation element (INR), and a downstream gene.

Transcriptional Factors

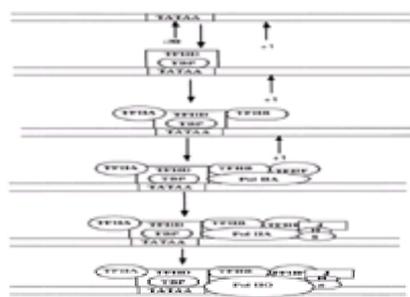
There are at least seven general transcriptional factors (GTFs) which have been defined to date. They are named transcriptional factor TF, IIA, IIB, IID, IIE, IIF, IIH, and IIJ.[64] Of these, only TFIID interacts with DNA independent of the other factors. TFIID recognizes and binds most tightly to the TATAA consensus sequence −30 to −25 nucleotides relative to the start site (Figure 1.10). Within TFIID there is a TATA-binding protein (TBP) and at least seven other associated factors called TBP-associated factors (TAFs) having molecular weights of 250, 125, 95, 78, 50, and 30. [65,66,67 and 68] TBP, as would be expected from its name, is the subunit within TFIID that specifically binds the TATA-box element.[69] Moreover, TBP also participates in RNA polymerase I and III transcription. [70,71] Human recombinant TBP is a 38 kD protein whose crystal structure shows it to be a saddle-shaped protein. [72] Most sequence-specific transcriptional activator and inhibitor factors recognize elements by binding to nucleotides within the major groove of the DNA, but TBP binds within the minor groove and severely distorts and opens the minor groove. [73,74] The avidity of TBP is greatest for the consensus TATAA but it does bind to lesser degrees to other AT-rich sequences in the −30 to −25 area. The decrease in binding to sequences that diverge from the consensus sequence may be a means of regulation. TBP binds to a small sequence of bases in the vicinity of −30; however, the holo-TFIID rests on nucleotides from −30 to +10. Moreover, TBP does not have to interact directly with RNA polymerase for there to be basal transcription, yet there is evidence to support that TFIID does directly interact with the carboxy or C-terminal domain (CTD) of the largest subunit of RNA polymerase II to increase the frequency of initiation of transcription. [75] Furthermore, TBP is not affected by sequence-specific activator-dependent transcription, but TFIID, that is, TBP with its associated TAFs, has been shown to interact with such factors. This implies that activators can bind to the TAFs and thereby enhance transcription by nucleating the promoter with TFIID at the −30 site. [76,77] Furthermore, the TAFs, by associating with TBP, probably determine the binding efficiency by which TBP binds to AT-rich sequences that have diverged from the consensus sequence. [78]


FIGURE 1.10. Demonstrates the cascade of transcriptional activation by the transcription factors (TF) for RNA polymerase II (Pol II). The TATAA box is -30 bp upstream from the transcription start site denoted by 0. TBP stands for TATA-binding protein. Pol IIA is the closed form of RNA polymerase II and Pol IIO is the open form of the RNA polymerase II.

Once TFIID associates with the TATA element, there is an ordered assembly of the other transcriptional factors. TFIIB associates with TFIID that has already associated with DNA to form the DB complex (TFIID-TFIIB complex).[79,80] TFIIB, like TBP, may be a sequence-binding cofactor that senses sequences immediately upstream of the TATA box and contributes to the evolving transcriptional complex. [81] TFIIB interacts with both RNA polymerase and TFIID and is probably responsible for the spacing between TFIID and RNA polymerase which allows for site-specific initiation of transcription. In addition to TFIIB directly interacting with TFIID, TFIIA associates with the DB complex to form the DAB complex.[82] Although there is controversy regarding the essential role of TFIIA in formation of the preinitiation complex, TFIIA does seems to function as an anti-inhibitor by preventing TFIID from being inhibited; consequently, TFIIA stimulates initiation of transcription. [83] TFIIB, in addition to its other function, may also interact with element-specific activators. [84] Once the DAB complex forms, then TFIIF (RAP30/74), along with RNA polymerase, associates with the DAB complex and binds to the DNA at the transcription initiation site (Inr). [85] Besides its role in binding to the DAB complex, RAP30/74 functions like bacterial s, in that the heterodimer binds to RNA polymerase in solution and prevents nonspecific DNA binding by RNA polymerase II. [86,87] Unlike s,[70] TFIIF does not directly bind to DNA; however, within the context of the preinitiation complex, TFIIF may bind to the Inr element. TFIIE then associates with the preinitiation complex to increase stability of the initiation complex by promoting binding of RNA polymerase to the Inr element. [88] Along with binding of TFIIE is the binding of TFIIH,[89] which promotes productive binding of the preinitiation complex. TFIIH is a complex transcriptional factor composed of at least five subunits (95–35 kD polypeptides)[90] that have, among other functions, ATPase, CTD kinase, and DNA helicase activity. [91] Each of these functional components are essential for RNA polymerase II to proceed beyond the initiation site. That is, ATPase activity is necessary for there to be energy for the RNA polymerase to activate. The CTD kinase

activity is absolutely required for the RNA polymerase II to switch from the unphosphorylated (IIA) [92] and therefore nonelongating polymerase to the highly phosphorylated (IIO)[93] RNA polymerase II that elongates or proceeds with transcription. It is obvious that in order for there to be transcription from one of the strands of the double-stranded DNA, there is a requirement for helicase, that is, unwinding of the DNA. So once the DBPo1F complex is formed, then TFIIE associates with the complex, followed then by TFIIH, TFIIJ. TFIIS may be analogous to prokaryotic Nus A, which functions as an anti-terminator. [94] When transcribing RNA polymerase comes to a pause site, TFIIS, by functioning to remove several nucleotides from the 3'-end of the nascent RNA, allows for "relocation" or backward movement of the RNA polymerase by several nucleotides and then for RNA synthesis to recommence.[95,96 and 97] The human retroviruses HIV and HTLV express anti-terminators, TAT and TAX respectively, which promote transcriptional elongation early in transcription by specifically binding the transcribed RNA so that termination of transcription is aborted. [98] Both TAT and TAX either directly interact with the transcriptional complex through space because they bind elements on the RNA which are free of the RNA polymerase complex and, therefore, not associated with DNA, or they indirectly promote transcription by interacting through adaptor proteins. In either case, the sum effect of these viral proteins is, like TFIIS, continuation of transcriptional elongation. The preinitiation complex has an aggregate molecular weight of greater than 3.2 million dalton and is composed of greater than 32 proteins. All of this care is involved in setting up the core apparatus for RNA polymerase II to begin transcription. Purified pol II transcribes about 300 nucleotides per minute; whereas *in vivo* the pol II complex transcribes about 2,000 nucleotides per minute. The discordant rates probably result in part from the delay in movement of the initiation complex from the initiation start site. Yet the pol II complex, once moving, encounters multiple impediments to smooth and rapid elongation, for example, the nucleosome structures. There are families of elongation factors that modulate the rate of transcriptional progression. Factors such as TFIIF, ELL, SII, SIII, P-TEBf, FACT, and HSF1 have been shown to be involved in changing the rate of transcriptional elongation. [99,100] In fact, the B-C component of SIII has been shown to interact with von Hipple-Linau (VHL) tumor suppressor gene.[101]

As mentioned previously, bacterial RNA polymerase core enzyme is composed of four subunits. In the case of mammalian RNA polymerase II, there are at least ten subunits ranging in molecular mass from 10 to 240 kD. [102] The two largest subunits of RNA polymerase II that are thought to be involved in nucleotide and DNA binding have homology that persists from the bb' of *E. coli,* through yeast, into *Drosophila* and higher mammals.[103,104] The large subunit of RNA polymerase II has a unique heptad repeat unit, Tyr-Ser-Pro-Thr-Ser-Pro-Ser, which is not present in RNA polymerase I or III. [105,106] In mice and humans the heptad repeats 52 times.[102,107,108] Genetic deletion of more than half of the heptads from the large subunit is lethal. As stated above, the heptad phosphorylation or the transition from the RNA polymerase IIA to the phosphorylated IIO form is a potential regulatory point that serves to transform the preinitiation complex to the active transcriptional complex.

In yeast, the TATA box may be anywhere from −40 to −100 nucleotides upstream of the start site of transcription, and the orientation of the TATA sequence is strict. This is not the case for higher eukaryotes. In fact, in higher eukaryotes there are promoters that do not contain TATA boxes or AT-rich regions approximately −30 to −25 nucleotides upstream from the start site. [61,109,110 and 111] These TATA-less promoters are divided into two classes; those with GC-rich promoters which are associated with housekeeping genes, [112] and several upstream sequence-specific SP1 sites. [113] For the TATA-less promoters, the Inr element is a weak consensus sequence of A at the +1 site and C at the −1 site and T at +3 with preferentially pyrimidine bases upstream and downstream of these sequence elements. [114] It is possible that the Inr sequence is recognized by a specific Inr-binding protein, and it is this protein which nucleates the ordered assembly of the transcriptional factors.[60] So even within these TATA-less promoters, the TFIID transcriptional factor containing the TBP is required for transcription; however, in this case the binding may be effected through adaptors or tethering factors which are probably one of an array of alternative TAFs that has been positioned by either the Inr-binding protein or sequence-specific activators (above). [84]

Regulatory Elements

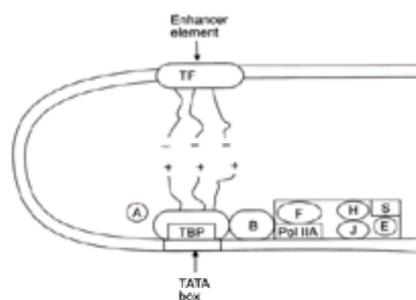
The line between what is the promoter region and what is the enhancer region in eukaryotic genes is blurred. The trend is to consider the core promoter as the sequence just upstream and through the Inr sequence, and the rest of the elements that modulate transcription are referred to as the regulon or some such name that connotes transcriptional regulatory function. Since many genes can be regulated by proteins that interact with DNA upstream, within, and downstream of the transcriptional unit of the gene, description of regulatory elements will be restricted to the more common elements usually found upstream of the Inr element. By no means do we mean that the other elements are not important for efficient transcription of any individual gene. Moreover, specific regulatory elements within higher eukaryotes are not necessarily directionally dependent, nor is it uncommon to find that one element will be repeated several times or that multiple elements will be employed within a given regulatory region, that is, the regulatory elements are modular, and all of the elements can be coordinated as a functional unit. Eukaryotic-regulating proteins or enhancer-element-recognizing proteins must interact with a specific sequence within the extended promoter and additionally interact with other sequence-specific recognition proteins or the transcriptional factors themselves (Figure 1.11).[115] *In vitro* the activator molecules typically enhance transcription by two- to five-fold; however, *in vivo* the activators can enhance transcription by a thousandfold. In contrast to TBP, typically transcriptional activators recognize specific elements and bind to the nucleotides within the DNA sequence through the major groove. These regulatory proteins frequently consist of more than one protein subunit. The interplay of these regulatory proteins with one another and with DNA for the most part determines the tissue specificity and timing and frequency of gene transcription.


FIGURE 1.11. Demonstrates a negatively charged transcription factor (TF) binding to an enhancer element on double-stranded DNA that is forming a looped structure. The transcription factor may, by virtue of its charge and position, act in assisting the position of TFIID which is positively charged and contains the TATA-binding protein and is also binding with TFIIA (A) and TFIIB (B). F, H, J, E, and S denote TFIIF, H, J, E, and S. Pol IIA is the closed complex of RNA polymerase II.

The CCAAT-box is an element that is frequently found in promoters approximately 75 bp upstream of the start site. [116] Multiple factors from different species bind the CCAAT element. Among those are the CCAAT-binding factor, CBF, which is a heterodimer,[117] CP1 functions in a-globin gene, CP2, which is g-fibrinogen activating, [118] CDP, which may function to displace CCAAT-binding factors,[119] which is analogous in function to NF-E that down-regulates fetal globin synthesis, [120] CCAAT transcription factor (CTF/NF-1),[121] CCAAT-enhancer binding factor (C/EBF),[122] and others.[123,124,125,126 and 127] The important thing to be learned from the CCAAT-binding factors is that given such an array of different binding proteins with possibly different preferences for the CCAAT element or mutations from the consensus sequence, regulation based on binding the same element may provide exquisite tissue and chronologic modulation of gene transcription.

The octamer element, ATTTGCAT, is another ubiquitous regulatory element which is usually bound by the Oct-1 factor and is an element module in promoters for the H2B histone,[128] U2 snRNA,[128] SV40 promoter,[129] g-globulin, and major histocompatibility HLA-DQb. genes. [130] The octamer element in lymphoid tissues regulates g-globulin synthesis and illustrates that a tissue-specific factor (Oct-2) recognizes the general octamer element, whereas Oct-1 does not function as a g-globulin regulatory protein. [131] Here is a clear example of tissue-specific gene regulation by tissue regulatory factor expression.

The GC-rich Sp1 element has a consensus sequence of GGCGGG and is found within the six 21 bp repeat units of SV40 early promoter. [113,132,133,134 and 135] The Sp1 element is a frequently used motif within numerous genes, including the monocyte chemo-attractant protein-1, [136] TGF-b.,[137] thymidylate syntase,[138] and apolipoprotein E,[139] among others. Sp1 is a heterodimeric structure composed of 105 and 95 kD subunits which seems to function as a single unit without subset subunit mixing to other factors.[140] Modulation of regulation from the Sp1 element is usually in concert with other regulatory factors or possibly, as discussed above for TBP, the

degeneracy of the element away from the consensus sequence may be a means of altering affinity and therefore modulating enhancement.

Since higher eukaryotic cells must regulate protein expression in the context of the entire organism, it is not surprising that molecular communication between cells results in transcriptional modulation. To that end, it is not surprising that there are transcription factors that are responsive to hormones and to membrane receptor stimulation. The hormone response elements interact with the steroid/thyroid superfamily transcriptional factors, which include estrogen, androgen, glucocorticoid, mineralocorticoid, vitamin D, retinoic acid, thyroid, and other orphan receptors. [141],[142] and [143] The action of the family of transcriptional factors is superficially reminiscent of bacterial activators and repressors in that the ligand (hormone) interacts with the intranuclear receptor, which subsequently results in a conformational change in the receptor that facilitates DNA binding and transcriptional activation or repression. The hormone receptors act as dimeric structures, either in a homo- or heterodimeric form. [144] Within this family there is a considerable degree of homology among the receptors. [145] In general members of this group of transcriptional factors share considerable functional homology. All of the steroid receptor proteins can be dissected into three functional domains. [146],[147] and [148] The N-terminal domain is highly variable, activates gene-specific transcription, and binds other protein factors. Domain II functions in DNA binding, provides response-element recognition specificity and is highly conserved. Domain III, which is the C-terminal region of the receptor, actually contains two separate motifs: the hinge and the ligand-binding portion of the receptor. The hinge contains the nuclear localization signal, participates in transcriptional activation, and functions in dimer formation. Lastly, the steroid-binding region binds the specific activating ligand, interacts with heat-shock proteins, contributes to nuclear localization, and for the same receptor species is highly conserved. Domain-swapping experiments in which chimeric proteins between one specific DNA-binding domain of one receptor with that of the ligand-recognition domain of different class of hormone receptor show that the DNA and ligand domains act functionally in an independent manner. The consensus recognition sequence for the hormone androgen, glucocorticoid, progesterone, and mineralocorticoid receptors is GGTACANNNTGTTCT; the consensus sequence for the estrogen and thyroid receptor is GGTCA(N)xTGACC, where x is equal to zero for the estrogen response element and three for the thyroid response element; and the consensus element for retinoids is AGGTCA. [149],[150] and [151] The mechanism by which the different hormone receptors compete for a common element may be mediated by concentration of the individual receptor within the cell, the interaction of composite elements within the promoter, changes of DNA structure, phosphorylation of the receptor, and/or the interaction of the hormone receptors with other proteins or tissue-specific nuclear factors. [152],[153],[154],[155],[156],[157],[158] and [159] Since phosphorylation can occur at multiple sites within the receptor and thereby change its structure, it would not be surprising that regulation of such transcriptional regulators could then be networked into other regulatory pathways such as tyrosine kinase, kinase A, and ultimately to signal transduction mediated from G-proteins. [160],[161],[162],[163] and [164] Moreover, the steroid receptors are known to regulate the synthesis of nuclear protooncogenes and facilitate or inhibit the binding of other transcriptional activators. [165],[166],[167] and [168] In those cases where the receptor interacts with such protooncogenic regulatory elements, mutation of the hormone receptor could very well result in loss of coordinate cellular control. [169]

Insight into regulatory control is found when one considers the structural activation of the steroid hormone receptor. [170],[171] These receptors do not exist intracellularly as monomeric or dimeric receptors; rather they are associated with a set of nonreceptor chaperone molecules that confer stability to the receptor such that they are held in a conformational state so that they may interact with the incoming ligand. The chaperone molecules are composed in part by heat-shock protein 94 and 70. [172],[173],[174] and [175] The heat-shock protein/receptor complex also associates with other proteins to form an aggregate species. [176] It is this aggregate species that functions to position the hormone receptor within the nucleus by associating with nuclear matrix proteins. [177] Such a display of positional control may imply that the topological position of segments of DNA within the nucleus is highly important and fixed by binding to specific proteins and potentially RNA molecules that match up with specific sequences of DNA. Furthermore, when the receptor reacts with its cognate steroid ligand, it may be released from some of the constraints of binding to the chaperone proteins and associate with another steroid receptor which allows binding to its respective response element within DNA. Since the aggregate is associated with nuclear matrix and DNA, then such changes in the aggregate structure can be translated into changes in chromatin structure or possibly into altering the bending patterns of DNA, which can then result in looping the composite enhancer region into a spatial position to associate with the transcriptional apparatus. [178],[179] Once again, by considering the simple steroid-receptor transcriptional activator, we find that the eukaryotic cell has networked multiple regulatory paths to ensure exquisite control.

In higher eukaryotic cells, genes are structured differently from those found in bacteria. For one thing, they are not arranged in an operonic motif. That is, in higher eukaryotes one promoter corresponds to one gene rather than a cascade of genes as is found in bacteria. Moreover, eukaryotic genes are usually substantially larger than those found in bacteria. In a bacterium, a single gene coding for a fairly large polypeptide having a molecular weight of 100,000 dalton (100 kDa) would be considered unusually large. If one estimates that the average molecular weight of an amino acid is 100 Da, then the number of amino acids in a 100 kDa protein would be 1,000. Since three nucleotides code for one amino acid, the 100 kDa protein would correspond to a gene composed of 3,000 nucleotides. In mammals, as in prokaryotes, a single polypeptide is rarely larger than 100 kDa. However, when compared to the size of an average higher eukaryotic genes, the large 3-kbase prokaryotic gene would be considered small because in mammals it is not unusual to find genes spanning more than 100 kbases. For instance, the cystic fibrosis gene spans over 500 kbases, and the breast cancer gene, BCII, may span 1,000,000 bases—approximately one third the size of the genome of *E. coli*. The average size of a higher eukaryotic gene is 10 to 20 kD. [180] The obvious conclusion is that gene structure in higher eukaryotic cells is much more elaborate than that found in prokaryotic cells. The gene has a dispersed structure. In mammalian cells most of the nucleotide sequences that are transcribed from a gene are not translated into protein. Intragenic, transcribed, but not necessarily translated, sequences within a gene are referred to as introns. The size and number of introns may vary depending on the gene but average between 6 to 8 introns per gene. Why would the cell invest so much energy into forming such long pieces of RNA only to have most of the nucleotide sequence degraded; and further, what are the advantages of having genetic material dispersed over so much of the DNA? The evolution of this mode of packaging eukaryotic genetic material probably reflects greater control of (a) transcription initiation—within introns cis-acting elements can reside, as well as elements for trans-acting proteins to activate or inhibit transcription, (b) genetic swapping of information, [181] and (c) development and specific tissue production of multiple isoforms of a particular protein at particular times during the life of the cell at the posttranscriptional level.

Posttranscriptional Processing Events

In prokaryotes, mRNA is translated as soon as transcription begins. This is not the case for eukaryotes. [180] Once transcription has occurred and the resultant RNA is synthesized, there is a vast array of events that occur. When RNA is synthesized, it is not in a suitable form to function as tRNA or rRNA or mRNA. Newly synthesized or nascent RNA is termed pre-messenger RNA or heterologous RNA (hnRNA). Pre-mRNA is single-stranded and corresponds to a one-to-one direct transcript of the original DNA representation of the gene. The RNA has a complex secondary structure that is not simply a linear array of nucleotides. [182] This secondary structure without doubt dictates how the pre-mRNA is processed and how other molecules within the nucleus interact with the nascent RNA. In such a state, hnRNA associates with intranuclear proteins and small nuclear RNA (snRNA). Introns and exons are present and there has been no RNA terminus processing, that is, no polyadenylation nor any modification of the 5'-bases. The panoply of processes that occur on hrRNA are referred to as posttranscriptional events.

The posttranscriptional processing events occur virtually immediately and simultaneously. For heuristic ease they will be discussed individually and as if these processes start at the 5'-end of hnRNA and end at the 3'-end. When the transcript is being made, the 5'-end begins to associate with proteins within the nuclear matrix. As discussed above in reference to transcriptional control, these proteins can impact on transcriptional elongation. But such proteins also begin to organize the growing RNA chain into a structure that lends itself to processing by specific modifying intranuclear complexes. With the exception of a few specialized cases, such as the picornaviruses that contain as part of their RNA genome-specific sequences that code for precise ribosomal recognition sites, invariably, mRNAs are processed before translation. [183]

Methylated 5' Cap

The original, start-site, transcribed nucleotide has a triphosphate group at the 5'-end. However, this nucleotide is never found in mRNA. The mRNA 5'-end is invariably processed or modified such that there is a special nucleotidyl structure composed of a 7-methylguanosine connected through an unusual triphosphate linkage to the first nucleotide of the pre-mRNA (Figure 1.12).[184] This results in a 5' to 5' bond between ^{7m}G and the penultimate nucleotide. The resulting $^{7m}GpppAp$ 5'-end in higher eukaryotes may then be further modified by secondary methylation at the 2'-hydroxyl group of the ribose, as well as potential nucleotide base methylation of adjoining nucleotides. [185],[186] Methylation of the 2'-OH group of the penultimate nucleotide stabilizes against base catalyzed hydrolysis because there is no chance of anchiomeric assistance from the adjoining hydroxyl group to facilitate the cyclic diester intermediate that would proceed hydrolysis. These methylations are catalyzed by specific methylation enzymes that recognize the $^{7m}GpppAp$ of the 5'-end of mRNA.[187] What determines the methylation pattern is not known. The $^{7m}Gppp^{2m}Ap$ structure also ensures that there is no free 5'-OH group, and as such the mRNA molecule has a 3' free hydroxyl group on both its 5'- and 3'-ends. Although mRNA stability may result from many factors, the absence of the free phosphorylated 5'-OH group protects the mRNA from 5'-OH-specific exoRNase catalyzed degradation and thereby the inverted linkage of 5' to 5' OHs stabilizes and preserves mRNAs. [188],[189],[190],[191] and [192] The collectively modified 5'-end of mRNA is referred to as the cap structure. This structure associates with a cap-binding protein which is integral to initiation of translation—decoding the mRNA into protein—and possibly the associated CPB is important in transport of mRNA out of the nucleus and into the cytoplasm to be translated by ribosomes. [193],[194] and [195] Further, the cap

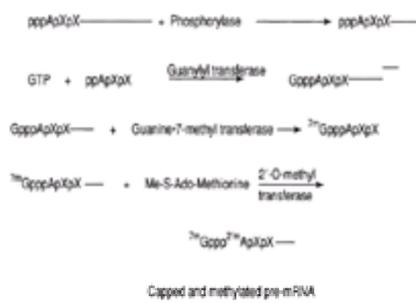
structure is crucial for binding and positioning pre-RNA into intranuclear complexes for further processing. [196]


FIGURE 1.12. The capping and methylation of pre-mRNA goes through several steps. pppApXpX represents the 5'-end of pre-mRNA. GpppApXpX is the unusual 5' to '5 capped structure without methylation of the 7-nitrogen of guanosine. ^{7m}Gppp^{2m}ApXpX is the fully methylated capped structure of pre-mRNA.

Transcriptional Termination

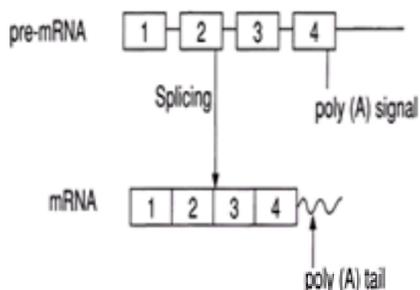
In prokaryotes termination of transcription is controlled by either the presence of specific proteins or terminating cis-elements within the gene. [37,197] For the most part, this is not the case in eukaryotes wherein the emphasis has changed from specific transcription termination sites to a more vague transcriptional end point with subsequent exquisitely accurately regulated 3'-end processing. [198] The pre-mRNA may terminate either shortly or considerably downstream of the end of the mRNA. The control of where the transcriptional apparatus stops transcribing is not known; however, considerable effort has been expended in understanding the processes that define the 3'-terminus of mRNA. [199,200 and 201] Approximately 10 to 30 nucleotides upstream of the pre-mRNA is a hexameric element that has a consensus of AAUAAA and defines the subsequent 3' cleavage site of pre-RNA. [202,203] Once 3' endonucleolytic cleavage of pre-mRNA occurs, then between 200 and 250 As are added by poly(A) polymerase to form the poly(A) tail of mRNA (Figure 1.13). [24,204] But not all AAUAAA elements define the 3' cleavage site. The AAUAAA element must be in the context of other regulatory elements that are downstream of the cleavage site. Two such downstream cognate sequences exist: the GU or U-rich sequences. [205,206] The enzyme that is responsible for polyadenylation has been isolated and purified. [207] Poly(A) polymerase must act in concert with other factors that determine 3'-end site selection and define endonucleolytic sites. There are several candidates for these factors such as cleavage and polyadenylation factor, CPF, and CF1. [208,209] As is seen in the selection of the exact isoform of diverse proteins such as dihydrofolate reductase, membrane or secreted IgM, a-amylase, and calcitonin and calcitonin gene-related peptide are subject to contextual constraints of cleavage site selection on the basis of tissue or cell development (Figure 1.14). [210,211 and 212] For instance, selection of which of two mRNAs will be made from the same pre-mRNA that codes for the membrane bound or secreted IgM forms appears to depend on specific factors that are present as a function of the developmental maturity of the lymphocyte, [213,214] whereas the selection of synthesis of calcitonin versus calcitonin gene-related peptide appears to depend on the function of tissue specific factors, in that the calcitonin gene-related peptide is primarily synthesized in the hypothalamus, and calcitonin in the thyroid. [215,216] So not only do we find that the 3'-end of mRNA is a regulatory checkpoint, but also that polyadenylation can be dependent on the choice of intragenic exon selection that is defined by splice site selection. [217]


FIGURE 1.13. Demonstrates the pre-mRNA being processed by sequential splicing of exon 1, 2, 3, and 4. The polyadenylation signal is denoted at the terminal region of exon 4.
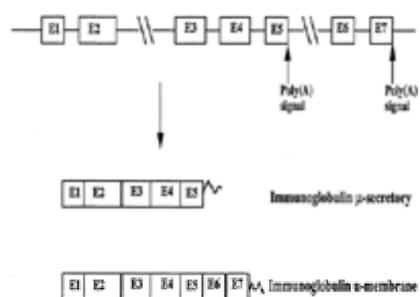

FIGURE 1.14. The selection of an immunoglobulin gene product for either secretion or membrane attachment depends on the use of one of two possible polyadenylation (poly[A]) elements within the immunoglobulin gene. When the first poly(A) site is selected, two exons are not incorporated into the gene product.

Spliceosomes

Since the ultimate mRNA is fashioned such that it will be efficiently utilized to translate genetic information into utilizable protein, it is not surprising that a major posttranscriptional regulatory checkpoint is compression of the dispersed pre-mRNA into RNA. The capped and poly(A) tailed prespliced RNA is composed in a modular fashion of exons and introns. The introns must be removed and the exons stitched together to result in a transcriptional unit that will be translated. The posttranscriptional process of removing introns and annealing the exons into a protein-coding RNA ready for translation is defined as splicing (Figure 1.15). [196,218,219 and 220] It is not surprising, considering the modular or motif nature of higher eukaryotic proteins, that exon sizes are fairly small and are usually less than 300 nucleotides. [221] This is not the case for introns, which can vary in size from approximately 60 to 100,000 nucleotides. [219,220] Since the initial pre-mRNA transcript for class II genes can be extremely large and composed of 50 or more introns of varying sizes, precise splicing must be maintained to ensure ultimate functional proteins. [219,221] There are three general classes of splicing reactions. The first two depend on autocatalytic splicing, which is highly dependent on the intron structure, whereas the third type of splicing, which is utilized for class II genes, depends on the pre-mRNA associating with an intranuclear structure referred to as the spliceosome complex. [220] The spliceosome is a 60S particle containing 5 small nuclear RNAs (snRNAs), U1, U2, U4, U5, and U6, as well as many small nuclear ribonuclear proteins (snRNP). [222,223 and 224] This spliceosome complex may form just after the capping modification has occurred; however, normally the complex forms on the capped and poly(A) tailed pre-mRNA. First U1 and U2 snRNP form with the pre-RNA and then U4, U5, and U6 snRNP, as well as small ribonuclear (SR)

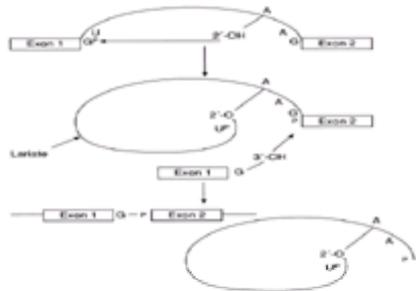
proteins associated with the pre-spliceosome to form the catalytic spliceosome. [225,226,227 and 228] The splicing reaction requires the obvious presence of pre-mRNA, the spliceosome, and ATP.[229] When considering the great variability in the size and number of exons and introns of a transcribed gene, it becomes intuitive that mandatory cis-elements within the intron/exon contribute to the precise recognition by the splicing apparatus. There are cognate cis-elements at the 5'- and 3'-ends, as well as intraintronic sequences, that define the splicing junctions for removal of intron. As is seen in Figure 1.15, the sequence of events for splicing proceeds first by cleavage at the 5'-end of the intron, followed by subsequent ligation of the 3'-end of the cleaved exon to the 5'-end of the exons with concomitant excision of the intron.[219,220] The first step of the splicing reaction involves a transesterification reaction in which the free 2'-hydroxyl group of an adenine at the branch point within the intron near the 3'-end of the intron reacts with the 5'-most guanosine within the intron to create a nucleotide that has phosphate esters on the 2' and 3' groups of the ribose sugar.[230,231] This creates the 5' exon with a free hydroxyl group and a lariat structure composed of the intron and its connected 3' exon. The second reaction, which appears *in vivc* to occur simultaneous with the first reaction, is the excision of the intron containing the lariat and ligation of the two exons. The U1 snRNP of the spliceosome interacts with pre-mRNA at the 5' splice junction site of the intron. [232,233] The 5' junction invariably contains a GU nucleotide; in a few cases GCs have replaced the GU.[234] The 5' GU dinucleotide is positioned in a consensus sequence of AG *GU*AAGU that spans from the 3'-end of the exon into the 5'-end of the intron.[235] It has been shown that changing the G or the U can completely inactivate the splice junction. [236,237] Furthermore, alterations within the consensus sequence of the 5' junction site may inactivate the primary junction site, decrease the rate of splicing, or activate alternative junction sites that may be either in the exon or intron.[237] These alternative or cryptic 5' junctional sites invariable have a GU dinucleotide. [237,238] For instance, in b[E]-thalassemia, a G to A mutation within the first exon of b.-globin changes the nucleotide sequence in the vicinity of GU, and thereby activates an intra-exon cryptic 5' junction site that results in aberrant mRNA. [238,239] Therefore, selection of the 5' splice is a function of its closeness to the consensus sequence and conjoining sequences as well as of the distance from the 3' junction site.[240]


FIGURE 1.15. The splicing reaction is shown diagrammatically. The exons are represented as boxes, the intron as a single line between the two exons. The 2'-hydroxyl group of the adenosine (A) at the branch point is shown with the intron. The lariat structure which results from the branch 2'-hydroxyl group reacting with the phosphate ester between G and U at the 5'-end of the intron is indicated by an arrow. The resulting processed and spliced exons are joined together.

The 3' junction site contains a rather large consensus sequence that is composed of an invariant AG which resides immediately before the second exon and an upstream pyrimidine-rich tract with an intervening single purine or pyrimidine and then a pyrimidine just before the junction site AG. The consensus is therefore, a $(Py)_{11}$ NYAG-exon.[218,235] The 3' pyrimidine-rich region interacts with the U5 snRNP as well as the U1 snRNP of the spliceosome. [241,242 and 243] The 3' junction site and the pyrimidine-rich tract are an absolute requirement for the first endonucleolytic cleavage of the 5' junctional site to occur. [244] The implication is that within the spliceosome, the recognition order probably is U1 followed by U2 and then U5 snRNP, or U1 in conjunction with U2 forms a complex with U5 and other snRNPs to conform to the 3'-end of the intron so that the branch point adenine which interacts with U2 can be positioned by the U1/U5/U4/U6/SR complex to react with the 5' junctional site. Alternatively, there is a stepwise assembly of snRNPs that forms complexes with prespliced mRNA which results in rearrangement of the snRNPs to conform the pre-RNA for splicing. In any case, U2 snRNP protects the branch point region from digestion by RNase. [245] Even though the branch point adenine is crucial for lariat formation and therefore intron excision, unlike yeast, in higher eukaryotes only a weak consensus sequence of UACUAAC exists. [231,246] What appears to be the case is that there is a strict requirement that the branch point of the lariat be 16 to 60 nucleotides upstream of the 3' junction site. [218,219] Deletion of the original branch point adenine slows the splicing reaction and unmasks a cryptic branch point site. [247]

Alternate Splicing

It must be that in addition to the normally found snRNPs that make up the spliceosome, other nuclear proteins function in the splicing event. This becomes particularly obvious when one considers the mechanism by which cells regulate the splicing reaction such that alternative splicing events occur. [180,248] Alternative splicing provides to the cell a regulatory control to produce alternative proteins or isozymes without the need to store within the genome genes that code for each individual protein. To effect alternative splicing, the cell type must produce a nuclear protein that acts directly with the spliceosome to result in selection of alternative splice sites or, because the pre-mRNA has considerable secondary structure, the tissue-specific protein may interact with the pre-mRNA while it is forming to fold it in such a fashion that certain splice sites are not available to the spliceosome. It may be that the tissue-specific proteins may associate with the spliceosome such that certain intronic or exonic sequences are recognized as alternative splice sites. Whatever the underlying mechanism(s) of alternative splicing the end result is that in either the case of normal sequential splicing or of alternative splice, pre-RNA, once it has been capped and polyadenylated and spliced, is ready to be carried from the nucleus to the ribosome for translation.

TRANSLATION

During translation the mRNA carrying the genetic code is decoded into amino acids. Each amino acid is represented by at least one codon found as a triplet within the nucleotide sequence of mRNA. Translation in prokaryotes is a very rapid process, which occurs while transcription is still in progress. This is possible within a prokaryotic cell because both transcriptional and translational events are in the same cellular compartment. On the other hand, translation and transcription in eukaryotic cells are in separate cellular compartments. Moreover, because of posttranscriptional modifications and transport, there is a lag of a few hours between the two molecular events.[249,250]

Ribosome Structure

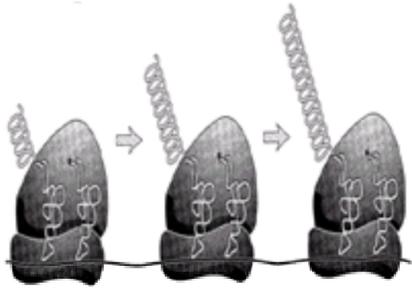
Ribosomes (ribonucleoprotein structures) provide the site for recognition between an mRNA codon and tRNA anticodon with subsequent assembly of translated amino acids into polypeptides. Ribosomes attach to the 5' end of mRNA, translating each nucleotide triplet into an amino acid as the triplets move in a 5' to 3' direction. A strand of mRNA can be simultaneously translated by more than one ribosome. Multiple ribosome constructs are referred to as a polysome. Polysomes contain variable numbers of ribosomes, each one synthesizing an individual polypeptide (Figure 1.16). There are generally a greater number of ribosomes per prokaryote mRNA molecule since the mRNA in these organisms is much longer than that found in eukaryotes. Bacteria can add approximately 15 amino acids to the growing polypeptide chain every second, therefore synthesizing a protein of about 300 amino acids in 20 seconds. Eukaryotic cells proceed at a slower rate, adding about two amino acids to the growing chain per second. [249]


FIGURE 1.16. Polysomes are many ribosomes simultaneously translating the same molecule of RNA, resulting in synthesis of many polypeptides of different lengths from the same RNA molecule. (From Lewin B. *The assembly line for protein synthesis.* New York: Oxford University Press, 1990:143, with permission.)

A ribosome is composed of two subunits which can be dissociated from each other by reducing the Mg^{2+} concentration. The subunits can be isolated through zonal centrifugation in Mg^{2+}-sucrose gradient.[251],[252] The sedimentation rate has been adopted as nomenclature for each subunit, with a higher S value indicating a greater rate of sedimentation and a larger mass.[253] Bacterial ribosomal subunits sediment at 30S (small subunit) and 50S (large subunit) forming a 70S reassociated ribosome. The small (30S) subunit is composed of 21 different proteins and 32 different proteins comprise the large 50S subunit. One of the small subunit proteins is identical to one found in the large subunit yielding a total of 52 different proteins within an intact prokaryote ribosome. [254] Eukaryotic cytoplasmic ribosomes are larger, sedimenting at 80S for the intact ribosome and 40S and 60S for the small and large subunits respectively. The ribosomal RNA has a molecular weight of 2,300 kD with an additional 1,700 to 1,800 kD of absorbed ribosomal proteins such as initiation factors, elongation factors, and enzymes. [255] Ribosomal proteins in both prokaryotes and eukaryotes have insoluble, basic properties. [256] The genes coding for ribosomal proteins are present 10 to 12 times in higher eukaryotic genomes, but there is only one copy of each ribosomal protein gene in prokaryotes. [257],[258] E. coli rRNA genes are cotranscribed as a 16S-23s-5s linked unit. [258] In higher eukaryotes the rRNA genes are linked as an 18s-5.8s-28s transcriptional unit while the 5s gene is transcribed separately by a different polymerase. [259],[260] and [261] A comparison of rRNA sequences between bacteria and chloroplasts reveals 74% homology between the 16S subunits [262],[263] and nearly 70% homology between the 23s subunits. [264],[265] However, comparison of *E. coli* and eukaryote 16S rRNA shows no homology except within nucleotides 9–51 at the 3'-end of *E. coli* 16S rRNA. The region of homology is located just upstream from an 8 nucleotide region in *E. coli* 16S rRNA which is a necessary sequence in initiation of translation. [266],[267],[268] and [269]

Initiation Complex

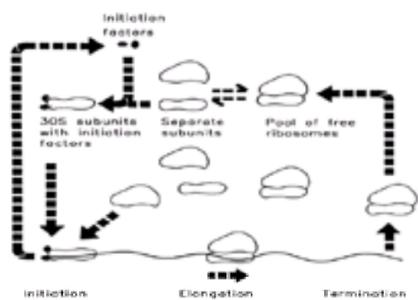
An initiation complex must first be formed before a ribosome can begin the process of decoding mRNA triplets into amino acids. Formation of an initiation complex requires initiation factors to function as chaperones in bringing together the small ribosomal subunit, mRNA, an initiator tRNA, and the large ribosomal subunit (Figure 1.17). The translational process involves association of the proper amino acyl tRNA anticodon with a complementary mRNA codon. Each ribosome has two sites for tRNA binding; the A or entry site is occupied by the incoming amino acyl tRNA whose anticodon is the compliment of the mRNA codon, which is next in line to be translated. The adjacent P (donor) site is occupied by the growing polypeptide chain bound to peptidyl tRNA. When both the A and P sites are filled, a peptide bond is formed between the newly translated amino acid in the A site and the previously translated amino acid in the P site (Figure 1.18). These complexes of proteins and other initiation factors associated with a ribosome make up the active site for participation in one of the three stages of translation: (a) initiation; (b) elongation; and (c) termination. The following discussion will address the general mechanisms in each of these stages as well as the regulatory events and deviations which can occur in translation.[270],[271]


FIGURE 1.17. Formation of an initiation complex requires the dissociation of the ribosomal subunits in the "free pool" before the initiation factors, small ribosomal subunit, initiator tRNA, and mRNA can begin assembly of the initiation complex. (From Lewin B. *The assembly line for protein synthesis. Genes IV* New York: Oxford University Press, 1990:113, with permission.)
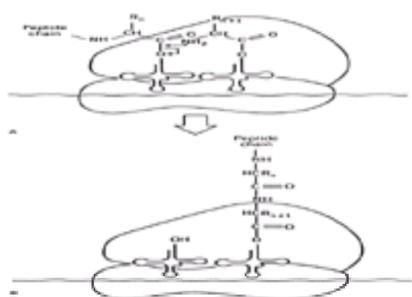

FIGURE 1.18. A: Each ribosome has two sites for tRNA binding. The entry (A) site is occupied by the incoming mRNA codon and the complimentary tRNA anticodon. The donor (P) site contains the elongation polypeptide bound to peptidyl tRNA. When both sites are filled, a peptide bond is formed between the two newly synthesized amino acids. **B:** The peptide chain with the most recently synthesized amino acid is translocated back to the A site.

Initiation of translation requires multiple steps to assemble a ribosomal initiation complex which can bind mRNA at or near a site containing an initiation codon (AUG). Formation of the initiation complex requires different initiation factors whose number and complexity of function increase from prokaryotic to eukaryotic translation. There are four main events in the initiation of translation: (a) dissociation of the small and large ribosomal subunits found in the free ribosome pool; (b) binding of the initiator tRNA to the small ribosomal subunit along with initiation factors to form a preinitiation complex; (c) binding of mRNA to the preinitiation complex to form an initiation complex with the small subunit; and (d) reassociation of the large and small subunits to form an 80S initiation complex. [272]

Initiation Complex in Prokaryotes

Assembly of the 30S preinitiation complex in prokaryotes requires three initiation factors (IF1, IF2, and IF3), GTP, 30S ribosomal subunits, initiator tRNA (formyl methionyl-tRNA), and mRNA. In order to form a preinitiation complex, the small ribosomal subunit (30S) must be available in the free ribosome pool. Normally 30S is

found tightly coupled with 50S as a 70S ribosome, which must be dissociated in order to make 30S available. [273],[274] Initiation factors IF1 and IF3 are part of the dissociation process. The IF1 association with the 70S ribosome increases the rate of dissociation of 30S from 50S. [275],[276] and [277] Once the subunits have separated from each other, IF3 complexes with 30S and prevents it from reassociating with 50S. [277],[278] and [279] All three initiation factors, IF1, IF2, and IF3 then bind 30S subunits in the free pool, forming a 30S-IF1-IF2-IF3 complex. Each of the three initiation factors are capable of independently binding 30S; however, the stability of the binding is enhanced by the addition of one or more of the remaining initiation factors. [280],[281],[282] and [283] The binding sites on the 30S subunit for all three initiation factors are adjacent to or overlapping the 3' end of 16S RNA. [284],[285],[286] and [287] IF2 is specifically needed for binding fMet-tRNA and chaperoning it to the 30S binding site. IF1 and GTP are present in complex formation. The presence of GTP reduces the number of molecules of IF2 needed to bind fMet-tRNA, and IF1 stabilizes the binding of IF2 to the 30S subunit. [280],[281],[288],[289] and [290] IF3 is required for formation of the 30S-mRNA complex at the ribosomal binding site near the initiation codon. IF3 remains complexed with 30S until the large subunit joins the initiation complex at the site of initiation (Figure 1.19).[291],[292] IF3 is present in exceedingly small amounts in bacterial cells, which makes it a determinant in how much 30S rRNA is available to initiate translation. [23]

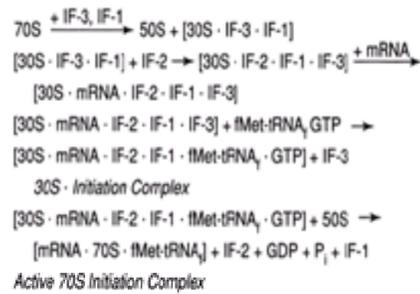
Active 70S Initiation Complex


FIGURE 1.19. The sequence of events and molecules involved with formation of an active 70S initiation complex.

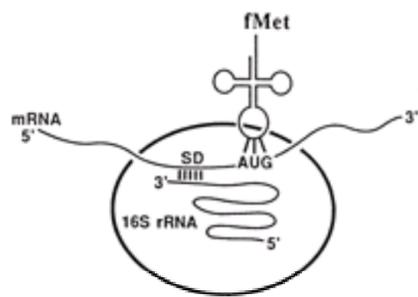
The ribosomal binding site, found in prokaryotic mRNA, contains important sequences: (a) the Shine-Dalgarno sequence, AGGAGGU, which is the ribosome recognition site; and (b) the initiation codon AUG (or also GUG or UUG). In 1974, Shine and Dalgarno showed that a purine-rich sequence located upstream from the initiator methionine codon is complementary to the 3'-end of *E. coli* 16S rRNA.[293] Since then, approximately 150 additional bacterial and bacteriophage rRNA sequences have verified the presence of a Shine-Dalgarno sequence, which can be found preceding each cistron in a prokaryotic polycistronic message. [294],[295],[296],[297] and [298] The efficiency with which the Shine-Dalgarno sequence binds the mRNA to initiate translation is contingent upon the number of nucleotides that form complementary base pairs with the 3' 16S rRNA nucleotide sequence. The stretch of complementary base pairing is usually three to nine continuous nucleotides. [294] However, the exact site within the 3' 16S rRNA where the Shine-Dalgarno sequence binds is dependent upon the degree of secondary structure present within that region, with the most favored sequence being CUCC found within the 3' pyrimidine-rich region (GAUCACCUCCUUA $_{OH}$3').[299] The advantage of this base pairing is that it brings the initiation codon into position for initiator tRNA binding. [288] The distance between the Shine-Dalgarno sequence and AUG is approximately seven nucleotides with 7 ± 2 being the ideal distance (Figure 1.20).[300],[301] and [302]


FIGURE 1.20. The Shine-Dalgarno (SD) sequence located upstream of the initiation codon is the motif recognized by ribosomes. The SD sequence forms complimentary base pairs with a 3' 16S rRNA. The number of nucleotides forming complementary bonds affects translation efficiency. (From Merrick WC. Eukaryotic mRNAs: strange solutions require unusual problems. In: Hill WE, Dahlberg A, Garrett RA, et al. *The ribosome: structure, function and evolution*. Washington, DC: American Society for Microbiology, 1990:292, with permission.)

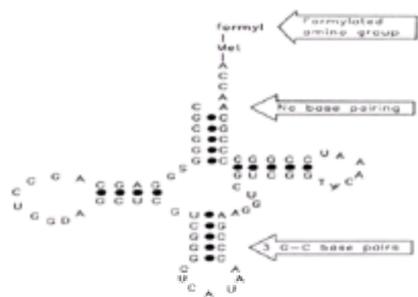
AUG, the initiation triplet, codes for methionine which can be carried by two different tRNA molecules—one is the initiator methionine and the other is recognized in elongation. In bacteria and mitochondria, the initiator tRNA is the formylated methionine, N-formyl-methionyl-tRNA, and it is the only amino acyl tRNA with which IF2 will interact (Figure 1.21).[303] The other methionine, whose function is to recognize an internal AUG codon, cannot be formylated. Formylated methionine (and eukaryotic initiator tRNAs) has the unique capability of bypassing the A site and entering directly into the P site of the ribosome to initiate protein synthesis. Once a growing polypeptide becomes 15 to 30 amino acids long, the formyl group at the NH2 terminus is removed. The function of the enzyme deformylase is to remove the formyl group and generate a normal NH2 terminus. The following set of reactions provides a summation of events in formation of an active 70S initiation complex. [270]


FIGURE 1.21. The prokaryote initiator tRNA is formyl methionyl-t-RNA which has a formulated amino group making it structurally different from all other tRNAs. (From Lewin B. *The assembly line for protein synthesis.* New York: Oxford University Press, 1990:113, with permission.)

In contrast to the bacterial initiation of translation, the eukaryotic process is different, more complex, and requires many more factors to orchestrate the event. The main differences are that: (a) eukaryotes have larger ribosomes; (b) eukaryotes have more initiation factors (8 eIFs); (c) the Met-tRNA is not formylated; (d) most mRNA has a 5' cap structure; and (e) mRNA is monocistronic.

Initiation Complex in Eukaryotes

Eukaryotic mRNA has two distinguishing structures: the 5' cap and poly A tail, both of which are shown to be part of (although not necessary to) the translation process. It has been demonstrated that without a 5' cap, mRNA can be translated,[304],[305] but the presence of the cap structure greatly enhances protein synthesis. The 5' cap structure, a methylated guanosine (position 7) that is connected to the first mRNA nucleotide by a 5' to 5' triphosphate bridge, functions to bring the 40S subunit of the ribosome to the mRNA to initiate translation. The four basic steps involved with the initiation of translation in eukaryotes are:

1. Dissociation of the 80S ribosome into two subunits: 40S and 60S;
2. Formation of a preinitiation complex consisting of methionyl-tRNA-40S-eIF2-GTP;
3. Formation of an initiation complex consisting of the preinitiation complex bound to mRNA;
4. Formation of an 80S initiation complex consisting of 40S and 60S subunits, initiator methionine, tRNA, and mRNA.

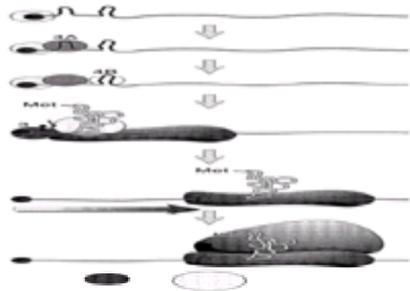
The initial step in eukaryotic translation is the formation of a complex containing GTP, eukaryotic initiation factor 2 (eIF2) and methionine-tRNA$_I$ (the initiator methionine in eukaryotes is not formylated). GTP binds to eIF2 to enhance the affinity of eIF2 for methionine-tRNA$_I$. Once the met-tRNA-eIF2-GTP complex is formed, it can then bind a free 40S ribosomal subunit found in the free ribosomal pool resulting in the formation of a 43S preinitiation complex.[306] The number of free 40S and 60S ribosomal subunits found in the free ribosomal pool is small since the formation of 80S is favored in the cellular milieu. The dissociation of the two subunits is maintained by eIF6 binding to the 60S subunit and eIF3 to 40S.[307],[308],[309],[310] and [311] The 43S complex binds to the 5' CAP region and moves along the mRNA until it reaches the AUG initiation codon. Here eIF5 triggers hydrolysis of GTP, which results in a conformational change in eIF2 and a reduced affinity for 40S; eIF2-GDP dissociates from the 43S; 40S forms an active 80S ribosome with 60S. eIF2 binds GDP with a 400-fold higher affinity than GTP,[312] resulting in a slow off rate of GDP. This would be a rate-limiting step in protein synthesis if it were not for the presence of another factor, guanine nucleotide exchange factor (GEF or eIF2B). GEF mediates the nucleotide exchange so that eIF2 now becomes GTP-bound, enabling this complex to be recycled in formation of another preinitiation complex. Protein synthesis begins when the 5' cap structure is recognized by the initiation factor 4E(eIF4E) component of the eIF4F complex that also includes eIF4G. The 24-kD eIF4E, also known as the cap-binding protein, recognizes, binds to, and cross-links the 5' cap structure.[313],[314] and [315] The N-terminal domain of eIF4G functions as a bridge between eIF4E and eIF4A and its C-terminal domain interacts with eIF3 complexed to 40S-tRNA-GTP structure, thus creating a bridge between the cap structure and the 40S subunit.[316],[317],[318],[319] and [320] After eIF4E has bound and cross-linked the 5' cap structure, eIF4A and eIF4B become part of the initiation complex. eIF4A alone is a single-stranded RNA-dependent ATPase and belongs to a family of RNA helicase (unwinding) proteins. eIF4B has several functions, the most important of which is stimulation of ATP-dependent RNA helicase activity of eIF4A (Figure 1.22).[321],[322] and [323] The coding region of eIF4B contains two sequence motifs, AFLGNL and KGFGYAEF, that are homologous with other RNA recognition motifs, suggesting that this factor acts as an mRNA cross-linking protein.[321],[322],[323] and [324] These two factors, eIF4A and eIF4B, are essential in melting the 5' untranslated region (5' UTR) of mRNA, making the initiation codon accessible to the ribosomes (Figure 1.23).


FIGURE 1.22. Eukaryotic initiation factors eIF-A and eIF-B function as helicase enzymes, unwinding the secondary structure of the mRNA in front of them as they move in a 5' to 3' direction. (From Lewin B. *The apparatus for protein localization.* New York: Oxford University Press, 1990:279, with permission.)
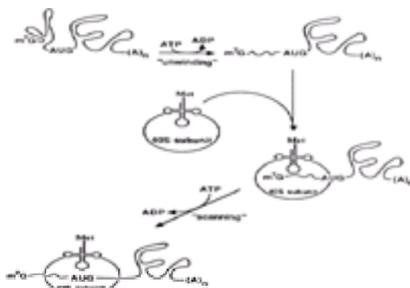

FIGURE 1.23. The initiation of translation in eukaryotes requires the formation of an initiation complex to initiate translation. This requires the functions of many enzymes performing their specific activity at the appropriate time. (From Merrick WC. Eukaryotic mRNAs: strange solutions require unusual problems. In: Hill WE, Dahlberg A, Garrett RA, et al. *The ribosome: structure, function and evolution*. Washington, DC: American Society for Microbiology, 1990:292, with permission.)

Initiation factor eIF4E is of considerable interest due to its important role in controlling the rate of initiation of translation as well as its role in the regulation of translation. For example, the promoter of the eIF4E gene has an E-box that c-Myc binds to activate transcription, thus increasing the level of eIF4A expression. Malignant transformation of cells overexpressing eIF4E has been demonstrated;[325],[326] cells supplemented with growth factors, hormones, and mitogens can stimulate phosphorylation of eIF4E, and posttranslational modifications such as phosphorylation have been shown to increase the initiation of translation by enhancing eIF4E affinity for the 5' cap;[327],[328],[329] and [330] cellular inhibitory proteins, 4E-binding proteins, function as negative regulators of gene expression. They act as repressors of 5' cap-binding by interfering with the association of eIF4E with the bridging factor eIF4G, thus inhibiting the formation of the initiation complex. The 4E-binding proteins contain an amino acid sequence homologous to the N-terminal domain of eIF4G. This sequence in eIF4G normally associates with eIF4E.[317],[331],[332] and [333] The x-ray crystallography structure of eIF4E bound to 7-methyl-GDP has recently been reported,[334] thus giving additional insight into the interactions of this initiation factor with other factors and mRNA.

As might be expected, some viruses have an efficient alternative to the 5' cap structure stimulation of translation. Positive-stranded picornoviruses (polio) have a 650 to 1,300 nucleotide long 5' noncoding region (5' NCR) containing many AUG codons and extensive secondary structure. This region is capable of efficiently initiating translation of the viral mRNA. These regions are named internal ribosome entry sites (IRES) and are found in all picornoviruses, hepatitis A and C viruses mRNA.[335],[336] and [337] IRES elements have been located in some cellular mRNAs, such as IgG heavy chain binding protein, Bip, fibroblast growth factor 2, *Drosophilia antennapedia* protein, and human eIF4G.[338],[339],[340],[341] and [342]

It should be noted that there is evidence from experiments performed in amphibian oocytes and yeast indicating that the 3' polyadenylation tail is involved in the stimulation of mRNA translation. These studies have shown that a poly(A) tail binding protein, Pab1p, is required for stimulation of translation and that it was capable of stimulating translation in the absence of eIF4E. It has also been shown that the poly(A) tail enhances the binding of the 40S subunit to mRNA as well as enhancing the joining of the 60S subunit to the initiation complex. Taken together, models of the poly(A) tail involvement in translation have been suggested, although many aspects remain unresolved.[343] At this juncture, the reader should make special note of these data and anticipate that this aspect of translation will be unraveled in the

near future.

Unlike bacteria, eukaryotes do not have a specific ribosome-binding site on the mRNA to direct the initiation complex to the proper initiation codon. The precise mechanism by which eukaryotes locate the AUG initiator codon is still unknown; however, there are several hypotheses, all of which are variations of a "scanning" mechanism. The current hypothesis is that the 40S ribosomes bind mRNA at or near the 5'-end cap and move toward the interior of the mRNA sequence. [344],[345] and [346] Recognition of the AUG initiator codon depends on the flanking sequences, with A/GNNAUGG providing the best context for binding of the initiation complex. If the first AUG is in this optimal context, then the 40S initiation complex will bind at that initiation codon without scanning the remainder of the mRNA. However, if the first AUG does not have the ideal flanking sequences, then the 40S will continue to scan the mRNA sequence until it locates another AUG, binds it and initiates translation at that codon.[347] In a few cases, some 40S subunits bind the first AUG flanked by nonoptimal sequences, while other ribosomes continue scanning and finally bind an AUG codon further downstream. Given these circumstances, two proteins would be synthesized from a single message. This is a highly unusual event in eukaryotes since they do not have bicistronic transcripts.[23] The ability of a mRNA to be actively involved in translation is determined by: (a) how accessible the 5' capped mRNA is to the initiation complex; (b) how readily the 40S ribosomal subunit can scan the mRNA downstream from its entry point at the 5' end; and (c) how easily the initiation complex can locate the AUG initiator codon in the optimal context.[272]

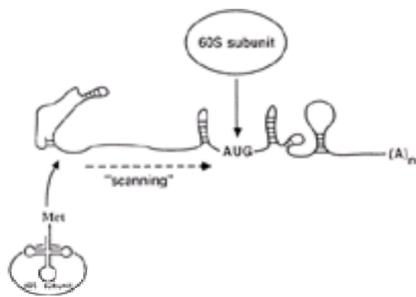
Ribosome "scanning" can be impeded by secondary structures in the mRNA. Extensive secondary structure, common to mRNA, can form stable stem-loop structures through complementary base pairing (Figure 1.24). If the stem-loop structure is so stable that it cannot be melted, then the 40S ribosome may not be able to pass the stem loop as it scans the mRNA. A stem loop at the 5' CAP region can prevent the initiation complex from binding the mRNA at its normal site of entry.[345]


FIGURE 1.24. Ribosome scanning can be impeded by the secondary structure of mRNA, which can potentially prevent initiation at the correct AUG site. (From Merrick WC. Eukaryotic mRNAs: strange solutions require unusual problems. In: Hill WE, Dahlber A, Garrett RA, et al. *The ribosome: structure, function and evolution.* Washington, DC: American Society for Microbiology, 1990:292, with permission.)

The formation of the initiation complex (joining of 60S to the preinitiation complex at the initiator codon) requires eIF5. This protein is a single polypeptide having ribosome-dependent GTPase activity. The function of this factor is to hydrolyze the GTP molecule bound to eIF2 prior to the addition of the 60S subunit. This hydrolysis reaction removes eIF2-GDP, eIF1 and eIF3 from the preinitiation complex so they can be recycled to continue their role in formation of new preinitiation complexes.[309],[311],[348],[349],[350] and [351]

Elongation

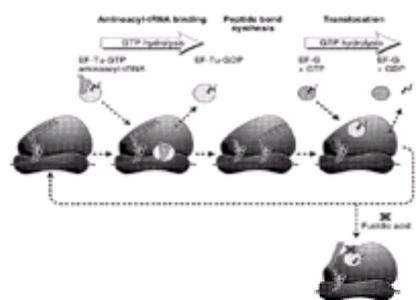
After the initiation complex is formed, the elongation step can begin. There are three major steps in the elongation that keep repeating themselves. They are: (a) binding of aminoacyl-tRNA to the ribosomal A site; (b) formation of a peptide bond; (c) translocation of the tRNAs and mRNA (Figure 1.25). There are elongation factors involved in the elongation steps. It should be noted that these factors are not a requirement, because the ribosome can carry out elongation without them.[352],[353] However, catalysis of these steps by two GTP-dependent factors increases the speed and fidelity of protein synthesis.[354] These factors bind to specific components and are then released and recycled for use in the addition of the next amino acid in the nascent polypeptide chain.[355]


FIGURE 1.25. The four major elongation steps in prokaryotes require the functions of elongation factors. (From Lewin B. *The assembly line for protein synthesis.* New York: Oxford University Press, 1994:163, with permission.)

The process of elongation in prokaryotes and eukaryotes is similar. At this time the elongation process is under intense investigation. As more precise data obtained from more sophisticated technology are being accumulated, they more specifically define the interactions and functions of the elongation factors with the tRNA, mRNA, and ribosome subunits.

The initial step in elongation begins with an initiator tRNA in the P (peptidyl) site and the small ribosomal subunit and initiation factors that bind to the mRNA in a configuration that allow entry only into the P site of the ribosome. The aminoacyl (A) site is now available for introduction of an aminoacyl-tRNA having an anticodon complementary to the mRNA codon that will occupy the A site. The appropriate aminoacyl-tRNA is escorted to the A site by a GTP-bound elongation factor (EF-Tu in prokaryotes and eEF-1a in eukaryotes) introduced as an aminoacyl-tRNA-EF-Tu-GTP complex. The GTP undergoes hydrolysis and EF-Tu (eEF-1a) is released. Another factor is required to displace the GDP from the elongation factor. This factor, EF-Ts in bacteria and EF-1bg in eukaryotes, forms an intermediary with EF-Tu and is subsequently displaced by GTP as shown in the following diagram:

EF-Tu-GDP®EF-Tu-EF-Ts®EF-Tu-GTP

The EF-Tu-GDP complex is then available to undergo another cycle in chaperoning a tRNA to the A site. This can be a rate-limiting step in elongation just as it was in initiation, because a subsequent binding reaction cannot occur until the EF-GDP is released for recycling.

Release of the EF-Tu-GDP enables the aminoacyl-tRNA to bind to the A site. The anticodon regions of the tRNA in both sites interact with the small subunit of the ribosome, and likewise the acceptor regions of both tRNAs interact with the large ribosomal subunit. A peptide bond is formed when an a-amino group of aminoacyl-tRNA attacks the peptidyl-tRNA bond in a reaction catalyzed by peptidyl transferase. Following formation of the peptide bond, the nascent peptide chain translocates to the A site. At the time of translocation, another GTP-dependent elongation factor (EF-G in prokaryotes and EF-2 in eukaryotes) binds to the ribosomes and catalyzes the movement of the two tRNAs and mRNA by one codon. The deacylated aminoacyl-tRNA moves from the A site to the exit (E) site[356] and then

dissociates from the ribosome.[354]

The GTP-dependent translocation step involving EF-G (eEF-2) is under intense debate. The previously viewed mechanism was that GTP-EF-G bound to the ribosome to induce translocation and ensure that translocation occurred in one direction. [357,358 and 359] This has been considered a rate-limiting step. Pre-steady-state experiments now show that GTP hydrolysis of EF-G occurs before translocation and increases the movement by more than 50-fold. [360] Recent evidence from experiments using directed hydroxyl radical probing and low-resolution electron microscope reconstruction to map the position of EF-G in the ribosome has led to the start of a new model which needs further verification. These studies indicate that the GTPase activity of EF-G triggered by the interaction of contacts in the G domain of EF-G with elements of 23S rRNA creates a conformational change in EF-G. [354,361] This conformational change would reposition domains in EF-G such that it contacts ribosomal elements, catalyzing the reaction for "unlocking" [358] of the tRNA-ribosome complex. The unlocking event would then allow relaxation of tRNA-binding contacts and movement of ribosomal substructures, followed by movement of tRNA and mRNA. As tRNA leaves the 30S A site, a domain of EF-G would occupy the site, thus preventing reversal of translocation while the ribosome is still in an unlocked state. This positional change of the EF-G domain would release it from the configurational state that enabled EF-G to catalyze unlocking of ribosome, thus reestablishing the locked position and release of EF-G. Such an event would explain the speed of translocation and diminish the likelihood of previous suggestions that this is a rate-limiting step in translation elongation. [354,360,361]

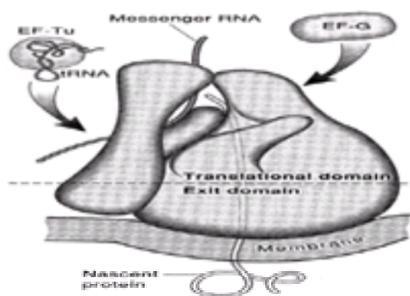
Once EF-Tu-GDP is released and a peptide bond is formed between the peptidyl-tRNA and the aminoacyl-tRNA, then the subsequent step—translocation—can occur. This step requires an elongation factor (EF-G in bacteria and EF-2 in eukaryotes), GTP, and the enzyme peptidyl transferase. The function of the elongation factor is to bind the ribosome while the polypeptide chain attached to tRNA in the P site is transferred to the aminoacyl tRNA in the A site (Figure 1.26). The elongation factor is then released from the ribosome by GTP hydrolysis, the polypeptide chain-tRNA moves to the P site, and the mRNA moves three nucleotides so that the next amino acid codon is in the empty A site. The cycle repeats itself. [362,363 and 364] This cyclical event continues until an in-frame termination codon—UAA, UGA, or UAG—enters the A site, signifying the end of the translatable sequence. However, in order to terminate protein synthesis: (a) the completed polypeptide must be released from peptidyl-tRNA; (b) the tRNA must be released from the ribosome; and (c) the ribosome must be dissociated from the mRNA.


FIGURE 1.26. Bacterial elongation factor EF-Tu escorts the appropriate tRNA to the ribosome entry site A. EF-G binds the ribosome while translocation is occurring. (From Oakes MI, Scheinman A, Atha T, et al. Ribosome structure: three-dimensional locations of rRNA and proteins. In: Hill WE, Dahlberg A, Garrett RA, et al. *The ribosome: structure, function and evolution*. Washington DC: American Society for Microbiology, 1990:292, with permission.)

Termination

An aminoacyl-tRNA with an anticodon for UAA, UGA, or UAG does not exist. Rather than the RNA-RNA interactions which normally occur in decoding, termination codons interact with protein factors for catalysis of the termination reaction. These proteins, called release factors, are found in both prokaryotes and eukaryotes. They recognize and decode the termination codons by an as-yet unknown mechanism.

Bacteria have two release factors (RF): (a) RF1 recognizes UAA and UAG; (b) RF2 recognizes UGA and UAA. *RF1* gene has a single reading frame which is directly translated into RF1 protein. *RF2* gene is in two open reading frames requiring a +1 frame shift for the entire RF protein to be synthesized. The first reading frame is terminated by an RF2-specific codon, UGA. It is postulated that RF2 is autoregulated. Evidence to support this idea was obtained from *in vitro* translation experiments in which addition of purified RF2 caused a significant decline in RF2 synthesis. [365] Other experiments using a *LacZ-RF2* fusion gene construct further demonstrated that RF2 frameshifting occurred 30% to 50% of the time. [366,367] The autoregulated mechanism would terminate protein synthesis at the first open reading frame termination codon when RF2 was in excess or unneeded. A frameshift would result in synthesis of both open reading frames yielding the RF2 protein when it was needed to terminate protein synthesis. [368,369]

The way RFs recognize termination codons remains unknown. However, there is evidence to support the idea: (a) that RFs bind directly to the termination codon; and (b) that rRNA is involved in this recognition mechanism. Competition experiments showed that repressor tRNA can compete with RF2 for binding to the termination codon, demonstrating that RF2 binds directly to the anticodon. [370] Other binding studies demonstrated that RF2 can bind termination codon UGA with a tenfold greater affinity than UAG in the presence of ribosomes, but does not bind UAG without ribosomes. [371] The RF2 in-frame UGA codon used when frameshifting occurs has a short sequence immediately upstream of UGA which interacts with the Shine-Dalgarno region of the 3' 16S rRNA. [367,372] This probably facilitates binding of RF2 to the appropriate termination codon just as it did for the AUG codon/tRNA in initiation.

Eukaryotic cells have only one release factor— eRF—which requires GTP for it to bind ribosomes. It is thought that eRF has a common recognition site for all three of the eukaryotic termination codons and that all three codons compete with each other to form the eRF-ribosome complex. [373] However, Brown and co-workers proposed a model for termination recognition in eukaryotes. They analyzed sequences surrounding the natural termination codon and found that UAA(A/G) is the codon and 3' nucleotide most preferred by eukaryotes. Based on this data they proposed a "tetranucleotide" termination signal which is recognized by RF rather than the trinucleotide. They further suggest that the total GC content of the mRNA would influence whether an A or G was selected in the fourth position. [374,375]

Stop codons do not always signal termination of protein synthesis. They can be read incorrectly by a normal or a suppressor tRNA and can incorporate an amino acid rather than terminate protein synthesis.

Regulation of Translation

When all of the tightly woven intricacies of translation are considered, it should not be a surprise that there are some regulatory mechanisms involved with the process. The regulatory differences between prokaryotes and eukaryotes are quite unalike. Prokaryotes have two basic regulatory mechanisms: (a) alteration in mRNA structure; and (b) repressor/activator proteins which bind to mRNA. Unlike prokaryotes, eukaryotes do not have mRNA-binding proteins, that is, repressor/activators that regulate translation. In eukaryotic cells, each protein is made in amounts proportional to the concentration of mRNA. For example, if the cell synthesizes more ribosomal proteins than the ribosomes can use, the ribosomal proteins are degraded. Many of the translational regulatory mechanisms in eukaryotes are reversible phosphorylation events with some examples of autoregulated translation.

E. coli and some bacteriophages have ribosomal proteins (rp) which regulate translation by binding mRNA and acting as a repressor of protein synthesis. Most translational repressor proteins bind a specific nucleic acid site having a characteristic stem-loop structure. The unpaired loop region frequently constitutes the binding region in these structures. [376,377 and 378] Nomura suggested that initiation may be regulated via these secondary structure formations. He thought that sites on a repressor molecule which bind mRNA may be homologous with the sequences in rRNA which bind the ribosome binding site (RBS). If that was the case, the repressor protein may compete with rRNA for the RBS thereby inhibiting protein synthesis. [379] Specific examples of this are found in *E. coli* L1, L10, and S4 repressor proteins. All three bind to a hairpin loop located very near the ribosome-binding site. This brings the repressor protein in close proximity to the Shine-Dalgarno and initiation site, thus interfering with rRNA accessibility to the RBS. The binding sites for L1 and L10 repressor proteins are hairpin loops located very close to the ribosomal binding site. [380,381] The ribosome repressor S4 binds a GGGC sequence in a stem loop distal to the RBS. The GGGC forms complementary base pairs with sequences located immediately downstream from a GUG initiator codon. This type configuration, called a pseudoknot, puts S4 in close proximity to the initiation site, where it acts

as an initiation repressor.[382]

Frameshifting is a translational event where the mRNA in the ribosome complex moves one nucleotide such that the pairing between the codon and anticodon in the P site is broken, allows pairing to occur with the nucleotide in the next codon, and in so doing has shifted the reading frame. A well-documented example is the +1 frameshift in translation of *E. coli* release factor 2 mRNA, as discussed earlier. Frameshift is also found in eukaryotes. For example, expression of the mammalian gene, ornithine decarboxylase (ODC), is needed for polyamine biosynthesis. When the ornithine decarboxylase antizyme protein binds to ODC, it targets ODC for ubiquitin-proteasome degradation. When the concentration of polyamines is high, it causes a frameshift in antizyme mRNA, resulting in more antizyme synthesis. More antizyme synthesis regulates the rate/degree of ODC degradation.[383,384,385 and 386] Further stimulation (2.5-fold) of the frameshift is provided by a 3' pseudoknot (stem loops whose sequence can pair with down- or upstream sequences) in the mRNA structure three nucleotides from the frameshift site.[386,387]

Frameshifting is a common regulatory event in expression of retroviral proteins. The common shift is a −1 at a heptanucleotide sequence that results in a gag-pol fusion protein rather than a gag or pol protein. This shift occurs at a particular stage in the life cycle of the virus.[388,389,390,391,392,393 and 394] Reversible phosphorylation is not an uncommon event in translational regulation in eukaryotes. Some steps in formation of the preinitiation complex are able to be regulated through reversible phosphorylation of initiation factors. The best-documented example is the phosphorylation of eIF2. As mentioned earlier, eIF2-GTP is bound to the 40S ribosomal subunit in the preinitiation complex. GTP hydrolysis causes a conformational change in eIF2, causing it to dissociate from 40S as an eIF2-GDP complex. Since eIF2 binds GDP with a 400-fold greater affinity than GTP,[312] it requires a guanine nucleotide exchange factor—GEF—to mediate the GDP to GTP exchange with eIF2. This is a rate-limiting step in protein synthesis because eIF2 must be bound to GTP in order for the factor to be recycled for a subsequent preinitiation complex formation. If an eIF2 alpha subunit becomes phosphorylated, then GEF has a 100-fold increased affinity for the phosphorylated eIF2, forming an eIF2(aP)-GDP-GEF complex. GEF is not an abundant protein and becomes less available. In fact, all of the available GEF can potentially become bound to eIF2(aP), stopping all new protein synthesis.[395] One example of eukaryotic autoregulation of translation is observed in alpha and beta tubulin. These proteins are the major constituents of tubulin, forming a heterodimer consisting of one alpha and one beta polypeptide. These heterodimers regulate the stability of tubulin mRNA.[396,397,398 and 399] Other requirements which are necessary for autoregulation are polysome-bound tubulin mRNA, free tubulin, and four specific amino-terminus b.-tubulin amino acids. Translation of the first 13 nucleotides of b.-tubulin mRNA (the first four amino acids are Met-Arg-Glu-Ile in b.-tubulin) is necessary for autoregulated destabilization/degradation of polysome-bound tubulin mRNA.[400,401 and 402] Although the exact mechanism for this example of autoregulation remains unclear, it is known that continued elongation of the polypeptide being synthesized from the b.-tubulin mRNA is a necessary step for autoregulated degradation of b.-tubulin mRNA bound by polysomes.[403]

A second example of autoregulation of eukaryotic translation is found in the mRNA for ferritin and the transferrin receptor. In higher eukaryotes, iron uptake and detoxification are regulated by two proteins, ferritin and the transferrin receptor. Once in the cytoplasm (delivered via the receptor-mediated endocytosis), iron is either utilized or, if in excess, is sequestered in ferritin.[404,405 and 406] The expression of both proteins is highly regulated by the amount of iron present in the cell. The number of receptors increases with an iron deficiency, and conversely the number of receptors decreases with an abundance of iron. Ferritin is decreased proportionately to a decrease in iron and increases with an iron increase. Both of the proteins have a cis-acting iron responsive element, IRE,[407,408] whose location is variable. It can be found in either the 5' untranslated regions (UTR) or 3' untranslated regions (UTR) of mRNA. An IRE-binding protein[409,410] can repress translation if it binds the IRE located in the 5' UTR. However, when this IRE-BP binds the IRE in the 3' UTR of the transferrin receptor mRNA, it represses the degradation of mRNA. Therefore, this IRE-BP can regulate translation by: (a) increasing the amount of transferrin receptor synthesis, thereby repressing degradation of mRNA; (b) downregulating expression of transferrin by binding the IRE in the 5' UTR in the transferrin mRNA.[407,408] Deletion analysis studies showed that a 350 base pair region in the 5' UTR is necessary and sufficient for these iron translational regulation mechanisms.[407]

There is a 680 nucleotide fragment in the 3' UTR of the transferrin receptor that has been found to be necessary for iron-dependent regulation. Within the 680 nucleotide region are five stem loops whose structure resembles the secondary structure found in the 5' UTR of the ferritin mRNA.[407,408] In fact the 3' UTR containing the transferrin receptor IRE could be substituted for the 5' UTR IRE in ferritin mRNA and regulate translation of ferritin mRNA.[409,410]

GCN4 is a transcriptional activating protein of yeast *Saccromyces cerevisiae.* It activates transcription of more than 30 genes in response to amino acid starvation. The expression of GCN4 itself is transcriptionally regulated by the amount of available amino acids. The GCN4 mRNA leader sequence has four upstream open reading frames (uORF) which inhibit translation of GCN4 when amino acids are abundant (nonstarvation). The uORFs are bound by negative regulatory proteins encoded by the GCD gene. Upon amino acid starvation, GCN2 and GCN3 gene products act as positive regulators by antagonizing the GCD protein's negative effect. The result is increased translation of GCN4 mRNA.[411] uORF3 and 4 in GCN4 mRNA inhibit GCN4 mRNA translation much better than uORF1 and 2. It has been demonstrated that uORF2 is more repressive than uORF1 because it is in closer proximity to the GCN4 AUG codon.[412,413] Hinnebusch's group showed that replacing the last codon and ten additional double-stranded nucleotides from uORF4 with the same nucleotides located in the uORF1 increased the repressor activity of uORF1 tenfold. It was proposed that this was due to the important relative distance of the termination codon of uORF1 to the AUG site in GCN4 mRNA.[414]

The general description and illustrations tend to give the reader the misconception that these beautifully designed and organized translational (like transcriptional) mechanisms are fail-proof (or nearly) systems. However, as in all replication, transcription, and translation reactions that function with precision, we hear ourselves frequently using the word "fidelitous." For a molecular biologist, fidelity means "exactness, as in a copy." How frequently can we expect to find error in the incorporation of the correct amino acid based on the genetic code? There is approximately one error for every 10,000 amino acids synthesized.[415]

The way in which the mRNA codon and tRNA anticodon interact has a major impact on fidelity and/or efficiency in incorporating the correct amino acid. These interactions can be less precise when: (a) the tRNA structure is altered through point mutation, modification of tRNA bases, or a point mutation in the tRNA gene; (b) changes occur in the mRNA sequence or the context of the codon.

Protein Modifications

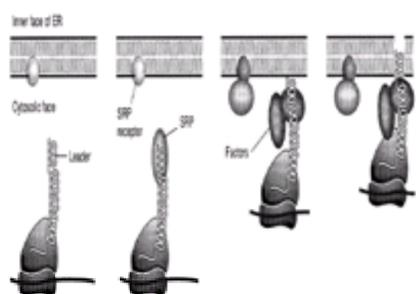
Newly synthesized proteins must be directed to the compartment where they perform their function (Figure 1.27). Most soluble proteins are synthesized on free ribosomes in the cytosol, which is also where they are generally needed. Proteins that function as membrane or transported proteins are synthesized on the ribosomes attached to the surface of the ER. Protein sorting begins in the ER, and certain proteins are restricted to either smooth or rough endoplasmic reticulum. The newly synthesized protein is transported through a hydrophilic channel whose function is to translocate proteins for secretion as well as inserting membrane proteins into a lipid bilayer. The channel is part of a complex that has a defined function in transport of each specific protein by either a cotranslational or posttranslational mechanism. In cotranslational translocation, the growing polypeptide chain is simultaneously being transported and synthesized, whereas a posttranslationally translocated protein is first synthesized, then transported.


FIGURE 1.27. Proteins are synthesized on ribosomes located in the cytoplasm or bound to the endoplasmic reticulum. The proteins are then directed to the cellular compartment where they perform a specific function. (From Lewin B. *The apparatus for protein localization.* New York: Oxford University Press, 1990:279, with permission.)

Proteins that are co- or posttranslationally transported are synthesized with a short peptide on the amino terminus called a "signal peptide" in eukaryotes and a

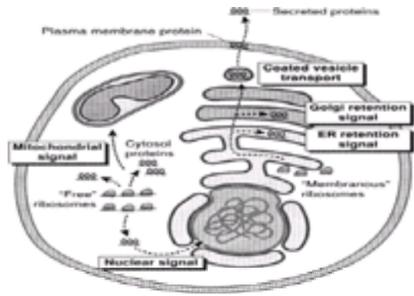
"leader sequence" in prokaryotes. In cotranslationally transported proteins, the newly synthesized signal peptide emerges from the ribosome and is recognized and bound by a signal recognition particle (SRP). The SRP then binds tightly to the ribosome, causing a pause (elongation arrest) in translation of the new protein. A complex made up of a ribosome, SRP, and a nascent protein with a signal sequence is needed for translocation or integration across/into ER membrane. The SRP interacts with the SRP membrane receptor. SRP is released from the complex, and the ribosome forms a junction with the ER membrane. This series of interactions targets the signal peptide to the ER membrane (Figure 1.28). Proteins that are posttranslationally translocated also have the same signal peptide, but the mechanism by which it functions in transport is still undefined.


FIGURE 1.28. Signal peptides are sets of specific sequences on the amino terminus of the newly synthesized peptide. They function to transfer the protein to a membrane receptor. (From Lewin B. *The apparatus for protein localization.* New York: Oxford University Press, 1990:185, with permission.)

The channel through which the proteins are transported/translocated also requires a Sec61P complex (eukaryotes) or a SecYEG complex (prokaryotes), a ribosome if translocation is cotranslational, Sec62/63P complex and BIP protein in yeast, or Sec A in bacteria. The signal sequence of the translocating substrate induces the opening of the Sec61 channel in the lumenal direction. Sec61p and ribosome form a tight seal over the channel, allowing the translocating polypeptide to move in only one direction, from the ribosome through the pore and into the ER lumen. Furthermore, the positioning of the ribosome over the pore forms a tight seal [416,417,418 and 419] that prevents other molecules from crossing the membrane along with the polypeptide. The exact mechanism by which the channel opens/closes and/or the components required for formation of the channel remain unknown. Interestingly, the Sec61p complex can transport proteins from the ER to the cytoplasm. This reverse transport is termed "retrograde" transport. [420,421]

The inside of the channel must open in order for transmembrane sequences of integrated membrane proteins to become localized in the lipid bilayer. This is an even more complex situation because the transmembrane proteins must cross the membrane more than once, therefore requiring a much greater level of control in opening and closing of the channel and ribosome binding to the channel. The details of a model remain uncertain. [422]

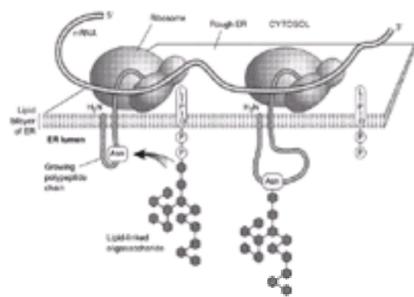
Proteins translocated to the ER lumen undergo further modifications and sorting to provide them with direction to their destination. Posttranslational modifications are additions of side chain groups to a polypeptide chain that is forming bonds necessary for a protein to fold properly or to be held in a particular configuration or location (Figure 1.29). The endoplasmic reticulum lumen is the primary location for proteins undergoing folding and modification. This compartment ensures that only those proteins that are completely assembled with appropriate folding and modification will be allowed further transport in the secretory pathway. Those proteins that do not meet that criteria are selected out by the ER-associated protein degradation pathway. While proteins are undergoing the folding process, they have exposed hydrophobic regions which cause them to aggregate to bury the hydrophobic domains. Aggregation causes proteins to fall out of solution; therefore it takes longer for them to become properly folded and exit the endoplasmic reticulum lumen. [423] Other proteins are retained in the ER and selected for degradation despite the lack of an aberrant nature. The secretion of such proteins can be dependent upon the differentiated state of the cell, as seen with IgM [424,425 and 426] or the metabolic status of the cell. [427,428 and 429]


FIGURE 1.29. Posttranslational modifications of proteins are additions of side chain groups to newly synthesized peptide. These modifications are necessary for a protein to be properly folded. (From Alberts A, Bray D, Lewis J, et al. *Intracellular sorting and maintenance of cellular compartments.* New York: Garland Publishing Inc., 1989:405, with permission.)

The ER serves as a "quality control" checkpoint making certain that newly synthesized proteins are properly folded, processed, and assembled before they leave the ER. Those proteins that do not pass the criteria for further transport are selected for degradation by the endoplasmic reticulum-associated protein degradation pathway (ERAD). The ER lumen contains chaperone proteins that are involved with selection of proteins for the degradation process. [430,431 and 432] There is recent evidence to show that newly synthesized proteins transported to the ER and subsequently selected for degradation are transported back to the cytosol, where they are degraded by the proteasomes. [433,434,435,436 and 437] To exit the ER, the aberrant proteins utilize the Sec61p complex retrograde transport mechanism.

When the retrograde transported proteins reach the cytosol, they undergo a posttranslational modification that adds ubiquitin to the protein, marking it for degradation in the proteasome. A proteasome is where most eukaryotic cellular protein degradation occurs, and is part of an ATP-dependent pathway. Proteasomal degradation by means of the ubiquitin-proteasome pathway is a highly selective, highly regulated form of posttranslational modification. In this process, single or multiple ubiquitin molecules are conjugated to a protein. Following the ubiquitin conjugating process, the protein is degraded by a proteasome consisting of a 26S protease complex that contains a 20S protease catalytic core. [438,439,440,441,442 and 443] By itself, the 20S core functions as a proteasome, capable of degrading small peptides or proteins that are already denatured, [442,444] whereas the 26S complex is required for degradation of an intact protein structure. [443,445] When a ubiquitin-bound targeted protein is degraded, the ubiquitin(s) are released and reutilized. There is a three-step mechanism for ubiquitin modification of a protein that requires three enzymes—E1, E2, and E3. E1 is a ubiquitin-activating enzyme that catalyzes the ATP activation of a ubiquitin C-terminal Gly to a thiol ester intermediate. The ubiquitin intermediate is then transferred to a substrate (protein targeted for degradation) that is bound by E3, a ubiquitin-protein ligase. The transfer of the ubiquitin intermediate to the substrate requires E2, the ubiquitin-conjugating enzyme. In the transfer, an isopeptide bond is formed between the ubiquitin C-terminal Gly and an e-amino group on a lysine residue in the targeted protein. [441]

There are specific examples of regulated protein degradation by the ubiquitin-proteasome pathway: tumor suppressor p53, IkB, yeast transcriptional factors AP-1, MATa2 (yeast) and GCN4 (yeast), cyclins that control eukaryotic cell cycle, Mos kinase involved in oocyte maturation, transmembrane proteins such as the T-cell receptor, platelet-derived growth factor receptor, and cystic fibrosis transmembrane conductance regulator. [439,442,445,446]

Although there is no clearly defined signal for ubiquitin-mediated degradation there are some reports of sequence motifs that have been shown to be involved with the

selection of a protein for degradation by the ubiquitin pathway. [447,448,449] and [450]

Other posttranslational modifications also occur within the cytosol. [451] Many of the cytosolic modifications function to regulate specific protein activity and are often reversible (e.g., phosphorylation/dephosphorylation).

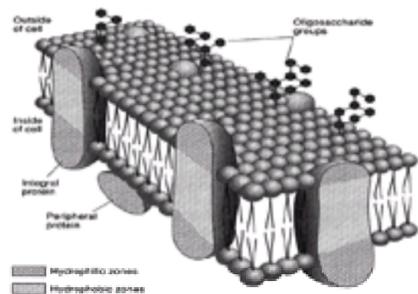
The addition of oligosaccharides to a protein is a post-translational modification called glycosylation (Figure 1.30). Glycosylation was thought to occur in all eukaryotic proteins destined for secretion. However, there is substantial evidence that glycosylation of nuclear and cytoplasmic eukaryotic proteins at multiple sites by single o-linked *N*-acetylglucosamine (O-GlcNac) is abundant. In many of the proteins where this is found, this type of glycosylation is found to be reciprocal to phosphorylation and on sites similar to phosphorylation sites. This type of glycosylation occurs in response to cellular signals or cellular stages and may, therefore, play an important role in regulation. There is evidence that glycosylated proteins exist in the nuclear pore complex and are involved in nuclear transport; [452,453] every RNA polymerase transcription factor that has been examined, [454,455,456,457] and [458] as well as the C-terminal domain of the largest subunit of RNA polymerase II; [459,460] the transactivation domain of c-*myc* that binds retinoblastoma;[461,462] p53 tumor suppressor;[463] microtubule-associated protein tau; [464,465] a 67-kD multiply glycosolyated protein that protects initiation factor 2 (eIF2) from phosphorylation, thus enabling the initiation of protein synthesis to continue. [466,467] For recent reviews see 468,469 and 470.


FIGURE 1.30. Glycosylation is the addition of sugar moieties to a protein. It is thought that these large sugar groups protect the protein from proteolytic degradation. (From Singer SJ, Nicolson GL. The fluid mosaic model of the structure of cell membranes. *Science* 1972:175, with permission.)

Glycosylation does occur in all eukaryotic proteins destined for secretion. For these proteins the sugar moieties can be added in either the endoplasmic reticulum or the Golgi. A single oligosaccharide added to the NH2 group of asparagine in the endoplasmic reticulum (N-linked glycosylation) can also be linked to many other proteins. The entire glycosylation process involves cleaving parts of the oligosaccharide while it is still in the endoplasmic reticulum, followed by further modifications or additions as the process continues in the Golgi. Similarly, addition of an oligosaccharide to the –OH group of hydroxylysine, serine, or threonine (O-linked glycosylation) entails multiple enzyme-catalyzed reactions to add sugar groups to the protein. [471,472,473 and 474] These large, protruding oligosaccharide molecules are thought to provide protection from protease digestion. [475]

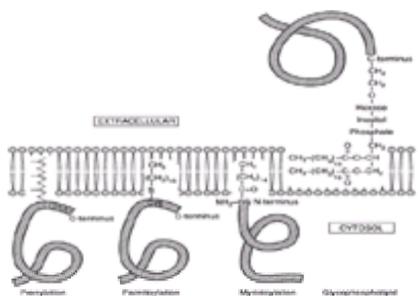
Prenylation is the addition of an isoprenyl to a cysteine by a thioester bond (Figure 1.31) which functions to maintain a protein at either the plasma or internal membranes.[476,477] There are two primary groups of prenylated proteins: those with a CAAX motif or those with a CC or CxC motif. The CAAX is most commonly found whereas the CC or CxC group consists mainly of Rab proteins that are GTP-binding proteins involved in intracellular membrane trafficking. [478] There are three enzymes that catalyzes the addition of isoprenoid to the cysteine of a CAAX motif protein. Farnesyl transferase transfers a farnesyl group from farnesyl diphosphate to the CAAX-cysteine, geranylgeranyl transferase type I transfers a geranylgeranyl group from geranylgeranyl diphosphate to a CAAX-cysteine, geranylgeranyl transferase type II transfers geranylgeranyl groups from geranylgeranyl diphosphate to both cysteins in a CC- or CxC-containing protein. The X in the CAAX motif determines which isoprenoid will be added. A protein with a serine, methionine, or glutamine in the X position will have a farnesyl group transferred to cysteine and a leucine will signal a geranylgeranyl modification to the CAAX cysteine. [479,480] The CAAX- and CxC-motif proteins undergo a methylation of the terminal carboxyl on cysteine following prenylation.


FIGURE 1.31. Some posttranslational modifications hold a protein in a specific configuration at a particular cellular membrane. (From Lewin B. *Receptors and signal transduction: channels and ion uptake.* New York: Oxford University Press, 1994:319, with permission.)

Prenylated proteins are predominant in signal transduction cascades; for example, ras proteins undergo farnesylation of a cysteine at a carboxy CAAX that anchors it into the cytoplasmic side of the plasma membrane. This modification is necessary for H-, K-, and N-ras mutants to display transforming capabilities. [480,481,482,483 and 484] Studies show that not only is the prenylation important for membrane association, but the methylation step enhances [485] the affinity of the protein for the membrane.

Additional stability in a prenylated protein's association with a particular membrane can be provided by further posttranslational modifications such as myristoylation or palmitoylation[486,487] Myristoylation is the formation of an irreversible covalent bond between 14-carbon unsaturated fatty acid and an amino group of a terminal glycine. An interesting example of this is found in the SRC oncogene (protein kinase activity), which has a myristic acid fatty chain covalently linked to an amino-terminal glycine. This myristoylation keeps the Src protein in a configuration that enables it to transform normal cells into cancer cells. If this specific glycine is changed to an alanine so that myristic acid cannot form a bond, then the src protein functions normally as a protein kinase without transforming cells. [488] Palmitoylation entails the linkage of a 16-carbon-chain saturated fatty acid—palmitic acid—to a cysteine residue near either end of the protein. However, it has been shown through biophysical measurements that the 14-carbon myristate does not have sufficient binding energy to maintain the association of a protein with a lipid membrane, and consequently myristoylated proteins are found in the cytoplasm. [489,490] In situations where a myristoylated protein needs to associate with a membrane in a reversible manner, the reversibility of membrane association is regulated by another mechanism, such as guanine nucleotide binding or phosphorylation. [491,492 and 493] Palmitoylated proteins are almost always membrane-bound and are able to undergo a palmitoylated/depalmitoylated process due to the labile thioester bond between palmitate and cysteine residue in the modified protein.

A modified protein will remain in the endoplasmic reticulum if it contains a specific K(H)DEL sequence at the carboxy terminus; [494] membrane proteins have either a di-lysine or di-arginine close to the end of their cytoplasmic domain; the di-lysine motif binds COP1, a cytosolic coat protein complex that signals a retrieval of the protein from the Golgi back into the endoplasmic reticulum. [495,496] The ER must maintain certain proteins necessary for its function, such as proteins needed for translocation and vesicle transport, folding chaperoning, posttranslational modifications, maintenance of a calcium supply, and additional protein needed for ER

function in a specific tissue type.

Protein Localization

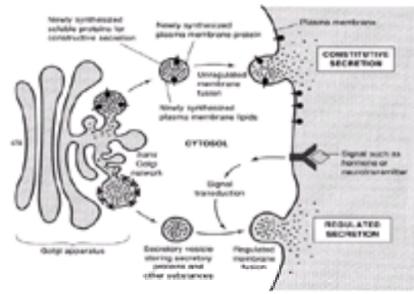
A newly synthesized peptide which has successfully reached the membrane of the ER, crossed the membrane, folded properly, and has been modified as it moves through the ER and Golgi is now ready to be transported to its destination. Transportation is done in coated vesicles, which are pinched-off regions of the Golgi membrane. The "coat" that covers the vesicle is made up of protein which is identified for direction to the proper membrane (Figure 1.32). Once the coated vesicle has delivered the encapsulated protein to the appropriate site, it becomes uncoated and fuses with the targeted membrane, depositing the protein through the membrane. There are specific proteins and ATP associated with the uncoating and fusion process (Figure 1.33).[497],[498],[499],[500],[501],[502] and [503]


FIGURE 1.32. Proteins which have been transported through the endoplasmic reticulum and the Golgi are transported inside small vesicles which are "pinched off" from the Golgi membrane. CANCER DEFINED AS UNREGULATED TRANSCRIPTION/TRANSLATION

In studying the molecular biology of cancer, the most essential requirement is having access to nucleic acid, that is, DNA and RNA, as well as proteins and other macromolecular structures of the cell. Typically, cancer cells that are harvested from an animal contain many normal cellular components, such as matrix substituents, vessels, and a diverse group of infiltrating and circulating cells. Additionally, there may be heterogeneity within the cancer cells themselves. Therefore, any biomaterial taken from such specimens invariably contain mixtures from varying cell types. Relatively pure cellular preparations can be acquired from *in vivc* samples when flow cytometric techniques are used to separate dispersions of cancer cells gathered from *in vivc* specimens; however, the number of cells harvested is usually limited, and the separation techniques depend on the ready availability of technical expensive equipment and extended acquisition times.

As will be apparent in subsequent chapters, many of the cellular and molecular biologic studies dealing with cancer depend on there being homogenous populations of normal and cancerous cells. The methodology of tissue culture, wherein cells are grown *ex vivc* in a glass or plastic petri dish containing a buffered solution supplemented with fetal calf serum or defined medium containing added growth factors, provides a method of growing large numbers of a pure population of cells. When normal cells are removed directly from an animal and placed in tissue culture, they are referred to as a cell strain or primary culture. Cells within a primary culture grow for a while, usually less than 50 divisions, and then undergo a crisis wherein the vast majority, or all, the cells die. The reasons for and mechanisms by which cells within the primary culture die are not understood.[482],[504] Rarely, a cellular clone—a population of cells derived from a single cell—will become immortalized. That is, the cells will continue to divide in tissue culture, and an established "normal" cell line will be formed. Immortalized cell lines rarely arise from human primary cultures but much more frequently result from murine primary cultures. Such cells do not have the characteristics of a malignant or cancerous cell; they are not transformed. The immortalized cells, not being malignant, have many of the characteristics of the primary culture. That is, they are still dependent on serum or growth factors and usually display cell-to-cell contact or density-dependent inhibition of their growth, and a need for attachment to a solid surface that is manifested by cytoskeletal organization that allows the cell to flatten and grow as a monolayer on the petri dish surface.[505] Frequently the immortalized cells do not have the normal chromosomal diploid number; rather they are aneuploid. In contrast, malignant cells have gone beyond the stage of immortalization and have transformed to a cell that is not contact inhibited, that is they tend to overgrow and pile up, have a tendency to assume a rounded structure and float in the tissue culture medium, have less or no dependency on serum factors, and, when injected into athymic or species-specific mice, grow as a tumor with the potential to metastasize—leave the initial site of implantation and grow in other sites within the animal.[506] Both primary and immortalized cells can be transformed to a malignant state. It is assumed that the immortalized cell with the capability of indefinite growth characteristic has assumed at least one characteristic that is different from a normal primary cell and, therefore, has progressed the path from normal to the transformed state. It is also assumed that by investigating the characteristics of malignant cells and comparing and contrasting those with normal cells, a molecular basis of cancer can be reached.

Usually multiple changes are required for a cell to become malignant. Normal cells can be made to undergo a malignant transformation by physical (x-ray), genetic (tumor viruses), or chemical (chemical carcinogens) means. Carcinogens can either initiate malignant transformation or promote transformation in a cell that has gone partially along the path toward malignancy. A means of studying carcinogenic promoters is provided by using immortalized 3T3 cells and exposing them to potential carcinogens, followed by noting phenotypic changes in the treated cells, that is, loss of contact inhibition or "focus" formation.[507],[508]

The genetic events that result in malignant transformation after exposure to agents such as x-rays or chemicals in some cases are beginning to be understood. Assuredly, there are certain families, kindred, or individuals who have a genetic predisposition toward cancer. In several instances we know that individuals who genetically lack the ability to repair specific types of DNA damage resulting from ultraviolet light exposure (xeroderma pigmentosum) or ionizing radiation (ataxia telangiectasia) have a marked propensity for developing cancers.[509],[510] Only most recently has additional insight into the mechanisms of malignant transformation been achieved by noting how certain viral infections produce cancers.[511]

In a number of instances a tumor-promoting virus such as an adenovirus or polyoma virus will infect a cell, undergo intracellular replication, and subsequently lyse the cell with release of the viral progeny. Those cell types that allow such a process are not transformable and are said to be permissive. There are instances in which the tumor virus infects a nonpermissive cell type—the virus is unable to go further in its life cycle to replicate and lyse the host cell—yet the cell assumes a malignant phenotype until the viral genome is degraded or diluted out by host cell duplication. Afterwards the cell assumes a normal phenotype. An abortive transformation has occurred. However, in other cases the tumor virus does not replicate and lyse the cell, does not degrade or dilute out, but rather the viral genome integrates into the host genome as a provirus. In such a state, viral-origin mRNA is produced that is subsequently processed and translated into protein that results in malignant

transformation. The gene that produces the protein that results in malignant transformation is referred to as an oncogene. [512],[513] and [514]

One property of an oncogene is that the transformed cell is released from some aspect of cellular regulation. Frequently, the oncogene (viral oncogene or v-oncogene) has a normal cellular component (protooncogene or c-oncogene) that is highly regulated. In the transformed cell either the protooncogene brought in by the virus is mutated to a v-oncogene so that it is no longer regulated, or the c-oncogene is introduced into a cell that normally does not express that protooncogene, or a c-oncogene is dysregulated by being produced in greater quantity than normal. In each case, the result is that the cell, because of having been infected by a tumor virus, has acquired unregulated or new function. Nearly 100 oncogenes have been identified. [515],[516]

Tumor-promoting viruses are either DNA or RNA tumor viruses. The major DNA tumor viruses carrying oncogenes are papovaviruses (polyoma and SV40 carrying T-antigen oncogene), herpes viruses, of which papilloma viruses are known to produce the E6 and E7 oncogenes, Epstein-Barn containing BNLF-1 oncogene, and adenoviruses having E1A and E1B oncogenes. Papovaviruses have small genomes containing only a few early genes (large T, small t, and possibly middle T antigen) and the late genes which result in viral coat protein. Of the papovaviruses, polyoma viruses have been identified that produce tumors in mice, SV40 in rhesus monkey, and BK and JC viruses in humans. SV40 large T antigen has been cloned into cells and shown to be capable of transforming them. Usually a normal cell has enough regulatory redundancy to overcome the effect of introducing only one oncogene. The fact that large T antigen as a single oncogene can malignantly transform a cell implies that large T antigen either must have multiple cellular functions or affects a major cellular switch that results in a cascade of events that leads to cancer. The most frequently seen transformations result from more than one oncogene, which implies that there is cooperativity among oncogenes. Such is the case with polyoma virus that produces three T antigens, of which large T antigen promotes indefinite growth and middle T antigen morphological transformation. [517],[518]

Another class of tumor viruses is the retroviruses that have a RNA genome of approximately 10 kbases. These viruses can effect transformation by at least two means. The retrovirus may insert into the host genome in such a manner that the viral LTR (long terminal repeat) acts as a nonregulable promoter of a protooncogene. This is seen when a retrovirus inserts itself within the first intron of the nuclear transcriptional factor *myc. Myc* has three exons, of which in a normal cell only the latter two are translated. When a retrovirus containing a LTR promoter inserts into the first intron, exon 2 and 3 are transcribed in excess amounts. The consequence of such a genetic event is transformation of the cell. In the example of *myc*-mediated transformation, a LTR containing potential enhancers can also insert both upstream and downstream of the gene and result in excess gene expression. [519],[520] Other protooncogenes that have been found to be activated by retroviral insertion include c-*raf,*[521] c-*mos,*[522] and c-*erbB.*[523]

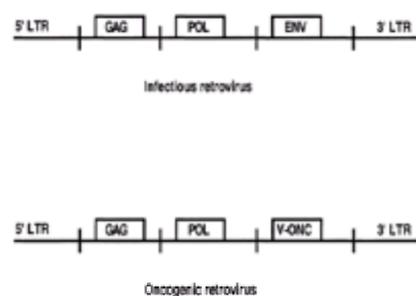
A more common means by which retroviruses effect malignant transformation is by having an oncogene inserted within their genome (Figure 1.34). Frequently, the protooncogene that is carried by the retrovirus has major deletions (*fms, erbB, erbA, src, myb*) or mutations (*myc, H-ras, K-ras, sis*) within regions of the gene that are responsible for regulation of the protooncogene. As would be expected, the retroviral oncogenes usually have a great degree of homology with the corresponding protooncogenes. Moreover, the v-oncogenes are invariably derived from recombination between the viral genomic RNA and host RNA, rather than by capturing the original DNA-formatted protooncogene, which would be much larger because of the normal dispersed nature of eukaryotic genes.


FIGURE 1.34. Retroviruses: the infectious retrovirus has a complete genome with *GAG, POL,* and *ENv* genes, flanked by LTRs. The oncogenic retrovirus has replaced the *ENv* gene with a viral oncogene through a recombination event.

The v-oncogenes can be divided into four major classes. The first class associated with growth factors is v-*sis,* which corresponds to the normal cellular *PDGFB* chain, v-*wnt1,* which is related to wingless, and v-*ini*2 and v-KS/*hst,* which have as a protooncogene counterpart FGF. The class II oncogenes are associated with cell receptors and include v-*kit,* which has as a cellular counterpart (c-*kit*) the steel receptor, v-*erb1* and 2(*neu*), which have the corresponding c-*erb1* and 2(c-*neu*) coding for EGF receptor kinase and receptorlike kinase respectively, v-*mas,* which is related to c-*mas* or the angiotensin receptor, and v-*fms,* which has the corresponding protooncogene CSF-1 receptor kinase. The class III viral oncogenes are divided into subclasses that are either membrane-associated or intracellular transducers such as v-*gsp* and v-*gip,* which are related to G protein/signal transduction, v-*ras,* corresponding to c-*ras,* which is a GTP-binding protein, v-*src,* which is membrane-associated and related to the normal cellular tyrosine kinase c-*src,* or intracellular transducers such as v-*abl* and v-*fps* and v-*met* and v-*yes,* which are related to their corresponding c-oncogenes that function as tyrosine kinases. [481],[488,524]

Other class III oncogenes that are associated with intracellular transducers are v-*raf* and v-*mos,* corresponding to the normal cellular protooncogene c-*raf* and c-*mos,* which are serine/threonine kinases, as well as the oncogenes that are associated with signaling, such as v-*crk* and v-*vav,* corresponding to c-*crk* (SH2/SH3 regulator with phospholipase C activity) and c-*vav* (SH2 regulator). The class IV oncogenes are nuclear transcription factors and include v-*jun,* v-*fos,* v-*myc,* v-*erbA,* v-*ski,* and v-*myb.*[525]

The most important lesson that the viral oncogene teaches us about cellular regulation is that excess or lack of control of a cellular function leading to stimulation of cell growth factor can result in cancer. We also learn from those viral oncogenes having cellular counterparts that oncogenesis generally requires the presence of more than one oncogene and that the oncogenes are invariably involved either in those processes that induce a cascade of events resulting in expression of multiple genes or where the oncogene itself is a nuclear transcription factor that promotes gene(s) expression. We also learn that protooncogenes that have acquired mutations resulting in changes in amino acid residues associated with regulatory regions within oncoproteins may result in malignant transformation. Additionally, we have examples wherein certain protooncogenes are expressed in excess quantities and as such produce cancer. Basically, studies elucidating the role of viral oncogenes provide information whereby we better understand how in normal cells alteration or mutations within a gene or DNA amplification or chromosomal translocations can result in the production of either an aberrant gene product or excess quantities of a gene product that then results in malignant transformation. Stated differently, the viral oncogene is a dominant mutation that results in overriding the corresponding normal allelic protooncogene.

Although oncogenes carry us a long way to understanding the mechanisms by which oncogenesis occurs, they do not present us with the possibility of understanding how loss of function of a gene may cause cancer. Such cases usually require that both allelic genes be lost, and as such represent the case whereby the normal function of the lost genes is tumor suppression. The RB and p53 protein represent such tumor-suppressor proteins. [526],[527] Retinoblastoma, osteosarcomas, and small lung cancer result from the loss of or mutation within the RB gene from chromosome 13. Papilloma virus E7, adenovirus E1A, and SV40 large T antigen are known to bind to RB and as such may result in removing one of the constraints on the path toward malignant transformation. It is now known that RB is a nuclear phosphoprotein that functions to regulate the cell cycle. Like RB protein, p53 functions as a tumor suppressor, and like RB, p53 is a nuclear phosphoprotein that functions to retard progression of cells through the cell cycle. [528],[529 and [530] p53 was originally found to be associated with SV40 large T-antigen. It is known from the Li-Fraumeni syndrome that mutation in p53 results in an array of tumor types. Many tumors are found to have increased levels of p53, but in each case such proteins are mutated and therefore do not function to restrain growth. Further, p53 probably exists as a tetrameric species that can lose function when just one of the proteins within the tetramer is aberrant. The loss of function of p53 results in unrestrained growth of the cell. Unrestrained growth may result in destabilizing DNA that may result in less efficient DNA repair with a concomitant increase in translocations and amplification that ultimately predisposes the normal cell to malignant transformation.

TECHNIQUES IN MOLECULAR BIOLOGY

Cloning Vectors

As stated at the beginning of the chapter, the techniques employed in molecular biology have allowed the elucidation of complex cellular biologic phenomena. Two aspects of bacterial metabolism are the foundational pins of molecular biologic research: (a) the existence of an array of restriction endonucleolytic enzymes, and (b) plasmids. Plasmids are small, circular pieces of DNA that exist in many types of bacteria and were initially found in bacteria that had acquired resistance to antibiotic treatment. That is, the plasmidal DNA that is not part of the bacteria chromosome (epichromosomal) was providing to the host bacterium a selective advantage by carrying a gene that detoxified a given antibiotic. Plasmids possess an origin of replication that allows their replication independent of bacterial chromosomal reproduction. Although a bacterium may carry only a single copy of a plasmid, over the years plasmids have been engineered so that large copy numbers—many copies of the individual plasmid are found within an individual bacterium—can be accommodated. With their high copy number and ability to be transferred from one bacterium to another, plasmids are useful in producing recombinant DNA molecules, since foreign DNA can be inserted into plasmids without inactivating essential genes. Additionally, a eukaryotic gene can be placed under the control of an appropriate bacterial promoter within the plasmid to provide means of producing or expressing eukaryotic proteins within bacteria, that is, recombinant protein production.

While the vast majority of plasmids are derived from bacteria, there are a few plasmids found in lower eukaryotic cells. In yeast, plasmid 2m exists as an independent epichromosomal replication element.[531] Many derivative plasmids containing the 2m replication elements have been constructed for use in yeast molecular biologic studies. In mammalian cells, plasmids have been constructed based on viral genes that can persist as epichromosomal elements in high copy number. These plasmids use replication elements from bovine papilloma virus, Epstein-Barr virus and BK virus, among others, to provide replication capability. [532,533]

Restriction Endonucleases

The field of recombinant DNA technology for all practical purposes began with the description in 1970 of the first restriction endonuclease enzyme, HindIII. Restriction enzymes are part of the normal armamentarium of bacteria to ward off bacterial-specific viral (phage) infections. The host bacterium modifies its genome by methylating its DNA in a species-specific pattern. Restriction endonucleases often do not cut methylated base sequences. Incoming viral DNA, which does not have the appropriate methylation pattern, is susceptible to digestion and destruction, and therefore the virus's host range is constrained. Restriction endonucleases fall into three broad categories depending on their ability to cleave and methylate DNA. [534] Type I restriction endonuclease enzymes have three protein subunits that are responsible for recognition of the target DNA. Their function is methylation if the DNA is recognized as host DNA and cleavage of foreign DNA at a nonspecific site at least 1,000 bases away from the recognition site. Type III restriction endonucleases have two subunits, one of which is responsible for recognition and methylation, the other for cleavage. Type II restriction endonuclease enzymes, such as HindIII, are those most commonly used in molecular biological applications, because the recognition and cleavage activities are on a single protein separate from the methylation activity. There are a number of different restriction enzymes and as such they have offered a cornucopia of potential reagents for use by molecular biologists. Depending on the choice of the particular restriction endonuclease enzyme, one can cut DNA that contains many different specific sequences of bases, usually a four-to-six-base palindrome. The resulting restriction cut DNA usually has compatible ends that can be annealed together and, by subsequent use of ligating enzymes, can be covalently joined together. As an example, the enzyme HindIII recognizes the following sequence:

5'-AAGCTT-3'

3'-TTCGAA-5'

and cuts both strands to leave these compatible ends:

5'-A and AGCTT-3'

3'-TTCGA A-5'

The ends can reanneal to form the noncovalently bound sequence as follows:

5'-A*AGCTT-3'

3'-T TCGA*A-5'

The addition of a DNA ligase, such as that from bacteriophage T4, will repair the broken phosphate bond in each strand, resulting in a double-stranded DNA again, indistinguishable from the starting material. This technology gives us the ability to cut DNA at reproducible sites and relegate to similarly cut DNA from any other source having compatible ends.

Restriction nucleases have become useful tools in genetic linkage analysis. A short, specific DNA sequence having a specific restriction nuclease recognition site is selected based on the genetic defect one wishes to identify. The DNA from two different individuals (or normal versus tumor tissue from the same individual) is cut with specific restriction endonucleases which create DNA fragments. The fragments are then annealed with a specific probe and visualized on a Southern blot autoradiograph. Analysis of the fragment sizes could indicate differences in single base pair change, deletions, insertions, or rearrangements. This technique, which is a sensitive means of detecting specific mutations, is called restriction fragment length polymorphism (RFLP). [535,536]

The availability of Type II restriction endonucleases has greatly simplified the cloning of DNA. Genomic DNA is cut into manageable pieces by the application of one or more restriction enzymes, leaving restricted ends. An appropriate plasmid is cut with the same endonuclease, leaving compatible ends that can then be ligated. The two types of DNA are mixed together under conditions that favor annealing of the ends of the plasmid DNA with the cut pieces of genomic DNA, followed by treatment with DNA ligase to form covalently bound DNA. The result is genomic DNA incorporated into a circular plasmid. The recombinant DNA within the plasmid is then transfected into bacteria wherein the plasmid can be amplified into a source of virtually unlimited quantities of a specific piece of exogenous genomic DNA.

DNA can be isolated from any eukaryotic cell, digested with appropriate restriction enzymes, and the collection of fragments cloned into plasmids. These plasmids can then be transfected into bacteria and amplified. The collection of DNA fragments, taken together, is called a library and represents the total genome divided into small, manageable pieces of DNA that can be individually isolated and amplified. The ability to clone DNA allows researchers to sort through an entire genome to find a particular gene of interest.

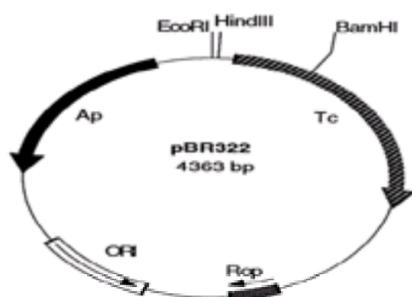
The most commonly used plasmid for DNA cloning has been pBR322 that was originally isolated from *E. coli* (Figure 1.35). Since pBR322 allows for only single copy plasmid per bacteria, other high copy number plasmids have been constructed, either as derivatives of pBR322 or from other sources. No matter the source of the plasmid, they all function in a fashion similar to pBR322. pBR322 is capable of accepting a piece of foreign DNA of up to 10 kbase pairs, approximately two and a half times its own size. The cloning of larger pieces of DNA causes the plasmid to become unstable, thereby slowing plasmid replication and causing the bacteria to delete the excess DNA. For these reasons other cloning systems have been developed which are more versatile than pBR322-like plasmids.


FIGURE 1.35. pBR322: a common plasmid found in *E. coli* and the basis for many artificial plasmids. Tc confers tetracycline resistance; Ap confers ampicillin resistance; ORI, origin of replication, allows the plasmid to be replicated epichromosomally.

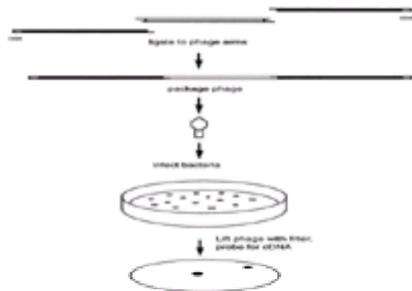
Phage I is a virus or bacteriophage that infects *E. coli*. Its normal genome is approximately 50 kbase pairs packaged into a protein coat for infection. Packing of I phage DNA can be accomplished *in vitro*, that is, outside a cell, by mixing the purified components of the phage together in a test tube. Normally I phage DNA forms long, multigenomic strands that are cleaved by a phage enzyme into the appropriate sizes for assembly into the coat protein structure. The I DNA sequence that is specifically cut is the *cos* site located at either end of the strands of the I genome. Since I has about 15 kbase pairs in the center of the genome that are not essential for replication, modified I cloning vectors have been developed in which the nonessential sequences have been removed so that foreign DNA to be cloned can be inserted.[537] I containing the foreign DNA is allowed to assemble into the infectious viral coat for use in transfecting *E. coli*. Each virally infected bacterium is carrying an individual I containing one segment of foreign DNA, not more than 15 kbases, to be subsequently isolated for study (Figure 1.36).


FIGURE 1.36. Production and screening of a cDNA library. cDNA is ligated to the arms of phage I, which can self-assemble *in vitro*. The phage infect *E. coli,* which are plated on agar. When colonies appear, a filter is laid on top of the plate, then the filter is hybridized with a synthetic DNA probe.

Unfortunately, for some purposes even longer pieces of genomic DNA are required for study. For such studies segments of DNA of 35 to 45 kbase pairs in length can be cloned into I phage using cosmid vectors. These cosmid plasmids containing a *cos* site, without any of the other phage genes, can be amplified in bacteria. When cleaved with appropriate restriction endonuclease enzymes and ligated to foreign DNA, the cosmid and foreign DNA form long linear chains or concatemers separated by *cos* sites. The concatemers can be cut by I protein A, which recognizes the *cos* sequence, and subsequently packaged into a viral coat for subsequent bacterial transfection. Within the bacterium the cosmid DNA circularizes because of the cohesive *cos* site sequences on either end of the recombinant I. Besides containing the foreign DNA and *cos* sites, the cosmid contains an origin of replication for intrabacterial replication and a gene(s) for antibiotic selection. The consequence of such a construction is that bacteria that do not contain the transfected cosmid will be killed when exposed to a selected antibiotic; whereas the bacteria containing the cosmid will be replicated and the foreign DNA contained within the cosmid will be amplified.

Libraries

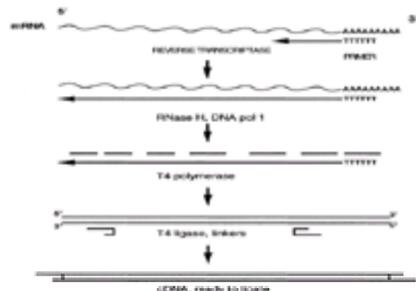
Although genomic libraries are important, when one wishes to study which genes are being expressed within a particular cell it becomes necessary to isolate mRNA. Libraries constructed from DNA retro transcribed from mRNA are called cDNA libraries. [538] To produce a cDNA library it is first necessary to reverse transcribe mRNA into DNA. Reverse transcriptase is an enzyme that uses RNA as a template to produce DNA. So once mRNA is isolated, DNA can be produced for packaging into a plasmid (Figure 1.37). Since most mRNA molecules contain poly(A) chains at their 3'-end, a short section of single-stranded synthetic poly(T) can be used to hybridize to the poly(A)-end of mRNA. The poly(T) then serves as a primer for reverse transcriptase, in the presence of the four deoxynucleotides A, T, G, C, because of its polymerase activity to produce a single strand of DNA complementary (cDNA) to the original mRNA. The resulting hybrid molecule is made of one strand of RNA and one of cDNA. The RNA can be removed by RNase H and the subsequent single-stranded DNA made into double-stranded DNA by DNA polymerase I. The resulting double-stranded DNA can be ligated into a plasmid or a cosmid to produce a cDNA library.


FIGURE 1.37. Production of cDNA from mRNA. Isolated mRNA contains a poly(A) tail which binds a synthetic poly(T) primer. Reverse transcriptase extends the primer, using the mRNA as the template. RNase H and DNA polymerase remove the RNA strand, leaving fragments of DNA. T4 polymerase fills the gaps, leaving double-stranded DNA. T4 ligase adds synthetic linkers containing restriction enzyme sites on the ends, ready to ligate into a cloning vector.

After a cDNA library has been made and amplified, it is necessary to screen the library to find the bacteria containing the cDNA of interest. The technique of filter hybridization allows tens of thousands of bacterial clones to be tested at the same time for the presence of an individual segment of DNA. Bacteria are spread on an agar plate and allowed to form colonies. Each colony is derived from a single bacterium that has been transfected, so all the bacteria in the colony carry the same piece of cloned DNA. However, each colony on the plate contains a different piece of cloned DNA. A nitrocellulose filter is laid over the plate, whereupon some of the bacteria from each colony stick to the filter. The nitrocellulose filter is removed and treated to lyse the bacteria and remove proteins, RNA, and the remaining DNA is fixed to the filter. A probe is made consisting of a short piece of DNA complementary to the cDNA sequence of interest and either radioactive or light-emitting. The probe is allowed to hybridize to the filter, that is, to bind to complementary DNA by specific base pairing. After the hybridization has occurred, the excess probe is removed and the nitrocellulose filter is placed on photographic film. Those colonies retaining the probe will cause black spots on the film (Figure 1.36). When the film is developed, the original colony containing the cDNA of interest can be identified and the bacteria grown in large quantity to provide DNA for further study.

Expression libraries are used to isolate cDNA which codes for the expression of a particular protein. A cDNA library is made as described above, using expression vectors—plasmids which allow the inserted foreign DNA to be transcribed into RNA and translated into protein. The bacteria or yeast containing the plasmid library are plated on agar to form colonies and overlaid with a nitrocellulose filter to pick up a sample of each colony. The filter is incubated with antibody directed against the protein of interest, which binds to the colonies producing that protein. The antibody can then be visualized using standard histochemical techniques, identifying the colonies producing the recombinant protein, and these colonies can then be grown in culture, producing large quantities of the protein.

Transfection

For simple plasmids containing recombinant DNA that one wishes to amplify, one must be able to target or transfect the plasmid into the desired cell. Although viral

transfection systems like l phage are convenient because the virus infects the cells and delivers the recombinant DNA to the interior of the cell for subsequent amplification, the host range for transfection is limited to the range of cells that the virus can infect. Therefore, extensive effort has gone into devising chemical and mechanical techniques to facilitate transfection. Previously, the most commonly used method for introducing a plasmid into eukaryotic cells consisted of mixing the plasmid DNA in a phosphate buffer with calcium chloride that precipitates the DNA as the calcium salt. When the precipitated DNA is added to cultured cells, the DNA is taken up by endocytosis and some of the DNA is transported to the nucleus wherein genes encoded on the DNA can be transcribed. Although calcium phosphate transfections has been used extensively with a variety of fibroblast and epithelial cells, producing stable transfection rates in as high as 10% to 50% of the cases, other cells such as immunocytes are poorly transfected by calcium phosphate. In addition, calcium phosphate has been found to be toxic to many cell types at the concentration needed for transfections. Therefore, other transfection methods have been devised.

Among the other transfections methods, Polybrene (Abbott Laboratonica, Abbott Park, IL) has been used to facilitate retroviral transfection. Polybrene, being a poly-cation, binds to the negatively charged retroviral coat, thereby removing the negative charge and leaving a positively charged surface on the retrovirus that is then more efficiently bound to the negatively charged surface of the cell to be transfected. The Polybrene method has been extended to use with plasmidal DNA because the poly-cation is attracted to the negatively charged DNA and facilitates DNA adhering to the surface of the cell. [539] Then dimethylsulfoxide (DMSO) is added to the mix to make the cell membrane more permeable, thereby causing uptake of the membrane-bound DNA, of which some is transported into the nucleus to be subsequently expressed or integrated into the host genome. Polybrene/DMSO has been reported to produce stable transfectants at a frequency of 0.01% to 0.1%.

When lipids are mixed in an aqueous environment under the right conditions, they are capable of forming small vesicles composed of bilayers with negatively charged groups on both sides of the bilayered membrane and enclosing an aqueous center; that is, a liposome is formed. Liposomes are frequently used to entrap small-molecular-weight chemicals within the aqueous center and subsequently fuse the chemical-carrying liposome with the membrane of a cell. By such means, one can deliver into the cell small molecules and occasionally larger protein structures. Unfortunately, plasmid DNA is much larger than simple proteins, and as such simple liposomes, although exceedingly interesting as drug carrier systems, have had limited success as DNA delivery systems. To overcome the limitation of simple liposomes, cationic liposomes have been developed which are made from a synthetic positively charged lipid, *N*1-(2,3-dioleyloxy)propyl]-*N,N,N*-trimethylammonium and dioleoyl phosphatidyl ethanolamine. [540] The mixture is marketed under the trade name Lipofectin (Life Technologies, Gaithersburg, MD). When Lipofectin is mixed with polyanionic DNA or RNA, complexes form that capture the nucleic acid with high efficiency. Due to the cationic nature of Lipofectin, the liposomes bind with high avidity to the negatively charged surface of the cell and fuse with the membrane, thereby discharging DNA into the cell without being engulfed and subsequently lysosomally degraded. Lipofectin has been used to transfect DNA as large as 130 kbases, as well as to transfect mRNA directly into cells, a capability not found with the use of other transfection systems.

In a conceptual fashion similar to the Lipofectin poly-cationic molecule used for transfection, poly- *L*-lysine has been used as a DNA carrier molecule for transfection. Poly-*L*-lysine, being a positively charged polypeptide, is capable of complexing negatively charged DNA. If appropriate targeting molecules are covalently bound to the poly-*L*-lysine, the resulting DNA/polylysine complex can be targeted to specific cellular receptors for uptake. For example, asialogalactosyl- *poly-L*-lysine has been used to target DNA to a unique receptor on the surface of hepatic cells, resulting in successful *in vivc* transfection.[541] Transferrin-poly-*L*-lysine has also been used to transfect a variety of cells using the transferrin receptor. In both cases, however, most of the DNA is degraded after endocytosis in lysosomes, and the intracellularly remaining DNA is not targeted to the nucleus for expression.

Adenoviruses infect a wide variety of cell types and have the useful property of being endocytosed yet not lysosomally degraded. Spike proteins on the surface of the virus cause disruption of the endosome before being taken up by the lysosome organelle. Additionally, once inside the cell, adenoviruses are transported in their entirety into the nucleus. With such properties, it is not surprising that adenovirus constructs have been engineered to effect transfection. Among the adenovirus transfection systems, one consists of a genetically engineered antigen on the surface of the virus coupled to poly- *L*-lysine bound to an antibody that can target specific antigens on the surface of a cell. [542] Upon mixing DNA with the adenovirus particle/polylysine/antibody, a complex is formed that can be used to deliver DNA to the surface of the cell, which is subsequently endocytosed, disrupted within the cytoplasm, and targeted to the nucleus. Such a transfection system is attractive because there is no size limitation to the transfected DNA and the adenovirus does not need to be infective to result in efficient transfection. In fact, the chicken adenovirus CELO, which is completely noninfectious to mammalian cells, has been successfully used to transfect DNA into mammalian cells. [543]

In addition to the chemical means mentioned above, physical means have been developed to transfect DNA into cells. When cells are placed in a strong DC electrical field, pores appear in the cell membrane, allowing intracellular molecules to escape and extracellular molecules to enter. [544] This technique of introducing molecules into cells, called electroporation, has been used extensively to transfect DNA into many types of mammalian cells and numerous species of yeast, bacteria, and plants. Electroporation is now the most commonly employed method in the research laboratory to transfect DNA into cells. However, because of the requirement for electrical fields in the range of 500 per V cm in mammalian cells, electroporation can be used only *ex vivo* and with small numbers of cells. Unfortunately, the greatest transfection efficiencies are found under conditions causing 50% to 90% cell death; therefore electroporation, although an efficient laboratory tool, has limited use in clinical application.

Biolistics is a unique form of DNA transfection which uses accelerated gold microspheres to carry DNA into cells. [545] In this method, the DNA-coated microspheres are accelerated to high velocity by helium gas and then physically shot into cells. Biolistics has been used to transfect DNA into a wide variety of plant and animal cells and potentially can be used *in vivo.* Recently, biolistics transfection was used to transfect DNA for HIV gp120 into mouse muscle cells that had been surgically exposed for this purpose. The DNA transfected in this manner was shown to express glycoprotein, as demonstrated by the host developing an immune response to gp120.

After DNA has been transfected into a cell, it exists epichromosomally or separate from the host's chromosome. Genes within epichromosomal DNA can be expressed; however, the expression will be transient, lasting at best only a few weeks, the time in which the DNA is degraded. In mammalian cells, such epichromosomal DNA is inherently unstable because the foreign DNA is subject to degradation or dilution as the cell continues to divide but the plasmid does not. The exception to this in mammalian cells is EB virus or bovine papilloma virus vector constructs that can remain epichromosomal, as was discussed earlier. At a very low frequency, plasmids will recombine with chromosomal DNA to become integrated into the genome. Such intragenomic incorporated genes can be stably expressed for the life of the cell and are passed on to the daughter cells like any other chromosomal gene.

Because of the inherent limitation of most of the transfection methods discussed so far producing primarily transient transfectants, much effort has gone into identifying methods to effect efficient integrated transfection. To that end numerous eukaryotic viral vectors have been studied. The most successful viral transfection systems to date have been those derived from retroviruses. Retroviruses have a relatively small genome (less than 10 kbases) made of RNA composed of a small number of genes, most of which can be removed and replaced. Most important, particularly for gene therapy, is that retroviruses efficiently integrate their genome into the host's genome, thereby effecting a permanent transfectant. A normal retrovirus consists of a protein capsid coat surrounding the diploid RNA genome and an envelope derived from the membrane of the cell in which the retrovirus was made. Protruding from the host-derived membrane envelope are envelope glycoproteins which are needed for binding to the target cell during the infectious phase of the life cycle of the virus. Once the retrovirus attaches to the specific receptors on the cell that is being infected, it is endocytosed. The envelope fuses with the endocytic vesicle, with subsequent release of the viral capsid into the cytoplasm. Once inside the cytoplasm, the host cell provides a tRNA molecule that is used by the reverse transcriptase to synthesize its genome in a circular DNA format. Once the DNA has been synthesized, then integrase, a viral protein found within the viral capsid structure, attaches to the virally derived DNA and also to the host genomic DNA. The viral genome, in the form of DNA, is then integrated into the host chromosome. From that point the integrated retroviral genome is a permanent part of the cell's genome, passed on to daughter cells like any other gene. After integration into the host genome, the virus makes full-length mRNA transcripts of its genome. The long terminal repeats (LTR) which are found on both the 5'- and 3'-end of the viral genome contain the viral promoter plus enhancer elements that vary as a function of the individual retroviral type. The mRNA copies of the viral genome can be either packaged as the genome of the daughter viruses or translated into protein.

Retroviruses are valuable vectors for transfecting DNA because the *gag, pol,* and *env* genes which code for the capsid proteins, reverse polymerase, and envelope proteins can be removed from the viral genome and replaced with foreign sequences without destroying the infectivity of the virus. Packaging cell lines have been engineered which do not produce infectious virions because they lack retroviral genomes with the *psi* packaging signal but yet are capable of producing all the proteins necessary to build a retrovirus. [546] When an appropriate genome is introduced into a packaging cell line, viruses are made which carry the altered genome and are made of the proteins from the packaging cell line. Such viruses are capable of infecting a new cell and integrating their genome into the host chromosome, but cannot produce progeny viruses because they lack the genes to produce the virion proteins.

Miller and Rosman have introduced a series of retroviral vectors that have been widely used both in the research laboratory and in clinical trials for gene therapy. [547] These so called pLN retroviral vectors have LTRs and a *psi* packaging region derived from murine retroviruses but lack *gag, pol,* and *env* genes (Figure 1.38). In their place is a promoter derived from either SV40 or cytomegalovirus that controls expression of a neomycin phosphotransferase gene, as well as space to insert a gene

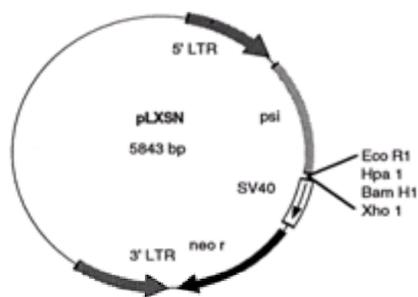
of interest. The viral sequences have been ligated into pBR322 so the recombinant DNA techniques described previously can be used to insert new genes into the viral genome. After the plasmid is transfected into a packaging cell line by electroporation or another methods, the cells begin producing replication-defective retroviruses that carry the engineered genome and are capable of infecting and integrating but cannot reproduce. A retroviral capsid can carry a genome of up to 10 kbases. Since as little as 2.5 kbases of the genome are necessary for efficient packaging and integration, retroviral vectors can theoretically carry inserted regions up to 7.5 kbases in length.


FIGURE 1.38. pLXSN: a retroviral expression vector. When transfected into an appropriate packaging cell line, pLXSN causes production of retrovirus particles containing the LTRs and everything between them as the genome. *psi* is the packaging region; 5' LTR (long terminal repeat), acts as a promoter for a gene cloned into one of the restriction enzyme sites; SV40, a viral promoter, controls expression of the neo ^{r} gene; neo^r is the neomycin phosphotransferase gene.

Retroviral transfection vectors have drawbacks resulting from inherent unique properties of their life cycle. Since the 3' LTR has the same promoter and enhancer elements as the 5' LTR, cellular genes downstream from the insertion site of the retroviral genome could theoretically be activated by the insertion of the virus upstream. If the virus were to insert upstream of a cellular protooncogene, the cell could become transformed into a malignant cell. Also, retroviruses have a very high recombination rate while in the RNA form and are, therefore, capable of incorporating genes expressed by the host cell into their genome. Early packaging cell lines were plagued by the problems of engineered viral genomes becoming replication-competent as a result of recombining with the mRNA transcription of the *gag, pol,* and *env* genes. Newer versions of packaging cell lines have much lower incidences of replication-competent revertants, but the inadvertent production of such viruses and their possible introduction into patients while conducting gene therapy protocols remains a grave concern. In addition, it has been found that promoters inserted into the region between the two LTRs tend to be repressed or silenced. This problem can be circumvented by using an inserted promoter for the antibiotic resistance gene and using the 5' LTR as the promoter for the gene of interest. Since very little enzyme is needed for inactivation of antibiotics, promoter repression is not a significant problem.

No matter which method is used to introduce DNA into a cell, the efficiency is not 100%. Therefore, it is often necessary to separate the transfected cells from those which are not transfected. This is easily accomplished by including a selectable marker in the transfected DNA. Commonly used selectable markers for eukaryotic cells are genes coding for resistance to the antibiotics hygromycin or the neomycin analogue G418 (geneticin). After transfection, the cells are given a brief period in culture to express the proteins coded for by the selection marker, for instance, neomycin phosphotransferase. Then G418 is added to the culture medium, and only those cells that carry the antibiotic resistance gene are able to inactivate G418 and grow in the presence of the drug. [548] The cells that were not successfully transfected are incapable of producing neomycin phosphotransferase, and are killed. This results in a pure population of cells that carry both the antibiotic resistance gene and the gene of interest.

Identification and Analysis of DNA

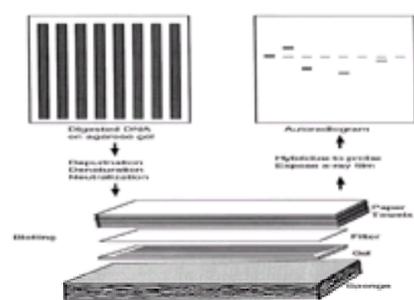
A wide variety of powerful techniques have been developed for the identification and analysis of DNA. The techniques allow the base sequence of the DNA to be determined accurately, the expression of mRNA from the DNA to be rapidly and accurately determined, the interaction of the particular DNA of interest with DNA-binding proteins to be determined, and the protein expressed from the genes to be studied and isolated. The simplest form of DNA analysis consists of digesting genomic DNA with restriction endonucleases and determining the size of the resulting fragments. With the development of the Southern blotting technique, the size of the fragment containing a particular DNA sequence could be determined readily. [549] A Southern blot is performed by digesting genomic DNA with one or more restriction enzymes to generate a large number of fragments of varying sizes (Figure 1.39). The fragments can be separated from each other on the basis of size by agar or polyacrylamide gel electrophoresis. Subsequently, the sized DNA can be transferred to a nylon or nitrocellulose filter by the application of an electric current or simply by buffers to carry the DNA out of the gel onto the filter. The filter can then be hybridized with a labeled probe that complements the DNA of interest. Southern blotting can be extremely useful for examining the large structure of DNA and for isolating specific fragments of DNA. Southern blots have also proven to be clinically useful in the diagnosis of malignancy, since the gene rearrangements found in a number of malignancies can be detected.


FIGURE 1.39. Southern blotting: genomic DNA is digested with restriction endonucleases and electrophoresed in agarose to separate the fragments by size. The DNA is transferred to the filter by the flow of buffers from the sponge to the paper towels. The filter is hybridized to a radioactive probe specific for a particular DNA sequence. Bands appear on the autoradiograph where that sequence is found on the filter.

The basic methodology of Southern blotting, by which nucleic acids are separated on a gel by size and immobilized on filters for further analysis, has spawned a number of variations. A Northern blot is prepared and used essentially as is the Southern blot technique, except that RNA is run on the gel instead of DNA. [550] The filter is then hybridized with a probe to demonstrate the presence of a particular RNA species. Since the intensity of the signal from the probe is proportional to the amount of probe that is bound, a Northern blot can demonstrate the production, quantity, and base sequence of RNA isolated from cells.

Like DNA and RNA, proteins can also be separated by virtue of size or charge on polyacrylamide gels and subsequently transferred and probed. The technique is referred to as Western blotting. [551] Total cell lysates are separated by size (PAGE-gel) or charge (isoelectrically focused), or both (two-dimensional gels), then the proteins are transferred by electrical current to and immobilized on a nylon filter. The immobilized proteins can then be visualized with stains, or individual proteins can be localized by probing the filter with monoclonal antibodies that can be used with immunochemical stains.

Nuclease S1 Protection Assay

Nuclease S1 protection assays are used extensively to locate the termini of mRNA and/or the position of introns within hnRNA. The method is basically a modification of Southern and Northern blotting. The basic procedure involves hybridizing denatured DNA with mRNA. Those segments of DNA that do not hybridize to mRNA represent introns. Nuclease S1 is an enzyme which degrades ssDNA or RNA so that those segments of DNA that have not hybridized with mRNA will be digested,

whereas those segments that have hybridized (exon) will be protected. Once the digestion has been completed, the protected fragments are separated by size on a gel and subsequently transferred to nitrocellulose and probed. As in Southern or Northern blotting, the DNA fragments are elucidative, thereby providing extremely valuable information regarding the length and concentration of the genomic DNA gene. [552],[553] and [554]

Nuclear Run-On

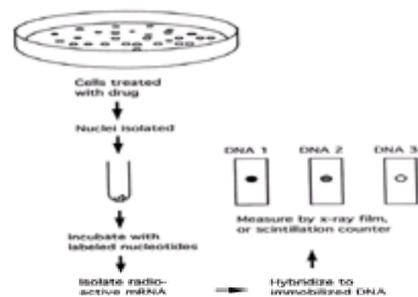
Nuclear run-on experiments are used to determine the relative changes in nuclear transcription that results from introducing a foreign molecule into the cell (Figure 1.40). For several hours a cell population is treated with a foreign molecule, cells are harvested and lysed. Nuclei are isolated and incubated with the four nucleotides needed for RNA synthesis plus a trace of radiolabeled GTP. Following incorporation of the radiolabel into mRNA, the nuclei are pelleted. mRNA is isolated from the nuclei and hybridized to DNA that has been denatured and immobilized on a nitrocellulose filter. After exposing the washed filter to x-ray film, the film is developed and assessed to determine the amount of synthesis that has occurred as a result of stimulating the cells with the foreign molecule. Increases in nuclear transcription can then be quantitated by densitometric analysis. The procedure provides a ready means of analyzing those factors that affect transcription. [553],[555],[556],[557] and [558]


FIGURE 1.40. Nuclear run-on assay: cells are treated *in vitro* with a drug. The intact nuclei are isolated from the cells and incubated with radioactive nucleotides which incorporate into nascent RNA molecules in the nuclei. The mRNA is isolated and hybridized to cDNA of known sequence immobilized on filter strips. The mRNA which binds is measured in a scintillation counter.

Single-Stranded Conformation Polymorphism (SSCP)

Single-stranded conformation polymorphism (SSCP) is a method that will detect sequence changes as minor as a single base difference. [559] The conformation of single-stranded DNA, under non-denaturing conditions, is dependent mainly on intrastrand interactions. Consequently, the mobility characteristics of the single-strand DNA in polyacrylamide gel electrophoresis will be based on its nucleotide sequence. In this technique, sample DNA, genomic or fragments amplified via polymerase chain reaction (PCR), is denatured and evaluated on polyacrylamide gels under non-denaturing conditions. Electrophoretic mobility changes of the DNA bands have been found to be indicative of base sequence changes. Single base changes in DNA fragments up to 200 nucleotides long can be detected as mobility shifts. [560] The sensitivity of this technique allows one to analyze specific DNA sequences for mutations, especially when combined with PCR technology.

Antisense

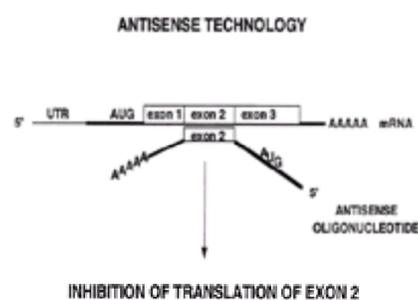
Antisense technology provides a powerful tool which has uses in the research laboratory and potential applications in the clinic. In general, the object of the method is to prepare oligonucleotides that will specifically hybridize to RNA sequence as they are being made or processed into mRNA (Figure 1.41). The result of introducing either an antisense oligonucleotide or a plasmid which has a DNA fragment coding for RNA that will hybridize to mRNA is inhibition of translation of a selective mRNA. Although fraught with numerous technical difficulties, the method has the potential to produce a *de facto* mutation (selective decrease in a functional protein product) without resorting to mutation of DNA. [561],[562] and [563]


FIGURE 1.41. Antisense technology: mRNA is normally single-stranded. A complementary piece of DNA or RNA which is capable of binding to a region of the mRNA will stop translation from that mRNA molecule.

DNA Sequencing

While DNA is composed of a combination of only four bases, it should be remembered that the genetic code is ultimately a language more powerful and expressive than any devised by humans. Within the sequence of bases is described the structure of all proteins, as well as information concerning when the proteins should be made and each step in their processing, distribution, and function. Through the action of the proteins encoded therein, the DNA contains all of the information for the all of the components of the cell or organism, including the lipids and carbohydrates that modify proteins as well as the individual synthesis of the lipids and carbohydrates that are key structural parts of the cell and its matrix.

Although there are two primary means of determining DNA sequence, the Sanger method, utilizing the dideoxynucleotide sequencing technique, has now become the most common.[564] Before sequencing, the DNA is first denatured into single strands, then synthetic primers specific for one site on the DNA are allowed to hybridize (Figure 1.42). In the presence of the appropriate nucleotides, a DNA polymerase will extend the primer sequence to create a copy of the DNA. The sheer genius of Sanger's simple method is that it employs the addition of either the A or G or C or T dideoxynucleotide to the reaction mixture. When the dideoxynucleotide is added to the elongating end of the complementary strand, the chain elongation is terminated. Then, for instance, if the reaction contains all four normal bases and a trace of dideoxythymidine, a collection of terminated DNA chains is produced. Each of these terminated chains ends with a dideoxythymidine substituting for a potential thymidine nucleotide. The length at which the chain terminates corresponds to the location of a thymidine within the sequence. In practice four parallel reactions are run separately with one of the corresponding radioactive dideoxynucleotides of A, G, C, or T. After the reaction is stopped, all four reactions are run in juxtaposed wells of a polyacrylamide gel which separates the strands according to length of the chain. The gel is dried and exposed to x-ray film. The resulting developed film is imaged as four ladders of bands, each indicating a synthesized DNA strand which ends at one particular base in the sequence. The complete sequence can be literally read directly from the film by starting at the bottom and observing the order of the chain length. For this technique, Sanger won his second Nobel prize in 1980. The Sanger sequencing technique has undergone many extensions and simplifications. The sequencing gel frequently yields the most reliable information when determined from a single strand of DNA, but single-stranded DNA is frequently difficult to obtain. Messing used an M13 bacteriophage as a cloning vector for insertion of DNA of interest. [565] To simplify the use of M13 for DNA sequencing, Messing inserted the M13 genome into a plasmid to create a phagemid. The phagemid contains all the sequences needed for replication and selection in bacteria and, in addition, carries a M13 phage genome that can be rescued by infecting the bacteria

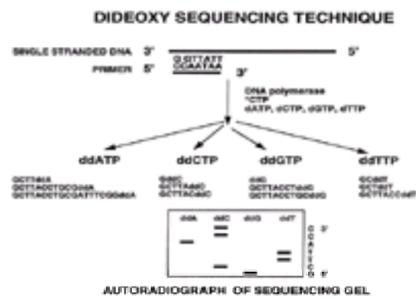
with a replication-defective helper phage. Upon infection of the helper phage, the phagemid begins rolling circle replication to produce single-stranded DNA copies of the phagemid that are packaged as infectious phage and extruded from the cell. The bacteriophage can be isolated and the single-stranded DNA isolated and purified for ready use in the Sanger sequence technique. The phagemid vectors have the advantage of being able to carry larger pieces of DNA without recombination or deletion seen in standard M13 phage. The pUC 119 phagemid, derived from pUC plasmid that was originally modified from BR322, is particularly useful for stably carrying large pieces of cloned DNA while still producing phage in high titer.


FIGURE 1.42. Sanger dideoxy sequencing: four reactions are run in parallel. A single-stranded DNA template is hybridized to a synthetic primer. DNA polymerase extends the primer, incorporating a radioactive label in the process. Each of the reaction tubes contains one dideoxynucleotide, which terminates the reaction at that base. The radioactive strands are separated on a polyacrylamide gel which is exposed to x-ray film. The sequence is read from the film.

Reporter Genes

In addition to the expression vectors, discussed above, which are used to express proteins in bacteria, yeast, insects, and mammalian cells, some protein expression systems are designed to examine the regulatory elements controlling gene expression. These vectors use reporter genes to provide easy measurement of gene expression under different conditions. Three popular reporter genes are chloramphenicol acetyltransferase or *cat,* the firefly gene luciferase, and a bacterial gene b.-galactosidase. Chloramphenicol acetyltransferase is a bacterial gene that inactivates the antibiotic chloramphenicol. The value of the *cat* reporter gene lies in the fact that there is no mammalian enzyme with a similar activity to confound measurement of expressed protein. The assay is performed by first expressing the *cat* gene within the cell, isolating the total protein lysate of the transfected cell, and finally, with the aid of scintillation counting of an organic extract of the protein lysate, one can determine the amount of radio-acetylchloramphenicol produced by transfer of radiolabeled acetate from acetyl CoA to chloramphenicol.

Luciferase is an enzyme which, when expressed and combined with luciferin and ATP, produces light. [566] The amount of expressed protein can be easily quantitated by a luminometer. Similarly, when the b.-galactosidase gene is placed downstream of a promoter containing regulatory elements, those aspects of cellular function that up- or down-regulate the expression of the gene can be followed simply by using visible spectroscopy, since the activity of b.-galactosidase can be measured by the production of a blue precipitate from its substrate, X-Gal. [567] Additionally, the luciferase and b.-galactosidase reporter gene methods have been extended to studying regulation of gene expression in viable cells, because whole intact cells can be used to measure light production or absorbance, respectively, in a dynamic manner.

DNA Amplification: Polymerase Chain Reaction (PCR)

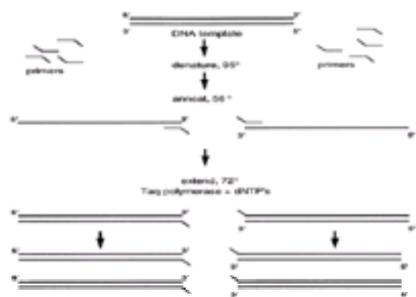
Since the beginning of molecular biology, scientists have been plagued with the problem of generating sufficient amounts of specific pieces of DNA to carry on research efficiently. For example, many genes exist as only a few copies in the genome and are expressed at very low levels, generating few copies of mRNA. Such genes can be extremely difficult to clone using the techniques described earlier, yet no simple and direct way existed until recently to select and amplify a particular piece of DNA. Kary Mullis solved the problem in a simple and insightful manner, for which he received the Nobel prize in 1993. [568] It had been known that DNA could be produced enzymatically *in vitro* by emulating the process by which DNA is replicated *in vivo.* Short stretches of chemically synthesized DNA (primers) could be mixed with the DNA (template) one wished to amplify (Figure 1.43). The mixture is heated to cause the double-stranded DNA strands to separate, then cooled to allow the primers to anneal to the long strands of DNA. In the presence of the four deoxynucleotides and DNA polymerase, a matching strand of DNA would be synthesized. Such a method would result in the production of only one strand of new DNA. Mullis made the key observation that if primers were made complementary to the regions flanking the DNA segment of interest, each cycle of the reaction would result in doubling the number of DNA strands available to use as template, thus causing the number of DNA strands to increase geometrically. Furthermore, the problem of heat inactivation of the polymerase could be avoided by using a heat-stable polymerase from *Thermus aquaticus,* a bacterium that thrives in the hot springs of Yellowstone Park.


FIGURE 1.43. The polymerase chain reaction: the DNA template is mixed with synthetic primers complementary to regions flanking the DNA to be amplified. The template is denatured at 95°, then the primers are allowed to anneal to the template strands. *Taq* polymerase extends the primers into full-length strands of DNA. Each PCR cycle results in a doubling of the number of template molecules of DNA.

In the short time since Mullis's insightful introduction of the polymerase chain reaction (PCR), the method has become an extremely powerful tool in any attempt to analyze DNA. Further, when the PCR is used following reverse transcription of mRNA, rare and scarce mRNA can be amplified by the RT-PCR technique. PCR is used extensively to search for genetic mutations, to match criminal suspects to evidence found at crime scenes, and in cancer diagnosis. The method has been elaborated on and extended to every aspect of molecular biology. Virtually every molecular biology laboratory now has at least one thermal cycler for use with PCR.

Transgenic and Knockout Technology

Most of the studies in molecular biology involve studying cells that are grown in tissue culture. However, no matter what cells are studied *in vitro,* the molecular biologist is ultimately presented with the fact that the cell types and systems that he has selected for use can bias his results and select for results that favor the initial assumptions of the researcher. When entire animals are used to investigate the importance of a particular gene product, we begin to understand a marvelous feature of the entire organism: there are many built in duplications. One method that is increasingly used in molecular biology is the creation of whole animals in which a foreign gene has been placed into the genome of embryonic cells (transgenic mice) or production of an animal in which a gene has been deleted or "knocked out." In the transgenic mouse technology, the role of overexpression can be studied. The mouse is the most commonly used animal to study expression of a foreign gene. The foreign gene or the gene construct having a promoter which allows for overexpression of a given gene is first placed into a single cell mouse embryo. The mouse embryo cells can be obtained by hormonally inducing ovulation, mating the mouse, and subsequently collecting fertilized embryo cells that can be manipulated for a short while in an *in vitrc* environment. Once the fertilized cells are obtained, linearized DNA containing the gene of interest is microinjected into the embryo and

subsequently incubated overnight. The transgenic embryonic cells are than introduced into the infundibulum of a pseudopregnant female mouse and, after the appropriate gestational period, live mice pups are obtained. The tails of the individual mice are then clipped and prepared for Southern blotting to determine if and which of the offspring contain the DNA insert. Then mRNA can be obtained to determine if gene expression is occurring. The most rapid and sensitive means of studying this for low-level expression is by RT-PCR. Alternatively, protein assay techniques (Western blotting) can be used. The techniques allow the study of oncogene expression and how that may affect tumor development.

For knockout mice technology, what is required is disruption of endogenous genes within the embryonic stem cells. [569] Since the stem cells have the potential to develop into a fully differentiated cell, mice can be produced that lack a particular gene product. The use of such models allows study of the importance of any gene and provides a clear means to study the manner by which the entire animal deals with a single mutation. The technique requires that homologous recombination occur between a transfected replacement vector and the endogenous gene of the stem cell. The insertion vector must contain between 3 and 10 bases of uninterrupted homologous sequence. Selection of the stem cell in which the gene has been knocked out is facilitated by the vector containing selectable markers such as neomycin phosphotransferase and herpes thymidylate kinase, whereupon the stem cell population is incubated with these selectable markers: G418 and gancyclovir. Although the selection marker greatly simplifies the task of determining which stem cells have undergone integration of insertion vector, it does not assure that there has been homologous recombination with resultant knockout. Therefore, DNA from clones of individual cells carrying the selection marker is further delineated by PCR to determine that there has been homologous recombination. Once this has been done, stem cells are injected into a blastocyst that has been implanted into a foster mother mouse. After gestation, the chimeric offspring are identified, which is frequently facilitated by hair color. These chimeras are bred with normal mice to determine if the germ line is chimeric. Then germ line chimeras are used to produce the homozygous knockout mice, in which the two copies of the target gene have been knocked out. The technique is extremely powerful in providing *in vivo* information regarding the importance of a particular gene in regulation of expression or suppression of tumor formation or development of disease.

MICROARRAY CHIP TECHNOLOGY

Biological experiments are frequently conducted in a manner that probes a single pathway or gene activation or event. The experimental consequence of such an approach is, for the most part, that a single assay or a small set of assays is used to probe the biological parameter that is being studied. With the most recent introduction of microarray technology to biology, it becomes distinctly possible that not only the face of the biological sciences will change, but likewise the manner in which experiments are thought of and executed will change.[570,571 and 572] Microarrays converge solid-state chemistry, transistor technology, laser optics, robotics, computer analysis, and biology to produce a new paradigm for the simultaneous study of multiple events. Although the technology will undoubtedly be applied to carbohydrate, protein, and lipid biochemistry, at the present time its main application is molecular biology. In particular, microarray technology is being applied to DNA sequencing, mutation analysis, and gene expression. When applied to gene expression, DNA chips or microarrays technology is an extremely powerful and informative tool.

At first glimpse, gene expression as assessed by microarrays appears to be an extension of membrane hybridization experiments. However, with the use of a glass template for affixing large number of DNA molecules to specific sites according to a predetermined XY coordinate system, the expression of thousands of genes can be selectively queried. The technique requires that an indexed expressed sequence tag (EST) be positioned precisely onto a solid matrix, usually a glass slide. The number of known sequences are ever increasing. A single chip can accommodate as many as 400,000 oligomers on a 1.6 cm^2 surface or up to 25,000 cloned DNA sequences on a 3.5 cm^2 surface.[571,572] Obviously such numbers cannot be positioned by hand, and so robotic technology is used to create slides with numerous precisely positioned ESTs, that is, DNA chips.

Within any given experiment, at any one time, steady-state mRNA is harvested and converted to cDNA (Figure 1.44). The cDNA is labeled with a specific fluorochrome, typically Cy3 or C5, and this sample is hybridized to the premade DNA chip. After rinsing, the individual XY coordinates are interrogated by laser light for the presence and extent of hybridized fluorochrome. In fact, two different expression sets can be studied at the same time by labeling one set of mRNA with Cy3 and the other with C5. Then the fluorescence from each set can be assessed simultaneously and a comparison generated between two different cell or tissue groups. Since there is a distinct chance of introducing intensity errors (particular when assaying different cells), sets of constitutively expressed housekeeping genes are used as internal standards. In that manner the entire data set can be normalized to the expression of housekeeping genes, and then the particular expressed gene and level of expression can be determined. Since thousands of genes can be queried simultaneously, the amount of data generated from any one experiment is frequently immense and, more important, the data are relational. Ultimately, one experiment will be compared with an array of other experiments. Therefore, there is an absolute requirement for bioinformatics to hold and catalogue results, as well as to provide ready access and easy querying sessions. A number of URLs are now being formed for compiling experiments in manner similar to that of Gene Bank. Likewise, URLs are becoming available to describe experimental conditions and results and availability of chips. Algorithms will be written to assist in processing and interrogating the large data sets. Such databases will permit perusal by investigators from anywhere. Patterns of up- and down-regulation of gene expression will undoubtedly emerge when comparing the results from similar and contrasting experiments.

FIGURE 1.44. Diagram of a microchip array illustrating a typical experiment in which a set of control and test DNA are being compared to define transcriptional changes that result from a given test experiment. The cDNA is labeled, mixed, and hybridized to the oligonucleotides that have been precisely placed on the chip. Two different frequency lasers are used to excite the hybridized cDNA. Thereafter, emission from each x-y coordinate is collected, stored, and processed for further interrogation as to new or changes in transcribed genes.

Already DNA chips are being used to catalogue changes in enzyme profiles that result from exposure of cells to drugs. An example is an experiment when DNA chips were used to monitor differential expression of cytochrome 450 isoforms after exposure to phenobarbital. Increasingly, such studies will be done with regularity to assess detoxication and to repair enzymes that are modulated with respect to different antineoplastic drug exposure, as well as for profiling of expression sets of similar histochemical types of cancers. [573,574] Such studies will invariably increase understanding of the molecular events of and new targets for cancer.

At this time the DNA chips can "see" as little as three copies of mRNA per cell. Moreover, not only can the method determine new mRNA synthesis, but down-regulation of a particular gene(s) can be queried. With the vast amount of new data, it will not be long before interrelations between different molecular cascades will be routine. Ultimately, the technology promises to provide a format that will enable subtle questions to be asked in a virtual biology environment. The technology is new, the cost is expensive, improvements are occurring at rapid rate, and availability is limited. Moreover, the databases are still being formed. When the human genome project is finished, every gene will be followed by high levels of certainty. As some of the technical and expensive aspects of the techniques are addressed, interrogation by microarray chips of transcriptional and mutational events as they apply to fundamental and applied cancer research will begin in earnest. Once the gene expression format has been attended to, more and more will chip technology shift to translational protein chips. The future is indeed bright for molecular biology discovery.

GLOSSARY

alternative splicing: RNA that is spliced at alternate sites, yielding different but related RNAs coding for related proteins.

amber codon: a UAG triplet that signals termination of translation.

aminoacyl t-RNA: an aminoacyl ester of a tRNA carrying an amino acid.

amplification: synthesis of additional copies of chromosomal or extrachromosomal DNA.

annealing: complementary base pairing of two single strands of DNA.

anticoding strand: the strand of duplex DNA that serves as the template for synthesis of a complementary strand of RNA.

Chromosome: a large (long) molecule of double strand of DNA containing many genes.

cis-acting protein: a protein that activates a sequence of DNA within the same molecule of DNA from which the protein was expressed.

cis-acting: activation of a sequence of DNA within the same molecule; compare with **trans.**

clone: a large number of cells (molecules) that are all identical to the single parent from which they were derived.

cloning vector: DNA containing necessary fragments of DNA to replicate a foreign gene inserted in an appropriate position within the vector.

closed complex: the configuration of DNA while RNA polymerase is bound to DNA but before the DNA has started to unwind.

codon: three continuous nucleotides that code for an amino acid or termination signal.

constitutive genes: genes whose product is expressed at a steady level through RNA polymerase/promoter interactions without additional regulation.

core particle: a fragment of nucleosome-associated DNA consisting of a 146 base pair histone octamer resistant to nuclease digestion.

CAAT-box: a conserved DNA motif found upstream of initiation site in eukaryotic genes and recognized/bound by transcriptional factors.

cap: a posttranscriptional modification in which a GTP is added to the 5'-end of eukaryotic pre-mRNA through a 5' to 5' triphosphate bond.

cDNA: a single strand of DNA complementary to the coding strand of DNA.

chromatin: compacted molecules of DNA complexed with specific DNA-binding proteins.

degeneracy: a term used in reference to amino acids having more than one codon with the variation found in the third nucleotide.

deletion: removal of a sequence of DNA followed by rejoining of surrounding fragments.

denaturation: separation of double strands of DNA or RNA into single strands.

direct repeats: identical sequences of DNA found in two or more copies in the same orientation within the same molecule of DNA.

DNA polymerase: an enzyme that catalyzes the synthesis of a complementary strand of DNA.

DNAse I hypersensitive sites: regions of DNA that are sensitive to nuclease degradation by the enzyme DNase I.

downstream: denotes those sequences of nucleotides found further 3' in the DNA strand.

elongation factors: proteins whose functions are required at a specific step(s) in polypeptide elongation of protein synthesis.

end labeling: addition of a radioactive or chemically labeled molecule to one strand of DNA.

endonucleases: enzymes that cleave bonds within a strand of single-stranded or double-stranded DNA or RNA.

enhancer: a sequence motif that acts in cis to increase the level of transcription of DNA from a eukaryotic promoter. It can be located either upstream or downstream from the promoter.

episome: circularized DNA that replicates epichromosomally but is capable of integrating into bacterial genomic DNA.

eukaryotes: organisms that have compartmentalized their DNA within a nucleus.

exon: a coding region of a gene which becomes part of the mRNA.

exonucleases: enzymes that cleave in a systematic way either the 5' or 3' nucleotides from the end of a strand of DNA or RNA.

expression vector: a cloning vector containing the required regulatory elements which will enable a gene of interest (if properly inserted) to be translated into the correct protein.

frameshift mutation: an addition or deletion of nucleotide(s) which alters the reading frame for protein synthesis, resulting in an incorrect sequence of amino acids, hence an incorrect protein.

gene: a sequence of DNA that codes for a protein.

genetic code: a sequence of DNA or RNA triplet codons which correspond to an amino acid.

helper virus: when cells are coinfected with helper virus and defective virus, the helper virus provides those proteins whose functions are necessary for the defective virus to be an infectious particle.

heterochromatin: a highly condensed, nontranslated region of the genome.

heterogeneous nuclear RNA: nuclear RNA transcribed by RNA polymerase II which has not undergone splicing or posttranscriptional modifications.

histones: DNA-binding proteins in eukaryotes which form the nucleosome.

housekeeping genes: genes whose product is constitutively expressed because it is necessary for a basic cellular function.

hybridization: base pairing between complementary strands of RNA and DNA.

inducer: a molecule that binds to a specific regulator, resulting in initiation of transcription.

initiation factors: specific proteins that interact with each other, with ribosomes, and/or with mRNA to form a translation initiation complex.

integration: insertion and chemical bonding of extracellular DNA into genomic DNA.

intron: a noncoding region of DNA which is transcribed into RNA but removed by splicing of primary transcript into mRNA placing exons adjacent to each other.

inverted repeat: the same sequence of DNA represented more than once in the same molecule of DNA but in opposite orientation.

kilobase (kbase or kb): or 1,000 base pairs of DNA or RNA.

lariat: a folded-over sequence of pre-RNA which forms a circular splicing intermediate resembling a loop of rope.

leader sequence: a nontranslated sequence located at either end or within the DNA sequence which directs translated proteins across membranes into a specific cellular compartment.

ligation: an enzymatic reaction requiring ligase and ATP to form a phosphodiester bond between two ends of nicked/cut double-stranded DNA.

lipid bilayer: the configuration of lipid membranes formed by phospholipids which align themselves so that the hydrophobic tail is in the interior milieu and the hydrophilic head is facing the exterior.

LTR: (long terminal repeat) sequences of DNA in a retroviral genome which are repeated at the 5'- and 3'-ends.

MAR: (matrix attachment site) an AT-rich region of DNA which attaches to the cellular matrix.

monocistronic: mRNA that codes for only one protein.

multicopy plasmids: plasmids that replicate themselves many times within a single cell per doubling.

mutation: any change in the nucleotide sequence of DNA.

negative regulators: molecules that can "turn off" transcription or translation.

nick translation: the enzymatic reaction which occurs when *E. coli* DNA polymerase I adds nucleotides to the free 3' hydroxyl end of nicked double-stranded DNA.

Northern blotting: a technique that involves transfer of RNA to nitrocellulose filter for hybridization to a complementary strand of DNA.

nucleosome: the basic foundational chromatin structure in eukaryotic cells.

oncogenes: genes whose product can transform normal eukaryotic cells into a growth pattern resembling tumor cells.

open reading frame: a series of codons coding for amino acids.

operon: a group of bacterial genes expressed and regulated from same promoter and promoter elements.

origin: a sequence of DNA where replication begins.

packing ratio: the ratio of the length of DNA when stretched out to the length of the structure formed when it is condensed.

PCR: (polymerase chain reaction) technique that amplifies nucleic acids by using thermophilic DNA polymerase to synthesize complementary strands of DNA into many copies through multiple cycles of denaturing, annealing, and elongation temperatures.

periodicity: the number of base pairs of DNA in one turn of the double helix.

phage: (bacteriophage) virus that infects bacterial cells.

plasmid: a circular piece of DNA capable of replicating itself extrachromosomally.

point mutation: any change in a single base pair.

polyadenylation: posttranslational modification in eukaryotic cells involving addition of multiple polyadenylic acids.

polycistronic: a single prokaryotic mRNA containing the genetic code for more than one gene.

polysome: multiple ribosomes simultaneously translating a single mRNA.

primary transcript: RNA that has been transcribed and has not yet undergone splicing or posttranscriptional modification.

primer: a short sequence of single-stranded DNA or RNA with a free 3' hydroxyl and complementary to one strand of DNA, therefore providing DNA polymerase a DNA synthesis start site.

prokaryote: an organism which does not have a nucleus.

promoter: a sequence motif found within DNA near the RNA polymerase transcriptional initiation site which forms a transcription complex when bound by transcriptional factors and RNA polymerase.

prophage: phage DNA covalently integrated into the host chromosome.

proteolytic enzyme: an enzyme that catalyzes hydrolysis of a peptide or protein.

protooncogenes: normal cellular genes from which oncogenes originate.

provirus: a viral genome covalently integrated into host genome.

reading frame: the alignment of bases in RNA to give a succession of triplets which are recognized as codons. Insertion or deletion of one or two bases will shift the reading frame; insertion or deletion of three bases will not.

regulatory gene: DNA whose gene product is a protein which functions in the regulation/control of nucleic acids or another protein.

repression: inhibition of transcription or translation when a repressor molecule binds to a specific region within the DNA or mRNA.

restriction enzyme: an endonuclease which cleaves DNA at a specific recognition sequence.

retrovirus: an RNA virus having the enzyme reverse transcriptase which transcribes the RNA into double-stranded DNA, enabling the viral genome to integrate into the host genome.

reverse transcription: synthesis of single-stranded DNA complementary to an RNA template by the enzyme reverse transcriptase.

RFLP: (restriction fragment length polymorphism) a technique used to detect nucleotide changes by comparing the sizes of restriction endonuclease cleaved genomic DNA fragments.

RNase: an enzyme which degrades RNA.

RNA polymerase: an enzyme which synthesizes RNA using a DNA template.

Shine-Dalgarno sequence: a 5 to 8 base pair purine-rich sequence located about 10 nucleotides upstream from the initiation codon which is complementary to 3' sequences in 16S rRNA; the complementary base pairing strongly influences binding of 30S rRNA to mRNA.

sigma factor: the subunit of bacterial RNA polymerase which is necessary to initiate transcription.

signal transduction: a cellular reaction involving the binding of a ligand to a cell surface receptor which in turn transmits an intracellular signal initiating a cellular pathway/mechanism.

SSCP: (single-stranded conformation polymorphism) a technique that will detect single base changes in DNA through electrophoretic mobility shifts of denatured DNA on a polyacrylmaide gel.

Southern blotting: a technique for transferring DNA from an agarose gel to a nitrocellulose membrane, followed by probing the membrane with a labelled primer; hybridization is visualized on an autoradiograph.

snRNPs: small nuclear ribonucleoproteins.

splicing: the removal of introns followed by the joining together of exons in the primary RNA transcript.

splice junctions: sequences that are found in RNA at the boundary of an exon and intron.

start point: the triplet of DNA at which RNA polymerase initiates transcription.

stop codons: specific triplets (UAA, UAG, UGA) that code for termination of translation.

structural gene: any gene that codes for a protein which is not under cellular regulation.

suppression: a change that reverses the effects of a mutation without altering the original DNA sequence.

Tm: the melting temperature of double-stranded nucleic acids.

tandem repeats: many copies of the same repeated sequence next to each other.

TATA-box: a conserved, short T-A DNA motif in a fixed location which is part of the transcriptional complex.

termination codon: a triplet sequence coding for amino acid, signaling termination of protein synthesis; the termination codons are UAG, UAA, and UGA.

tertiary structure: the three-dimensional configuration of a biopolymer.

trans: sites located on two different molecules of DNA; compare with **cis.**

transcription: the enzymatic reaction that uses one strand of DNA as a template to make a complementary strand of RNA.

transduction: the transfer of genetic material from one cell to another with the use of a virus (usually phage).

transfection: introduction of new genetic material into cells.

transformation: the acquisition of new characteristics by a cell as the result of introduction of new genetic material or modification of endogenous genes.

translation: the process that translates the genetic information carried by the codons in mRNA into amino acids forming a polypeptide.

translocation: when a copy of a gene is found in a location within the genome different from the location where it was originally found.

transmembrane protein: a protein that protrudes through a lipid bilayer and is therefore exposed to an aqueous environment on both sides of the membrane.

transposon: a DNA sequence that moves to new location within the genome.

transposition: movement of transposon to a new location within the genome.

upstream: the nontranslated sequences of DNA found prior to the initiation site for transcription.

vector: a molecule or structure used to carry genetic information into a cell; a vector can be, for example, DNA plasmid or a virus.

OVERVIEW OF CELL CYCLE AND APOPTOSIS

ANJALI K. GUPTA
ELEANOR E.R. HARRIS
ERIC J. BERNHARD
RUTH J. MUSCHEL
W. GILLIES McKENNA

Normally, cells respond to extracellular signals by either undergoing division or withdrawing into a resting state. Cancer, on the other hand, is characterized by uncontrolled cell proliferation. Cancers, including those of the lung, frequently have alterations in genes that directly regulate the cell cycle, thereby disrupting cell cycle controls. Molecular changes that have been demonstrated in lung cancer include activation of oncogenes such as *ras, myc, bcl*-2, and c-*erbB*-2, and loss of tumor suppressor genes such as *p53, RB*, and p16^{INK4A}. Most oncogenes and tumor suppressor genes function in signal transduction pathways that regulate cell proliferation. The activation of oncogenes provides persistent mitogenic stimulation, while inactivation of tumor suppressor genes removes the blocks to uncontrolled growth. Understanding the cell cycle and its control points has provided a better understanding of how a cell is transformed into cancer. More importantly, however, this knowledge will now point to new approaches for the treatment and prevention of cancer.

In this chapter, we will first review the cell cycle and its regulation. We will then review the signals that trigger apoptosis and the relationship between the cell cycle checkpoints and apoptosis. The molecular changes in oncogenes and genes for cell cycle control proteins that are found in lung cancers will then be reviewed. Finally, potential therapeutic options provided by our knowledge of cell cycle progression and apoptosis will be discussed.

THE CELL CYCLE

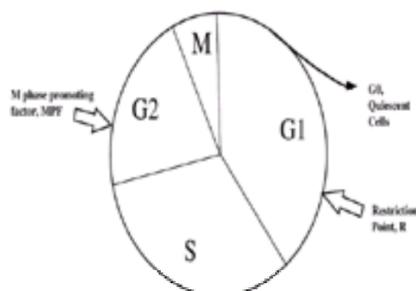
A normal cell exhibits a highly regulated system of proliferation and differentiation that responds to both extra- and intracellular signals. Cancer cells have escaped these regulatory constraints through mutations in genes controlling cell proliferation, such that they are able to grow and proliferate with little restriction. Understanding the mechanisms controlling the cell cycle in both normal cells and cancer cells may enable researchers to develop more specific anticancer therapies by targeting alterations in cell cycle control exhibited by the cancer cell. Normal cells may be in a state of quiescence (G0) where the cell remains metabolically active but is not progressing through the cell cycle towards division. Certain populations of quiescent cells are terminally differentiated and no longer have the ability to cycle or proliferate. In contrast, in response to growth stimuli, cells that are not terminally differentiated may enter the cell cycle, passing through the various phases: G1, the gap prior to replication; S, the DNA synthesis phase; G2, the gap after replication; and M, the mitotic phase leading to cell division (Figure 2.1).


FIGURE 2.1. The cell cycle. The cell cycle consists of four phases—G1, S, G2, and M. Normal cells in G1 can go into a state of quiescence (G0) where they remain metabolically active but are not progressing towards division. Cells must pass the restriction point, R, to proceed from G1 to S.

G1 is the phase during which the cell prepares for DNA replication and division by accumulating the macromolecules, such as histones and enzymes, that are required for cell cycle transit. Cellular differentiation may be initiated in G1. [1] While the other cell cycle phases are of relatively constant duration among different cell types, G1 phase has the most variable duration—over a range of zero to several hours. Cells are required to pass a regulatory point to proceed from G1 to S. This commitment point has been defined most clearly in yeast cells, where it is called "Start." The comparable point in animal cells is called the restriction point, (R). Quiescent cells are considered to have withdrawn from the cell cycle into another state resembling G1 but distinct because they are unable to proceed directly into S phase. This noncycling state is called G0. Some cells can be stimulated to leave G0 and reenter the cell cycle. Withdrawal from or reentry into a cell cycle occurs before the restriction point in G1. After the restriction point, inhibitors will not reverse progression to S-phase.

The DNA synthesis phase (S-phase) results in the replication of the entire cellular DNA content and associated architectural apparatus. The total content of DNA increases from a diploid value of 2 n to the fully replicated value of 4 n. Through specific, highly regulated patterns, multiple sites of bidirectional replication are initiated. S-phase is usually of constant duration within a given cell type. Initiation requires a change in the conformation of the DNA at replication sites. Upon initiation, clusters of replication units called replicons begin simultaneously, although different replicons initiate at different times in S-phase. [2] Individual genes have been shown to replicate at specific times within S-phase[2] with genes that are transcribed as part of S-phase replicating early on. [3]

After the completion of S-phase, the cell enters G2 phase, during which events lead to the commitment to and completion of mitosis. It is during this phase that replication errors and other DNA damage can be repaired. DNA damage may prolong G2 and prevent the progression into M-phase. [4,5] Under normal circumstances, G2 tends to be of constant duration. The coordination of the numerous processes required for cell division, including the ability to recognize the completion of synthesis, nuclear envelope dissolution, chromatin condensation, and organization of the cytoskeleton, are all initiated in G2 prior to entry into mitosis.

Mitosis itself is the process by which the cell equally divides its chromosome complement at cell division, and is composed of four stages. In prophase the replicated chromosomes condense while the microtubule assemblies rearrange, forming a centrosome which guides the movement of the chromosomes. The chromosomes are then positioned and oriented in association with the spindle fibers in prometaphase. These originate at the centrosome and are attached to kinetochores on the chromosome. Anaphase is characterized by the separation of the chromosomes and movement to opposite poles of the cell. This separation requires action of the spindle fibers. Finally, in telophase the nuclei are reformed around each group of chromosomes, after which they decondense. Once nuclear division is complete, cell division usually occurs. [6]

REGULATION OF THE CELL CYCLE

Identifying the factors that trigger the transitions between the cell cycle states (G1, S, G2, M) has been a major goal of cell cycle research. Initial work was done with cell fusion experiments where cells were synchronized at various stages of the cell cycle, then fused with nonsynchronized cells. [7,8] These studies revealed that S-phase nuclei contain a factor, S-phase promoting factor (SPF), capable of inducing G1 cells to enter S-phase. These studies also demonstrated that only cells in G1 are capable of initiating DNA synthesis. If S-phase nuclei were fused with G2 cells, no DNA replication occurred. In addition, late G2 or M-phase cells contain an M-phase promoting factor (MPF) capable of accelerating the onset of mitosis in early G2 cells. [9] Subsequent studies have identified the components of SPF and MPF, which are now known to be a complex of regulatory cyclin proteins and catalytic kinases known as cyclin-dependent kinases (CDK). In higher eukaryotes, more than ten CDK-related proteins have been discovered with numerous cyclin interactions. [10]

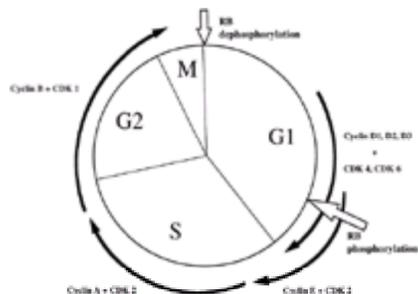
The activation of CDKs is tightly regulated by complex mechanisms to ensure proper timing and coordination of cell cycle events. This regulation is primarily posttranscriptional, and CDK levels remain fairly constant during the cell cycle. [11] Different kinases are active in different phases of the cell cycle (Figure 2.2). Their activity is controlled in part by the formation of complexes with cyclin proteins, so named because their expression varies throughout the cell cycle. The cyclins have homologous conserved domains, called cyclin boxes, responsible for CDK binding and activation. This binding is predicted to activate the partner CDK by altering the conformation of the N-terminal region, displacing a region called the T-loop that partially obscures the substrate binding site of the kinase. Complete activation of CDKs requires more than just cyclin binding; the CDK subunit must also be phosphorylated. [10,11] A CDK-activating kinase (CAK, also MO15 or CDK7) phosphorylates a conserved threonine residue which sits in the CDK substrate binding site (the T-loop). [10] Its phosphorylation seems to induce structural changes allowing the cyclin to bind the CDK protein and the complex to form. [12] Mutation of the threonine residue in the T-loop greatly reduces the kinase activity. [10]


FIGURE 2.2. The molecular regulation of the cell cycle. Different cyclins, such as A, B, D, and E, complex with specific cyclin-dependent kinases (CDKs) during specific phases of the cell cycle. These cyclin/CDK complexes are held in an inactive state by physical interactions with CDK inhibitors such as p16, p21, and p27. Cyclin/CDK complexes phosphorylate key substrates, resulting in progression through the cell cycle at specific points.

Further regulation of the cyclin CDK complex is provided by controlled phosphorylation and dephosphorylation. Major CDKs involved in cell cycle control can be inhibited by phosphorylation of the CDK subunit at a conserved tyrosine (Tyr15) and the adjacent threonine (Thr14). For example, inhibitory phosphorylation contributes to the timing of mitosis in many organisms. [13,14] Prior to mitosis, CDK1-cyclin B complexes are held in an inactive state by phosphorylation at both these sites. At the end of G2, abrupt dephosphorylation triggers CDK1 activation and mitosis. [13,14] This phosphorylation is catalyzed by transmembrane kinases located in the endoplasmic reticulum of cells, Wee 1 and Myt 1. [15,16] Dephosphorylation of both sites is carried out by phosphatases of the Cdc25 family. [17] Inhibitory phosphorylation may control progression through early cell cycle stages as well. During S-phase, human CDK2 is extensively phosphorylated at both inhibitory sites, [18] and expression of a nonphosphorylated CDK2 mutant is lethal in human cells. [19]

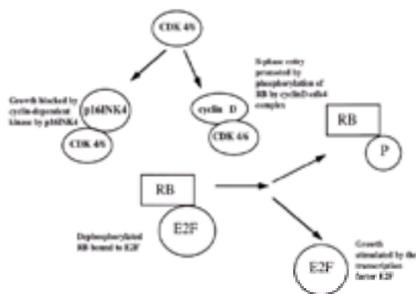
Negative regulation of CDKs is also mediated by a family of inhibitory subunits called cyclin-dependent kinase inhibitors, or CKIs. The CKIs bind to the activating phosphorylation sites and inactivate CDK complexes. The CKIs are a diverse family of proteins including p21 (CIP1/WAF1), and p27 (KIP1), which associate with CDK2, and p16^{INK4} and p15^{INK4} (Figure 2.3), which act on CDKs 4 and 6. [20] The transcription of the CKIs is induced by p53, although p27 seems to be regulated posttranscriptionally. [21] Many human tumors demonstrate p16^{INK4} rearrangements or deletions, while p16^{INK4} expression is elevated in cells that are senescent. [22]


FIGURE 2.3. Regulation of the restriction point. Passing of the cell through the restriction point (R) is a key step in cell cycle progression. Cyclin D interacts with CDK 4 and 6 during G1, and phosphorylates RB. This releases the transcription factor E2F, allowing it to interact with nuclear targets to stimulate the synthesis of various proteins required for progression. Cyclin kinase inhibitors such as p16 ^{INK4A} are able to bind to CDK 4/6 and thus prevent the binding of CDK 4/6 to cyclin D.

During the course of normal cell cycle progression, cyclin-CDK complexes are inactivated at specific times through degradation of the cyclin partner by regulated proteolysis. [10] The importance of cyclin degradation is most apparent in the control of the exit from mitosis, where destruction of mitotic cyclins is required for the onset of telophase, as well as for preparation for the next cell cycle. [23] Cyclin degradation results from ubiquitin-dependent proteolysis [24] and requires a small sequence motif (the destruction box) near the N-terminus of mitotic cyclins. [24] Recent work has identified the key regulated component in mitotic cyclin destruction as a large multi-subunit complex known as the anaphase-promoting complex (APC), or cyclosome, which acts as an E3 enzyme to catalyze the transfer of ubiquitin in various mitotic substrates, including cyclins and putative inhibitors of anaphase. [25] The APC is thought to be activated by CDK1-cyclin B. [25] APC activity remains high in G1 and then declines concurrent to the appearance of G1 cyclins. [25] In yeast, APC activity was recently shown to require binding to an activating protein called Hct-1. [26] Binding of Hct-1 to the APC was regulated by CDK-mediated phosphorylation, and mitotic cyclins and CDK activity were in turn absent when Hct-1 was not phosphorylated. Thus Hct-1 in yeast (and the human CDK1 homologue[27]) appear to regulate mitotic cyclin degradation by APC.

The cell cycle phases are coordinated by the expression and/or activation of regulatory proteins, including complexes of cyclins and cyclin-dependent kinases. In the early G1-phase, D-type cyclins (D1, D2, and D3) and early CDKs (CDK4 and CDK6) accumulate. In addition, the protein levels of proliferating cell nuclear antigen (PCNA), a factor that stimulates the processing ability of DNA-polymerase-delta and associates with cyclin D-CDK4, increases. [28] High levels of CKIs (cyclin-dependent kinase inhibitors) decline on induction of cell cycle entry in mitogen-deprived (G0) cells. [29] The CKI binds to and inhibits G1-phase CDKs and cyclin/CDK complexes.[30,31] Free cyclin D-CDK4-PCNA complexes are activated through phosphorylation by CAK (cyclin-dependent kinase activating kinase). [29] The decline of CKIs, which results both from the down-regulation of CKI protein levels and from the stoichiometric titration of CKI to cyclin D-CDK4-PCNA complexes, also allows an enzymatic activation of CDK2.[25] Cyclin E synthesis follows cyclin D accumulation in G1. Cyclin E interacts with CDK2 in late G1 and at the beginning of

S-phase to induce the initiation of DNA synthesis, and then it is rapidly degraded. After cyclin E is degraded, CDK2 binds cyclin A throughout the rest of S-phase.

Passage through G1 into S-phase is regulated by an elaborate feedback loop involving pRb, the retinoblastoma gene product, a growth-suppressing protein, and a family of related proteins, including p107, p130 and p300 (see also Chapter 7). pRb exerts most of its effect in early and mid-G1 by binding and sequestering E2F transcription factors[28] (Figure 2.3). Repression of transcription by pRb may also involve histone deacetylase recruitment and modification of chromatin structure.[32,33] pRb levels are relatively constant throughout the cell cycle, but its phosphorylation state varies.[34] Cyclin D- and E-dependent kinases have been implicated in the phosphorylation of Rb. It is known that loss of cyclin D-dependent kinase activity before the restriction point prevents many cultured cell lines from entering S-phase, but its absence later in the cell cycle is without effect.[35] Complete inactivation of pRb requires sequential phosphorylation first by cyclin D-CDK 4 or 6 complexes and subsequently by cyclin E-CDK2.[36,37] Also, cyclin D-dependent kinases are dispensable for passage through the restriction point in cultured cells that lack functional Rb, and in this setting, ectopic expression of INK4 proteins does not induce G1 phase arrest.[38] Thus INK4 proteins inhibit cyclin D-dependent kinases that, in turn, phosphorylate Rb. Conditions that cause pRb phosphorylation favor cell proliferation. Hypophosphorylated pRb can bind the transcription factor E2F, while phosphorylation leads to a loss of this association.[34]

E2F is actually a group of transcription factors which contain a consensus binding site specific for sequences in the promoters of a number of cell growth control genes, such as dihydrofolate reductase, PCNA, CDK1, cyclin E, cyclin A, c-*myc,* and TK.[39] One model of this negative feedback loop involves pRb sequestration of E2F in order to control the transcription of genes necessary for cell cycle progression. Upon phosphorylation, pRb releases E2F, leading to the induction of p16 ^{INK4}. This CKI binds to CDK4 and 6, preventing their binding cyclin D, which is subsequently degraded. This cascade of events mediates the transition into S-phase. Various growth inhibitory signals prevent pRb phosphorylation via CDK activity and thus block the cell cycle. Such signals include transforming growth factor b (TGF-b), cyclic AMP (cAMP) and contact inhibition. TGF-b can induce expression of the CKI, p15 ^{INK4B}, which also targets CDK4 and CDK6 and competes for binding with cyclin D. Cell proliferation by this pathway occurs only in cells with functional pRb. TGF-b also reduces CDK4 levels in some cells. Another CKI, p27, interacts with CDK2 in cells treated with TGF-b. DNA damage by radiation or other damaging agents blocks pRb phosphorylation through the CKI, p21, to maintain the pRb regulated cell block in order to complete DNA damage repair.[34]

The primary structures of pRb, p107 and p130, have several regions of highly conserved sequences that likely represent functional domains. The most strongly conserved regions correspond to binding sites. Both p107 and p130 contain a spacer region in common which is not found on pRb and is required for interaction with cyclin A and possibly cyclin E. These two proteins are phosphorylated, but the function of this change is not known. Both proteins can bind the same transcription factors which associate with pRb, including E2F. p130 is found in E2F complexes, primarily in G0, and is lost at the G1/S transition. At that time, E2F is found in complex with p107 instead. Both complexes associate with cyclin A and E complexes. Overexpression of p107 results in growth arrest in some cell lines, and this does not seem to relate to E2F binding. Overexpression of p130 results in arrest of cell proliferation in some tumor cell lines as well.[40] In general, the pRb family of proteins is thought to have similar, possibly overlapping, but not identical roles in the regulation of cell cycle. The fourth protein, p300, has a bromodomain distinct from the other members of the family, implicating a role as a transcriptional co-activator. It also interacts with the TATA-binding protein, indicating a role in transcriptional regulation.[41]

After DNA replication is complete, the cell progresses into the G2-phase. At this time, the levels of cyclin B increase. This protein then forms a complex with CDK1, also known as CDC2, to form the M-phase promoting factor (MPF). Activation of MPF requires the phosphorylation of CDK1 on a threonine residue (Thr161) by CAK and dephosphorylation of a tyrosine residue (Tyr15) by CDC25 phosphatase. Activated MPF then initiates prophase and also induces the ubiquitin proteosome pathway that subsequently causes cyclin B destruction and the initiation of anaphase.[42] Finally, CDK1 is inactivated by the dephosphorylation of Thr161, and the cell cycle clock is reset.[43]

Cell proliferation often requires the presence of external growth factors, which usually influence the cell's commitment to division in G1. Growth factor stimulation of cell cycle entry is believed to be mediated by the upregulated transcription of the protooncogenes c-*fos,* c-*myb,* B-*myb,* and *ras.* Their gene products act as transcription factors that increase the expression of specific cell-cycle regulatory genes.[44] For example, stimulation of smooth muscle cells or fibroblasts results in a rapid induction of c-*fos,* which in turn increases cyclin D1, CDK4, and cyclin E mRNA expression.[45] Growth factors also increase levels of c-*myc,*[46] a protein crucial for the progression through both the G1- and the G2-phases of the cell cycle.[47] Like c-*fos,* c-*myc* induces early G1-phase cyclin accumulation and augments cyclin D- and cyclin E-associated kinase activities.[48,49] H-*ras* is a membrane-associated, guanine nucleotide-binding protein that couples growth regulatory signals from cell surface tyrosine kinase receptors to cytoplasmic second messenger pathways.[50] Abolition of *ras* activity, through the use of dominant negative mutants or neutralizing antibodies, inhibits entry of cells into S-phase,[51] while activation or constitutive overexpression of *ras* protein increases cyclin D levels and shortens G1-phase.[52] Furthermore, *myc* and *ras* proteins collaborate in activating cyclin E/CDK2 and E2F coincident with the loss of the CKI p27Kip1.[53]

A role for the tumor suppressor protein p53 in cell cycle regulation has also been suggested (see also Chapter 6).[54] It was recently proposed that p53 was induced by expression of oncogenic *ras* through the intermediary p19Arf.[55] p53 can act as a transcription factor to up-regulate the expression of a number of genes, including that for p21. Expression of p53 can arrest cells in the G1-phase in response to DNA damage and provides the primary mechanism of the antiproliferative effect in G1 of irradiation. This protective mechanism has been linked to p53-stimulated accumulation of p21.[54,56] p21 is able directly to block the ability of PCNA to increase the processing ability of DNA-polymerase-delta, thereby arresting DNA replication and allowing DNA repair.[57] Alternatively, p53 can promote apoptosis, particularly in the presence of free E2F, providing another defense against the propagation of damaged DNA in cells that have progressed past the restriction point R.[58]

Many cells exhibit a G2 arrest following exposure to DNA-damaging agents, including ionizing radiation as well as drugs such a nitrogen mustard, cisplatinum, and etoposide. It has been hypothesized that this arrest may serve a protective function, perhaps allowing cells to repair damage before progressing through the cell cycle.[4] There is evidence correlating length of G2 delay following radiation to survival. In the budding yeast *S. cerevisiae,* a particular mutant, *rad9,* which fails to arrest G2 following radiation, displays much greater radiosensitivity that the wild type which does not arrest in G2.[5] It has been found that rat embryo fibroblasts transfected with H-*ras* and *myc* were significantly more radioresistant than cells transfected with *myc* alone (Do 1.68–2.17 versus 1.06–1.08) and that they also showed a greater duration of G2 delay following radiation.[55] No differences were found in the induction of rate of repair of DSBs between these lines.[60] In addition, drugs such as pentoxyfilline and caffeine, which shorten the length of the G2 arrest following radiation, increase radiosensitivity.[61,62]

Further study of the mechanism underlying G2 arrest has shown that synchronized HeLa cells irradiated with 10 Gy in S-phase remained in G2 phase for at least nine hours longer than control unirradiated cells.[63] Since it is known that cyclin B in complex with CDK1 is required for exit from G2 and entry into mitosis, the effect of radiation on cyclin B expression was studied. In these cells, a profound suppression of both cyclin B mRNA and protein expression was seen compared to unirradiated control cells which corresponded temporally to the G2 delay.[64] In addition, this suppression of cyclin B was seen with doses as low as 2 Gy.[64] HeLa cells irradiated in G2-phase at a time when cyclin B message expression was elevated with 10 Gy also remained in G2 much longer than control cells and showed a depression in cyclin B protein levels. In contrast, cyclin A expression was not suppressed following radiation; in fact, its level actually rose to a higher level than seen in unirradiated control cells.[64] Both caffeine and staurosporine, which reduce the length of G2 arrest following radiation, also reversed the suppression of cyclin B expression.[65]

However, cyclin B suppression is not the only regulator of G2/M progression. Studies by Kao and co-workers demonstrated that forcing increased expression of cyclin B1 after irradiation using a plasmid encoding cyclin B1 on a dexamethasone inducible promoter only partially reversed the G2 arrest.[66] Thus further controls exist that regulate the passage through G2/M after DNA damage. Phosphorylation of Thr14 and Tyr15 on CDK1 renders the cyclin B/CDK1 complex inactive. These residues must be dephosphorylated in order for the complex to become activated.[11] Paules and co-workers found that irradiation of normal human diploid fibroblasts with 3 Gy led to a rapid inhibition of entry into mitosis (G2 delay) which was accompanied by an accumulation of hyperphosphorylated CDK1.[67] Likewise, this effect has been seen during the G2 arrest in CHO cells[68] and in human lymphoma line[69] after treatment with etoposide and nitrogen mustard respectively.

APOPTOSIS

Apoptosis, or programmed cell death, is a genetically regulated form of cell death which, under normal circumstances, is involved in organogenesis, tissue homeostasis, and the editing of the immune system to remove autoreactive clones.[70,71] However, apoptosis is also linked to cellular proliferation and can be triggered by the loss of cell-cycle controls resulting from the activation of oncogenes that leads to cell transformation.[70] Thus apoptosis also serves as a protective mechanism against the development of tumors. Apoptosis can also be triggered in response to external stimuli, including hormonal or growth factor manipulations,[71] and in response to a number of toxic agents, including chemotherapeutic drugs and x-rays.[72] It is for these reasons that apoptosis has generated great interest among oncologists and cancer biologists, both because of the potential insights the study of apoptosis may yield into carcinogenesis, and in the hope of improving

established treatments or developing new strategies for cancer treatment to maximize tumor cell apoptosis.

An apoptotic cell loses contact with its neighbors, decreases in size, and shows condensation of chromatin, [73] characteristics which allow for the identification of apoptotic cells in tissue. In apoptotic cells, the DNA is often degraded by nucleases at internucleosomal linker sites, yielding DNA fragments in multiples of 180 bp which can be detected as nucleosomal ladders after DNA extraction and agarose gel electrophoresis. [73] However, nucleosomal DNA cleavage is not universal, [73] and sometimes the DNA is degraded into larger fragments. [74] This enzymatic degradation of DNA forms the basis for one method of apoptosis detection, the TUNEL assay, [75] which relies on the labeling of enzymatically cleaved DNA fragments by the enzyme terminal deoxynucleotidyl-transferase. Apoptotic cell membrane proteins are cross-linked, making the membrane more rigid. [76] The altered membrane characteristics lead to phagocytosis of apoptotic cells by adjacent cells or macrophages. The removal of apoptotic cells by this means greatly reduces the inflammation that would otherwise occur with cell death and lysis. [71]

As discussed in the previous section, in response to DNA damage, cells greatly increase their transit time through the cell cycle, due primarily to arrests at G1 and G2. These arrests were described in the first paper accurately defining the phases of the cell cycle. [77] In this classic work Howard and Pelc described the G1, S, G2, and M components of the cell cycle and noted that both G1 and G2, but not S or M, were prolonged in irradiated cells. It was subsequently noted that all eukaryotic cells undergo a G2 delay after irradiation but that many tumor cells fail to arrest in G1. [78] Many of the genes that affect the G1 arrest also influence whether cells undergo apoptosis. For example, overexpression of *myc* leads to a bypass of the G1 arrest normally induced by serum starvation. However, accompanying the loss of the G1 checkpoint is the induction of apoptosis in response to serum withdrawal. [79] Similarly, p53 both functions in the regulation of the G1/S checkpoint, [80] and is a positive regulator of apoptosis. The loss of G1 arrest resulting from absent or mutated p53 does not necessarily lead to apoptosis however, since the proapoptotic function of p53 is also lost. [81] Induction of wild-type p53 expression will cause certain cells to undergo a G1 arrest, while in other cases wild-type p53 leads to apoptosis. For example, irradiated fibroblasts with wild-type p53 undergo a G1 arrest but do not undergo apoptosis over the first 72 hours after irradiation, [82,83] whereas thymocytes rapidly undergo apoptosis that is p53-dependent. [84] Since p53 mutations are among the most frequent lesions present in human tumor cells (seen in 50% of NSCLC and 80% of SCLC[85]), loss of this checkpoint may have a considerable impact on the survival of tumor cells during chemo- or radiotherapy. An important question under investigation is what the determinants are that regulate whether a cell will arrest in G1 or will instead undergo apoptosis. Kastan and co-workers have postulated that in one system, that of a cell line dependent upon IL-3, the absolute level of p21 (WAF1/CIP1) might contribute to this determination, [86] but while intriguing, there is as yet no general support of this observation (see also Chapter 6, Chapter 33).

Apoptosis has also been linked to the expression of oncogenes such as *bci*-2. It has been shown that expression of bc1-2 can delay or even prevent apoptosis. [87,88] Conversely down-regulation of *bci*-2 has been shown to promote apoptosis. *bci*-2 is a membrane-associated protein that in the intact cell is largely found in the nuclear envelope, endoplasmic reticulum, and mitochondria. [89,90] It is a member of a family of genes including Bax, Bcl-X (which gives rise to protein products, Bcl-X$_L$ and Bcl-X$_S$) Mc1-1 and A1. It is also similar to the ced-9 gene of *C. elegans*, [91] and related in function and, to some extent, in sequence to a number of viral proteins such as p19-E1B of adenovirus, p30 of baculovirus and BHFR-1 of Epstein-Barr virus. [92,93] Some of the gene products of these genes function like Bcl-2 in preventing apoptosis (p19-E1B, Bcl-X$_L$,) others (Bax, Bcl-X$_S$) oppose *bci*-2 action and hence promote apoptosis. It has been suggested that apoptosis is regulated not by *bci*-2 alone but by the ratio of *bci*-2 to Bax in the cells where both are found. Korsmeyer and co-workers have suggested that the *bci*-2/Bax heterodimer constitutes a "preset rheostat within cells" determining the extent of apoptosis. [92] Another *bci*-2-binding protein, BAD, may act in a similar way to Bax. [93]

In normal tissues there is a counterbalance between cell proliferation and programmed cell death or apoptosis. A characteristic feature of many tumors is the loss of G1-specific regulators of proliferation. [94] However, if tumor cells are to continue to proliferate and to increase in cell number, then they must also lose the apoptotic response. Mutation of p53 appears to confer both deregulation of the G1/S checkpoint and diminished apoptosis. One example where p53 loss has been shown in tumor progression is during ultraviolet-light-induced skin carcinogenesis. Cells with DNA damage may die by apoptosis after irradiation due to induction of wild-type p53, but cells that have p53 mutations will continue to proliferate and actually establish sectors of skin bearing the mutation. [95] Zarbi and co-workers have described similar sectors of cells with *ras* mutations in the mammary glands of mice that give rise to tumors upon N-nitroso-N-methylurea exposure. [96] These mutations may also act to suppress apoptosis during mammary carcinogenesis, as *ras* can inhibit apoptosis in some settings. [83,97] These observations have led to the hypothesis that the loss of G1-specific regulation must be accompanied by suppression of apoptosis as a necessary step in carcinogenesis. Similar selection for p53 mutations may occur during severe hypoxia in tumors. Graeber and co-worker [98] showed that cells with wild-type p53 undergo apoptosis at very low oxygen tensions, while cells with mutations in p53 do not, leading to a selection for cells with mutations in p53 under hypoxic conditions both *in vitro* and *in vivo*.

The loss of the G1 checkpoint in itself does not lead to the inability of cells to undergo apoptosis. Many tumor cells that have lost components of G1 regulation, including loss of G1 arrest after serum starvation or irradiation, can nonetheless be induced to undergo apoptosis after treatment with a variety of other stimuli, including radiation and some chemotherapeutic drugs. [83,99,100] The study of human tumor cells in tissue culture and oncogene transfection of cells allows modeling of some of these situations. We have studied oncogene-transfected rat embryo fibroblasts and found that *myc*-transfected rat embryo fibroblasts lack a radiation-induced G1 block, but are induced to undergo apoptosis by radiation or by serum withdrawal. [83] Co-transfection of *ras* with *myc* overrides the apoptotic effect of x-rays but not of serum withdrawal. *Ras* transfection does not restore the G1 checkpoint but greatly increases the radiation-induced G2 delay. [59] A similar situation is seen in HeLa cells, which are very resistant to radiation-induced apoptosis, lack a G1 checkpoint, but have a pronounced G2 checkpoint after x-rays. [78] Thus effects at the G1 checkpoint cannot be the sole determinants of apoptosis in tumor cells, and we have proposed the hypothesis that events controlling the G2 checkpoint also can impact on the induction of apoptosis similar to the effects at G1. [83] This checkpoint, however, will come into play only in those situations where a G2 checkpoint is induced.

Finally it should be noted that apoptosis is clearly independent of cell-cycle effects in some cases. Treatment of thymocytes with steroids occurs while the cells are in G0, and the resulting apoptosis is a p53-independent process. [70,84,101] There is also no evidence that apoptosis induced by hormone withdrawal from prostate or breast tissue is related to the cell cycle. [102,103]

MOLECULAR CHANGES IN LUNG CANCER

Lung cancer has been shown to be associated with molecular and genetic abnormalities, many of which affect cell cycle control and apoptosis. These include expression of oncogenes such as *ras, myc, bcl*-2 and c-*erb*B-2, and loss of tumor suppressor genes like p53, RB, and p16^{INK4A}. In the following section, we will examine each of these in detail and its association with lung cancer (see also Chapter 4, Chapter 5, Chapter 67).

RAS

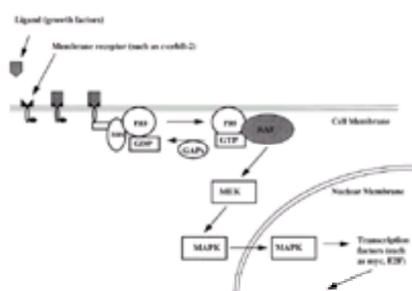
The *ras* genes code for 21 kD proteins that are known as G proteins because they bind GDP or GTP (see also Chapter 4). G proteins are members of signal transduction pathways which transmit signals from the cell's extracellular environment to the machinery that controls gene expression (Figure 2.4) thereby controlling cell proliferation and the cellular response to its environment. Signaling is initiated by growth factor binding to an extracellular receptor domain. This leads to guanine nucleotide exchange factors' (GEFs) recruitment to promote the formation of the active, GTP-bound form of *ras*.[104] GTPase activating proteins (GAPs) accelerate the intrinsic GTP hydrolytic activity of *ras* to promote the formation of the inactive, GDP-bound form of *ras*.[104] Activated *ras* interacts with several downstream signal transduction pathways, such as the raf, rac/rho, and PI3 kinase pathways, [105] thereby causing the signal to move to the nucleus. Mutations in *ras* at amino acids 12, 13, or 61 make *ras* consituitively active by making it nonresponsive to GAPs. [106] This causes a sustained signal to be transmitted through *ras* to the downstream effectors.


FIGURE 2.4. Signal transduction. Many oncogenes and tumor suppressor genes are members of the signal transduction pathway. In this model, a growth factor in the extracellular environment interacts with its receptor. This event is signaled to the nucleus via a G protein (ras) which leads to alterations in kinase activity. The activation of the kinase cascade results in the binding of a transcription factor to the regulatory sequence of a gene, which causes a change in its expression by alteration in mRNA transcription.

There are three forms of *ras*: H-*ras* (homologous to the Harvey murine sarcoma virus oncogene), K-*ras* (homologous to the Kirsten murine sarcoma virus oncogene) and N-*ras* (initially isolated from a neuroblastoma cell line). Activating mutations of *ras* can be seen in up to 30% of all human tumors. In addition, *ras* activity is up-regulated in many cancers by overexpression in the absence of activating mutations.[107,108] *Ras* overexpression has been shown to impact on treatment of cancers as well. In a series of experiments by McKenna and co-workers with rat embryo fibroblast cells transfected with H-*ras* and *myc* or *myc* alone, it was noted that cell lines transfected with both oncogenes were significantly more radioresistant than if transfected with *myc* alone. The more resistant cell line also showed a greater G2 delay following irradiation.[59]

In lung cancer, K-*ras* has been shown to be mutated or overexpressed in 30% of adenocarcinomas, 30% of carcinoid tumors, 13% of large-cell carcinomas, and none of the squamous or small-cell carcinomas (see also Chapter 4).[109,110] K-*ras* overexpression has been shown to correlate with a worse prognosis in resectable cases.[111,112 and 113] A retrospective review of 244 patients with stage I non-small-cell lung cancer (NSCLC) treated surgically at the Brigham and Women's Hospital (Boston, MA) evaluated the effect of a number of molecular and clinical factors on cancer-free survival. They found K-*ras* mutations as an independent predictor of recurrence on multivariate analysis.[114] Although *ras* mutations have been shown to affect response to radiation and chemotherapy in cell culture,[115] no difference in response has been noted in patients with or without *ras* mutations in terms of treatment with chemotherapy.[116] Genetic changes including *ras* mutations can occur in bronchial epithelium well before the development of a tumor that can be clinically detected. In adenocarcinomas, point mutations of *ras* were detected in sputum samples of 11 out of 22 patients by the Point-EXACCT method one month to almost four years prior to the clinical diagnosis of lung cancer.[117] It is possible that screening of sputum samples in high-risk patients may potentially improve survival by leading to earlier diagnosis.

MYC

Three forms of *myc* have been described: c-*myc* is cellular, n-*myc* was originally isolated from neuroblastoma cell lines, and l-*myc* was isolated from small-cell lung cancer (SCLC). *myc* proteins are transcription factors that act via an amino-terminal transactivating domain and are involved in both cell proliferation and apoptosis.[118] Although they may be activated by truncation, *myc* genes are not usually mutated in carcinogenesis; instead they are activated by overexpression by either up-regulation or gene amplification.[119] In nontransformed cells, *myc* expression is linked to mitogenic stimuli and is a prerequisite for cell growth. *myc* expression has been shown to be both necessary and sufficient to cause G0 fibroblasts to enter the cell cycle.[120] Conversely, immortalized fibroblasts that constituitively express *myc* are unable to exit the cycle upon serum withdrawal and then undergo apoptosis.[119] The *myc* oncogene is an early-response gene whose expression rises rapidly at the G0-G1 transition and whose currently known functions are largely linked to G1 and early S. Unlike most early-response genes, however, *myc* expression is sustained throughout the cell cycle. In addition to its proliferative function, *myc* can be shown to induce apoptosis in G0 and G1.[118]

In lung cancer, *myc* amplification is most commonly found in SCLC (see also Chapter 5). In NSCLC, *myc* amplification is rare (5% to 10%), and if it occurs, it is in adenocarcinomas without *ras* mutations.[121] *myc* amplification in SCLC is associated with the variant morphology. In classic SCLC (approximately 70% of small-cell lung cancers), the cells grow as tightly packed floating cellular aggregates with long doubling times and low colony-forming efficiencies. They also have a typical biochemical profile. The remaining 30% of small-cell lung cancers can be subdivided into the biochemical variant category that only have altered biochemical profile, or the morphological-variant category that have an altered biochemical profile with morphologic features of large-cell undifferentiated carcinoma. The morphological variant of SCLC is almost exclusively associated with *myc* gene amplification.[122] Analysis of RNA expression shows that 80% to 90% of all SCLC overexpress *myc* as compared to normal lung tissue.[123] The overexpression of *myc* has been associated with poorer survival. In cell lines established from SCLC patients, 7 of 52 (11%) untreated patients had *myc* amplification, as compared to 16 of 44 (36%) patients who had relapsed after chemotherapy.[124] *myc* expression, however, has not been definitively shown to alter radiosensitivity.[125]

BCL-2

The *bcl*-2 oncogene was discovered as a gene whose expression was increased by chromosomal translocations in B-cell malignancies.[126] During development, *bcl*-2 is expressed in tissues from all three germ layers. In adults, however, it is expressed in tissues that are renewed from stem cells, have proliferative ability, or that are long lived.[127] In the past, the function of *bcl*-2 was viewed like that of many other oncogenes as promoting proliferation or cooperating with other oncogenes in doing so. More recently, however, expression of *bcl*-2 has been shown to delay or even prevent apoptosis.[87,88]

The expression of *bcl*-2 in small-cell lung cancer is quite high at 75% to 80%.[128,129] It has not been associated with any particular histological subtype.[128] In NSCLC, *bcl*-2 protein expression is found in 25% of squamous-cell carcinomas and 12% of adenocarcinomas.[130] The studies are inconclusive to whether *bcl*-2 has any affect on prognosis. In one study, results in squamous-cell carcinoma were improved for patients that had *bcl*-2 expression.[130] Other studies in squamous-cell carcinomas, however, have failed to show a difference in survival.[131,132]

c-*erb*B-2

(see also Chapter 4.) The stimulation for cells to grow with out regulation can also occur through the expression of growth-factor receptors on the surface of the cell membrane. The c-*erb*B-1 protooncogene is known to encode for a tyrosine kinase growth factor receptor. The c-*erb*-B2 gene (also known as the *HER*-2/neu) encodes a protein originally isolated from rat neuroblastomas by virtue of structural similarities to EGF receptor.[133] In the rat neuroblastomas, a mutation in the transmembrane domain of neu resulted in constitutive receptor activation. c-*erb*-B2 is rarely mutated in human tumors, but is rather overexpressed or amplified.[134] The EGF and c-*erb*-B2 receptors have a glycosylated extracellular amino terminus where the ligand binds, a hydrophobic transmembrane region, and a kinase domain contained within the intracytoplasmic carboxy terminus. In the cytoplasmic domains of these receptors are several tyrosines that can become phosphorylated upon activation and thereafter bind to proteins that contain SH2 (*src* homology) domains. The SH2 domains mediate binding of these proteins to the phosphorylated tyrosine residues on the receptor.[134,135]

Gene amplification or overexpression of c-*erb*B-2 is rare in SCLC, whereas overexpression occurs in approximately 25% of NSCLC.[136,137] The highest expression levels are found in adenocarcinomas. c-erbB-2 overexpression, as documented by immunohistochemistry, has been shown to correlate with decreased survival in NSCLC[138] and to chemoresistance.[139] Since NSCLC has also been shown to produce EGF like substances, the possibility of an autocrine loop is raised such that a tumor cell expresses both a growth factor and its receptor.[140] An antibody against p185neu has been shown to inhibit proliferation of NSCLC cell lines.[141]

P53

(See also Chapter 6.) P53 mutations are the most common genetic changes in human cancer.[142] They are seen in more than 50% of NSCLC and 80% of SCLC.[85,143,144] Mutant p53 was first isolated as what was believed to be a dominant cooperating oncogene which behaved in many ways like *myc* or the E1A gene of adenovirus, in that it would cooperate with *ras* in transformation assays of 3T3 cells.[145] Subsequently it was realized that the form of p53 which was first isolated encoded a mutant, inactive, but long-lived form of the protein which displaced the wild-type but short-lived native form from its binding site and because of this acted as a dominant oncogene. p53 is now correctly thought of as a tumor suppressor gene. The action of p53 is complex. It binds to many important cellular proteins and is involved in the control of gene expression.[146] The last several years have seen an intense focus on its roles in cell-cycle delay in G1 phase and in apoptosis. It is now recognized that p53 can both regulate cell proliferation and induce apoptosis, depending on the circumstances and cellular background.[54,56]

The p53 gene is located at 17p13.1 and encodes a 53 kD nuclear protein.[85] Mutations in p53 in lung cancer are of all types: missense, nonsense, splicing, and large deletions.[147] Missense mutations are associated with prolonged protein half-life and thus with increased steady-state protein level which can be detected via immunohistochemistry.[148] Immunohistochemical staining, however, misses about one third of mutations in p53 (mostly splicing and nonsense) and occasionally yields

false positives.[148] Antibodies to p53 have been observed in lung cancer patients and appear to be correlated with the presence of a mutation in the tumor. [149] Antibodies to p53 may precede the development of clinical cancer. [150]

Abnormal expression of p53 has been shown to correlate with both better and worse prognosis. Early studies reported strong adverse prognostic impact, [151] but subsequent studies found either no association or even a survival advantage in patients with tumors bearing p53 mutations. [152] More recently, the multidrug-resistance-associated protein (MRP) expression in NSCLC was found to be correlated with p53 mutation, and this resulted in a worse prognosis. [153]

RB

(See also Chapter 7.) The RB gene is located on chromosome 13q14.11 and encodes for a 106 kD nuclear protein. It is phosphorylated in a cell-cycle-dependent manner, interacts with the transcription factor E2F, and is important in regulating cell cycle during G0/G1-phase. [34] When the cell enters late G1-phase to transition into S-phase, the RB protein becomes hyperphosphorylated. [34] RB protein, when hypophosphorylated, is complexed to E2F. [28] A crucial event in progression of the cell cycle is dissociation of the RB-E2F complex when RB becomes hyperphosphorylated. E2F is actually a group of transcription factors which contain a consensus binding site specific for sequences in the promoters of a number of cell-growth control genes, such as dihydrofolate reductase, PCNA, CDK1, cyclin E, cyclin A, c-*myc,* and TK.[39]

The RB gene is mutated or absent in more that 80% of SCLC and 40% of NSCLC. [154] In addition, disruptions of the RB pathway (RB, cyclin D1 and/or p16) can be seen in 90% of NSCLCs.[155] Thus the RB pathway plays an important role in tumorigenesis in lung cancer. Prognostically, however, no correlation has been found with alterations in RB and clinical outcome. [156] Like p53, it has been shown to be correlated to the multidrug-resistance gene and may be a marker for the assessment of sensitivity to some chemotherapeutic drugs.[157]

P16^{INK4a}

P16^{INK4A} is a cyclin-dependent kinase inhibitor which binds to CDK4 and 6, preventing their binding cyclin D. [34] As a result, RB is hypophosphorylated, and E2F is not released. P16^{INK4A} therefore functions as a tumor suppressor by contributing to the G1/S cell cycle checkpoint. Mutations in p16 ^{INK4A} are found in 50% of NSCLC and not reported in SCLC.[158] These mutations are frameshift, methylation, or homozygous deletion. [158] There is an inverse relationship between the presence of p16 ^{INK4A} mutations and RB expression in tumors.[159] Levels of p16^{INK4A} have not been shown to correlate with prognosis.

CLINICAL APPLICATIONS IN LUNG CANCER

Lung cancer is one of the most prevalent and lethal cancers. Despite recent advances in treatment, the long-term survival data show that only 10% of all patients are long-term survivors for NSCLC and 3% for SCLC.[160],[161] To make an impact on the curability of lung cancer, we need to understand the biology of the disease and apply this to the development of novel diagnostic and therapeutic approaches. As outlined in the previous sections, numerous advances have been made recently in understanding the biology of lung cancer. These have led to potential techniques for diagnosing lung cancer at earlier stages, prognostic information to identify poor-risk patients, and various therapeutics under investigation such as gene therapy, antisense therapy, monoclonal antibody therapy, biologic response modifiers, and agents to enhance apoptosis.

Diagnosis of lung cancer at earlier stages can certainly make an impact on survival. Surgery in stage I/II disease can lead to five-year survival rates of 40% to 60%. [162] Development of *ras* mutations in bronchial epithelium can be detected in sputum samples as early as one month to four years prior to the clinical diagnosis of lung cancer.[117] p53 protein has also been found in sputum samples of patients with bronchial dysplasia. [163] Antibodies to p53 have been observed in lung cancer patients and appear to be correlated with the presence of a mutation in the tumor. [149] Antibodies to p53 may precede the development of clinical cancer.[150] Aberrant methylation of p16^{INK4A} has been found to be an early event in lung cancer, with its frequency increasing with disease progression from basal cell hyperplasia (17%) to squamous metaplasia (24%) to carcinoma *in situ* (50%).[164] With the application of these advancements in molecular biology techniques, it is possible that lung cancer could be detected in the preinvasive stages.

Mutations in *ras, myc,* and c-*erb*B-2 have been shown to correlate with a worse prognosis.[111],[112] and [113],[124],[138] In addition, mutations of p53 and RB have been associated with the multidrug-resistance gene and may be markers for the assessment to some chemotherapeutic drugs. [153],[157] It is plausible that assessing the bimolecular profile of the patient's tumor may assist in selecting the best therapy and prognostic category for patients to determine whether more aggressive treatment is warranted (see also Chapter 33).

With the various molecular changes seen in lung cancer, it can be hypothesized that replacing the defective gene/protein or decreasing the expression of the overexpressed ones may be a potential treatment. Studies have mostly focused on p53, c-*erb*B-2, and *ras.* Work on p53 done by Roth and co-workers has shown that administration of an adenoviral p53 vector to 21 patients with advanced non-small-cell lung cancer produced little toxicity and increased the sensitivity to cisplatinum in a phase I clinical trial. [165] A phase II clinical trial is being planned. In addition, a liposome-p53 complex delivered through the airway was effective in inhibiting lung tumor formation in transgenic mice with p53 deletions. [166] This may be a more direct way of getting p53 to the involved tissue (see also Chapter 6, Chapter 16).

Both K-*ras* and c-*erb*B-2 are overexpressed in lung tissue. One way to decrease their expression is by antisense therapy where a construct that binds to the active form is introduced into the cells. In nude mice, the introduction of a retroviral vector expressing antisense K- *ras* was reported to induce a marked reduction in tumor size and number of tumors with established tumor nodules created by intratracheal inoculation of human lung cancer cells. [167] With the overexpression of surface vectors such as c-*erb*B-2, toxins that specifically bind to the surface receptor have been tried. In mice with renal cell carcinoma, which also overexpresses c- *erb*B-2 as lung cancer does, systemic treatment with a recombinant c- *erb*B-2 receptor-specific tumor toxin reduced the number and size of pulmonary metastasis. [168]

We have been investigating molecular events that occur following ionizing radiation leading to DNA damage and repair, apoptosis, and cell cycle arrests. [59],[60],[63],[64],[65] and [66] We and others have studied the radiosensitizing effect of drugs such as caffeine [61] and pentoxyfylline[62] which alter G2 arrest. Unfortunately, these compounds are too toxic for clinical use in the doses that are required for radiosensitization. However, less toxic analogues are being developed. [169],[170] *ras* has been implicated in the radioresistant phenotype,[171] and we have been investigating drugs that can inhibit its function so that tumors may become more radiosensitive. We have studied farnesyl transferase inhibitors that block *ras* processing that is required for its activity. [172] The treatment of tumor cells with FTI's has been shown to radiosensitize these tumors that express activated H- and K-*ras in vitro.*[100],[173] Studies of their effect *in vivc* are underway.

CIGARETTE SMOKE DAMAGE TO DNA AND OTHER BIOMOLECULES

WILLIAM A. PRYOR

The oxidants in smoke, including both free radicals and nonradical oxidants, are responsible for the biological damage caused by smoke, including damage to DNA,[1,2,3,4,5,6,7,8,9,10,11,12 and 13] proteins,[8] and lipids.[14,15,16 and 17]

Cigarette smoke is operationally divided into two phases: a particulate phase ("tar"), and gas-phase smoke. The two phases are separated using a filter, typically a Cambridge filter made of glass fibers that retains more than 99.9% of the particles 0.1 μm or larger. The principal compounds in gas-phase smoke and tar are shown in (Table 3.1). Gas-phase smoke and tar contain very different types of free radicals and oxidants.

Tar	mg/Cigarette	Gas-Phase Smoke	mg/Cigarette
Nicotine	1.6	NO	0.3
Polyphenols	0.6	Ethylene	0.2
Aldehydes	0.5	Isoprene	0.4
Nitrosamines	1.5	Methanol	0.2
PAH	0.004	Acetaldehyde	0.9

TABLE 3.1. CONSTITUENTS IN TAR AND GAS-PHASE (MAINSTREAM) SMOKE[26]

GAS PHASE SMOKE

Gas-phase cigarette smoke contains high concentrations of both oxy-radicals and nitrogen oxides (which also are free radicals), particularly nitric oxide. [18] The organic radicals produced by the flame itself are too short-lived to reach the lung. The organic radicals in gas-phase smoke are formed by the slow oxidation of nitric oxide, •NO, to nitrogen dioxide, •NO$_2$ (Reaction 1). Nitrogen dioxide, which is more reactive toward organic compounds than is •NO, then adds to isoprene and other reactive olefins in the smoke to produce carbon-centered radicals, as shown in Reaction 2. The carbon-centered radicals then react with dioxygen to form peroxyl radicals (Reaction 3), and these species can cause lipid peroxidation and other types of biological oxidations. [2,19,20,21 and 22] The peroxyl radicals also can react with nitric oxide to form esters of peroxynitrite (Reaction 4).[7,22]

$$\cdot NO \ + \ \tfrac{1}{2}O_2 \text{—slow} \rightarrow \cdot NO_2 \qquad [1]$$
$$\cdot NO \ + \ \text{isoprene} \rightarrow R \cdot \ (\text{carbon-centered radicals}) \qquad [2]$$
$$R \cdot \ + \ O_2 \rightarrow ROO \cdot \qquad [3]$$
$$ROO \cdot \ + \ \cdot NO \rightarrow ROO\text{-}NO \ (\text{peroxynitrite esters}) \qquad [4]$$

The radicals in gas-phase smoke are very short lived and react within a fraction of a second on entering the lung. [2,19] When smoke is absorbed by models of the lung lining fluid, these species produce a complex mixture of reactive oxygen species (ROS), such as hydrogen peroxide, peroxyl and alkoxyl radicals, and reactive nitrogen species (RNS), including peroxynitrite, peroxynitrate, and their esters, as shown above. [2,7,20,22] The oxidants in gas-phase smoke initiate lipid peroxidation.[14,15,16 and 17] They also oxidize the principal human anti-proteinase, a-1-proteinase inhibitor; in this case, it is H$_2$O$_2$ that is the principal oxidant.[8,23]

AQUEOUS CIGARETTE TAR (ACT) EXTRACTS AND DNA DAMAGE

In contrast to the short-lived radicals in the gas phase, cigarette tar contains high concentrations (more than 10[17] radicals per gram) of extremely stable radicals. These stable radicals can be directly observed by EPR methods, either directly on the filter or in organic [24] or aqueous solutions.[7,8,9,10,11,12 and 13] At least four different radicals have been identified in tar, based on their EPR characteristics; [24] the most interesting is a low-molecular-weight semiquinone (QH•) that is in equilibrium with quinones (Q) and polyphenols (QH$_2$).[2,19] The principal polyphenols in aqueous cigarette tar (ACT) extracts are hydroquinone and catechol. [6,11,25,26 and 27]

The tar-radical system is readily water-soluble and can be extracted into aqueous solutions; the EPR spectra of ACT solutions contain a broad signal with a G value of 2.0035 that is typical of organic semiquinones. [7,26] (The G value of a radical can be used to characterize its chemical type.)

Since the tar radical is water-soluble, the aqueous fluids bathing the lung will contain this long-lived radical; for this reason, we have concentrated our studies on the biological damage that this tar radical can produce. [2,3,7,8,9,10,11,12 and 13,19,24] ACT solutions nick plasmid DNA,[29] producing nicks of a type that are not easily repairable. [4] Thus error-prone mechanisms may be involved in the repair of the tar-radical–induced nicks, and these erroneous repairs could lead to mutations. The tar-radical system can also penetrate rat thymus cells, reach the nucleus, and bind to and nick the nuclear DNA. [7,10,11,12 and 13] Thus the radical system is sufficiently stable to be able to diffuse through the lung lining fluid, reach and penetrate cells and subcellular organelles, and thus reach nuclear DNA.

The first interaction of the tar-radical system with DNA appears to be an association of the semiquinone radical with DNA; this association is probably a complexation of the quinones, polyphenols and semiquinones with DNA, and this complex also probably binds metal ions. [10,11 and 12] We demonstrated this binding by isolating DNA from intact rat alveolar macrophage (RAM) cells that had been exposed to ACT extracts and showing that the tar radical EPR signal becomes incorporated into the DNA. After binding, DNA nicks are observed, and the nicking follows saturation kinetics, suggesting that the binding occurs to certain sites on the DNA chain that then become saturated.[7,10,13,30] The EPR properties and the DNA-damaging effects of mainstream and sidestream tar solutions are comparable to those of aged catechol solutions, as shown in (Table 3.2).[27]

TABLE 3.2. COMPARISON OF DNA DAMAGE, HYDROGEN PEROXIDE PRODUCTION, AND THE EFFECTS OF INHIBITORS FOR TAR EXTRACTS FROM MAINSTREAM AND SIDESTREAM SMOKE AND AGED CATECHOL SOLUTIONS

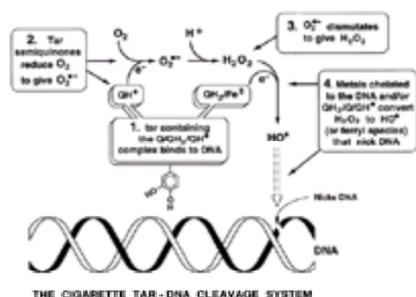
Based on these nicking and binding studies, we have proposed a model in which the tar radical first binds to and then nicks DNA. [3,13] This model is shown in (Figure 3.1).


FIGURE 3.1. Model of the tar radical binding to and nicking DNA. **1:** Aqueous extracts of cigarette tar contain a semiquinone/hydroquinone/quinone radical in a low-molecular-weight polymeric matrix that binds to DNA. **2:** The semiquinone radicals reduce dioxygen to form superoxide. **3:** Superoxide then dismutates to form hydrogen peroxide. (Hydrogen peroxide may also diffuse into the nucleus from other loci in the cell.) **4:** Metals chelated to the tar react with hydrogen peroxide to form hydroxyl radical (or ferryl) species that nick DNA. (From Pryor WA. Cigarette smoke and the involvement of free radical reaction in chemical carcinogenesis *Br J Cancer* 1987;55[Suppl. VIII]:19; Pryor WA, Stone K. Oxidants in cigarette smoke: radicals, hydrogen peroxide, peroxyritrate, and peroxynitrite. In: Diana J, Pryos W, eds. *Tobacco smoking and nutrition: influence of nutrition on tobacco associated health risks.* Annals of the New York Academy of Sciences, Vol. 686, New York: New York Academy of Sciences, 1993:12; Pryor WA. Cigarette smoke radicals and the role of free radicals in chemical calcinogenicity. *Environ Health Perspect* 1997;105:875, with permission.)

FRACTIONATION OF ACT SOLUTIONS

Fractionation of ACT extracts by Sephadex chromatography allows the isolation and identification of those fractions that contain the $Q/QH_2/QH\bullet$ system. These fractions absorb dioxygen and undergo autoxidation to produce superoxide and hydrogen peroxide, as shown in Reaction 5, Reaction 6 and Reaction 7.

$$QH_2 + O_2 \rightarrow QH\cdot + O_2\cdot^- + H^+ \qquad [5]$$

$$QH\cdot + O_2 \rightarrow Q + O_2\cdot^- + H^+ \qquad [6]$$

$$2O_2\cdot^- + 2H^+ \rightarrow H_2O_2\cdot + O_2 \qquad [7]$$

Cigarette tar binds metals such as iron, and either this tar-bound iron or iron present in the biological mileau causes the iron-catalyzed production of hydroxyl radicals, as shown in Reaction 8 (the Fenton reaction).

$$H_2O_2 + Fe^{2+} \rightarrow HO\cdot + O_2 + HO^- \qquad [8]$$

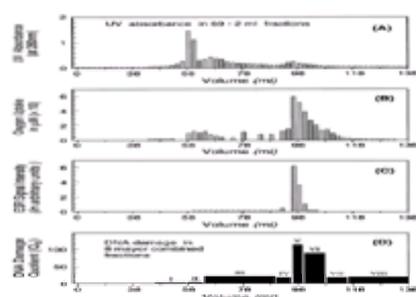
We find that the DNA-nicking activity of the tar is virtually exclusively possessed by the fractions that contain the $Q/QH_2/QH\bullet$ system[11,13,27] (Figure 3.2). We believe it is the hydroxyl radical, produced in the close vicinity of the DNA strand by the Fenton reaction (Reaction 4), that is responsible for the DNA nicks that ACT solutions cause.[13,26,31]


FIGURE 3.2. The separation of ACT solutions by Sephadex chromatography, showing that the DNA nicking activity is primarily in the fractions that contain the tar radical. **A:** Absorbance at 280 nm for 78 fractions of ACT subjected to Sephadex chromatography. **B:** Hydrogen peroxide production (determined indirectly as the uptake of dioxygen) for all 78 fractions. **C:** The EPR signal intensity of the stable free radical signal for all 78 fractions. The EPR signal intensity was estimated by the height of the highest peak. EPR parameters were: microwave power, 10 mW; modulation amplitude, 0.63 G; time constant, 0.2 s; receiver gain, 2×104; scan time, 200 s. **D:** The 78 ACT fractions were consolidated (based on their UV spectra) into eight major fractions, and these eight fractions were assayed for DNA-damaging activity in rat thymocytes (Qd, DNA damage quotient). (From Pryor WA. Cigarette smoke radicals and the role of free radicals in chemical carcinogenicity. *Environ Health Perspect* 1997;105:875; Pryor WA, Stone 15, Zhang L-Y, et al. Fractionation of aqueous cigarette tar extracts: fractions that contain the tar radical cause DNA damage. *Chem Res Toxicol* 1998;11:441, with permission.)

ACT solutions also contain large amounts of nicotine and nitrosamines. To test if the $Q/QH_2/QH\bullet$ system is the agent in cigarette tar that causes DNA damage, and to dissociate the toxicity of nicotine from the effects of the tar-radical system, we developed a simplified model to study the tar radical. Aged solutions of catechol form a

radical that has a similar G value, 2.0035, to the radical observed in ACT. [2,7] Fresh solutions of catechol do not nick DNA;[32,33 and 34] however, catechol autoxidizes to give semiquinone radicals. We have used autoxidized solutions of catechol as a simplified model for ACT; these solutions contain a radical similar to that in ACT solutions, yet any unreacted (unoxidized) material would have no effect. Aged solutions of catechol, like tar extracts, nick DNA in rat thymocytes. (Thymocytes are a frequently used cell type in the DNA nicking assay. [35])

These aged catechol solutions, like the ACT solutions, contain a semiquinone radical that becomes associated with double-stranded DNA in RAM and then causes nicking with saturation kinetics.[10,13,27] In addition, using radiolabeled catechol, we have shown that this tarlike $Q/QH_2/QH\bullet$ system binds to DNA and in about the expected amounts based on nicking data (unpublished work by Dr. M.G. Salgo). The similarily of aged catechol solutions and the cigarette tar radical extracts leave little doubt that it is the $Q/QH_2/QH\bullet$ system in tar that is responsible for the nicking observed.

PRODUCTION OF HYDROGEN PEROXIDE AND RADICALS FROM TAR EXTRACTS

It is our hypothesis that superoxide and hydrogen peroxide result from the reduction of dioxygen by the semiquinone radicals in aqueous tar solutions and in aged catechol solutions (see Reaction 5, Reaction 6 and Reaction 7). Superoxide and hydroxyl radicals have both been observed in aqueous tar extracts by EPR methods.[11] We detect hydrogen peroxide in ACT extracts from both mainstream and sidestream smoke and also from aged catechol solutions, as summarized in Table 3.2.[7,11,27] (Sidestream smoke rises into the environment between puffs.) Hydrogen peroxide can be reduced to the hydroxyl radical by metals such as iron (reaction 8), and iron is present in tar extracts. The hydroxyl radical is known to be able to nick DNA. In addition, superoxide can lead to the liberation of iron from ferritin.[6]

DNA NICKING AND SCAVENGERS

Cigarette tar extracts from both mainstream and sidestream smoke nick DNA in rat thymocytes, and aged catechol solutions also cause DNA nicking. This nicking appears to follow saturation kinetics in all three cases. To investigate the mechanism of DNA nicking by smoke extracts and aged catechol solutions, we studied the effects of catalase, superoxide dismutase, glutathione, deferoxamine, and diethylamine pentaacetic acid (DTPA). Catalase protected DNA against damage by both mainstream and sidestream tar extracts. Catechol did not protect DNA against nicking, probably because catechol is an effective inhibitor of catalase. Superoxide dismutase (SOD) did not protect against DNA damage. Deferoxamine and DTPA are divalent metal ion chelators and neither had a very dramatic effect. Our model of tar causing DNA nicking involves the presence of metals; however, the metals probably are tightly complexed to the cigarette tar or to the DNA, and thus unaffected by chelators in solution. Table 3.2 summarizes our results for these inhibitor studies.

CONCLUDING REMARKS

The oxidants in gas-phase smoke and in cigarette tar are quite different, but both appear to be involved in the damage to biomolecules that cigarette smoke causes. The oxidants in gas-phase smoke are shorter lived and more transient, but those in tar are long lived and can be expected to be a part of the aqueous fluid that bathes a smoker's lungs. In particular, we have shown that the tar radical, a semiquinone radical that reduces dioxygen to form superoxide, hydrogen peroxide, and ultimately the hydroxyl radical, can penetrate cells and cause DNA damage.

RAS and *ERBB* 2

JOHN F. LECHNER
JOSEPH M. FUGARO

Malignant transformation of a normal lung epithelial cell is the culmination of multiple genetic aberrations, [1,2] and two that are frequently associated with human lung cancer are *ras* and *erb*-B2. This chapter overviews these two oncogenes, their mechanisms of action, and their effect upon clinical outcome.

(Genes are denoted in italics and protein products are written in capital letters.)

RAS ONCOGENES

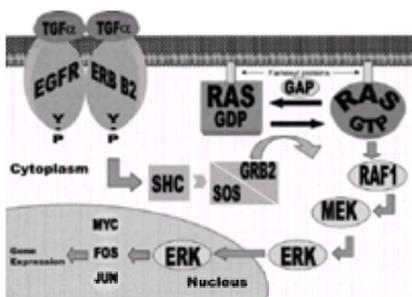
The family of *RAS* genes of H-*RAS,* K-*RAS,* and N-*RAS* is differentiated by their homology to different sarcoma oncogenes. Each of these codes for a 188 amino acid, 21 kD (p21) guanine-binding protein that is localized to the inner side of the plasma membrane. Such location and composition enable *RAS* proteins to "transduce" an appropriate signal from the extracellular milieu to the cell nucleus, thereby affecting gene transcription and directing cellular response to external stimuli. *RAS* constitutes the a subunit of a complex that also includes a receptor, an effector, and a bg dimer (see Figure 4.1). Most *RAS* protein within a cell exists in an inactive state with bound guanosine diphosphate (GDP). The bg subunit connects the a subunit to the receptor. When a signal ligand binds to the receptor, there is a conformational change in the guanine-binding site on the a molecule that promotes the exchange of guanosine triphosphate (GTP) for GDP. This action also moves the a molecule from the bg subunit to the effector molecule. The effector for *RAS* is a tyrosine kinase that can phosphorylate amino acid residues of proteins such as RAF1, one of the mitogen-activated protein kinases (MAPK). [3]


FIGURE 4.1. *Ras* signaling transduction pathway. *Ras* functions as a switch to relay extracellular ligand-stimulated signals from the inner cell membrane surface through the cytoplasm, and to the nucleus. The pathway places *RAS* downstream from a receptor tyrosine kinase, such as the epidermal growth factor receptor (EGFR)/*ERB* B2 heterodimer, and upstream of multiple serine/threonine kinases. A signal can be carried from outside the cell to the cell nucleus, where activated extracellular signal-regulated kinase (ERK) can be transported across the nuclear membrane and activate transcription factors known as *MYC, JUN,* and *FOS.* Tumor growth factor alpha (TGF-a), Src homologous complex (SHC), Son of Sevenless (SOS), growth factor response binding protein (GRB2), GTPase activating protein (GAP), guanosine diphosphate (GDP), guanosine triphosphate (GTP), MAPK/ERK kinase (MEK). (From Vojtek AB, Der CJ. Increasing complexity of the Ras signaling pathway. *J Biol Chem* 1998;273:19925, with permission.) (See Color Figure 4.1.)

An example of *RAS* signal transduction is the epidermal growth factor receptor (EGFR) and *ERB* B2 heterodimer receptor, as shown in Figure 4.1. When TGF-a binds to this receptor complex, *RAS* is activated, subsequently inducing nuclear transcription factors that enhance cellular proliferation. In the process, the receptor is phosphorylated and the associated tyrosine kinase activates the Src homologous protein complex (SHC) that promotes dimerization of two other tyrosine kinases, Son of Sevenless (SOS) and growth factor response binding protein (GRB2). The newly formed dimer binds and activates RAS by producing a conformational change that enables *RAS* to bind GTP. [4] Thus, *RAS* acts as a "switch" that initiates a cascade of protein activations, beginning with RAF1, to transmit a signal from the cell membrane to the nuclear transcription machinery. Ultimately, the *RAS* signal transduction pathway activates nuclear protooncogenes that can form leucine zippers or helix-loop-helix transcription factors such as *MYC, FOS,* and *JUN.* These latter factors influence many cellular activities including transcription, translation, cytoskeletal organization, Golgi trafficking, vesicle formation, and cell-cell interactions. The effector will remain active until the a subunit's GTPase dephosphorylates the bound GTP to GDP.

RAS Oncogenes and Lung Cancer

One can imagine that if *RAS* became constitutively activated, there would be an exaggeration of the downstream effects, especially cell division. In keeping with this supposition, researchers have found two general mechanisms for aberrant *RAS* activation. The first is point mutations that cause irreversible binding of GTP. The most common mutations are within codons 12, 13, or 61, although Japanese and Chinese studies have also implicated codons 59 and 63. [5] While mutational activations of *HRAS* and *NRAS* are rare events in human lung cancer, several laboratories have reported a frequent association with *KRAS.* [6] For example, Richardson's study of 52 lung cancer patients revealed a prevalence of 15% to 20% of all non–small cell lung cancers (NSCLC), with the most common subtype being adenocarcinoma. In this study as well as others, the incidence of *KRAS* mutations for adenocarcinoma tumor tissue is approximately 30%. [2] Similar mutations are rarely detected in small cell lung cancer (CLC). Richardson noted that 85% of the lung cancer specimens that had *KRAS* mutations showed point mutations on codon 12, and nearly 70% of these were G-to-T transversions that change a glycine codon (GGT) to valine (GGT) or cysteine (TGT). [7]

In an attempt to establish a link between carcinogen exposure and *RAS* mutations, Prahalad and associates examined the mutational spectra of *RAS* exposed to benzopyrene, one of the carcinogenic ingredients of tobacco smoke. [8] The predominant mutations found in chemically induced murine lung tumors were transversion mutations in codons 12 and 61. Cells which acquired mutations in both *p53* and *KRAS* lost the G1 arrest phase of the cell cycle. [9] These cells are unchecked and grow with progressive cellular dysregulation, leading to overt neoplasia.

The second model of *RAS*-mediated oncogenesis involves protein overexpression. Theoretically, the affected pulmonary epithelial cells could produce enough *RAS* protein that some *RAS* could bind GTP without the "activation" of the SHC/GRB2/SOS complex. Anti-H-*RAS*-specific antibodies have been shown to improve sensitivity of tumor tissue screening to 80% in adenocarcinomas and 40% in squamous carcinomas. [10] A tenfold increase in transcription of H-*RAS* is sufficient to confer a functionally active amount of GTP-bound *RAS* in a cell, [11] and since signal-transducing protein dysfunctions downstream from *HRAS* should produce similar oncologic phenotypes, overexpression can initiate malignancy. However, the importance of H-*RAS* activation in human lung cancer by overexpression is controversial

because the observed levels may be insufficient, based upon *in vitro* studies with human and murine cells.[12] Yet overexpression of *HRAS* detected by immunohistochemistry has been reported to be a highly frequent character of lung squamous cell carcinomas. [13]

RAS as a Biomarker of Early Detection of Lung Cancer

Recently studies to identify individuals at high risk for lung cancer have assessed cells from sputum, [14] bronchial alveolar lavage (BAL) [15] or endobronchial biopsies[16] for *KRAS* mutations. The Johns Hopkins Lung Project utilized sputum samples to retrospectively assess for an incidence of *KRAS* mutations. From 15 patients who later developed adenocarcinoma of the lung, eight sputum samples showed *KRAS* mutations in codon 12. The sputum PCR analysis was positive as early as four months prior to clinical diagnosis and reverted following curative resection in all cases. Lehman and colleagues [15] used BAL specimens from patients who have already been surgically treated for NSCLC. Using a ligase chain reaction, these researchers were able to detect *KRAS* mutation in five out of 12 patients in spite of a background of 99% normal airway DNA. Clements and associates evaluated bronchoscopic biopsies of patients with varied histological diagnoses of lung cancer. The biopsies were paired samples of endobronchial lesions and distant airway sites. The patients' airway epithelium exhibited cellular changes ranging from histologically normal to metaplastic to frankly malignant. The samples were then assayed for K-*RAS* mutations. In only 50% of the eight patients with adenocarcinoma, *KRAS* mutations were present at the site of the lesion. Meanwhile, two of the nine patients with histologic inflammatory changes showed evidence of *KRAS* mutations. Clinical experimentation shows that while *KRAS* mutations can predict the presence of carcinogen-insulted bronchial epithelium, this molecular marker is not ubiquitous in neoplasms, nor is it activated only in oncologic states. [17] Therefore, a positive *RAS* assay may correlate to DNA damage without necessarily conferring malignant potential.

Prognostic Impact of *RAS*

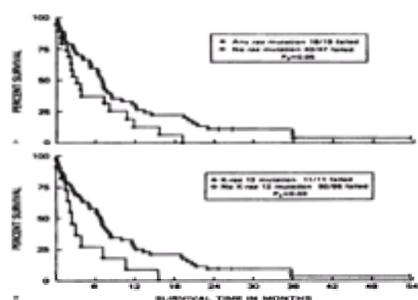
Many researchers suggest that K-*RAS* mutations portend a poor clinical prognosis for patients with adenocarcinoma. [13,18,19] See Figure 4.2 as an example of this relationship. Clinicians have attributed the increased mortality to therapeutic resistance. However, this largely retrospective observation was not supported when Rodenhuis performed a prospective study on late-stage (inoperable) cancers. [20] The study showed that *KRAS* mutations had no correlation with late-stage cancer survival or chemosensitivity. This conclusion was confirmed by a later Japanese study. [21] Furthermore, Tsai and associates used an *in vitro* model to refute the contention that cancers with *KRAS* mutations have increased resistance to chemotherapy and radiotherapy.[22] The prognostic impact of *RAS* may be more relevant to patients with lymphatic involvement. A Japanese study of 115 surgical patients without lymph-node metastasis showed a significant survival advantage in stage I and stage IIIA cancers without *KRAS* mutations (see Figure 4.3).[23] Therefore, the survival advantage of patients without K-*RAS* mutations is seemingly limited to premetastatic stages of lung cancer.


FIGURE 4.2. Comparison of survival with RAS mutations. Survival is significantly elevated in patient populations without RAS mutation in evaluating the time from tissue acquisition with respect to **(A)** any RAS mutations, and **(B)** K-*RAS* codon 12 mutation. (From Mitsudomi T, Steinberg SM, Oie HK, et al. *Ras* gene mutations in non–small cell lung cancers are associated with shortened survival irrespective of treatment intent. *Cancer Res* 1991;51:4999, with permission.)
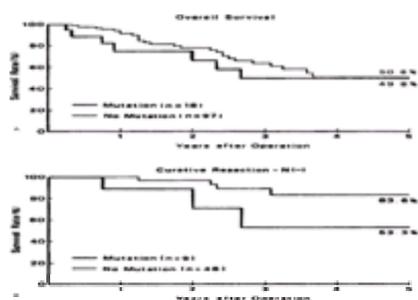

FIGURE 4.3. Comparison of nonmetastatic survival with RAS mutations. The Kaplan Meier survival curves after surgery for adenocarcinoma of the lung with respect to presence or absence of RAS mutations. Overall survival is unaffected by presence of RAS mutations **(A)** p = 0.1513 by generalized Wilcoxon test. However, absence of RAS mutation in patients without lymph node metastasis following curative resection had a significant impact upon survival **(B)** p = 0.212 by generalized Wilcoxon test. The numbers of patients with stage I and stage IIIA disease were 44 and 4 in the RAS negative group, and 8 and 1 in the RAS positive group respectively. (From Sugio K, Ishida T, Yokoyama H, et al. *Ras* gene mutations as a prognostic marker in adenocarcinoma of the human lung without lymph node metastasis. *Cancer Res* 1992;52:2903, with permission.)

Therapy

The well-described details of *RAS* protein (p21) biochemistry have prompted many to generate antitumor therapy through inhibiting the activity of this protein. Several pharmacologic approaches to this end have been proposed to interfere with the effective cellular activity of p21. To date, there are five approaches to *RAS* inhibition in antitumor therapy: antisense exposure; ribozymes that block expression of the protein; GTPase activating proteins (GAP) stimulation to dephosphorylate activated *RAS;* signal transduction interference; and blocking membrane localization of *RAS.*

Experiments with antisense oligonucleotides have also shown that it is possible to inhibit selectively the expression of mutated *RAS* with little interference upon the wild-type *RAS* gene expression. Employing antisense oligonucleotide methylphosphates, concentrations in the range of 100 µM have been required to achieve selective inhibition of mutated *KRAS* mRNA. Using phosphorylated oligonucleotides of optimal size (17 nucleotides), somewhat lower concentrations may be effective, but it is not clear whether it will be possible to create the conditions under which it is possible *in vivo.* In a preclinical study of gene therapy to cause complete inactivation of the mutated gene transcript, a retrovirus that transduces an anti-K-*RAS* antisense construct has been instilled intratracheally in mice. [24] This treatment prevented outgrowth of orthotopically implanted human lung cancer cells, and human trials are anticipated. An alternative approach could be gene therapy in which DNA coding for ribozymes that specifically cleave mutated *KRAS* mRNA is introduced. Ribozymes directed against mutant *HRAS* have been shown to inhibit colony formation and induce reversion of cell morphology to a more normal appearing phenotype. [25]

The GAP proteins (see Figure 4.1) for *RAS* are novel and responsible for stimulation of the GTPase activity associated with the a subunit of a protein. *KRAS* mutations are thought to decrease the sensitivity of *RAS* to GAP, and leave *RAS* in a GTP-bound, activated state. These suppositions have been borne out in *in vitro* studies.[26,27] Therefore, the generation of an engineered *RAS* GAP may serve to stimulate GTPase activity even in oncogenic *RAS.*

As previously mentioned, activated *RAS* undergoes a conformational change to promote GTP binding. If the signal cascade were interrupted directly or indirectly, the

increased *RAS* signal would not reach the cell nucleus. Accordingly, some researchers have suggested a GTP analog to bind the activated *RAS* and inhibit RAF1 phosphorylation (see Figure 4.1).[25] Others suggest blocking signal transduction from the MEK (MAP/ERK kinase) and MAP kinases of the cascade.[26,29] However, MEK and RAF1 mutants do not transform lung cells nor are they found in lung cancer cells except in exceedingly rare cases. Thus, successful applications of these approaches appear remote.

A particularly interesting target for pharmacologic interventions may be the enzyme farnesylprotein transferase, which is responsible for farnesylation of p21.[30] Farnesylation is a requirement for membrane attachment of the molecule. The enzyme can be inhibited *in vitro* by small peptides that compete with *RAS* protein; however, the toxicity to normal tissues might be significant. Lastly, data from *in vitro* studies employing plasmids containing antisense *KRAS* constructs suggest that blocking K-*RAS* mRNA translation may result in inhibited growth and in decreased tumorigenicity.

RAS is only one of many proteins that are responsible for signal transduction and cell fate determination. This protein has a historical role in molecular oncology in that it represents the first direct link of genetics to malignancy. However, other researchers have confirmed that RAS mutation or *RAS* overexpression is not alone sufficient to transform normal epithelial cells.[31] Therefore this pathway requires further clarification of mechanism and utility as an oncogenic focus.

ERBB-2

Ligand binding is used to categorize the first three of the four members of the *ERE* B gene family of receptor tyrosine kinases. The first group includes epidermal growth factor (*EGF*), transforming growth factor-a (TGF-a), and amphiregulin; these all recognize the original member of this family, *EGF* receptor (*EGFR*). In the second group are the ligands betacellulin (BTC), heparin-binding EGF-like growth factor, and epiregulin; these bind to both *EGFR* and HER4. Neuregulin-3 (NRG3) is the only known member of the third category; it has specificity only for *erbB-4.* The last group of ligands are the heregulin differentiation factors HRGb1, sensory and motor neuron-derived factor (SMDF), and neuregulin-2 (NRG2); they all bind to *erbB-3* and *erbB-4.* The last member of the family, *erbB-2* (also designated as HER2 or p185^{neu}) is a 185 kD glycoprotein. The molecule has a glycosylated amino-terminal extracellular region containing the ligand binding site, a hydrophobic transmembrane region, a cytoplasmic carboxyl terminal domain containing the kinase activity, and presumed regulatory sites. However, it does not directly bind any known ligand. Instead, it heterodimerizes with the three other family members, and enhances ligand-binding affinity and reduces the rate of dissociation. These heterodimers also amplify the elicited signal through activation of the *erbB-2* intracellular kinase domain and auto-cross-phosphorylation. The phosphorylated tyrosine residues in the receptor's cytoplasmic tail, in turn, serve as high-affinity binding sites for cytosolic substrates containing SRC-homology 2 (SH2) domains, for example, GRBs. Depending on the heterodimerization partner, the signal then traverses the *RAS,* P13K, or CDC42 cascades to the nucleus.[32,33,34,35,36,37 and 38] These signal cascades culminate in the nucleus, where they regulate transcription. Elevated expression of *ERE* B family members has been reported in a variety of human cancers. With respect to lung tissue, normal epithelial cells, carcinoids, and NSCLC cells are either negative, or minimally positive for expression of *erbB-2 to 4.*[39,40,41,42 and 43] In contrast, *erbB-2* is highly expressed in 30% to 90% of SCLC tumors. However, contrary to the common gene amplification mechanism seen in most other cancers,[32] lung tumors overexpress this receptor by a mechanism that remains to be delineated.[2] *erbB-3* is also frequently overexpressed in NSCLC tumors, and information on the potential importance of elevated expression of *erbB-4* in NSCLC lung carcinogenesis has been intimated.[44,45 and 46]

The mechanism(s) whereby excess *erbB-2,* and possibly *erbB-3* and *erbB-4,* contribute to lung carcinogenesis is unclear. However, recent observations by Gerwin and co-workers[46,47,48 and 49] have shown, using an *in vitro* model system, that excess autocrine expression of the ligand TGF-a can be involved. By transfecting Beas2B human airway epithelial cells with a constitutively expressing *erbB-2* construct, these investigators found that conversion of the cells to tumorigenicity was directly associated with excessive autocrine expression of TGF-a.[48] They have shown elevation of MAPK activity in tumorigenic cells (see Figure 4.1), and signaling pathway depression of cells transfecting with a TGF-a antisense construct. The antisense-expressing cells also lost the tumorigenic phenotype. These studies indicate that overexpressed *erbB-2* implements TGF-a manifested tumorigenicity. More recent work supports this supposition by showing that excess *erbB-2* forces constitutive heterodimerization with EGFR and constitutively activates transcription of the signal transducer and activator of transcription (STAT).[49] Thus these workers propose that although overexpression of *erbB-2* alone is insufficient to convey the tumorigenic phenotype, it is necessary for tumorigenicity to arise through the TGF-a signal transduction pathway.

Gerwin and associates also report that TGF-a antisense reduces the steady-state levels of *erbB-3* and *erbB-4.* Thus a possible role of excess constitutive *erbB-2/erbB-3* and *erbB-2/erbB-4* dimers cannot be ruled out as also having a role in producing tumorigenicity. In keeping with this latter suggestion is the recent report by al Moustafa and colleagues.[43] These investigators showed that *erbB-2, erbB-3* and *erbB-4* are all constitutively activated in lung cancer cell lines. Lastly, Funayama and co-workers[45] reported that overexpression of *erbB-3* is frequently seen in squamous cell carcinomas, and its level of expression in metastatic nodules was higher than in the primary tumor.

By immunohistochemistry, Sozzi and colleagues[50] detected overexpression of *erbB-2* in three of 13 normal bronchial specimens from patients with a second primary lung tumor, suggesting that receptor overexpression is an early genetic change in the evolution of a NSCLC. However, four large studies[51,52,53 and 54] comprised of approximately 400 NSCLC specimens used different antibodies from those used by Sozzi and colleagues, and failed to detect *erbB-2* overexpression in nontumor lung epithelial cells. Reconciliation of these disparate results, as well as the prognostic interpretations described below, can be attributed to fact that these investigators used different antibodies and antigen retrieval techniques. Furthermore, not all studies deemed the specimens positive by scoring only the cells that specifically exhibited membrane staining. Another possible reason is illustrated by Tesfaigzi and colleagues.[55] These investigators studied rats exposed to a single intratracheal dose of the noncarcinogen endotoxin. Using immunohistochemical staining and Western blotting, they characterized a wave of hyperplasia followed by epithelium remodeling in the lungs of these animals. Interestingly, the hyperplastic cells exhibited a transient and marked expression of both *EGFR* and *erbB-2.* Therefore, the results of Sozzi and co-workers[50] may reflect a background of subclinical infections or smoking-associated epithelium wound repair.

Prognostic Associations of *erbB*-2

Kern and colleagues[52] were the first to report a statistical association of shorter survival time for adenocarcinoma and *erbB-2* overexpression. Subsequently, data from 119 adenocarcinomas and 84 squamous cell tumors showed that detectable *erbB-2* expression was statistically associated with shorter five-year survival, larger tumor size, and higher stage.[53] In addition, a study of 120 NSCLC tumors found that the frequency of overexpression was statistically higher in adenocarcinomas than in squamous cancers (81% versus 44%). However, expression was more frequent in clinical stages II and III than in stage I, regardless of histology. *erbB-2* expression was also positively correlated with lymph node metastasis in a cohort of 50 squamous lung carcinomas but not in a group of 32 lung adenocarcinomas.[54] Together these earlier studies supported a prognostic significance for *erbB-2* expression in NSCLC.

Subsequent studies have supported and refuted the correlation between *erbB-2* overexpression and shortened survival. Yu and colleagues[56] found significant relationships between *erbB-2* overexpression, a higher incidence of earlier recurrence, and an overall survival for 69 patients diagnosed with adenocarcinoma, but not for 47 with squamous tumors. A study by Hsieh and co-workers[57] of 42 stage I adenocarcinoma patients also showed that patients with *erbB-2* overexpression had a significantly higher incidence of early tumor recurrence and a lower overall survival expectation. Nemunaitis and colleagues[11] arrived at the same conclusion from studying 103 adenocarcinoma and large cell cancer patients. Most recently, D'Amico and colleagues[58] studied 408 stage I NSCLC patients and found that *erbB-2* overexpression equated with a "hazard ratio" of 1.43. Sloman and co-workers[59] and Guddo and co-workers[60] also reported that shorter survival correlated with *erbB-2* expression. Lastly, Diez and colleagues[61] have suggested that the risk of recurrence is directly related to the amount of *erbB-2* activity, and that for every increase of 100 units there is a 30% increase in risk. Interestingly, Yu and colleagues[62] have reported that high *erbB-3* expression is also associated with shortened survival, but the significance is associated only with advanced disease.

In contrast to the above reports, other studies, such as Pastorino and co-workers[63] failed to find any prognostic relationship between *erbB-2* overexpression and disease outcome. However, because of highly stringent scoring criteria, only 4% of their tumors were scored as positive; thus their small numbers precluded reliable inferences. On the other hand, Giatromanolaki and co-workers[64] examined *erbB-2* as a prognostic marker for 176 early-stage NSCLC patients and failed to find any significant relationship between survival of either adenocarcinomas or squamous carcinomas and survival. Likewise, Greatens and colleagues[65] studied 101 consecutive patients with primarily stage I or II NSCLC and failed to find any significant prognostic survival value for *erbB-2* overexpression. Interestingly, both Giatromanolaki and colleagues and Greatens and colleagues suggest that differences between their results and those studies that revealed a correlation could be due to chance, population differences, or interobserver variability. Finally, Fontanini and co-workers[66] reported a study of 195 patients; no significant correlation was found for either *erbB-2* or *erbB-3.*

ERBB-2 as a Target for Antitumor Therapy

Although an association between overexpression of *erbB-2* and adverse prognosis has not been firmly established, unlike *RAS, erbB-2* overexpression has been associated with enhancement of the metastatic properties and chemoresistance of lung cancer cells. The metastatic relationship was uncovered through transfection of the pSV2*erbB-2* plasmid DNA into low-expressing lung NSCLC cells.[62] Three independent clones were isolated that exhibited varying degrees of *erbB-2* expression. The untransfected, antisense transfected, and low-expressing cells exhibited minimal motility and ability to invade Matrigel, and produced few sites of pulmonary and extrapulmonary metastasis when injected into nude mice. In marked contrast, the two high-expressing clones were highly mobile and invasive, and produced multiple sites of metastasis.[22,67] With respect to chemoresistance, Tsai and colleagues[22] have shown that introduction of an *erbB-2* construct into lung cancer cells made them more resistant to doxorubicin, cisplatin, mitomycin, and etoposide. Interestingly, Tsai and associates[67,68] have also reported lung cell lines that are intrinsically high expressers of *erbB-2* lung cells lines are more chemoresistant. Importantly, chemoresistance was attenuated if the chemotherapeutic agent was combined with tyrosine kinase inhibitors that preferentially inhibited *erbB-2* kinase.[68,69]

The above studies all support the assertion that overexpression of *erbB-2* is involved in lung carcinogenesis and, therefore, it is a potential target for mechanism-directed chemoprevention modalities. Support for this hypothesis came when lung tumor cells constitutively expressing *erbB-2* antisense RNA exhibited a reduced level of anchorage-independent growth, and fewer sites inoculated subcutaneously with the cells developed tumors.[70] Further, studies with anti-*erbB-2* antibodies have shown that cell growth is inhibited if the antibodies are incorporated into the culture medium.[71] In addition, mice with orthotopically implanted lung tumor cells developed smaller tumors if they received five weeks of injections of recombinant anti-*erbB-2* antibodies coupled with *Pseudomonas* endotoxin.[72] As a consequence of these encouraging results, a phase I trials for Herceptin anti-*erbB-2* antibodies is in progress.[73,74 and 75]

Finally, serum levels of *erbB-2* protein have been shown to correlate with extensive clinical cancer, and to be reduced after surgery.[76] Also, Brandt-Rauf and co-workers[77] showed that significant increases in the level of receptor protein in serum could be detected up to 60 months before clinical diagnosis, supporting the conclusion of Sozzi and colleagues[50] that the extracellular portion of the protein may be a useful biomarker of early disease.

THE ROLE OF *MYC, JUN,* AND *FOS* ONCOGENES

PASI A. JÄNNE
BRUCE EVAN JOHNSON

The *MYC, JUN,* and *FOS* families of protooncogenes all share sequence homology with retroviruses, code for nuclear binding proteins with short half-lives, and share common structures. These proteins all contain a basic region of amino acids followed by a leucine zipper which allows the protein to dimerize with other proteins and bind to DNA. The protein products of these gene families localize to the nucleus and regulate gene transcription. The functions and characteristics of the *MYC* and *JUN* and families genes have been recently reviewed.[1,2,3,4,5,6,7,8,9 and 10] Structural DNA, mRNA expression and protein studies have implicated them in the pathogenesis and progression of lung cancer. The following chapter provides information about the normal structure and function of each of these protooncogenes and focuses on the evidence for the *MYC, JUN,* and *FOS* families' playing a role in the development and maintenance of lung cancer. The readers are referred to other reviews for more detailed information about the function of *JUN* in other animal and human tumor systems.[1,2 and 3,5,6,7,8 and 9]

MYC FAMILY PROTOONCOGENES

MYC Family Gene Structure

The *MYC* family genes studied in lung cancer include *MYC, NMYC,* and *LMYC.* The studies of the human *MYC* gene were prompted by the studies of the RNA tumor virus v-*myc.* The v-*myc* gene was first identified in an avian RNA tumor virus, MC29, which caused leukemias, carcinomas, and sarcomas in chickens.[11] This virus carried incomplete retroviral gene sequences along with the transforming gene, v-*myc.* v-*myc* shared a greater than 99% nucleotide sequence and amino acid homology with the normal second and third exon of the chicken *MYC* gene. This suggested that the retrovirus MC29 had picked up sequences of the chicken *MYC* gene by inaccurate recombination of retroviral gene sequences.[11] The human *MYC* gene was able to be cloned from normal DNA because of the close sequence homology between the previously cloned murine *MYC* gene and the human *MYC* gene.[12]

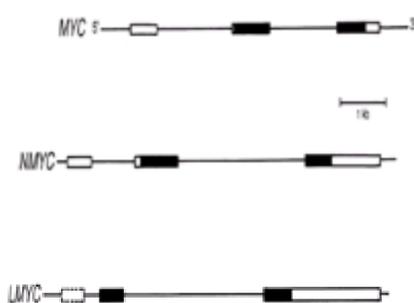
The human *MYC* gene is a 3 exon gene spanning approximately 5 kbases located on chromosome 8q24 Figure 5.1. mRNA transcription originates from at least two different promoters separated by 150 nucleotides in the first exon and gives rise to mRNA of 2.2 and 2.4 kbases. [12,13,14 and 15] *MYC* protein translation starts in exons 1 or 2 to give rise to phosphoproteins of 439 and 453 amino acids with an apparent molecular weight of 64,000 and 67,000 D and a half-life of approximately 30 minutes.[12,16,17]


FIGURE 5.1. Gene structure of the *MYC* family genes: This diagramatically depicts the structure of the *MYC* family genes (*MYC, NMYC,* and *LMYC*). The boxes represent the exons and the lines between represent the introns. The black portions of the boxes represent exon domains that correspond to the protein-coding signals.

The *NMYC* gene was initially identified in neuroblastomas and neuroblastoma cell lines because of DNA amplification of sequences homologous to the MC38 avian retrovirus v-*myc* but different from the human *MYC* gene.[18] A fragment of the *NMYC* gene was also subsequently cloned from DNA fragments isolated from a homogeneously staining region (HSR) in a neuroblastoma cell line. [19] Hybridization of this radiolabeled fragment to DNA isolated from neuroblastoma cell lines showed intense signals representative of DNA amplification.

The human *NMYC* gene is a 3 exon gene spanning approximately 6.5 kbases located on chromosome 2p25.[1,20,21,22 and 23] mRNA transcription gives rise to a predominant mRNA of 3.1 kbases.[19,24,25] The *NMYC* protein is translated from exons 2 and 3 to give rise to phosphoproteins of 453 and 456 amino acids with apparent molecular weights of 65,000 and 67,000 D and half-lives of 30 minutes. [1,26,27,28 and 29]

The human *LMYC* gene was initially identified in small cell lung cancer cell lines and tumors because of DNA amplification of sequences homologous to but different from the human *MYC* and *NMYC* gene.[18] The human *LMYC* gene is a 3 exon gene spanning approximately 6.5 kbases located on chromosome 1p32. [30,31] Transcription of the *LMYC* gene gives rise to 3.6 and 3.9 kbase mRNAs but alternative processing in small cell lung cancer cells can give rise to smaller forms of the *LMYC* mRNA which will be described later.[1,29,30] The *LMYC* protein is normally translated from exons 2 and 3 and produces a phosphoprotein of 364 amino acids with an apparent molecular weight of 60,000 to 66,000 D and a half-life of 45 to 120 minutes. [30,32,33]

The *MYC* family genes share a similar structure and a close sequence homology, and have similar functions in biological assays. *MYC, NMYC,* and *LMYC* all have 3 exons with 2 introns. The predominant areas of sequence homology are contained within exons 2 and 3. The first exons of the *MYC* family genes are not closely related and do not typically code for protein. Translation initiation typically takes place within the second exon in all three genes and the major protein coding regions lie within exons 2 and 3 (Figure 5.1).

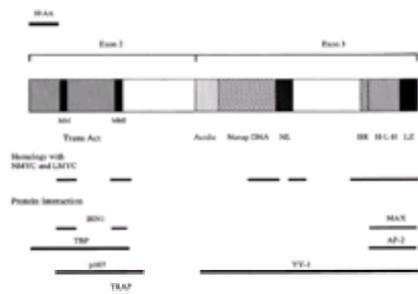
There are five areas of close sequence homology in the second and third exons of *MYC, NMYC,* and *LMYC* Figure 5.2. The area of sequence homology in the carboxy-terminal is contained in the 85 amino acids of the *MYC* family proteins. This region contains a basic region, helix-loop-helix structure, the leucine zipper. [34] The basic region contains a high proportion of basic amino acids and binds to the DNA; the helix-loop-helix has two amphipathic helices of 12 and 13 amino acids separated by a loop structure, a leucine zipper characterized by a leucine or hydrophobic amino acid every 7 amino acids for four repeats in the carboxy-terminal amino acids. [35] This helix-loop-helix and leucine zipper structure allows proteins to form homo- or heterodimers which allow the basic portion of the molecule to contact the DNA and regulate gene transcription. The amino-terminus contains the transactivation domain and the highly conserved *MYC*-box (Mb I and Mb II) domains. [6] The Mb I domain is located at amino acids 45 to 63, while the Mb II domain is at amino acids 129 to 141 of the human *MYC* protein. [6] The Mb domains are evolutionarily conserved, show a greater than 90% homology between the *MYC* family members, and are sites of protein interactions, diagrammatically depicted in Figure 5.2. [4,36] In addition, the Mb II domain is essential for *MYG*-mediated cell transformation in a rat embryo fibroblast assay. [37] Thus the *MYC* family of genes has the ability to participate in diverse functions, including protein-protein interactions, binding of DNA sequences, and modulation of gene transcription.


FIGURE 5.2. Functional domains of the *MYC* protein and the location of protein-binding sites: This diagramatically represents the functional domains of the *MYC* protein. The portions of the *MYC* protein encoded by exon 2 and 3 are represent by the brackets above the bar. The letters below the bar represent abbreviations for the functional domains of the *MYC* protein. The initial diagonal region represents the transactivation domain (Trans Act), the black dots represent the acidic domain (Acidic), the next diagonal lines represent the nonspecific DNA-binding domain (Nonsp DNA), the white dots represent the nuclear localization domain (NL), the crosshatched lines represent the basic region (BR), the dark dots represent the helix-loop-helix domain (H-L-H), and the dark diagonal lines represent the leucine zipper (LZ). The black boxed areas represent the *MYC*-binding domains (Mb I and Mb II). The dark lines below the bar represent the areas of close sequence homology between the other two *MYC* family proteins. The dark lines below represent the regions where *MYC* interacts with various proteins, and the specific proteins are listed on the right-hand column: TBP (TATA-binding protein), BIN-1 (box-dependent *MYC*-interacting protein-1), and TRAP (transformation associated protein).

Molecular Mechanisms of *MYC* Action

The *MYC* family of genes contains two highly conserved dimerization motifs: the helix-loop-helix domain, and the leucine zipper domain. *MYC* proteins do not homodimerize, and it was subsequently discovered that *MYC* forms heterodimers with another BR-HLH-Zip protein known as MAX (see Figure 5.2). All of the biologic activities of *MYC* occur as a heterodimer with MAX. *MYC, NMYC,* and *LMYC* all heterodimerize with MAX. [6] These heterodimers bind DNA at sequence-specific sites known as the E-box with the consensus sequence of CAC(G/A)TG, and activate transcription. The E-box elements are found in *MYC* target genes and are located in promoter regions, the first or second introns, and even in protein coding sequences. [4] In addition to heterodimerizing with *MYC,* MAX can homodimerize or bind to a multitude of other BR-HLH-Zip proteins, including MAD, MAD 3, MAD 4, MXI, and MNT. [3] These complexes can compete with *MYC*-MAX heterodimers at the E-box sites and act as transcriptional repressors. This provides a complex network of regulation and allows for transcriptional activation or repression depending on the intracellular stoichiometry of the *MYC* binding partners.

The *MYC* family of proteins also binds with various other proteins through highly conserved motifs (Figure 5.2). In addition to MAX, *MYC* can form complexes through the BR-HLH-Zip domain with the transcription factors YY-1, AP-2, and MIZ-1. In general, the binding of *MYC* to these proteins leads to repression of transcription either by inhibiting the native transcriptional activation of the binding partners (YY-1 and MIZ-1) or by interfering with *MYC*-MAX transcriptional activation (AP-2). [4] The amino-terminus of *MYC* can combine with proteins including TRAP (transformation associated protein), the p107 tumor supressor, BIN-1, TBP (TATA-binding protein), and a-tubulin (see Figure 5.2). These interactions can regulate *MYC* function by different mechanisms and can occur in the presence of MAX. TRAP binding to the Mb II region appears to be required for *MYC*-mediated transformation. [43] The Rb family member p107 interacts with *MYC* at Mb I, and its binding inhibits the transactivation activity of *MYC*. [4] BIN 1 association with *MYC* occurs via the Mb I and Mb II domains. BIN 1 inhibits *MYC*-mediated transformation of primary rat embryo fibroblasts. [38] BIN 1 expression is frequently reduced or absent in various tumor cell lines (including half of lung cancer cell lines examined) and in some primary tumors. [38] Thus BIN 1 potentially functions as a tumor suppressor gene. These various protein interactions underscore the diverse functions of *MYC* and specifically its role as a transcriptional activator and repressor.

The Biology of the *MYC* Family of Genes

The *MYC* proteins are important regulators of cell proliferation. The regulation of *MYC* expression is crucial for normal cellular proliferation. Deregulated expression characterized by constitutive, inappropriate, or nonphysiologic expression is seen in a variety of tumor cells and primary tumors. [4,6] The majority of this type of expression occurs via gene amplification, increased mRNA expression, or chromosomal translocations. The *MYC* genes also play key roles in differentiation and apoptosis. [6,39] The expression of *MYC* is tightly regulated in normal tissues and is controlled at multiple levels by signal transduction pathways. [36] Several potential targets of *MYC* activation and repression have been identified. These include genes coding for enzymes regulating the production of essential molecules for DNA synthesis, proteins involved in RNA structure and metabolism, proteins involved in cell cycle control, and those with no known function. [4] *MYC* protein mediation of these downstream events by either direct or indirect mechanisms is presently under investigation. [40] Thus, the *MYC* family of genes is involved in many diverse biologic functions. The various roles of *MYC* and their relationship to the pathogenesis of human lung cancer have not yet been thoroughly investigated.

MYC Family mRNA Expression Studies in Developing and Adult Mouse and Human Tissues

The pattern of *MYC* family mRNA expression has been studied by Northern blot analyses and *in situ* hybridization in normal tissues of mice during fetal development through adulthood, in human embryos, and in nonneoplastic lung tissue. [41,42,43 and 44] *myc*, N-*myc*, and L-*myc* are expressed in murine tissues during development. By *in situ* hybridization, N-*myc* is expressed in both the embryonic ectoderm and extraembryonic ectoderm. As development proceeds, N-*myc* expression becomes more restricted and is abundantly expressed in the developing nervous system. [45] This includes expression in both the developing central nervous system and in the cranial and spinal ganglia of the developing peripheral nervous system. [45] N-*myc* is also expressed in the developing gut, kidney, and lung. Its expression is located in the luminal areas of the developing lung; these will later go on to form bronchioles. N-*myc* expression is low or undetectable in most adult tissues. [41] Thus N-*myc* may play a role in early differentiation as its level of expression decreases with development. Also expressed in early development during active cellular proliferation is *myc.* The levels of *myc* expression in general are much lower than of N-*myc.* It is expressed in the majority of tissues but during early development is predominately found in the extraembryonic tissues. *myc* expression is also found in the mesenchymal cells of the developing gut and lung, and in the developing liver. *myc* continues to be expressed in adult mice in various tissues including the lung. [33,37,38] The expression of L-*myc* in development is more limited than that of *myc* or N-*myc.* In early developing embryos, L-*myc* is expressed at high levels in the neuroectoderm of the brain and neural tube. [46] By day 12 of mouse development, L-*myc* is expressed at the highest levels in the CNS, nasal epithelium, metanephric kidney, and the developing lung. Newborn mice express high levels of L-*myc* in the brain, kidney, and lung. [46] Thus L-*myc* may also play a role in differentiation. From these studies, it also appears that L-*myc* is expressed in cells that express either c-*myc* or N-*myc,*

whereas this observation does not hold for the other *myc* gene family members.

In situ hybridization studies of human embryos studied three to ten weeks after conception showed abundant *MYC* mRNA expression in more than 20% of the cells of the lung.[47] *NMYC* and *LMYC* mRNA expression was not studied. The human adult nonneoplastic lung has also been studied in patients whose lung cancer has been resected. *In situ* hybridization showed detectable *MYC* mRNA expression in all samples of nonneoplastic cells studied. [48] The expression was most detectable in the basal cell layer of the bronchial epithelium, type II alveolar cells, and endothelial cells. *NMYC* and *LMYC* mRNA expression was not detected in the adult nonneoplastic tissues.

The studies of mRNA expression from the *MYC* family genes in the lungs of mice and humans show that *MYC* is expressed during fetal development and in the adult lung. The various family members may be important for different functions in developing and adult lung tissues.

Functional Studies of *MYC* Family Genes

The role of the *MYC* gene family in multistage carcinogenesis initially proposed by Land and colleagues was defined in a rat embryo fibroblast system. [49] Transfection of an activated *HRAS*1 gene into the rat embryo fibroblasts allowed the formation of cells with an altered cellular morphology or foci which formed colonies in soft agarose but did not form tumors in athymic nude mice. Established cancer cell lines will typically grow and form tumors in athymic nude mice. The cells transfected with the activated *H-RAS*1 and a *MYC* gene provided an establishment function in the rat embryo fibroblasts which allowed the cells to continue growing and form tumors in athymic nude mice.[31,50,51 and 52] *NMYC* and *LMYC* complement the *RAS* family in this assay as well. However, the transforming activity of *LMYC* is only 1% to 10% of that of *MYC*.[52,53] This appears to be due to amino acid differences in the transactivation domains of these two proteins. [54] The transforming ability of *NMYC* is also less than that of *MYC* but stronger than *LMYC*.[53] Further proof of the role of *MYC* in carcinogenesis has been obtained from studies performed in mice. Transgenic mice have been used to study the role of *MYC* in tumorigenesis and its effects on proliferation and differentiation. [55] Using tissue-specific promoters, high levels of *MYC* expression have been obtained in tissues such as the mammary gland, the lymphoid system, the liver, the pancreas, the heart, and the lens. Tumorigenesis was observed in the mammary gland, lymphoid system, liver, and pancreas, while hyperplasia was seen in the heart. The neoplastic phenotypes and the effects on differentiation and proliferation vary depending on the *MYC* family member used. For example, mice overexpressing L-*MYC* in the lens (using a A crystal promoter) show abnormalities in differentiation, while mice with *MYC* overexpression have abnormal lens cell proliferation. [56] The onset of tumor formation is accelerated in double transgenic mice containing cytoplasmic oncogenes, including *HRAS* and *PIM*1.[31,55] These studies confirm the oncogenic role of *MYC* family genes and have allowed further study into the role of the *MYC* family members in differentiation and proliferation. These studies have not specifically addressed *MYC* overexpression in the lung.

The role of the *MYC* family members in normal development has been studied using mice lacking the normal *MYC* family members. Mice deficient in all of the *MYC* family members have been generated using homologous recombination techniques. Mice homozygously deficient in *myc* die early in development, usually by day 10.5.[57] The homozygous mice show a generalized delay in development, with pathologic abnormalities including cardiac enlargement, pericardial effusion, and neural tube defects.[57] N-*myc* homozygously deficient mice die between day 10.5 and 12.5 of development.[45,58] The homozygous mice exhibit multiple developmental abnormalities, mostly in tissues where N-*myc* is normally expressed. The developing lungs from these mice demonstrate nonbranching of the trachea and bronchi with a hypoplastic epithelium. Similar findings of organ hypoplasia are seen in the developing of gut and genitourinary system, suggesting a role for N-*myc* in regulating cellular proliferation. In marked contrast, mice deficient in L-*myc* develop normally into adulthood and have no detectable phenotypic consequences. [46] It is possible that one of the other family members compensates for the lack of L-*myc.* As mentioned above, L-*myc* is often coexpressed with either N-*myc* or c-*myc,* whereas this is not the case for the other two family members.

These studies demonstrate that genes of the *MYC* family share some similar functions but that they also have unique roles in normal development.

***MYC* Family DNA Structural Abnormalities in Lung Cancer**

DNA Amplification

A rodent cell line selected *in vitro* for resistance to methotrexate developed gene amplification of dihydrofolate reductase, the target enzyme for methotrexate. [59,60] This increased the amount of dihydrofolate reductase enzymatic activity and allowed the cells to escape the growth inhibition caused by methotrexate. The amplified gene encoding dihydrofolate reductase localized to homogeneously staining regions and double minute chromosomes. This association of gene amplification with double minute chromosomes and homogenous staining region led to the discovery of oncogene amplification in human cancers. The initial discovery of *MYC* DNA amplification in human cancer was initially identified in a leukemia cell line which had double minute chromosomes, HL-60, and a colon cancer cell line (COLO 320) which had both homogeneously staining regions and double minute chromosomes. [61,62] A radiolabeled fragment of the chicken *MYC* gene DNA hybridized intensely to the DNA from the HL-60 cell line and a radiolabeled fragment of v-*myc* hybridized to the DNA from COLO 320, representing DNA amplification. *In situ* hybridization studies of metaphase spreads from COLO 320 showed a radiolabeled *MYC* fragment hybridized to the homogeneously staining region on the X chromosome. Therefore *MYC* DNA amplification and high levels of expression were present in these human cancer cell lines and localized to a marker associated with gene amplification, a homogeneously staining region in a different location (the X chromosome) from the normal locus on chromosome 8q24.

Double minute chromosomes and homogeneously staining regions had been identified by karyotypic analyses of small cell lung cancer (SCLC) cell lines. [63,64] The screening of these cell lines with DNA fragments from oncogenes and protooncogenes identified DNA amplification of the *MYC* gene in a subset of SCLC cell lines.[65,66] Amplification of all three members of the *MYC* family has been identified in lung cancer cell lines. [24,65,67] These cell lines with amplified *MYC* family DNA contain 4 to 135 copies of the *MYC* family genes.[68,69,70 and 71] The size of the DNA segment amplified in the SCLC cell line NCI-N417 has been estimated at 120 and 130 bases of DNA and NCI-H82 at 300 bases.[71,72] The amplified *MYC* DNA in this SCLC cell line, NCI-N417, has been localized to a homogeneously staining region on chromosome 1.[71] Therefore, in both COLO 320 and NCI-N417 the amplified *MYC* gene is localized to chromosomal loci different from its location in normal cells.

DNA Rearrangement

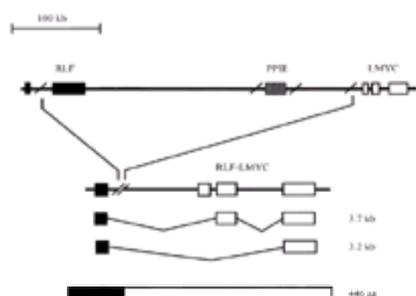
Additional signals have been detected in lung cancer cell lines that have *MYC* family DNA amplification which represent rearrangements of the DNA.[24,67] Rearrangements of the *LMYC* gene in SCLC with *LMYC* DNA amplification have been extensively investigated. The initial studies involved immunoprecipitation of the *LMYC* protein in two SCLC cell lines which showed proteins of 72 to 77 kD, 10 kD larger than expected for *LMYC* proteins from other lung cancer cell lines. [58] Subsequent investigations of the DNA and mRNA from SCLC cell lines with *LMYC* DNA amplification identified a gene RLF, which stands for Rearranged L-*myc* Fusion.[73,74] The RLF gene is approximately 500 bases 5' from the LMYC gene on chromosome 1p32 (Figure 5.3). The RLF/L-*MYC* locus undergoes an intrachromosomal rearrangement and RLF is brought into proximity to the L-*MYC* gene in some SCLCs with L-*MYC* DNA amplification.[73] The mechanism involved in the generation of this fusion transcript is complex and can occur at different breakpoints sites 5' of *LMYC*.[73] These breakpoints appear to cluster in regions containing highly repetitive DNA sequences.[75]


FIGURE 5.3. Chromosomal rearrangement of *RLF* and *L-MYC:* The bracket at the top represents distance covered by 100 kbases of DNA on the uppermost diagram, representing the normal configuration of the *RLF* gene and the *LMYC* gene. The black boxes represent the hypothetical exons of the *RLF* gene, but the exon-intron structure beyond the first exon and intron have not yet been reported. The open boxes represent the three exons of the L-*MYC* gene. The PPIE is located in between

RLF and *L-MYC:* its exact position is not known. (From Kim JO, Nau MM, Allikian KA, et al. Co-amplification of a novel cyclophilin-like gene [PPIE] with L-*myc* in small cell lung cancer cell lines. *Oncogene* 1998;17:1019, with permission). The diagonal lines connecting the exons represent the mRNA splicing which brings the exons together. Kb represents kilobases, and aa represents amino acids. (From Vastrik I, Makela TP, Keskinen PJ, et al. *myc, max,* and a novel *rlt-*L-*myc* fusion protein in small-cell lung cancer. In: Harris CC, ed. *Multistage Carcinogenesis.* Boca Raton: CRC Press, 1992:307, with permission.)

The mRNA studies show that the first exon of the RLF gene is spliced to the second or third exon of the *LMYC* gene, giving rise to novel mRNAs of 3.7 and 3.2 bases (Figure 5.3).[58,60] The 3.7 base mRNA gives rise to a protein with 466 amino acids—79 from RLF exon 1, 3 from previously untranslated sequences in exon 2, and 364 amino acids from the *LMYC* coding sequences. These rearrangements give rise to the fusion proteins which have only been observed in SCLC cell lines and tumors and which have DNA amplification of *LMYC.* These rearrangements have not been observed in 99 cell lung cancer (NSCLC) tumors studied.[74] The fusion protein formed by RLF and *LMYC* appears to take place in a subset of SCLC cell lines with *LMYC* DNA amplification and therefore is present in less than 10% of the SCLC cell lines studied.

The normal RLF gene encodes for a 1914 amino acid protein containing six zinc finger motifs and a leucine zipper.[76] Thus its function appears to be that of a transcription factor, and the spacing of the zinc fingers suggests that it is related to the transcription factor Zn-15. Zn-15 is a transcription factor involved in the transcriptional activation of the growth hormone gene. However, there are large regions without homology between these two proteins. RLF expression has been analyzed by Northern and RNAse protection analyses. It is widely expressed in human fetal and adult tissues, including the fetal lung but not in the adult lung.[76] The RLF-*LMYC* fusion product contains only the first 79 amino acids of the normal RLF gene, and this does not include the zinc finger motifs. In a transformation assay of primary rat embryo fibroblasts, the RLF-L-*MYC* fusion protein had a similar transforming capacity as the normal L-*MYC* gene.[76] Attempts to create transgenic mice using this fusion gene (under the normal RLF promoter) failed to create mice expressing the chimeric transcript.[77] When this construct was introduced into embryonic stem (ES) cells, the cells failed to develop into proper embryoid bodies. Taken together, these experiments suggest that the deregulation of the normal L-*MYC* expression brought about by the RLF promoter is critical to the phenotypic findings and not a novel function associated with the RFL/*LMYC* fusion product. The significance of this for SCLC is unknown. The phenotype of SCLC cells lines with *LMYC* amplification compared with those additionally containing the RLF-*LMYC* fusion appears to be similar with respect to doubling times, cloning efficiency in soft agar, and *in vitro* and *in vivo* morphology.[65,78]

A second rearrangement product from the same locus has also been identified. This involves a novel cyclophilin-like gene named PPIE (pedtidyl-prolyl *cis-trans* isomerase E) and shows 83% amino acid identity with the central conserved region of cyclophilin A.[78] In a subset of SCLC cell lines that have *LMYC* amplification, 64% (7 of 11 cell lines) showed amplification of PPIE, whereas RLF amplification was seen in 36% (4 of 11) of the cell lines. Consistent with the higher rate of PPIE amplification, it appears that the PPIE gene lies in between RLF and *LMYC* on chromosome 1. One of amplified cell lines, NCI-H378, shows a PPIE fusion product with exon 2 of *LMYC* in the antisense orientation.[78] The function of this chimeric transcript (if any) is not know and to date has not been identified in primary lung cancers.

Other rearrangements of the *MYC* family genes have been in SCLC cell lines[24,65,67,79,80,81 and 82] and tumors[24,83,84 and 85] as well as NSCLC tumors.[84,85,86 and 87] The rearrangements can appear or disappear after the cells are placed in culture.[82,83] Several of the cell lines with rearrangements of the *MYC* family genes give rise to a different-sized mRNA.[24,65] Most rearrangements of the *MYC* gene family take place with gene amplification and are present in both the lung cancer cell line and the lung cancer from which it arises, although there are examples where the rearrangement takes place in cell culture or in xenografts. These rearrangements can bring a novel segment of DNA near the *MYC* family locus, but relatively few of these rearrangements have been well characterized.

MYC DNA Amplification and Phenotype of Small Cell Lung Cancer Cell Lines

Some experimental evidence shows that increased amounts of *MYC* gene product are associated with increased growth in multiple tumor systems.[1,29] There is less evidence that increased amounts of *NMYC* and *LMYC* gene product are associated with growth.[1,29]

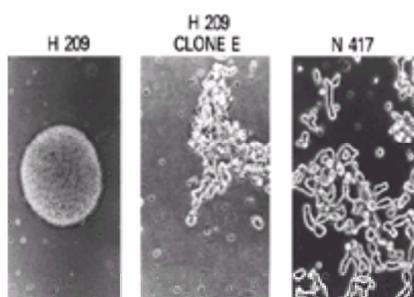
The definition of classic and variant subclasses of SCLC cell lines was proposed in 1985 using biochemical, morphologic, and growth properties.[69,88] The majority of cell lines (classic subclass) grew as tightly packed floating aggregates in cell culture media (NCI-H209 Figure 5.4) and formed intermediate histology when injected into athymic nude mice.[86] They grew with long doubling times and low colony-forming efficiencies in soft agarose. The classic SCLC cell lines had markers of neuroendocrine differentiation. The cell lines had enzymatic L-dopa decarboxylase activity (an enzyme in the pathway to form dopaminergic amines), bombesinlike immunoreactivity, neuron-specific enolase, and the brain isoenzyme of creatine kinase.


FIGURE 5.4. Cellular morphology of small cell lung cancer cell lines and a transfected clone: Small cell lung cancer cell lines NCI-H209 and NCI-H209 transfected with six copies of the normal *MYC* gene, and NCI-N417 growing in log phase. The cells have been photographed using a phase contrast Nikon photomicroscope (100 × magnification). (From Johnson BE, Battey JF, Linnoila I, et al. Changes in the phenotype of human small cell lung cancer cell lines after transfection and expression of the c-*myc. J Clin Invest* 1986;78:525 by copyright permission of the Society of Clinical Investigation.)

In contrast, the variant cell lines grew as loosely attached floating aggregates (Figure 5.4; NCI-N417) and formed small cell/large cell morphology when injected into athymic nude mice.[86] The variant cell lines had shorter doubling times and higher cloning efficiencies in soft agarose than classic cell lines. The variant SCLC cell lines retained the brain isozyme of creatine kinase but had lower concentrations of neuron-specific enolase and L-dopa decarboxylase.

The original description of *MYC* family DNA amplification in lung cancer cell lines showed the five SCLC cell lines with greater than 20-fold *MYC* DNA amplification were all in the variant subclass of SCLC cell lines.[65] Subsequent studies showed that amplification of the *MYC* gene was associated with the shorter doubling times and higher cloning efficiencies in soft agarose.[69] The variant cell lines NCI-N417 and NCI-H82 were also found to be relatively resistant to low doses of radiation, NCI-H146 had intermediate sensitivity, and NCI-H249, NCI-H187, NCI-H209, and NCI-H69 were all sensitive to low doses of radiation.[90] NCI-N417 and NCI-H82 had greater than 20-fold *MYC* family DNA amplification, NCI-H146 did not have DNA amplification but did have abundant expression of the *MYC* gene, and NCI-H249, NCI-H187, and NCI-H209 did not have detectable *MYC* expression.

Other authors have commented on the association with the variant phenotype and *MYC* family amplification and expression. H22, H24, H86, GLC16, GLC 19, and SCLC-SK2 have high degrees of *MYC* DNA amplification but do not have a variant phenotype.[70,81,91] Although it appears that there is a link between *MYC* DNA amplification and the variant phenotype, numerous convincing examples of classic phenotype with *MYC* DNA amplification have been published.[70,81,91] In addition, cell lines with variant characteristics have been reported with *NMYC*[24] DNA amplification and *LMYC* DNA amplification.[81] We await additional information about additional potential etiologies for the variant phenotype in other cell lines.

Further support for the *MYC* gene playing a role in the increased growth of SCLC cells came from transfection studies. The normal human *MYC* gene with its own

promoter, 5 kbases of upstream regulatory sequences, and a selectable marker were transfected into a tumor cell line (NCI-H209) which did not express detectable *MYC* mRNA.[15] One to six copies of the gene were introduced into a clone of NCI-H209 and different amounts of the mature form of *MYC* mRNA were expressed in the transfected clones (Figure 5.4). The amounts of *MYC* mRNA expressed in clones A to C and E were similar to the amount expressed in NCI-H146, the cell line which did not have *MYC* DNA amplification but did express abundant *MYC* mRNA. There was no detectable *MYC* mRNA in clone D because the third exon of the *MYC* gene was deleted. The amount of *MYC* mRNA in all the clones was less than the amount expressed by the cell line with *MYC* DNA amplification, NCI-N417.

The clone with the most abundant expression of *MYC* mRNA (clone E) used the first promoter (P1) in preference to P2, similar to Burkitt lymphoma cell lines which have a *MYC* gene translocated into the immunoglobin locus.[12] Therefore, in both these system where the *MYC* gene is placed into an altered location in the genome by transfection or translocation in Burkitt's lymphoma, the promoter utilization is changed.

The morphology of the original clone, NCI-H209, formed the typical tightly packed floating aggregates typical of a classic subclass cell line while NCI-N417 formed loosely attached floating aggregates typical of a variant cell line (Figure 5.4). The *MYC*-transfected clone E of NCI-H209 changed to loosely attached floating aggregates and formed small cell/large cell morphology when injected into athymic nude mice. The NCI-H209 clone E cells had a shorter doubling time and greater cloning efficiency but no difference in L-dopa decarboxylase enzymatic activity and bombesinlike immunoreactivity than the original clone. Therefore *MYC* transfection with increased gene expression is associated with a change in morphology and increased growth characteristics but not detectable change in biochemical characteristics. We were unable to examine these transfected clones for changes in the sensitivity to radiation because of the low cloning efficiency in soft agarose of the original clone, NCI-H209.

Retinoic acid studies have also provided evidence for the *MYC* gene playing a role in the increased growth of rate of SCLC cells.[92,94] The variant cell lines NCI-H82 and NCI-H417 have *MYC* DNA amplification and high levels of *MYC* mRNA expression. The addition of retinoic acid dramatically reduces *MYC* mRNA expression, which is associated with development of typical features of classic SCLC cells. In addition, NCI-H82 and NCI-H417 have a reduction in the growth rate of the cells and cloning efficiency in soft agarose and development of a classic morphology in cell culture after addition of retinoic acid.[92,94] However, retinoic acid treatment of these cell lines did not result in an increase in L-dopa decarboxylase activity, a feature of classic SCLC lines.[92] L-*MYC* expression increased dramatically in NCI-H82 cells treated with retinoic acid.[94] The mechanism by which retinoic acid induces *LMYC* expression is by an increase in *LMYC* transcriptional initiation.[95] This can be observed at a retinoic acid concentration of 1 μm; a concentration that is easily achievable in the plasma of patients undergoing treatment with retinoic acid. The mechanism by which the addition of retinoic acid leads to an increase in *LMYC* transcriptional initiation is presently undefined. The mechanism of *MYC* down-regulation appears to involve an increase in transcript attenuation at the exon 1 intron 1 boundary.[95] Transcript attenuation is a transcriptional regulatory mechanism reducing the elongation of mRNA molecules at the exon 1/intron 1 boundary of the *MYC* gene.[96] Thus these experiments demonstrate that the addition of retinoic acid to NCI-H82 SCLC cell lines leads them to assume a classic SCLC cell morphology and decreases their growth rate and cloning efficiency, which are accompanied by an increase in *LMYC* and a decrease in *MYC* gene expression.

The findings from these cell culture studies have been applied to a clinical study. A phase II clinical trial incorporated retinoic acid (all- *trans*-retinoic acid) with cisplatin and etoposide for previously untreated patients with extensive stage small cell lung carcinoma.[97] Retinoic acid was given at 150 mg per m^2 and was begun on day 1 of treatment and continued for one year. Of the 22 evaluable patients, 59% discontinued retinoic acid due to toxicity. These included mucocutaneous reactions, headaches, anorexia, fatigue, nausea/emesis, myalgias, and confusion.[97] The overall response rate was 45%, with a median survival of 10.9 months. Presently the combination of retinoic acid with combination chemotherapy is not effective enough and too toxic for routine use. Newer synthetic retinoids which have less toxicity and are more potent inhibitors of SCLC cell growth in culture than retinoic acid are presently being evaluated.[98]

MYC FAMILY AMPLIFICATION, mRNA EXPRESSION, AND PROTEIN STUDIES IN HUMAN LUNG CANCER

The *MYC* family genes have been studied in a large number of tumor cell lines and tumors. Table 5.1, Table 5.2, Table 5.3, Table 5.4 and Table 5.5 list the studies done of lung cancer cell lines and lung cancers. If a lung cancer or lung cancer cell line is reported in more than one publication, the cell line in the table is listed with the article in which it first appeared and is not included when studied in subsequent publications.

TABLE 5.5. MYC FAMILY DNA AMPLIFICATION AND EXPRESSION IN TUMORS FROM PATIENTS WITH NON—SMALL CELL LUNG CANCER

MYC Family DNA Amplification and Expression in Small Cell Lung Cancer Cell Lines

MYC family DNA amplification and expression have been studied in 185 and 73 SCLC cell lines and xenografts respectively. Approximately 40% of tumor cell lines established from patients with SCLC have *MYC* family DNA amplification (Table 5.1). *MYC* and *LMYC* DNA amplification are present in 15% and 18% respectively of the tumor cell lines, while N-*MYC* is present in 7%. Three cell lines have been described that have amplification of more than one member of the *MYC* family of genes. These include Lu-135 (*MYC* and *LMYC*), DMS-273 (*MYC* and *LMYC*), and NCI-H2552 (*LMYC* and *NMYC*).[80,99,100]

Four different reports describe *MYC* family DNA amplification in 16 tumor cell lines established from seven patients with SCLC at different times during their clinical course.[70,81,91,99] In three of these studies, the *MYC* family DNA amplification status appears to be consistent in five of the patients.[70,81,99] In the tumor cell lines established from the individual patients, the same *MYC* family gene was amplified in each series of cell lines. *MYC* was amplified in five cell lines from two patients, LMYC in four cell lines from two patients, and none in four cell lines from two patients. An exception to this observation has been reported.[91] Hole and colleagues have described a series of three cell lines established from a single patient with SCLC at presentation, at recurrence after nine cycles of chemotherapy, and after a subsequent course of radiotherapy. The tumor cell lines established prior to the initiation of treatment had *NMYC* DNA amplification, while the two cell lines established after the patients recurred had *MYC* DNA amplification. This is the single example where tumor cell lines established from the same patient at different times during treatment course had a different *MYC* family gene amplified.

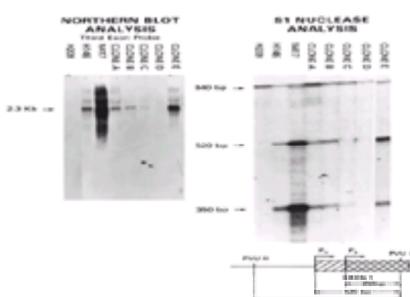
MYC family mRNA expression in SCLC cell lines have been studied by Northern blot analyses, nuclear run-off studies, S1 nuclease analyses, and *in situ* hybridization.[12,15,25,10] An S1 nuclease analysis (Figure 5.5) using an antisense *MYC* probe encompassing the first exon showed that the SCLC cell lines NCI-H82, NCI-H146, and NCI-N417 use both promoters (P1 and P2) within the first exon.[15,101] The second promoter is preferentially used, as has been typical of normal cells.[12,101] *In situ* hybridization of the cytospins and xenografts of SCLC cell lines with DNA amplification of *MYC* (NCI-N417, NCI-H82), *NMYC* (NCI-H526), and L-*MYC* (NCI-H378) showed cell lines which had easily detectable *MYC* family mRNA expression.[102] *MYC* family mRNA expression is detected more commonly than *MYC* family DNA amplification in SCLC cell lines and xenografts. *MYC* mRNA expression is present in approximately half, and *NMYC* and *LMYC* mRNA expression is present in 26% and 39% respectively (Table 5.2). Multiple cell lines have been described that have detectable mRNA expression of more than one *MYC* family member.[99] The mRNA expression of the *MYC* family genes is two to four times as common as DNA amplification of the genes. Therefore SCLC cell lines and xenografts commonly have increased mRNA expression of the *MYC* family genes without evidence of DNA amplification.


FIGURE 5.5. Northern blot and S1 nuclease analysis of small cell lung cancer cell lines and transfected clones: Cells grown from a clone of NCL-H209 were transfected with the normal human *MYC* gene with a selectable marker, individual clones were grown, and RNA was isolated. Northern blots were prepared and S1 nuclease analyses done as described in reference 15. NCI-H209, NCI-H146, and NCI-N417 represent SCLC cell lines, and clones A to E represent different clones transfected with the human *MYC* gene. Clones A to C have one intact *MYC* gene, clone D has deleted the *MYC* gene, and clone E has six copies of the *MYC* gene. The Northern blot was hybridized with a Cla-Eco R1 third exon fragment of the human *MYC* gene, and the signal at 2.3 kilobases (Kb) represents the mRNA. The S1 nuclease analysis shows a first exon probe hybridized to the mRNA, and the single strands of mRNA and antisense probe are digested away with S1 nuclease. The signal at 840 base pairs (bp) represents undigested probe, the signal at 520 bp represents the mRNA initiated at the first promoter, and the signal at 350 base pairs represents the mRNA initiated at the second promoter. (From Johnson BE, Battey JF, Linnoila I, et al. Changes in the phenotype of human small cell lung cancer cell lines after transfection and expression of the c-*myc*. *J Clin Invest* 1986;78:525, by copyright permission of the Society of Clinical Investigation.)

The regulation of *MYC* family mRNA expression has been studied in a subset of SCLC cell lines.[101,103] The DNase I sensitivity patterns and methylation patterns of the *MYC* gene in the SCLC cell lines NCI-H82 and NCI-H378 have been investigated. Chromosomal regions undergoing active transcription tend to be sensitive to DNase I treatment and are hypomethylated in the CpG (cytosine-guainine) dinucleotides, while chromosomal regions that are quiescent are not sensitive to DNase treatment and are hypermethylated. NCI-H82 has 40 to 50-fold *MYC* DNA amplification and abundant expression, while NCI-H378 has a single copy of the *MYC* gene

and undetectable mRNA expression. The DNase hypersensitivity sites were identical in the two cell lines, and the hypomethylation and partial methylation patterns in the *MYC* gene locus were very similar. Therefore these structural chromatin patterns did not appear to be the mechanism of altered *MYC* gene expression.

In addition to an increase in *MYC* family mRNA expression caused by amplification, attenuation of mRNA expression takes place within the first intron in *MYC* and *LMYC,* which reduces the amount of steady-state mature mRNA.[103] Attenuation blocks the transcription of a gene after it is initiated. This attenuation takes place in tumor cell lines which do and do not have amplification of the same *MYC* family gene. The loss of this attenuation in intron 1 of the *MYC* gene (NCI-H146) and *LMYC* (NCI-H432) is associated with increased mRNA expression of these genes. Increased expression of *NMYC* is associated with increased promoter function and gene amplification.

Antisense mRNA expression of the *NMYC* gene has been shown to play a potential role in the regulation of the *NMYC* gene.[25] Antisense mRNA expression refers to the transcription of the DNA strand complimentary to the strand coding for the *NMYC* gene product. Antisense *NMYC* mRNA initiates within the first intron and transcribes through the first exon in NCI-H249. Most of this antisense *NMYC* mRNA exists as a complex with the first exon and intron of sense *NMYC* mRNA, suggesting that this duplex could control mRNA processing and thereby regulate the production of the *NMYC* gene product.

Eleven tumor cell lines from nine patients have been studied for their mechanisms of increased *MYC* family mRNA expression in the absence of DNA amplification. The mechanism for increased *MYC* family mRNA expression in the absence of amplification has not been established in the vast majority of tumor cell lines. However, mechanisms that increase *MYC* family mRNA expression other than gene amplification are likely to be important because the majority of lung cancers and lung cancer tumor cell lines with *MYC* family mRNA expression do not have *MYC* family DNA amplification of the corresponding gene.

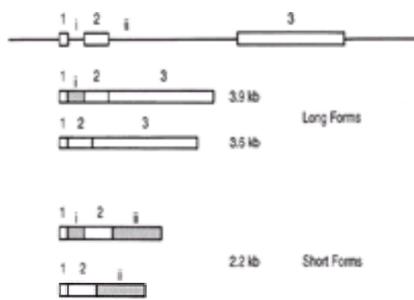
Variability in processing of mRNA can also give rise multiple forms of the mRNA, leading to altered protein products in SCLC (Figure 5.6).[30] The *LMYC* gene can give rise to two different long forms of mature mRNA, which can either retain the first intron sequences (3.9 kbase mRNA) or process them out (3.6 kbase mRNA). The presence or absence of the first intron *LMYC* sequences has been demonstrated in mRNA extracted from normal human testis as well.[104] This shows alternative *LMYC* mRNA processing can take place in both normal tissue as well as tumor tissue.


FIGURE 5.6. mRNA processing of the *LMYC* gene: The upper diagram depicts the genomic structure of L-*MYC.* The open boxes represent the three exons and the two lines between the boxes are the two introns. The four boxes below the genomic structure represent the portions of the introns and exons included in the mRNAs in both the long and short forms of mRNA. (From Kaye F, Battey J, Nau M, et al. Structure and expression of the human L-*myc* gene reveal a complex pattern of alternative mRNA processing. *Mol Cell Biol* 1988;8:186, with permission.)

The *LMYC* gene can also give rise to two different short forms of mature mRNA when the RNA polymerase continues reading into the second intron and uses one of several potential polyadenylation signals to terminate transcription in the second intron. These short forms can either retain the first intron or process it out (2.2 kbase mRNA). These four different forms are present in two different SCLC cell lines. The predicted amino acid sequence of these short forms will be different because they do not contain the protein coding sequences contained in the absent third exon. Antibodies generated by immunizing rabbits detected only proteins predicted to be translated from the long forms of mRNA.[32] In contrast, antibodies directed against homologous sequences present in all three *MYC* genes identified proteins the size predicted from the short forms of mRNA as well as the long forms.[33] The presence of proteins translated from the short forms of mRNA remains unresolved and their potential role remains undefined.

MYC FAMILY DNA AMPLIFICATION AND EXPRESSION IN SMALL CELL LUNG CANCER TUMORS

MYC family DNA amplification and expression have been studied in 219 and 40 tumors respectively from patients with SCLC (Table 5.3). Approximately 22% of the tumors from patients with SCLC have *MYC* family DNA amplification. *MYC* family DNA amplification is less common in tumors than in tumor cell lines and xenografts. *MYC* DNA amplification is about one third as common in tumors as in tumor cell lines (5% versus 15%), *NMYC* DNA is similar (8% in both), *LMYC* DNA amplification is two thirds as common in the tumors as in the tumor cell lines (12% versus 18%). No tumor from a SCLC patient has DNA amplification of more than one *MYC* family gene.

Two studies showed that the *MYC* family DNA copy number was similar in multiple sites of metastatic disease from 26 different patients with SCLC. [68],[81] Wong and associates reported on four patients where all ten metastatic lesions had amplified copies of the *MYC* family genes two patients with *MYC* and two with N-*MYC* DNA amplification).[68] In addition, 17 patients' original tumors did not have *MYC* family DNA amplification, nor did their 41 metastatic lesions. Takahashi and co-workers reported on five SCLC patients' 11 simultaneous tumor samples. [81] One patient's tumor samples had *MYC,* one had *LMYC,* and three had no *MYC* family DNA amplification. In addition, one patient with SCLC had *MYC* DNA amplification in the tumor before treatment and at postmortem examination.

In contrast, two other reports have described different *MYC* family DNA copy numbers in different sites from the same SCLC patient. Yokota and colleagues reported on a patient with SCLC where they studied the primary tumor and four different sites of metastases. [80] The primary tumor, pulmonary hilar lymph node, and pleural metastasis all had about 100-fold amplification of *NMYC,* while a liver metastasis and para-aortic lymph node did not have *NMYC* DNA amplification. Noguchi and co-workers were able to study tumors from 47 patients with SCLC.[105] Eleven patients had *MYC* family DNA amplification in their primary tumor. Nine of the 11 had similar degrees of *MYC* family DNA amplification in the metastatic sites as in the primary tumor site. One of the other two patients had *NMYC* DNA amplification in part of the primary tumor and three metastatic sites, while a different part of the primary tumor and three metastatic sites did not have *NMYC* DNA amplification. The other patient had *LMYC* DNA amplification in metastatic lymph nodes present at postmortem examination but not present in the primary lesion which had been resected prior to the patient death. No investigators found DNA amplification of multiple members of the *MYC* family DNA in the same sample.

MYC family mRNA expression is detected more commonly than *MYC* family DNA amplification in tumors obtained from patients with SCLC (Table 5.3). *MYC* and *LMYC* mRNA expression is present in approximately one fourth to one third respectively, and N-*MYC* mRNA expression is detectable in only a single tumor. The mRNA expression of the *MYC* and *LMYC* is three to four times as common as DNA amplification of the genes, while *NMYC* expression is less common. Therefore SCLC cell lines and xenografts commonly have increased mRNA expression of the *MYC* family genes without evidence of DNA amplification. The incidence of *MYC* family DNA amplification and mRNA expression is less common in the tumor than in the tumor cell lines.

MYC Family DNA Amplification in Tumors, Tumor Cell Lines, and Xenografts from the Same Patient with Small Cell Lung Cancer

The *MYC* family copy number is nearly always similar in the tumors and the tumor cell lines plus the athymic nude mouse xenografts established from tumors obtained from patients with SCLC. One report showed that the *MYC* family DNA copy number was similar in tumors and tumor cell lines from 16 patients with SCLC.[106] Figure 5.7 shows examples of *NMYC* DNA amplification in tumors and tumor cell lines from the same individuals but having a single copy in the normal tissue. The intense signals in NCI-H720, the tumor from patient 1, NCI-H526 and the tumor from patient 2, NCI-H526 and the tumor from patient 2, NCI-H689 and the tumor from patient 3, and the tumor from patient 4 show *NMYC* DNA amplification. The normal tissues from all these patients show a less intense 1.9 base signal, representing a single copy of the gene, which shows that the amplification takes place only in the cancer and not in the patients' normal tissue. The single exception was in a patient where

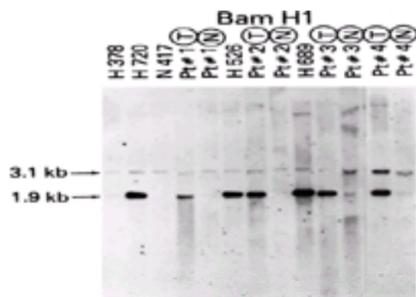
the tumor DNA had degraded so the DNA copy number of the tumor could not be accurately determined.


FIGURE 5.7. N-*MYC* DNA amplification in patients' tumors and tumor cell lines: Southern blot of 10 micrograms of DNA digested with the Bam H1 restriction endonuclease from SCLC tumors, normal tissues, and tumor cell lines hybridized to N-*MYC* exon 2 fragment. The tumor for each patient is designated T and the normal tissue is designated N. SCLC cell line NCI-H526 was derived from a tumor from patient number 2, and NCI-H689 was derived from a tumor from patient number 3. The signals that appear at 1.9 kb represent the signal from the fragment N-*MYC*. The signal at 3.1 kilobases represents gastrin-releasing peptide gene, present in a single copy. (From Johnson BE, Makuch RW, Simmons AD, et al. *myc* family DNA amplification in small cell lung cancer patients' tumors and corresponding cell lines. *Cancer Res* 1988;48:5163, with permission.)

Yokota and associates reported that the cell line Lu-135 was amplified for both *MYC* and *LMYC*.[80] The tumor from which Lu-135 was established had *LMYC* DNA amplification but did not have *MYC* DNA amplification. Dr. Yokota also reported on a second tumor cell line, Lu-139, which had *MYC* DNA amplification while the original tumor did not. Takahashi and colleagues reported on two patients with SCLC who had both their tumors and tumor cell lines studied. [81] One had *MYC* DNA amplification in two tumor samples as well as two tumor cell lines established from these tumor specimens. The other patient with SCLC did not have *MYC* family DNA amplification in either the two tumor cell lines or the tumors. Kok and colleagues reported on the *MYC* family DNA amplification status of a tumor and tumor cell line established from the same patient prior to starting his therapy. [91] The supraclavicular lymph node and the tumor cell line established from it, GLC-14, had *MYC* DNA amplification. In contrast, the tumor cell lines established from tumors after treatment, GLC-16 and GLC-19, had *MYC* DNA amplification and the tumors were not available for study.

The *MYC* family DNA copy number was also examined in tumors and xenografts from 13 patients with SCLC. Four of the 13 patients with SCLC had *MYC* family DNA amplification (two *MYC*, one N-*MYC*, and one L-*MYC*) in both their tumors and xenografts. Two patients had *MYC* DNA amplification in their xenografts but not in the primary cancer. All primary cancers and xenografts which had *MYC* family DNA amplification had abundant expression of that *MYC* family gene.[93]

There is evidence that *MYC* DNA amplification occurs more commonly in tumor cell lines and xenografts than in tumors (Table 5.3 and Table 5.4). This is likely to be caused by a combination of *MYC* gene amplification which takes after cells are placed in culture [80] or in xenografts,[83,85] and the tumor cell lines are more likely to grow if they have *MYC* DNA amplification. These two reasons likely explain the more than three fold higher incidence of *MYC* family DNA amplification in tumor cell lines and xenografts (15%) than in the tumors taken directly from patients (4%). The incidence of *NMYC* and *LMYC* DNA amplification in tumors, tumor cell lines, and xenografts is similar.

MYC Family DNA Amplification in Tumors from Patients with Small Cell Lung Cancer: Clinical Status and Course

MYC family DNA amplification and expression in tumors and tumor cell lines from patients with SCLC have also been associated with chemotherapy treatment and shortened survival. [105,106 and 107] However, all three studies are retrospective, and two studied the tumors or tumor cell lines obtained after the patients died [105] or had relapsed after initial treatment. [106]

Brennan reported on *MYC* family DNA amplification in tumors and tumor cell lines obtained from patients either before or after chemotherapy treatment. [106] *MYC* family DNA amplification was detected in 19 out of 67 (28%) of the specimens (35 tumor cell lines and 32 tumors) from patients previously treated with chemotherapy. Seven specimens from previously treated patients had *MYC*, seven had *NMYC*, and five had *LMYC* DNA amplification. This was significantly more than the incidence of *MYC* family DNA amplification detect in the specimens obtained from patients prior to the initiation of treatment (3 of 40; p=0.01) where one had N-*MYC* and two had L-*MYC* DNA amplification. Other authors have not directly analyzed the effect of chemotherapy treatment on the incidence of *MYC* family DNA amplification, so information from other groups is not available (Table 5.1).

Noguchi and his colleagues obtained tumor samples from 47 patients with SCLC who underwent postmortem examination. [105] Dot blot hybridization of the DNA extracted from paraffin-embedded tissue was used to determine the DNA copy number of the *MYC* family genes. One patient had *MYC*, five patients had *NMYC*, and five had *LMYC* DNA amplification in their tumor sample. If the five patients whose tumor had *MYC* family DNA amplification of ten or less (two with *NMYC* and three with *LMYC*) were removed from the analysis, the patients with *MYC* family DNA amplification of ten copies or greater lived a shorter time than patients without *MYC* family DNA amplification (p=0.06). This study's shortcomings include that the studies were done on the tumors from patients with SCLC after they had died of their cancer, they were done after the patients had been treated with chemotherapy, and their data were extensively analyzed before arriving at a survival difference.

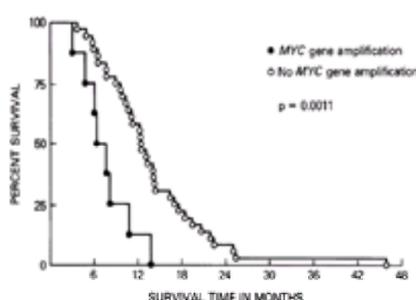
The other study evaluated 69 tumor cell lines established from patients with SCLC, [106] with a recent update including additional 27 cell lines. [100] Fifty-two were established from patients who had not been previously treated with chemotherapy, while 44 were established from patients previously treated with chemotherapy. The survival of the patients who had tumor cell lines established prior to the start of chemotherapy was much shorter than patients whose tumor cell lines were established after the start of therapy, so the two groups were analyzed separately. Eight of the 44 tumor cell lines established from patients previously treated with chemotherapy had *MYC* DNA amplification. The patients whose tumor cell lines had *MYC* DNA amplification lived a shorter time (median of 25 weeks) than the patients whose tumor cell lines did not (median of 54 weeks) Figure 5.8. There was no association between *NMYC* or *LMYC* DNA amplification in the patients' tumor cell lines and patient outcome. However, this study's shortcomings include that the studies were done on tumor cell lines instead of the tumors from patients with small cell lung cancer, they were done on a small subset of the entire patient group (44 out of 306), and they were done after the patients had been treated with chemotherapy.


FIGURE 5.8. Survival from the initiation of chemotherapy of small cell lung cancer patients whose cell lines established at relapse had *MYC* DNA amplification compared with patients whose cell lines did not. Patients whose cell lines had DNA amplification of *MYC* lived a shorter time compared to those patients without *MYC* amplification (p = 0.0011). (From Johnson BE, Russell E, Simmons AM, et al. MYC family DNA amplification in 126 tumor cell lines from patients with small cell lung cancer. *J Cell Biochem Suppl* 1996;24:210, with permission.)

A single small study has examined *MYC* family mRNA expression and patient outcome.[107] Fifteen patients with SCLC who underwent mediastinal biopsies were selected. The seven patients whose formalin-fixed, paraffin-embedded mediastinal biopsies had abundant expression of *NMYC* mRNA by *in situ* hybridization were less likely to have a complete response and lived a shorter time than the eight patients whose tumors did not have detectable *NMYC* mRNA. The shortcomings of this study were that the other *MYC* family genes were not evaluated, only a small number of patients were examined, and there were potential patient selection factors.

Despite the defects in these three studies, *in vitro* evidence shows *MYC* amplification and expression being associated with growth of SCLC, and there is prospective data showing that DNA amplification of N-*MYC* in pretreatment specimens of childhood neuroblastoma is associated with shortened survival.[108]

MYC Family DNA Amplification and Expression in Non–Small Cell Lung Cancer Cell Lines

The information of *MYC* family DNA amplification and expression in tumor cell lines and xenografts established from patients with NSCLC is much less extensive than that from patients with SCLC. *MYC* family DNA amplification and expression has been studied in 26 and 18 NSCLC cell lines and xenografts respectively. Less than one third of tumor cell lines established from patients with NSCLC have *MYC* family DNA amplification (Table 5.4). *MYC* DNA amplification is present in 23% while *NMYC* and *LMYC* are present in a single cell line.

MYC family mRNA expression is detected more commonly than *MYC* family DNA amplification in tumor cell lines and xenografts obtained from patients with NSCLC (Table 5.4). *MYC* and *LMYC* mRNA expression is present in approximately two thirds to one fourth respectively and N-*MYC* mRNA expression is detectable in only a single tumor. The mRNA expression of the *MYC* and *LMYC* is three to four times as common as DNA amplification of the genes, while *NMYC* expression is less common. Therefore, NSCLC cell lines and xenografts commonly have increased mRNA expression of the *MYC* family genes without evidence of DNA amplification.

MYC Family DNA Amplification and Expression in Non–Small Cell Lung Cancer Tumors

MYC family DNA amplification and expression have been studied in 279 and 69 tumors from patients with NSCLC. Approximately 10% of the tumors from patients with NSCLC had *MYC* family DNA amplification (Table 5.5). *MYC* and *LMYC* DNA amplification was present in the tumors in 8% and 3% respectively. None of the tumors from 257 patients with non–small cell lung cancer had *NMYC* DNA amplification. In addition, no tumor from a patient with NSCLC patient had DNA amplification of more than one *MYC* family gene.

MYC mRNA expression was detected more commonly than *MYC* DNA amplification in tumors from patients with NSCLC. *MYC* mRNA expression was present in one third and *NMYC* and *LMYC* mRNA expression were so uncommon that they were not examined in the following reference.[84] *MYC* mRNA expression was four times as common as DNA amplification of the genes.

MYC Proteins in Patients with Non–Small Cell Lung Cancer

The presence of *MYC* protein has been studied by flow cytometry and immunohistochemistry on clinical samples of surgically resected NSCLC. Two studies examined 30 NSCLCs for the presence of the *MYC* protein in the surgically resected cancers.[109,110] Fifteen NSCLCs were surgically resected, frozen, cell suspensions prepared, and incubated with a murine monoclonal antibody directed against the *MYC* protein. The cells stained with the antibody were passed through a cell sorter, and the percentage of cells staining with the murine monoclonal antibody was determined. Of the 15 (67%) NSCLCs seven adenocarcinomas and three squamous cell carcinomas, ten had abundant *MYC* protein detected.[109] Another study examined 15 frozen sections of NSCLCs with antibodies directed against *MYC*.[110] Six of the 15 (40%) had protein detectable by immunuhistochemistry. Three of these six also had foci of squamous metaplasia, and the *MYC* protein was detectable in all three of these foci.

Two different reports from the same institution showed the percentage of NSCLC with *MYC* protein detectable by immunohistochemistry of paraffin-embedded tissues and its relationship to clinical outcomes.[110,111] About one half of patients (48% to 57%) had detectable *MYC* protein in their NSCLC. The authors showed a statistically significant association between the presence of *MYC* protein in the surgically resected NSCLC and the presence of metastases in a univariate analysis.[111] These studies show the presence of the *MYC* protein in approximately half of NSCLCs, which is similar to the percentage of NSCLC cell lines and tumors expressing *MYC* mRNA. However, *MYC* DNA amplification, mRNA expression, and protein have been studied in very few NSCLC cell lines and tumors, so the studies are only correlative to date.

Gene Therapy with *MYC* in Lung Cancer

The *MYC* family of genes appears to have a prominent role in the pathogenesis and progression of SCLC. These genes are attractive targets for gene therapy. One approach is to inhibit *MYC* mRNA by using antisense oligonucleotides. This technology has been used successfully to inhibit *MYC* expression in hematopoetic cell lines, colon cancer cell lines, and neuroblastoma cell lines. Studies using *LMYC* antisense constructs have been performed using the SCLC cell line NCI-H209.[112] The antisense oligonucleotide was used at a concentration of 10 μM and was shown to inhibit cell growth *in vitro* in a sequence and dose-dependant manner (range 1.6 to 10 μM). The levels of *LMYC* protein were also shown to be decreased (to ~30% of control) in the treated cells. This antisense inhibition was *LMYC*-specific, as the construct was unable to inhibit the growth of cell line NCI-H82, which is known to contain an amplification of *MYC*.[112] Antisense studies using c-*myc* have also been performed in SCLC cell line GLC$_4$ and its two drug-resistant (*in vitro* acquired) subclones to cisplatin (GLC$_4$-cDDP) and adriamycin (GLC$_4$-Adr).[113] These studies have been performed using both purified antisense oligonucleotides and using a plasmid construct containing a dexamethasone-inducible expression system.[113,114] These studies resulted showed aon ~30% growth reduction in the GLC$_4$ cell lines tested. In addition, increased cisplatin sensitivity (12% more cell kill at IC25 and 16% more cell kill at IC50) was observed in the cisplatin-resistant subclone (GLC$_4$-cDDP) after treatment with antisense *MYC* but not in the native cell line.[114] In NSCLC cell lines, *MYC* antisense oligonucleotides have been used with NSCLC cell lines A427, A549, and SKMES-1. This also resulted in a 20% to 40% reduction in cell proliferation in these cell lines.[115]

A second gene therapeutic approach is to take advantage of the *MYC* family overexpression in SCLC cells. Kumagai and colleagues constructed a plasmid containing an E-box element upstream of a herpes simplex virus (HSV) thymidine kinase (TK) promoter and structural gene.[116] Using a chloramphenicol acetyltransferase system, they could demonstrate that any *MYC* gene family member could activate the TK promoter. When this construct was transfected into cells and the cells were treated with gancyclovir, a significant increase in gancyclovir sensitivity could be demonstrated due to the presence of this construct. The increase varied depending on which *MYC* family member was overexpressed and was 33-fold for *MYC* (cell line OC-10), 500-fold for *LMYC* (cell line OS-2-R), and 22-fold for *NMYC* (cell line OS1).[116] Similar findings were seen *in vivc* when these tumor cells were placed into nude mice that were subsequently treated with gancyclovir. Complete tumor regression was seen in 7 of 10 (OC-10 cells) and 5 of 10 mice (OS2-R cells). Interestingly, mice with tumors containing a mixture of the TK construct transfected cells (with OS2-R cells) and parental cells showed greater inhibition of growth after gancyclovir administration than would be expected on the basis of the transfected cells alone. This suggested that the nontransfected cells were also being effected, a process known as the bystander effect.

The data presented above using a cell culture systems and mice are encouraging but preliminary and far from being applied as effective treatment options for patients with lung cancer. One of the main problems is delivery of the DNA (oligonucleotides or constructs) to the tumor(s) in adequate concentrations to achieve the effect observed *in vitro*. A proposed mechanism to improve the delivery problem has been the use of lipid-packaging systems. *In vitro,* incorporation of *LMYC* antisense oligonucleotides into cationic virosomes resulted in decrease in *LMYC* protein expression (32% of control) and an inhibition in thymidine incorporation (by 60% to 70%) in NCI-H209 cells using only picamolar concentrations of the oligonucelotide.[117] This may be a more efficient system to try in patients. However, as mentioned above, not all SCLC tumors overexpress *MYC* family genes, and thus patient's tumors would have to be intially analyzed to identify appropriate targets for treatment. Our knowledge of the *MYC* family of proteins and their interacting partners has grown significantly in the last few years. These binding partners also provide new targets of therapeutic intervention but have not yet been used *in vitro* in lung cancer.

JUN AND *FOS* FAMILY PROTOONCOGENES

The AP-1 (activating protein-1) family of transcription factors is composed of *JUN, FOS,* and *ATF* (activating transcription factor) proteins. These transcription factors form homo- and heterodimers and bind DNA at (TGACTCA or TGACGTCA) sequence-specific sites to activate transcription. These genes belong to a group of immediate early genes and are induced by a variety of mitogens including growth factors, serum, and phorbol esters. The information available on the *JUN* and *FOS*

family of protooncogenes in lung cancer is sparse. Therefore the information given in this review will be brief, and readers are referred to the more complete reviews for mechanism of *JUN* and *FOS* family function.[7,8,9 and 10]

The human family of *JUN* protooncogenes is comprised of *JUN, JUNB,* and *JUND*. These human protooncogenes share sequence homology with the oncogene contained in the avian sarcoma virus 17 (ASV 17.[118] This avian retrovirus was isolated from a sarcoma in an adult chicken, and the retrovirus can transform chicken embryo fibroblasts into neoplastic cells. *JUN, JUNB,* and *JUND* human sequences have cloned. *JUN* and *JUNB* are approximately 2 to 3 kbases long and do not have any introns in their gene structure.[119,120] These genes code for predominant mRNAs of 2.0 to 2.7 kbases with a predicted number of amino acids in the *Jun* proteins of 331 and 347 amino acids. An incomplete human *JUNB* cDNA sequence has also been reported.[121]

The human family of FOS protooncogenes is comprised of the related genes *FOS, FOS-B,* and *FRA*1 and *FRA*2. These human protooncogenes share sequence homology with the oncogene contained in the FBJ murine osteosarcoma virus.[122] This murine retrovirus was isolated from a spontaneous sarcoma in a mouse, and the retrovirus can transform fibroblasts into neoplastic cells. Human genomic *FOS* sequences show that *FOS* has four exons contained within approximately 3.5 kbases of DNA.[123] The *FOS* gene codes for an mRNAs of 2.2 kbases with a predicted protein sequence of 380 amino acids. The cDNA sequences for the murine-related gene *FOS-B,*[124] and human *FRA*1 and *FRA*2 have been reported.[125] Although *FOS-B, FRA*1, and *FRA*2 have been have been identified in other systems, their specific role in lung cancer remains undefined.

The *JUN* and *FOS* family genes all code for a basic region of amino acids followed by a leucine zipper similar to those described within the *MYC* family genes, but they do not have the helix-loop-helix structure present in the *MYC* family genes.[8] The *JUN* proteins dimerize with themselves or with *FOS* proteins to form an activation protein complex (AP-1).[126,127,128] This AP-1 complex recognizes and binds to the consensus DNA sequence TGAGTCAG upstream from a number of genes, including collagenase and metallotheonein II, which stimulates their mRNA expression. The mRNA expression of these two genes increases rapidly following addition of exogenous growth factors or nonspecific stimulation by adding serum to serum-starved cells.[7,8,9] In addition, *JUN* is regulated posttranscriptionally by phosphorylation at serine and threonine residues, whereas *FOS* is primarily regulated by a transcriptional mechanism.[10] These genes are involved in various biologic mechanisms including cell proliferation, differentiation, and apoptosis.[129]

JUN and *FOS* Expression in NSCLC Cell Lines, Primary Tumors from Patients, and Clinical Course

The published information available on the *JUN* and *FOS* genes in lung cancer is somewhat conflicting. *JUN* and *FOS* mRNA expression increases within 30 minutes in primary bronchial epithelial cells and in the SCLC cell line NCI-H345 in response to exogenously added growth factors or serum.[130] Serum stimulation of SCLC cell line NCI-H345 is accompanied by an increase in *FOS* and *JUN* mRNA expression (analyzed by Northern), whereas there is no increase in NCI-H82 cells. This cell line also contains an amplified *MYC* gene (25 copies), whereas NCI-H345 cells have a single copy of the *MYC* gene. The association of *MYC* amplification with the expression of *FOS* and *JUN* following serum stimulation is undefined. In the NSCLC cell line NCI-H125 there is low baseline mRNA expression of both *FOS* and *JUN*. Their expression increases rapidly following serum stimulation (*JUN* more than *FOS*) followed by a down-regulation of *FOS* expression.[52,96] Another NSCLC line (A549) also shows increase in *JUN* and *FOS* mRNA expression, but the level of *FOS* expression is greater (11-fold) than *JUN* (nine fold) in these cell lines. These cell lines also show increase in *FOS* and *JUN* mRNA expression comparable to that seen with serum following stimulation with TGF-b, insulin, and IGF-1.[96] This increase in expression is accompanied by an increase in AP-1 transcriptional activity. Lee and colleagues described the level of *FOS* and *JUN* expression as being higher in normal bronchial epithelial cells (HBE) than in tumorigenic HBE cells (these cell lines have been immortalized and developed in nude mice).[132] This is accompanied by a decrease in AP-1 transcriptional activity and has also been observed in NSCLC cell lines Chago K1 and SKMES-1.[131] This decrease in AP-1 transcriptional activity appears to be due in part to suppression of *FOS* transcription.[132] The mRNA expression of the *FOS* and *JUN* family members has also been studied. *JUNB* and *JUND* MRNA expression (by Northern analysis) was detected in ten of ten NSCLC cell lines studied while *FRA*1 mRNA expression was high in two of ten cell lines (NCI-H1299 and NCI-H441) and minimal in four of ten cell lines.[133]

The expression of *JUN* appears to occur early in the process of lung carcinogenesis.[133] *JUN* is not detectable in normal bronchial epithelium but is found by immunohistochemistry in bronchial hyperplasias (two of three specimens), squamous metaplasias (five of five specimens), bronchial dysplasias (three of three positive), and carcinomas *in situ* (four of five positive). In NSCLC tumor specimens, *JUN* was detected by immunohistochemistry in 31% of specimens including squamous cell carcinomas, adenocarcinomas, and large cell carcinomas. There was no statistically significant difference in expression between the various histologic subtypes. However, Levin and colleagues have found that *FOS* and *JUN* were expressed at high levels in normal tissues and that the expression was much lower in the adjacent malignant tissues (in 72% of cases) in the same specimen.[134] This was confirmed both by RNA expression studies and using immunohistochemistry with four different histologic subtypes of NSCLC.

The clinical significance of *JUN* or *FOS* expression in human lung tumors is presently under investigation. *JUN* protein has been detected in 31% to 51% of the tumors, and *FOS* protein was detected in 42% to 60% of the NSCLC cancers.[110,111,133] In a xenograft model, tumors (squamous cell carcinomas) overexpressing *FOS* or *JUN* grew better in athymic nude mice compared to those without overexpression.[135] Analysis of patients with squamous cell carcinoma showed that *FOS* expression in the tumor specimen (as assayed by immunohistochemistry) was a significant negative prognostic factor independent of lymph node involvement.[133,136,137] Patients whose tumors were positive for either *FOS* (60% of tumors) or *JUN* (49% of tumors) had significantly shorter median survivals. These studies were retrospective and nature and need to be confirmed prospectively and in additional patient populations. Szabo and colleagues report no association between *JUN* protein expression in NSCLC and survival.[133] However, this study included four different histologic subtypes of NSCLC.

FUTURE STUDIES OF THE *MYC, JUN,* and *FOS* FAMILIES IN LUNG CANCER

Over the last few years, a great deal has been learned about the *MYC* family of genes and their dimerization partners. In addition, the role of the *MYC* family of genes in normal development (including lung development) has been elucidated. The role of the various *MYC*-binding proteins in lung cancer (if any) remains to be defined. The lung cancer cell lines and tumors have been extensively characterized for *MYC* family mRNA expression and protein production. There are numerous examples of increased expression and protein production of various members of the *MYC* family in different lung cancers and lung cancer cell lines. This will offer fertile territory for investigation into the interaction of MAX, MAD, and MXI1 gene products within a class of human cancers known for its abnormalities with this family of genes. In addition, these dimerization partners may be appropriate for gene therapeutic interventions.

Extensive work will need to be done on the *JUN* and *FOS* family of protooncogenes to understand their role within lung cancer. We already know that the genes are expressed in bronchial epithelial cells and lung cancer cell lines, though there appear to be discrepancies regarding their expression in primary lung cancers. The role of *FOS* and *JUN* in the generation and maintenance of lung cancer is yet to be elucidated. Future studies of these nuclear oncogenes will be needed to understand better their role in lung cancer.

SUMMARY

The extensive studies on the *MYC* family protooncogenes in lung cancer have shown that *MYC* plays a prominent role in the growth in lung cancer. *MYC* mRNA expression is present in the normal developing and mature adult lung. The majority of lung cancers express one or more *MYC* family mRNAs, while a minority of lung cancers have *MYC* family DNA amplification. The *MYC* gene appears to be more closely linked with more rapid growth than *NMYC* and *LYMC,* because it is more active in establishing permanent cell lines in the rat embryo fibroblast system, is more closely linked with the variant SCLC phenotype and appears to select for increased chance of growth in xenografts and cell culture. Amplification of the *MYC* gene is associated with more rapid growth of SCLC as measured by doubling times and increased cloning efficiency in soft agarose. Transfection of the *MYC* gene into a SCLC cell line that does not express *MYC* mRNA changes its morphology into a variantlike cell line and increases its growth rate. Retinoic acids decrease the amount of *MYC* mRNA expression and the growth rate of SCLC cell lines. In addition *MYC* family DNA amplification in SCLC is associated with shortened patient survival. Therefore, the *MYC* gene appear to be active in the development of the phenotype of lung cancer cells *in vitro* and *in vivo* in patients with lung cancer.

The *JUN* and *FOS* nuclear protooncogenes are in their very early stages of study in lung cancer and additional studies are needed to define their role.

P53

SUZANNE T. SZAK
JENNIFER A. PIETENPOL
DAVID P. CARBONE

Cancers arise by a multi-step process in which cells become malignant by multiple genetic alterations affecting cell growth, differentiation, and survival. To suppress tumor formation, multicellular organisms have evolved mechanisms to protect against the uncontrolled growth of cells. One such mechanism involves the tumor suppressor gene *p53*.

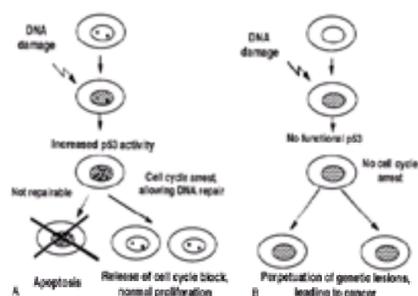
p53 is a tumor suppressor that is activated in cells that have undergone stress, such as exposure to genotoxic agents or oncogene activation (Figure 6.1). Once active, p53 initiates either cell cycle arrest or programmed cell death (apoptosis). It does so, in part, by binding to specific DNA sequences that control the expression of genes whose products govern cell growth and cell death. The timepoint in the genesis of a tumor at which p53 mutation occurs depends on the tumor type and can vary from an early event to a late step in tumor progression. Relatively early mutation of p53 appears to occur in cells that are chronically exposed to DNA-damaging agents and inflammation. The differences in the timing of p53 loss during tumor progression among different tumor types suggest that the tumor suppressor is active under specific conditions, and only then does tumor progression select for cells that have lost normal p53 activity. This selection then requires the inactivation of p53 for continued tumor growth because restoring p53 function to these tumor cells results in either growth arrest or death. Loss or mutation of the *p53* gene occurs often in lung cancers.


FIGURE 6.1. Survival from the initiation of chemotherapy of small cell lung cancer patients whose cell lines established at relapse had *MYC* DNA amplification compared with patients whose cell lines did not. Patients whose cell lines had DNA amplification of *MYC* lived a shorter time compared to those patients without *MYC* amplification (p = 0.0011). (From Johnson BE, Russell E, Simmons AM, et al. MYC family DNA amplification in 126 tumor cell lines from patients with small cell lung cancer. *J Cell Biochem Suppl* 1996;24:210, with permission.)

Research on p53 over the past decade has demonstrated that p53 is a protein toward which many signals are directed and from which many signaling cascades emanate. This chapter focuses on the p53 protein, outlines the biochemical signals that are upstream and downstream of p53, and discusses its clinical relevance to human lung cancer. Understanding the signaling pathways that regulate and are regulated by p53 have allowed, and will continue to provide, increased understanding of the clinical behavior of lung cancer and opportunities for clinical intervention in lung cancer cells lacking functional p53.

P53 STRUCTURE AND FUNCTION

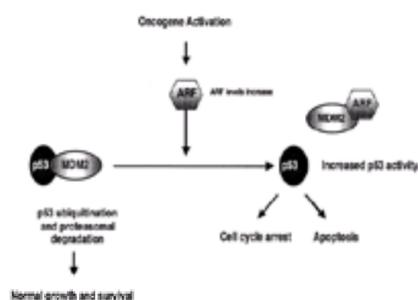
The p53 protein can be divided into three functional domains (Figure 6.2). Each individual domain plays a critical role in p53 function. The amino terminus (amino acids 1–100) of the protein contains an acidic transactivation domain. Proteins that bind this domain either stimulate or inhibit the ability of p53 to regulate transcription of genes. When basal transcription factors (TF) such as TFIID [1] or the TFIIH complex[2] are recruited to this domain, transcription of p53 downstream target genes is activated. In addition to its role in transcription, TFIIH is required for transcription-coupled DNA repair, which has led to the speculation that p53 may have a role in DNA repair.[3,4,5,6,7,8 and 9] The transcriptional co-activator p300 also binds p53 at its amino-terminus.[10] This interaction is proposed to be necessary for p53-mediated G1/S arrest and apoptosis[10] and has been shown to result in p53 acetylation *in vitro*.[11] Inhibitors of p53-mediated transcription, such as murine double minute 2 (MDM2)[12,13] and the 55 kDa adenoviral protein E1B, have been shown to bind to the amino-terminal domain of p53 and are hypothesized to block access of the basal transcriptional machinery to p53. The crystal structure of the amino-terminus of p53 bound to the MDM2 protein has been solved. It reveals that the hydrophobic amino acids that constitute an amphipathic helix in the amino-terminus of p53 are involved in MDM2 binding. [14] A proline-rich subdomain in the amino-terminus of p53 has also been shown to be critical for the growth-suppressive effects of p53 but unnecessary for transcriptional activation. [15]


FIGURE 6.2. Schematic representation of the p53 protein. The protein has 393 amino acids. Five regions, shown in gray, are evolutionarily conserved in sequence content. Amino acids 1–60 constitute the transactivation domain. Conserved region 1 within this domain is the site at which the MDM2 protein binds p53. The center of the protein, from amino acid 100 to 300, is the DNA-binding domain and contains four conserved sequences. The basic C-terminal regulatory domain of p53 is encompassed by amino acids 363–393 and is represented by the checkered region in the diagram. The hatched area shows the location of the tetramerization domain within the C-terminus (amino acids 323–356). Circles in the diagram represent sites of posttranslational modifications. Seven amino acids in the

amino-terminus can be phosphorylated. Of note, the ATM kinase and DNA-dependent protein kinase (DNA PK) phosphorylate Serine 15 of p53 after DNA damage. DNA PK has also been shown to phosphorylate Serine 37. Serine 33 can be phosphorylated by cdk-activating kinase (CAK). Following phosphorylation of Serine 15, p53 is thought to be acetylated by p300 (Lysines 373 and 382) and/or pCAF (Lysine 320). In addition to acetylated amino acids, the carboxyl-terminus may be phosphorylated by casein kinase II (CKII), protein kinase C (PK-C), and cdk complexes (CDK).

The central domain of p53 is required for sequence-specific DNA binding. [16] A majority of tumor-derived p53 mutations reside in this domain, underscoring the importance of p53 DNA-binding activity in tumor suppression. [17] The mutations predominantly occur in the four regions of the central domain that are highly conserved across many species. In lung cancer, p53 codons 157, 248, and 273 are often found mutated, [18,19] abrogating the ability of p53 to bind DNA. When the crystal structure of a complex containing the central domain of p53 and a cognate DNA-binding site was solved, [16] it provided great insight into how tumor-derived mutations inactivate p53 function. The structure of the core domain revealed a b sandwich motif that acts as a scaffold for two large loops and a loop-sheet-helix configuration. These latter motifs are required for the interaction of p53 with DNA. The two large loops involved in DNA binding are connected by a stretch of amino acids that includes a cysteine and histidine; together, these two amino acids coordinate a zinc ion, which is required for p53 activity. [20] Mutations in p53 either destroy the structural integrity of the central domain or alter the amino acids that directly contact the DNA. In addition to binding DNA in a sequence-specific manner, p53 can interact with insertion/deletion mismatches (IDLs). An intact central domain is required for complex formation with IDLs because tumor-derived mutants lack this activity.

The carboxyl-terminus (amino acids 293–393) of p53 is basic and appears to be the site of numerous posttranslational modifications that regulate p53 activity, including phosphorylation, acetylation, and glycosylation. [11,21,22,23 and 24] The carboxyl-terminus of p53 also reportedly binds nonspecifically to both short, single-stranded DNA, RNA and double-stranded DNA containing nucleotide loops. [8,25,26 and 27] Many functional motifs are encompassed within the carboxyl-terminus, such as the nuclear localization signal and an amphipathic helix involved in oligomerization; [28] p53 is thought to be transcriptionally active when it is in a homodimeric or homotetrameric form. [29] A crystal structure of the oligomerization domain of p53 has been solved. [30,31 and 32] Solution of this structure predicts a tetramer or dimer of a dimer. Each p53 monomer has a large hydrophobic area composed of both b strands and a helices that is buried upon tetramerization of the protein. The oligomerization capability of p53 is the basis for the dominant-negative effect of mutant p53 proteins; oligomerization of mutant p53 with wild-type p53 inhibits DNA-binding ability and thus transcriptional activation of the wild-type protein. [33]

The biochemical analyses of p53 that defined the transactivation and sequence-specific DNA-binding domains have led to the classification of p53 as a transcription factor that can regulate the expression of other gene products. These downstream target genes of p53 are thought to mediate its apoptotic and cell cycle effects. As targets, these genes have consensus p53 DNA-binding sites in their promoters, and the level of gene product increases after p53 activation. In addition to its role as a transcriptional activator, p53 can act as a transcriptional repressor. This repressor function is thought to be mediated by p53 binding to the basal transcriptional machinery, sequestering it from certain promoters. [34,35] Expression of several genes has been reported to be down-regulated by p53. These genes include bcl2, topoisomerase IIa, MAP4, Wee1, proliferating cell nuclear antigen (PCNA), c-fos, b-actin, and hsp70. [36,37,38,39,40 and 41]

P53 TUMOR SUPPRESSION

What are the tumor-suppressive functions of p53 and how are they regulated? Initially, it was observed that the wild-type but not the mutant form of p53 blocks cells at the G1 phase of the cell cycle. [42,43] Recent studies have confirmed that an important role of p53 is to regulate cell proliferation and survival following DNA damage and perhaps during disruption of normal differentiation pathways, [44,45] p53 levels and/or activity increase in cells that have activated oncogenes [46,47 and 48] or cells exposed to genotoxic agents. [49,50] Whether the increased level of p53 protein, [49,50] posttranslational modification, [23,51] or both are responsible for transcriptional activation of downstream genes is not well understood. The increase in p53 protein level is thought to be caused by metabolic stabilization of the protein and is associated with the transcriptional induction of specific genes, cell cycle arrest, or in some cases, apoptosis. However, the mechanisms involved in regulating p53 levels and biochemical activity in normal and damaged cells is still not completely known.

P53 AND CONTROL OF THE CELL CYCLE

The G1/S cell cycle arrest mediated by p53 is governed by one of its target genes, p21 $^{Waf1/Cip1}$ (see also Chapter 2). [52,53] The p21$^{Wof1/Cip1}$ protein is a cell cycle inhibitor. [54,55] One way in which p21$^{Wof1/Cip1}$ exerts its effect is by binding to and inhibiting cyclin/cdk complexes; the kinase activity of these complexes is essential for the coordinated transitions between cell cycle phases. [56,57,58 and 59] The enzymatic activity of cyclin/cdk complexes is suppressed by p21 $^{Waf1/Cip1}$ binding, and thus the cell cycle arrests. A second way in which p21 $^{Waf1/Cip1}$ can inhibit DNA replication (the S-phase of the cell cycle) is to bind and block the function of proliferating cell nuclear antigen (PCNA), a DNA polymerase processivity factor. [60] GADD45, another gene transcriptionally activated in a p53-dependent manner after DNA damage, [61] also binds PCNA, preventing the onset of S-phase. [62] Similar to p21,$^{Waf1/Cip1}$ however, the role of PCNA in DNA nucleotide excision repair is unaffected when bound to GADD45. [63,64 and 65]

In addition to monitoring the G1/S cell cycle checkpoint, p53 may also play a role in regulating the G2/M transition. The cdc25C phosphatase is essential for activating the cyclin/cdk complex that stimulates transition of a cell from the G2 phase of the cell cycle into mitosis (M); however, it is inactivated when bound to a 14-3-3 protein family member. [66,67] After DNA damage, when p53 is activated, the transcription of the 14-3-3s gene has been shown to be upregulated. [68] However, the relevance of this observation is unclear because the 14-3-3s isoform is not detectable in any cell type after irradiation, and its binding to cdc25C has not been demonstrated. Nevertheless, overexpression of p53 in the absence of DNA damage causes accumulation of cells in the G2/M phase of the cell cycle. [69,70] In the absence of either p53 or p21, the G2 arrest following DNA damage cannot be sustained, and the cell advances into mitosis. [71]

Integral to cell cycle regulation is the proper coordination of mitotic exit and subsequent S-phase entry. Intact checkpoint pathways are needed to prevent the S-phase entry of cells that have failed to properly segregate their chromosomes during mitosis. Recent studies have demonstrated that after treatment with microtubule inhibitors (MTIs), cells may undergo an aberrant mitotic exit, reenter G1 with a 4N DNA content, and enter S-phase, a process known as endoreduplication that results in polyploid cells. Although how mitotic slippage occurs is not understood, studies have shown that cells with deficient spindle checkpoint function endoreduplicate after treatment with drugs that inhibit microtubule dynamics. [72] Furthermore, cells lacking the gene products involved in G1/S checkpoint function, including p53, [73,74 and 75] pRb[73,76] or p21,[75,76 and 77] endoreduplicate if aberrant mitotic exit occurs after MTI treatment. These studies suggest that, in addition to playing a role in checkpoint function after DNA damage, p53 also functions to prevent inappropriate S-phase entry after an aberrant mitotic exit and thus is critical to proper coordination of S-phase and mitosis. Moreover, Stewart et al. have shown that epithelial tumor cells with defective p53 signaling pathways have enhanced sensitivity to Taxol and vincristine-induced apoptosis. [78]

Insulinlike growth factor binding protein 3 (IGF1-BP3) has been shown to be upregulated by p53 after inducible expression of p53 as well as after treatment of cells with genotoxic agents. [79] IGF-BP3 is secreted from cells and blocks the mitogenic action of the growth factor insulinlike growth factor 1 (IGF1). These observations suggest that p53 may play a role in cell cycle regulation by paracrine or autocrine growth factors.

P53 AND APOPTOSIS

Several studies have shown that p53 transcriptional activity is necessary for the growth-suppressive effects of p53; [29,80] however, the importance of p53 transcriptional activity for promoting apoptosis is debatable (see also Chapter 2). Genes upregulated by p53 that mediate the apoptotic effects of p53 are less well characterized than those involved in cell cycle arrest. Nevertheless, several genes involved in apoptosis have been found to be upregulated in a p53-dependent fashion, suggesting that the role of p53 in initiating programmed cell death is that of a transcription factor.

p53-induced genes (PIGs) were found to be differentially expressed in cells undergoing p53-dependent apoptosis. [81] PIGs are hypothesized to be involved in the generation of intracellular reactive oxygen species that are thought to trigger a cascade of biochemical events culminating in the release of proteins from the mitochondria and initiating apoptosis. Bax, a member of the bcl-2 family of proteins that has a proapoptotic effect when overexpressed in cells, is upregulated by

activated p53 in some cells and may therefore have a role in p53-mediated apoptosis. [82]

However, p53-dependent apoptosis may not require the transcriptional upregulation of these genes. Some studies have demonstrated p53-dependent apoptosis in the absence of new RNA or protein synthesis, [83] or in the presence of MDM2, an inhibitor of p53 transcriptional activity. [84] Thus the p53-directed signaling to the initiators or effectors of apoptosis is currently unclear. Cell fate, whether cell cycle arrest or apoptosis, is likely to be dictated not only by p53 but also by a combination of other genetic alterations present in the cell and other stimulated signaling pathways. [85]

INHIBITORS OF P53 ACTIVITY

The fact that normal cells express p53 without adverse effects implies that the tumor-suppressive functions of the protein are tightly regulated. In normal, nonstressed cells, the level of p53 protein is low because of its short half-life. After a stress event, the levels of p53 increase resulting from a posttranslational modification that prolongs its half-life. The rapid turnover of wild-type p53 *in vivo* may be caused by degradation by the ubiquitin proteolytic system, and the stability of the protein observed after DNA damage is likely caused by an inhibition of this process. [86,87]

A cellular protein proposed to play an integral role in p53 half-life is MDM2. MDM2 is transcriptionally activated by p53. [88] In turn, the MDM2 protein binds to the transactivation domain of p53, terminating its action as a transcription factor. [89] Additionally, MDM2 can target p53 for ubiquitin-mediated proteolysis. [90,91] In effect, an autoregulatory feedback loop is created. The MDM2 protein is oncogenic, and although the gene is often amplified in tumors, this is not usually the case in lung cancer. [92] The oncogenic phenotype observed with MDM2 overexpression is believed to be through its binding to p53 protein. The importance of MDM2 in regulating the apoptotic and growth arrest functions of p53 is suggested by the MDM2 $^{-/-}$ mouse model; these animals die as embryos, but the double p53 $^{-/-}$, MDM2 $^{-/-}$ knockout mice are viable. [93,94]

Cells with mutant p53 also exhibit high p53 levels; this overexpression is probably caused by loss of the p53/MDM2 biofeedback loop. The increased half-life of mutant p53 protein allows the detection of mutant p53-containing cells by immunohistochemistry. The latter has been used as a prognostic tool in lung cancer. The high levels of mutant p53 in cells may also result from selective binding of p53 mutants by heat-shock protein 70. [95]

Viruses have evolved mechanisms to hijack the growth control of a host cell. One of the ways in which many DNA viruses exert their oncogenic effects is through the inactivation of p53. Indeed, much p53 biology was pioneered in virology studies. The E1B 55 kDa protein expressed by adenovirus binds, and therefore blocks, the transactivation domain of p53. SV40 large T antigen associates with the central domain of p53, inhibiting its DNA-binding ability. In fact, SV40 induces mesotheliomas in hamsters, and 60% of human mesotheliomas contain and express SV40 sequences. [96] Whether SV40 contributes to the development of human mesothelioma is not known and requires further investigation. Lastly, the human papilloma virus type 16 (HPV-16) partially exerts its tumorigenic action through its E6 protein that, together with the E6-associated protein (E6-AP), binds and inactivates the p53 tumor-suppressor protein [97,98] by targeting it for degradation through the ubiquitin proteolytic system. [98,99]

STIMULATORS OF P53 ACTIVITY

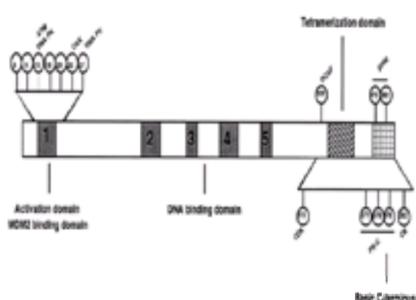
Hyperproliferative signals in cells resulting from aberrant or excessive activity of oncogenes can elevate p53 levels and/or activity. For example, overexpression of c-myc[46] or Ras[48,100] can activate apoptosis and growth arrest, respectively, in a p53-dependent manner; however, the absence of functional p53 under these conditions results in cell transformation. In the case of oncogene activation, signaling to p53 is mediated by the p19 ^{ARF} tumor suppressor, an alternative reading frame of the INK4A locus[101] (Figure 6.3). p19^{ARF} can bind MDM2, preventing both the MDM2-mediated degradation of p53 and inhibition of p53 transactivation. [102,103,104,105 and 106] p19^{ARF} is not required in DNA damage signaling pathways involving p53.


FIGURE 6.3. Schematic of molecular interactions after oncogene activation. In normal cells, MDM2 binds p53, targeting it for degradation. With oncogene activation, levels of the ARF protein increase. ARF protein is thought to bind MDM2, freeing p53 to trigger either cell cycle arrest or apoptosis in the cell.

p53 is also activated in hypoxic conditions. [107,108] The lack of oxygen resulting from restricted blood supply at the core of many tumors represents a stress event that can activate p53. In such a milieu, p53 causes the cell to undergo apoptosis. However, if the cells at the core of the tumor are mutant for p53, these cells do not die but rather adopt a selective growth advantage in such an environment over cells with intact p53. [108] The stress sensor stimulated in hypoxic conditions, which activates p53, is probably an altered cellular redox environment; both REF1 [109] and HIF1-a proteins regulated by hypoxia have been shown to stimulate p53 transcriptional activity.

Radio- and chemotherapy manifest pleiotropic effects, but the DNA damage they induce is a potent activator of p53. [60] In fact, merely introducing nucleases or a damaged DNA template into cells induces a p53-dependent cell cycle arrest. [110,111] A cell can acquire DNA damage in many ways. Each form of genotoxic insult triggers an independent pathway to p53 activation even though the end result is the same. For example, phosphorylation of p53 on the amino acid serine 15 and acetylation at lysine 382 occur after cells are treated with ionizing or ultraviolet radiation. [23] The kinase responsible for the serine-15 phosphorylation after ionizing radiation is either ATM or DNA-dependent protein kinase (DNA-PK), whereas the activity of these kinases is not necessary for this site-specific phosphorylation after ultraviolet radiation. The acetylation of p53 may be regulated by phosphorylation of its amino-terminus by either the ATM kinase or DNA-PK. [23,112,113 and 114] Finally, serine 392 is phosphorylated after ultraviolet, but not ionizing, radiation. [115] Generally, these posttranslational modifications of p53 following a cellular stress event activate p53 for DNA binding. [11,114,116,117]

P53 MUTATIONS ARE COMMON IN LUNG CANCERS

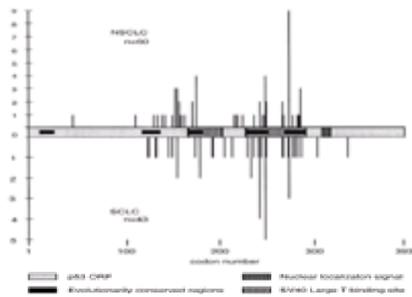
p53 mutations in lung cancer were first described in 1989. [118] Since then many authors have analyzed hundreds of lung cancer tumors and cell lines for somatically acquired abnormalities of p53.[119] In non–small cell lung cancer (NSCLC), most series report that 50% to 60% of tumors have identifiable mutations, [120,121] and in small cell lung cancer (SCLC) the frequency is 90% or greater. [122,123] In contrast to *ras,* where the mutations occur overwhelmingly in a single codon, the mutations in p53 are distributed throughout the open reading frame (see Figure 6.4). The majority of mutations are substitutions of one amino acid residue for another at a single codon, but frame shifts, insertions, deletions, and splicing mutations have been reported. [124] p53 consists of 11 exons, divided into 3 functional regions as discussed previously. The majority of mutations are found in the central region, composed of exons 5 through 8. Although apparent "hotspot" codons exist, at which multiple tumors have been found to have mutations (e.g., codon 248 and 273 in Figure 6.4), this condition is still the minority of cases. Mutations at these "hotspot" codons result in several different amino acid substitutions as well.


FIGURE 6.4. Histogram showing the distribution of mutations in the p53 open reading frame (ORF) from non–small cell lung cancer and small cell lung cancer. The vertical axis represents the number of mutations at a given codon, and the horizontal axis represents codons in the p53 open reading frame. Above the bar are data from non-small cell lung cancer, and below the bar are those from small cell lung cancer. (From Mitsudomi T, Steinberg SM, Nau MM, et al. p53 gene mutations in non-small cell lung cancer cell lines and their correlation with the presence of *ras* mutations and clinical features. *Oncogene* 1992;7:171, and D'Amico D, Carbone D, Mitsudomi T, et al. High frequency of somatically acquired p53 mutations in small cell lung cancer cell lines and tumors. *Oncogene* 1992;7:339, with permission.)

Cigarette smoke is the greatest risk factor for lung cancer, accounting for approximately 85% of cases, and contains polycyclic aromatic hydrocarbons and nitrosamines.[125] These compounds are metabolically hydrolyzed, resulting in the formation of benzo[a]pyrene, a potent carcinogen and mutagen that can form adducts on DNA that manifest as G-to-T transitions in DNA (see also Chapter 3). In smokers with lung cancer, codons 157, 158, 179, 248, 249, and 273 of the p53 gene are the most commonly mutated.[15] Interestingly, benzo[a]pyrene diol epoxide (BPDE), when added to cells in culture, preferentially forms covalent adducts to the guanine residues at codons 157, 248, and 273, precisely the hotspot mutations observed in smokers with lung cancer.[18] Also interestingly, the mutation spectrum observed in colon cancer, a tumor not strongly associated with polycyclic aromatic hydrocarbons, is predominantly G to A, and the hotspots differ, with colon cancer having a strong predominance at codon 175. The mutational spectrum of the p53 gene in nonsmokers with lung cancer differs from that observed in smokers as well. For nonsmokers, codons 179 and 249 are hotspots for mutations, and nonsmokers generally have fewer G-to-T transitions and more G-to-C transversions.[19] These observations suggest that exposure to certain mutagens can lead to specific mutations in the p53 gene.

At least two known homologues to p53 are present in the human genome, but abnormalities in the known p53 homologues are uncommon in human tumors. A few mutations have been observed in one of them, known as p73, in cell lines containing mutant p53.[126] A recent report has also found a single, apparently functionally significant mutation in 80 tumors examined for abnormalities in a new p53 homologue, p51A/TAp63 gamma.[127]

INHERITED LESIONS OF P53 AND LUNG CANCER

Inherited lesions of p53 lead to the Li-Fraumeni syndrome, and affected individuals have a greatly increased risk of brain and breast tumors, as well as soft tissue sarcomas. Lung cancer is also found in these families, although it is such a common malignancy that increased predisposition is not apparent. Transgenic mice that have a mutant p53 expressed in every cell in their bodies develop a high incidence of tumors,[128] as do mice that have a homozygous deletion of p53,[129] although both are viable. Neither of these strains of mice exhibit a high incidence of lung cancer. Among known Li-Fraumeni families few cases of lung cancer are reported, with a recent series reporting 81 breast cancers, 25 brain tumors, 19 bone tumors, 18 sarcomas, and only 8 lung cancers in 91 families.[130]

A known polymorphism at codon 72 in p53 (Arg versus Pro) has been associated with alterations in lung cancer risk,[131] with the Pro/Pro genotype associated with increased risk. Nonsmoker lung cancer patients had a significant excess of Arg/Arg homozygotes in another study.[132] Several studies have recently looked at whether apparent familial clustering of lung cancer cases might be associated with otherwise unrecognized inherited mutations of p53. In a study of 64 lung cancer patients with early-onset tumors or affected first-degree relatives, one family was found to have an inherited mutation at codon 235, and no increased frequency of the codon 72 Pro/Pro genotype was observed.[133] In another study, of 1,068 families of patients with lung cancer, only 4 had more than three relatives affected. Two successive generations were affected in 36 families, and one family had Li-Fraumeni syndrome.[134] Thus although p53 mutations are common in lung cancer, having an inherited p53 mutation does not seem to dramatically increase the lung cancer risk, relative to other cancer types. This correlation is likely to be caused by the relatively late role of p53 in lung cancer carcinogenesis.

P53 IN PRENEOPLASIA

p53 overexpression has been observed in preneoplastic epithelium adjacent to overt lung cancers (see also Chapter 23).[135,136] Most studies indicate that in the development of squamous cell lung cancer, loss of heterozygosity at 17p (suggesting loss of wild-type p53 function) occurs at the transition of preneoplasia to carcinoma *in situ*.[137] With the advent of polymerase chain reaction-based detection of mutations in p53, it has become possible to analyze ever-decreasing amounts of tissue for abnormalities in oncogenes possibly allowing molecular early detection of lung cancer. Sidransky et al. have detected oncogene mutations in pulmonary cytological specimens.[138,139] Unfortunately, these assays require prior knowledge of the precise location of the mutation, which eliminates most of its usefulness as a screening procedure for p53, unless complex banks of oligonucleotide probes are used. However, molecular detection of residual disease at surgical margins would be feasible with this approach. A recent study of the lungs of a smoker without lung cancer showed a single mutant p53 gene present at seven of ten sites sampled from widely dispersed areas of both lungs.[140] This finding suggested to the authors that a single progenitor bronchial epithelial cell clone harboring a p53 mutation had spread to distant sites within the bronchial tree. If this phenomenon is common, then sputum, or perhaps even something as simple as a buccal wash, could be used to detect occult genetic damage leading to upper aerodigestive malignancies in presymptomatic populations. Studies of allele loss, gene mutation, and other genetic abnormalities in preneoplastic tissues are underway toward that end.

PROGNOSTIC SIGNIFICANCE OF P53 MUTATIONS IN LUNG CANCER

The prognostic significance of p53 mutations in lung cancer is controversial, and the answer may depend on the precise technique used to assay for it and the patient population selected. In SCLC, such a study would be difficult because as almost all SCLC have p53 mutations. In NSCLC, however, many groups have studied this problem. Horio et al. analyzed resected Japanese lung cancer cases and found adverse prognostic significance, especially in early-stage tumors.[141] Other groups have evaluated the prognostic significance of p53 abnormalities as measured by immunohistochemical analysis. An early report found a highly significant adverse effect on survival,[142] and another report the same year found no effect whatsoever,[143] using similar numbers of patients from the United States and England, respectively. In fact, another group found that extremely high p53 protein expression was associated with a favorable prognosis.[144] One study to evaluate both gene mutations and immunostaining on the same group of patients found no prognostic significance to mutations in the gene, but a modest adverse prognosis to p53 overexpression.[145]

Recently, several large studies have been published (see also Chapter 33). D'Amico et al. published on 408 consecutive resected stage I NSCLC patients and showed a modest adverse prognostic impact of p53 overexpression (RR1.68, p = 0,004.[146] An even larger study of 515 resected stage I NSCLC showed no difference in survival for p53 positive immunostaining,[147] but rather that the pathologic T-stage was the only important factor. In summary, the isolated impact of having a mutant p53 or p53 overexpression on time to recurrence or overall survival in lung cancer is unclear and probably not clinically significant.

P53 STATUS AS A PREDICTOR OF CLINICAL RESPONSE TO CHEMOTHERAPY AND RADIATION

The previous studies evaluated stage I patients treated with surgery alone for overall survival. When stage I lung cancer recurs, the second-line treatment modalities vary widely, and time to death is often short. In addition, the general efficacy of therapy in this setting is limited. Thus if p53 had an effect on whether patients responded to radiation or chemotherapy, it might not be detected unless it is specifically evaluated. Several studies have attempted to evaluate this relationship.

Stage III NSCLC is often given initial chemotherapy or chemoradiation therapy, and several studies have evaluated these tumors for p53 status in relation to response. In one study, 52 patients with stage IIIA NSCLC were evaluated for p53 expression and response to cisplatin-based induction chemotherapy. High levels of

p53 expression were found to be predictive for lack of pathologic response at the time of surgery. [148] Interestingly, no correlation existed with clinical response assessed radiographically. Other studies have found positive immunostaining to be predictive of resistance. [149] In one of these studies a cohort of stage III patients were analyzed for both p53 mutations and immunohistochemistry, [150] and a normal p53 genotype was found to be highly predictive of response to chemotherapy (p < 0.001). No association of response was found with immunohistochemistry, but surprisingly, no association was found between genotype and immunohistochemistry. Because most studies find at least a good correlation between mutations and immunostaining, [145] the immunostain results of this study are questionable.

Response to radiation therapy has also been analyzed. In a group of 34 NSCLC patients with recurrent disease treated with radiation therapy alone, p53 gene sequence abnormalities significantly predicted resistance to treatment (15% response vs. 62% response). [151] When stage III patients are treated with radiation alone, a significant correlation has been observed between lack of p53 immunostain positivitity and both response and survival. [152]

Thus the response of clinical lung cancers to chemotherapy or radiation appears worse in the presence of a mutation in p53; however, larger prospective studies specifically addressing this issue are needed to confirm these data. If confirmed, p53 status could potentially be used to select the subset of lung cancers most likely to benefit from nonsurgical interventions and to allow those patients with a small potential benefit to avoid the toxicity of treatment.

ANTI-P53 IMMUNE RESPONSES IN LUNG CANCER PATIENTS

Lung cancer patients sometimes spontaneously make antibodies in their serum that react specifically with p53. [153] We found that 13% of lung cancer patients (but none of the controls) had such naturally occurring antibodies. All patients with antibodies had missense mutations of p53 in their tumors and had detectable levels of protein by ELISA. [153] None of these antibodies were mutant-specific on Western blot, indicating that they are detecting a conformational epitope rather than the actual altered amino acid sequence. Subsequent studies have confirmed these findings, including a recent study of 188 resected NSCLC patients, 38 of whom had detectable anti-p53 antibodies. [154] No relationship existed between antibodies and survival in the subset of 171 patients resected with curative intent. Other studies have evaluated the correlation of anti-p53 antibodies with survival and reported that it was a favorable predictor of survival after radiation therapy [155] or an adverse prognostic factor in the subset of tumors overexpressing p53. [156] Antibodies are consistently reported to be more prevalent in large cell and squamous cell than in adenocarcinomas. [157] In SCLC, a study of 170 patients reported an incidence of 16% and no prognostic impact. [158]

The development of antibodies to p53 when tumors express mutant p53 suggests that antigen presentation to the humoral immune system may indeed depend on the presence of particular protein abnormalities commonly associated with cancer. Antibodies to other proteins such as HuD in lung cancer patients lead to the autoimmune paraneoplastic syndromes, [159] but no such syndrome has been identified for p53. Antibody development has even been reported to be detectable before the development of clinically apparent cancer, [160] but its low frequency limits its usefulness as a screening marker. Correlation with the ability to bind to hsp70 has been described in cases of breast cancer, [161] implicating hsp70 in the antigenic presentation of p53 to the humoral immune system. The significance of these antibodies in a host antitumor immune response and their association with outcome is unknown.

Antibodies can only detect surface proteins in intact cells, but the cellular immune system, and MHC class I-restricted cytotoxic T lymphocytes in particular, can readily detect single amino acid missense substitutions in intracellular and even intranuclear proteins. [162] It has recently been shown that mutant p53-specific cylotoxic T lymphocytes (CTL) can be generated by mutant oncopeptide vaccination, and that these CTL can kill tumor cells that endogenously present the intact mutant p53. [163],[164],[165] and [166] Effective p53-specific immunity can also be induced using a recombinant adenovirus to overexpress wild-type p53 in dendritic cells. [167] We have also recently shown that we can detect these responses in cancer patients and induce them with peptide vaccination. [168] The therapeutic potential of these p53-specific CTL remains to be determined (see also Chapter 16).

THERAPEUTIC POTENTIAL FOR *P53* GENE THERAPY AND P53-TARGETED SMALL MOLECULES

As discussed previously, expression of wild-type p53 has been shown to result in growth arrest or death of lung cancer cell lines. For example, the H358 lung cancer cell line contains a homozygous deletion of the *p53* gene and thus expresses no p53 protein at all. When expression vectors containing mutant p53 were transfected into this cell line, many stable transfectants that expressed the mutant protein were observed. However, when wild-type p53 was transfected, many fewer clones were isolated, and none of those expressed the normal p53 protein. [169] In contrast, in another tumor expressing a dominant mutant p53, decreased numbers of colonies were found, but stable co-expression was observed. This finding suggests that despite the multiple genetic abnormalities associated with lung cancer, expression of normal p53 protein can inhibit tumor cell growth. Both retroviruses and adenoviruses have been used in animal models [170],[171] and humans[172],[173] to deliver wild-type p53 for therapy, and these applications are discussed in more detail elsewhere in this book.

Another interesting potential therapeutic approach was suggested by the fact that a subset of p53 mutations are "conditionally mutant." For example, the temperature-sensitive mutation Val-135, which is biochemically mutant at 37.5°C but wild-type at 32.5°C. [174] Similar mutants have been found in human lung cancer.[175] Subsequently, certain antibodies were shown to cause this conformational shift, and the activity of p53 was found to be regulated by phosphorylation as described previously. These facts suggest, at least in a subset of mutant p53 molecules expressed in tumors, that it may be possible to switch p53 from a mutant to a wild-type conformation pharmacologically with therapeutic intent. These strategies are currently under investigation.

CONCLUSION

p53 is often mutated in the process of lung tumor development, and recent studies are beginning to clarify its role in normal and tumor cell physiology. Knowledge of these lesions in clinical samples is beginning to be used for genetic counseling, early and more accurate diagnoses, prognoses, and detection of residual disease. Therapeutic strategies or drugs that can directly affect mutant p53 function may ultimately allow more effective and more tumor-specific treatments of lung cancer patients.

ANTONIO GIORDANO

GENETIC BASIS OF CANCER

Cancer is a genetic disease that results from multiple genomic changes. These changes ultimately lead to the deregulation of the cell cycle machinery and to autonomous cell proliferation. Neoplastic transformation involves four sets of genes: (a) oncogenes; (b) tumor-suppressor genes; (c) mutator genes; and (d) apoptotic genes. In the hematopoietic system, the first step in oncogenesis is the activation of an oncogene, which may then be followed by the activation of an additional oncogene and/or the loss of function of a tumor-suppressor gene. The activation of oncogenes may play a predominant role in the formation of sarcomas as well. Tumors of both the hematopoietic system and soft tissues exhibit a karyotype close to normal. On the other hand, carcinomas, the most prevalent forms of cancer, are predominantly caused by the loss of function of tumor-suppressor genes with multiple sites of loss of heterozygosity (LOH), and they have dramatic alterations in the karyotype.[1]

The discovery of tumor-suppressor genes revolutionized the field of cancer research and of cell cycle molecular biology. According to Knudson's "two-hit" hypothesis,[2] the development of several human cancers is thought to involve LOH of putative tumor-suppressor genes, several of which are not yet identified. Many forms of malignancies have been linked to mutations in the retinoblastoma-susceptibility gene (*RE*), the first tumor-suppressor gene identified. RB provides a link among the cell cycle machinery, the G1/S cyclins, and cyclin-dependent kinases (Cdks), and the transcription of genes necessary for entry into S-phase. Another tumor suppressor, p53, is found mutated in more than 50% of human tumors.[3] Both tumor-suppressor genes, *RE* and *p53,* are negative regulators of the cell cycle and are involved in growth arrest. p53 is also implicated in the recognition and repair of DNA damage, as well as in the induction of programmed cell death, apoptosis. Recently, it has become increasingly clear that these two proteins interact with each other through various pathways in order to exert their effects on cellular events.

THE CELL CYCLE CLOCK

The mammalian cell cycle machinery involves the formation, activation, inactivation, and degradation of sequential complexes of cyclins with Cdks. This process is governed by positive and negative feedback regulations at various critical transition points to ensure that the necessary molecular events occur in each phase of the cell cycle prior to progression to the next stage. Uncoupling of this intricately controlled regulatory process often results in cellular transformation and oncogenesis.

Disruptions in the cell cycle machinery are implicated in the development of certain cancers. Cyclins are cell cycle regulators first identified in marine embryos and named for their cyclical accumulation and degradation at each stage of the cell cycle.

In humans the overexpression of certain G1 cyclins is associated with oncogenesis. Hepatitis B viral integration into the cyclin A gene is found in some cases of hepatocellular carcinoma.[4] Elevated levels of cyclin A are also correlated with hematologic malignancies.[5] Gene derangement and aberrant expression of cyclins are reported in breast, esophageal, and skin malignancies.[6,7 and 8] The candidate oncogene, PRAD1, found to be overexpressed and rearranged in parathyroid tumors, actually encodes for the cyclin D1.[9] Certain colorectal cancer cell lines have amplifications of cyclin D2 and cyclin E.[10] Unregulated, persistent expression of cyclins D1 and D3 are found in various human tumor cell lines,[11] and an overabundance of cyclin D3 expression is detected in subsets of breast tumors and lymphomas.[12] The transforming protein E1A, from a DNA oncovirus, associates with cyclin A in adenovirus-transformed cells.[13,14] This association is the first evidence for the linkage between the cell cycle and the process of neoplastic transformation. The binding of E1A may promote cellular proliferation by disrupting the normal interaction between cyclin A and the E2F/DRTF1 transcription factor.[15] DNA oncoviruses, via their oncoproteins targeting key regulatory and proliferative proteins of the cell cycle, serve as valuable tools in the attempt to elucidate the complex mechanisms governing the cell cycle machinery.

It is well established that p34^{cdc2} protein kinase plays an important role in the regulation of the cell division cycle. In fission yeast, cdc2 function is required at two points of the cell division cycle: prior to the initiation of DNA replication and at the time of initiation of mitosis. In *Xenopus* the cdc2 gene product has been identified as a component of M-phase promoting factor (MPF), a factor that causes an interphase cell to enter mitosis; other components include the product of the Suc1 gene and p62, homologous to the human cyclin B gene. The MPF complex also acts as a histone H1 kinase that is maximally active at mitotic metaphase. In mammalian cells the cdc2 kinase is required for mitosis and for the transition from G1 to S-phase (DNA replication).[16] At least two complexes of mammalian p34^{cdc2} have been identified, the p62 (cyclin B)-p34^{cdc2} complex and the p60 (cyclin A)-p34^{cdc2} complex.[13,17] The p60 (cyclin A)-p34^{cdc2} complex also displays a cell cycle–dependent histone H1 kinase activity, but it shifts the timing of maximal activity to interphase.[13] Another complex has been identified between p50 (cyclin E) and Cdk2, a member of the extended cdc2-related protein family.[18] These three complexes (cyclin B–Cdc2; cyclin A–Cdc2; cyclin E–Cdk2) display a cell cycle–dependent histone H1 kinase activity that has different timings of activation during the cell division cycle.[13,17,18]

G1-Phase

Throughout the G1 phase of the cell cycle, growth factors exhibit their effects by binding to specific surface receptors. This process leads to the activation of signaling cascades that control the transcription of immediate and delayed early-response genes. Even within cells that ultimately undergo divergent long-term responses, many of the same intracellular signaling molecules exhibit uniform activation. Withdrawal of growth factors in mammalian cells leads to arrest of the cells in early G1 into what is known as the G0-phase. In order for cells to reenter the cell cycle from quiescence, the Cdk complexes in the cells must be activated (Figure 7.1). Activation of the Cdk complexes requires the aggregation of cyclins and Cdk subunits, the derangement of inhibitory molecules such as p15, p16, p21, and p27[19,20,21,22 and 23] from the Cdk complexes, and phosphorylation by the Cdk-activating kinase (CAK).[24,25 and 26] The cyclins involved in G1 of mammalian cells include cyclins C, D, and E. In yeast these cyclins are encoded by CLN genes whose protein products regulate cdc2 activity at START, the point at which a cell commits to DNA replication.[27] Neither cyclin A nor B is available prior to S-phase. Throughout the cell cycle, cyclin C levels do not oscillate very much, exhibiting only a slight increase in early G1. However, this invariability is not the case for cyclin E, which has periodic expression and peaks at the G1/S transition, suggesting a possible role for it in the regulation of S-phase entry.[18,28]

FIGURE 7.1. Schematic diagram of the cell cycle clock. (From "neoplastic transformation: oncogenes, tumor suppressors, cyclins, and cyclin-dependent kinases" by Candace M. Howard and Antonio Giordano in *Hormones and Cancer* 1996, Birkhaäuser Boston, with permission).

There are three D-type cyclins, which vary in their relative levels among cell types. [29] Following serum addition to quiescent cells, D-type cyclins are induced. Subsequent induction and maintenance of D-type cyclin mRNAs depend on the presence of growth factors. [30,31] The D-type cyclins pose a possible link among cell cycle, signal transduction, and oncogenesis because the overexpression of cyclin D1 has been found in some tumors. The D-type cyclins have been shown to associate with four members of the Cdk protein family, Cdk2, 4, 5, and 6; however, the major catalytic partners of the D-type cyclins are Cdk4 and Cdk6. [31,32] Similar to all nascent cyclin–Cdk complexes, those containing cyclin D become activated only when phosphorylated by Cdk-activating kinase (CAK). In mammalian cells CAK has recently been shown to complex with cyclin H (thus termed Cdk7) and then to phosphorylate and activate Cdk2, Cdc2, and Cdk4 complexes. [24,25] Depletion of CAK from the cell lysates prevents the activation of cyclin–D-Cdk4 complexes. [25] This reaction demonstrates that the CAK protein is a necessary component of the Cdk4-activation kinase.

The three D-type cyclins may not be functionally equivalent because cyclin D1 forms a much less stable complex with pRb than either cyclins D2 or D3. [32,33 and 34] Unlike cyclin E or A, the D-type cyclins share the sequence Leu-X-Cys-X-Glu (LXCXE) near their amino-termini with the DNA viral oncoproteins, which bind pRb and pRb-related p107. Point mutations within this region disrupt the ability of D-type cyclins to bind to pRb and to p107 *in vitro;* thus, D-type cyclins can be more effectively complexed by oncoprotein-derived peptides containing the LXCXE residues. [34,35] Additional evidence of the possible functional divergence among the D-type cyclins comes from the observation that the overexpression of cyclins D2 and D3 in hematopoietic cell lines inhibits differentiation of granulocytes; however, overexpression of cyclin D1, which is not a normal constituent of these cells, does not affect their differentiation. [32] The effects of the D-type cyclins are cell type specific because in some cell types their overexpression results in an enhanced capacity of the cells to enter S-phase and lowers the cells' requirements for growth factors. [36,37]

Microinjection of antisense plasmids or antibodies of cyclin D1 during mid-G1 into quiescent fibroblasts is inhibitory to cell cycle progression upon serum stimulation, but it is ineffectual when administered near the G1/S boundary. [38] This relationship indicates a functional role for the D-type cyclins occurring after the G0/G1 transition. Recent studies have pointed to the possible necessity of down-regulation of cyclin D1 levels and/or their removal from the nucleus at the end of G1, which more precisely delineates the timing of the functional activity of the D-type cyclins. This conjecture originates from the findings that as cells enter S-phase, cyclin D1 vanishes from the nucleus and the total concentration of the protein markedly decreases. [36] This notion is also supported by the observation that the ectopic expression of cyclin D1 arrests fibroblasts prior to entering S-phase and prevents their repair of damaged DNA. [39] When pRb becomes hyperphosphorylated by Cdk4, complexes between pRb and cyclin D2 and D3 become destabilized. However, this disruption may be overridden by the expression of a kinase-defective Cdk4 mutant instead of the wild type, and stable ternary complexes are formed once again. [35] This resolution suggests that the D-type cyclins may serve as multifunctional regulators by also targeting Cdk4 and other partners to specific substrates.

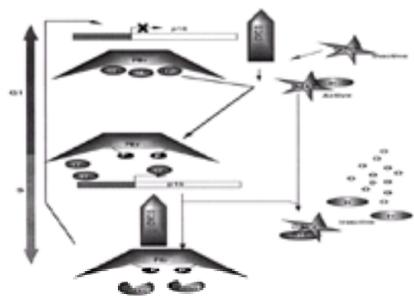
The D-type cyclins as well as their Cdk partners associate with proliferating cell nuclear antigen (PCNA), the auxiliary subunit of DNA polymerase delta, and with a 21 kD protein, p21. [40] As a subunit of DNA polymerase delta, PCNA is involved in DNA replication and excision repair. [41,42] The D-type cyclins, along with cyclins E and A, are implicated in the regulation of DNA replication. PCNA is not a phosphoprotein; however, other proteins present at replication origins are Cdk substrates. [43] The polypeptide p16, a Cdk inhibitor, binds Cdk4, resulting in destabilization of cyclin D complex formation and thus halting Cdk4 activity. The presence of p16 prevents the phosphorylation of pRb by the Cdk4–cyclin D complex that prevents the stimulation of releasing factors that would otherwise turn on DNA transcription and/or replication. This autoregulatory loop (as depicted in Figure 7.2) then comes full circle as the inactivation of pRb leads to the enhanced expression of p16 as cells approach S-phase.


FIGURE 7.2. A schematic representation of the pRb regulatory loop.

Current evidence indicates that the D-type cyclins serve primarily as stimulants for the progression through the G1 stage of the cell cycle instead of as promoters of the G1/S transition. This concept is supported by the timing of D-type cyclins accumulation in relation to cyclin E. In cells of nonlymphoid origin, prior to the arrival of cyclin E, both cyclin D1 and Cdk4 amass in mid-G1. Cyclin D2 and its associated kinases, Cdk4 and Cdk6, accumulate early in G1 in stimulated human T lymphocytes. [30,44,45,46 and 47]

Cyclin D3 follows D1 and D2 in its appearance. [44,48,49] Most important, removal of growth factors from macrophages in S-phase results in a rapid decrease in cyclin D1–Cdk4 complexes; however, the cells are still capable of the completion of S-phase and division. [30] The importance of the timing of the microinjection of antisense constructs or antibodies to cyclin D1 early in G1 in order to elicit an inhibitory effect, as mentioned earlier, also lends further credence to the notion that the D-type cyclins are stimulants for the progression through the G1 phase, rather than promoters of the G1/S transition.

The G1/S Transition

The rate-limiting factor involved in the G1/S transition is hypothesized to be cyclin E (Figure 7.1). Cyclin E associates primarily with Cdk2. [18] Currently, the precise mechanisms involved in the inactivation of cyclin E are unclear. The short half-life of the protein is thought to be mediated by its PEST sequences [28,50] because the removal of such sequences from yeast G1 cyclins increases their half-life. [51] In human foreskin fibroblasts and in Rat-1 cells the stable, ectopic overexpression of human cyclin E has been found to shorten their G1 interval, to decrease cell size, and to reduce their serum dependence for accomplishing the transition from G1 to S-phase without altering the generation time. Thus the shortened G1 interval is accompanied by lengthened S and G2 phases. The reduction in cell size suggests that the cell size may depend more on G1 cyclin levels than on the length of the cell cycle. Stepwise withdrawal of serum from the cells slowed the rate of decline in their S-phase fraction and created a less profound lengthening of their G1 interval. The generation times of the cyclin E overexpressors and the control group

increase in parallel, and both growth arrest in 0.1% serum.[52,53] This finding means that cyclin E does not induce cell transformation and further, that overexpression of cyclin E retains the requirement for serum-dependent signals to continue cellular proliferation. Thus this study demonstrates that cyclin synthesis in mammalian cells is rate limiting for the G1/S transition. Possible oncogenic properties for cyclin E have been uncovered by the discovery of cyclin E overexpression in breast cancer resulting from a gene rearrangement.[54]

S-phase

Entry into S-phase does not depend on the presence of cyclins A or B.[55] The initiation of DNA replication, conversely, depends on the presence of functional cyclin A,[56] and a disruption of cyclin A function may upset the normal timely sequential relationship between the S and M phases.[57] Both cyclins A and B are first synthesized after the start of S-phase, and the synthesis and destruction of cyclin A occurs prior to that of cyclin B.[14,58] In humans, cyclin A localizes to the nucleus in interphase and is first detected near the G1/S transition, whereas cyclin B accumulates in the cytoplasm and does not enter the nucleus until just before the breakdown of the nuclear membrane.[14]

Progression through S-phase depends on the presence of cyclin A as shown by studies where the functional knockout of cyclin A–associated kinase activity, either by expression of plasmids encoding antisense cyclin A mRNA or by injection of anti–cyclin A antibodies, halts mammalian fibroblasts progression into S-phase.[56,59,60] The localization of the Cdk2–cyclin A complex to DNA replication foci by immunofluorescence,[61] and the demonstration of its ability to phosphorylate the p34 subunit of the DNA single-strand-binding protein, RPA p34,[62] illustrates the direct involvement of the Cdk2–cyclin A complex in DNA replication. A model has been proposed that implicates the cyclin A–Cdk2 complex and RPA p34 in playing an integral role in the DNA re-replication block that limits DNA synthesis to only one round of replication.[61] In this model, RPA p34, which is bound to DNA in G1-phase, is dissociated from the DNA and is translocated to the cytoplasm following phosphorylation by cyclin A–Cdk2. Within the cytoplasm, phosphatases may act on p34. As the activity of the cyclin A–Cdk2 complexes decreases in early G2, hypophosphorylated RPA p34 may regain its ability to bind DNA and signal the cell that the DNA has replicated and inhibits further DNA synthesis until the activation of Cdk2–cyclin A complexes in the next cycle, thus preventing endoreduplication.

Cyclin A–Cdk2 as well as cyclin E–Cdk2 associated subunits are able to form higher order complexes with pRb, p107 (Rb-related), and the transcription factor E2F. Such dynamic associations infer that Cdk2 may be functioning on a secondary level as a temporal regulator of gene transcription during the G1 and S phases of the cell cycle,[63] depending on which complexes it forms.

Mitosis

Cyclin B bound to p34^{cdc2} is linked to entry of the cell into the mitotic phase; however, the complex is present throughout the S and G2 phases (Figure 7.2). Hyperphosphorylation of the cyclin B–Cdc2 complex at Thr-14 and Tyr-15 within the p34^{cdc2} ATP-binding site inactivates the kinase to allow normal progression of the cell through the S and G2 phases. Dephosphorylation of the previously mentioned residues by the appropriate phosphatases and phosphorylation of the p34^{cdc2} at Thr-161 (thought to stabilize cyclin B binding) lead to activation of the p34^{cdc2} kinase and stimulate entry into mitosis.[64] Recent evidence, however, shows that the Thr-161 phosphorylation of p34^{cdc2} kinase has no effect on cyclin B binding ability, leaving the biologic significance of this event undefined. [65] This process does exhibit negative regulation in some systems. Unreplicated DNA in *Xenopus* egg extracts blocks the activation of the cyclin B–cdc2 complex by preventing the removal of the phosphates from the inhibitory sites in cdc2 (Tyr-15 and Thr-14). The inhibition of the cdc2 kinase occurs by the activation of the Wee1-Mik-1–related protein kinases that phosphorylate these residues. [66] Following successful DNA replication and progression past the G2/M transition, the cell divides and is able to exit mitosis by the abrupt degradation of cyclin B through ubiquitin mediation in anaphase. This process releases the p34^{cdc2} as a monomer, which is subsequently inactivated.[64]

CDK INHIBITORS

One of the most exciting findings in the area of the cell cycle and its connection to tumorigenesis has been the isolation of a family of small cyclin–Cdk inhibitor proteins. This discovery has uncovered an additional layer of regulation to the cell cycle machinery.

p27^{KIP1}

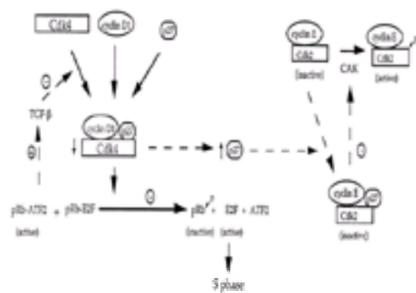
Cells are arrested in late G1 by inhibitors, transforming growth factor beta (TGF-b) prior to the phosphorylation of the retinoblastoma protein. [67] TGF-b inhibits the expression of Cdk4 in G1 while having no such effect on cyclin D; however, this inhibition blocks the activation of the cyclin D–Cdk4 complex Figure 7.3[68] Because overexpression of Cdk4 in TGF-b–responsive cells negates the TGF-b block of the cell cycle, this relationship suggests that the inhibition of Cdk4 expression is an important event in TGF-b–mediated cell cycle arrest. TGF-b has no effect on the expression levels of cyclin E or Cdk2; however, active cyclin E–Cdk2 complexes fail to form in cells treated with TGF-b.[69]


FIGURE 7.3. A model of the actions of the growth inhibitor transforming factor (TGF-b). TGF-b inhibits the expression of Cdk4 in the G1-phase of the cell cycle, leading to a decrease in the number of cyclin D–Cdk4 complexes. Because the majority of the Cdk-inhibitor p27 in cycling cells is found juxtaposed in the cyclin D–Cdk4 complexes, this results in an indirect induction of p27. The association of p27 with newly formed cyclin E–Cdk2 complexes inhibits their activation by CAK. The suppression and inhibition of cyclin D–Cdk4 and cyclin E–Cdk2 prevents the phosphorylation of pRb and the release of the E2F transcription factor required for the progression into S-phase. pRb is also able to bind and enhance the transcription factor ATF-2, which is thought to be involved in the expression of TGF-b, thus serving as a positive feedback loop for the G1 growth arrest.

The TGF-b–mediated cell cycle arrest involves the indirect induction of an inhibitor of cyclin–Cdk complexes, p27 ^{KIP1}, which has recently been cloned.[20,22] The majority of p27 found in cycling cells is juxtaposed in the cyclin D–Cdk4 complexes (Figure 7.1).[68] TGF-b does not induce the transcription of p27. [20] Rather, by repressing the synthesis of Cdk4, TGF-b reduces the number of cyclin D–Cdk4 complexes, which then possibly frees p27 to inhibit other Cdks. The inactive form of cyclin E–Cdk2 in TGF-b–treated cells is found to complex with p27.[20,69]

Newly formed complexes of cyclin E–Cdk2 are activated by phosphorylation of Cdk2 on the residue Thr-160 by the activation enzyme CAK; however, the association of p27 to these new cyclin E–Cdk2 complexes effectively inhibits CAK and thus blocks the activation of the new complexes. [21] Both events, the decrease in the number of the cyclin D–Cdk4 complexes and the inactivation of the cyclin E–Cdk2 complexes, block the phosphorylation of not only pRb but also other regulatory factors by cyclin–Cdks that are necessary events for the transition of cells into S-phase.

The G1-specific cyclin–CDK inhibitor, p27 ^{KIP1}, is subject to various levels of translational and postranslational regulation, which include phosphorylation, noncovalent sequestration, and the ubiquitin-proteasome pathway. In S-phase, the abundance of p27 is regulated predominantly by specific proteolysis of the protein by the ubiquitin-proteasome pathway.[70] While in quiescent cells (GO), the accumulation of p27 is caused by an increase in the synthesis rate of p27 resulting from an enhancement in the amount of p27 mRNA associated in polyribosomes.[71] The complexity of the regulation of p27 increases considering that p27 also serves as a

substrate for the cyclin E–Cdk2 kinase, whose activity p27 inhibits. [72] A kinetic model has been proposed where the binding of ATP to the Cdk determines whether p27 acts as a negative regulator of the cyclin–Cdk complex (low ATP concentrations, <50 mM) or as a substrate (higher ATP concentrations > mM). [72] Cyclin E–Cdk2 specifically phosphorylates p27 on threonine-187, which is a conserved C-terminal Cdk target site (TPKK). [72,73 and 74] Mutational analysis has shown that the selective degradation of p27 by the proteasome pathway depends on the association of p27 with active cyclin E–Cdk2 and subsequent phosphorylation by Cdk2 on the TPKK site.[74]

Because p27 is targeted by the adenovirus E1A oncoprotein, [75] the human papillomavirus E7 oncoprotein dissociates p27 from cyclin–Cdk complexes, [76] p27-deficient mice develop tumors of the pituitary gland with 100% penetrance, [77,78] and overexpression of p27 using a recombinant adenoviral vector triggers apoptosis in several different human cancer cell lines; [79] p27 is thought to be involved in neoplastic transformation. However, studies examining the genomic structure of p27 in cancer cell lines and primary human tumors have either failed to find abnormalities in the p27 [KIP1] gene in a variety of cancers[80] or have found p27 mutations to be rare. [81] The scarcity of p27 mutations found to date does not necessarily mean that this cell cycle regulatory protein is not involved in tumorigenesis, especially considering the complex levels of regulation of this protein. In fact, enhanced ubiquitin-proteasome–mediated degradation of p27 is found in aggressive colorectal carcinomas [82] and in NSCLC, where p27 is an independent prognostic factor correlating with the overall survival time of the patients. [83] In essence, functional inactivation of p27 is associated with tumorigenesis.

p21

Other mammalian Cdk inhibitors in addition to p27 have also been found, including p21, p16, p15, and p18 to name a few. In fact, p21 is the first Cdk inhibitor to be isolated, discovered simultaneously by several laboratories using various approaches, and has been termed Cip1, p21, p20 [CAP1], Waf1, and Sdi1.[84,85,86,87 and 88] The importance of p21 presently seems to lie in three areas: (a) the p21 gene is transcriptionally regulated by the tumor suppressor protein p53; [87] (b) p21 is a Cdk inhibitor,[84,86] and (c) p21 may block the entry of senescent cells into the cell cycle. [88] In fact, p21 inactivation in normal diploid human fibroblasts by two sequential rounds of targeted homologous recombination renders cells capable of bypassing senescence. Cells lacking p21 fail to arrest the cell cycle in response to DNA damage at the checkpoint between the prereplicative phase of growth and the phase of chromosome replication; however, their apoptotic response and genomic stability are intact.[89] Interestingly, p21 induction during initiation of terminal differentiation occurs in a p53-independent manner. [90] This independence hints to a more universal function for p21 in differentiation as well as growth control. The Cdk inhibitors p21 and p27 share 44% identity in their amino-terminal regions, and *in vitro* p27 is able to inhibit the same gamut of Cdks as p21.[21] Normal fibroblasts exhibit a wide range of cyclin–Cdk complexes associated with p21. Strong associations occur with cyclin D–Cdk4 and cyclin E–Cdk2 complexes in the G1/S transition, as well as to the cyclin A–Cdk2 complex during mitosis. [40,84,85,91] However, cyclin B–Cdc2 forms only a weak partnership with p21 in M phase.[40] The strength of association of the cyclin–Cdk complexes with p21 is directly proportional to the ability of p21 to inhibit their functions *in vitro.* In addition to exerting negative control of the G1/S-phase transition, p21 may play a role at the onset of mitosis. In nontransformed fibroblasts, near the G2/M-phase boundary, p21 transiently reaccumulates in the nucleus, concurrent with the nuclear translocation of cyclin B1, and associates with a fraction of cyclin A–Cdk and cyclin B1–Cdk2 complexes in normal fibroblasts. Premitotic nuclear accumulation of cyclin B1 is reduced or not detectable in cells that are nullizygous for p21 (p21-/-), cells such as fibroblasts transformed by the viral human papillomavirus type 16 E6 oncoprotein, which functionally inactivates p53, or tumor-derived cells with low p21 levels. Such cells exhibit accelerated entry into mitosis with concomitant higher levels of cyclin A- and cyclin B-associated kinase activities. This correlation suggests that p21 may aide the execution of late cell cycle checkpoint controls by promoting a transient interlude late in G2.[92]

In response to DNA damage, the expression levels of p53 dramatically increase, which leads to the transcriptional induction of DNA damage inducible genes. Within the promoter of the p21 gene are two consensus p53-binding sites. [87] Exposure of cells to DNA-damaging agents enhances transcription of p21, leading to the agglomeration of p21 in cyclin E–Cdk2 immune complexes. This reaction culminates in decreased kinase activity that is thought to mediate the G1 arrest of the cell cycle.[93,94] This scenario only occurs if the cells have wild-type p53 (and fails with mutant p53), thus supporting the hypothesis that p21 is the primary mediator of p53-dependent G1 arrest. Ectopic overexpression of p21 alone in normal fibroblasts is also able to elicit growth arrest. [84,88] Basal levels of p21 may also depend on the functional activity of p53 because p21 is absent from the Cdk complexes of various transformed cell lines lacking an active p53. [40,87,93] To date p21 mutants have not yet been identified in human cancers, thus leading medical researchers to look for additional p53-inducible genes involved in growth regulation.

In addition to serving in DNA-damage checkpoint regulation by causing G1 arrest through the inhibition of Cdks, the p21 protein has also been implemented in the cells proofreading system during cellular replication to improve fidelity. PCNA enhances processivity of DNA polymerase delta (pol D) by forming a homotrimer that holds the complex of pol D with its replication factor C (RFC) to the DNA template to allow synthesis of both the leading and lagging strands of DNA. *In vitro* studies show that p21 can effectively associate with PCNA and block pol D–dependent DNA replication, which may be overcome only by the addition of PCNA. [95,96] p21 may be serving important functions in this manner. p21 may be acting to reduce the processivity of the lagging strand, which is desirable because the rate-limiting step here is the dissociation of the DNA polymerase at the end of the Okazaki fragment. By inhibiting the elongation step of polymerization. [96] p21 is effectively slowing the replicative process to allow for the proofreading mechanisms of the replicative machinery to correct any errors in replication. The *in vivo* verification of these results is still pending. Whether p21 is able to affect other functions of PCNA is not currently known. This relationship is of interest because PCNA is also involved in excision repair. Here, one may again hypothesize a role for p21 in decreasing the processivity of the DNA polymerase repair complex because this activity would be beneficial in filling the excision repair gaps. If this correlation is the case, eukaryotes would have another similarity with bacteria because bacteria alter the processivity of polymerase III by interactions with proteins, where eukaryotes were thought before to augment processivity only by the implementation of three different DNA polymerases. This new model calls for a higher order of regulation of processivity of DNA polymerase than once thought.

p16[INK4]

The Cdk inhibitor p16, also known as Multiple Tumor Suppressor 1 (MTS1), is implicated as a tumor-suppressor gene directly linked to the cell cycle. [97] In certain transformed cells lacking the normal components of the Cdk4 complexes, such as the D-type cyclins, PCNA, and sometimes p21,[40] Cdk6 is found in association with p16. Complex formation of p16 with Cdk4 is thought to block or upset the D-type cyclin association.[23] This dissociation contrasts with the inhibitory mechanisms employed by the Cdk inhibitors, p21 and p27. p16 is the first Cdk inhibitor where structural homologues such as MTS2 (p15) have been indicated. [97] Also, p16 seems to have a higher selectivity than the other two Cdk inhibitors because p16 appears to specifically inhibit the D-type Cdks, Cdk4 and Cdk6. These unique characteristics of p16 suggest that this protein may play a specialized and important role in growth regulation. In addition, the human p16 gene maps to chromosome 9p21 (MTS1 locus), a region that is often deleted in gliomas and melanomas. [97,98] MTS1 is found homozygously deleted in cell lines derived from tumors of lung, breast, brain, bone, skin, bladder, kidney, ovary, and lymphocytes. In addition, nonsense, missense, or frameshift mutations are found in at least one copy of the gene in melanoma cell lines.[97] However, only 10% to 20% of primary tumors demonstrate an alteration in the locus. [97,99]

Direct evidence of the inhibitory ability of p16 on cell growth has been provided. Ectopic expression of p16 effectively blocks entry into S-phase of cells induced to proliferate by the H-*ras* oncogene and suppresses cellular transformation by oncogenic H-*ras* and *Myc*.[100] As an inhibitor of G1 Cdks (Cdk4/6), p16 serves as an upstream regulator of the tumor-suppressor pRb as they cooperate through feedback mechanisms to regulate cell cycle progression. [101,102] Essentially, pRb becomes hyperphosphorylated by the D-type cyclin-associated kinases in late G1 and subsequently releases several active transcription factors that induce transcription of p16. As p16 expression reaches threshold levels, the kinase activity of Cdk4/6 is inhibited. Phosphatases then return pRb to its active hypophosphorylated form, allowing pRb to sequester the transcription factors and thereby down-regulate the p16 promoter to a basal transcription level (Figure 7.2).[101] Supporting this model, cells that are nullizygous for the RB gene (RB -/-) overexpress the p16 gene, which disrupts the formation of complexes between Cdk4/6 and the D-type cyclins [102] such that no cyclin D–Cdk complexes are detectable.[103] The dependence on endogenous wild-type pRb for ectopic expression of p16 or p16-related proteins p15 and p18, homologues of the cyclin D–Cdk 4 inhibitor p16 that form binary complexes *in vitro* and *in vivo* with Cdk4/6, to suppress cell growth also supports the idea that p16 and pRb are involved in the same pathway. [23,104]

p15[INK4b/MTS2]

The TGF-b pathway also involves the induction of a Cdk-inhibitor, p15 [INK4b/MTS2], a p16 homologue that also maps to the 9p21 locus. TGF-b transactivates p15, which inhibits the D-type–Cdk complexes (Cdk4/Cdk6). [105] This reaction releases additional p27 to inhibit other Cdks and thus promotes cell cycle arrest. The p15 [INK4b/MTS2] gene is homozygously deleted in 20% of primary advanced head and neck squamous cell carcinomas. [106] Deletion of the p16/p15 locus (9p21) is common in NSCLC.[107] In multiple myeloma, a high incidence of p16 and p15 alterations occur solely by hypermethylation of the 5' CpG islands, such that these alterations are the most common genetic abnormalities in this disease. Hypermethylation of p16/p15 is associated with blastic disease, whereas concomitant hypermethylation of

both genes is related to development of plasmacytoma.[108] Additionally, codeletion of p16 and p15 in pancreatic tumors is found often. [109]

TUMOR SUPPRESSORS

The Retinoblastoma Protein (RB1)

The genetic characteristics and the epidemiologic studies of Knudson concerning familial and nonfamilial retinoblastoma led to the "Knudson Two-hit Hypothesis." This hypothesis laid the groundwork for the discovery of tumor-suppressor genes and for a revolutionary new way of thinking about oncogenesis. Knudson concluded that the familial form of retinoblastoma results when an individual inherits a mutant (nonfunctional) allele from the affected parent, and the childhood tumor manifests when the wild-type (normal) allele of the same gene is functionally "knocked out" by a somatic event, resulting in LOH. The nonfamilial form of retinoblastoma requires two separate somatic mutations of both alleles of the gene and thus accounts for the sporadic nature of this form of retinoblastoma and its appearance later in life. [2] Subsequent studies confirmed that all retinoblastomas carry mutations in both alleles of the same gene. Prior to this finding oncogenesis was thought to evolve by dominantly acting oncogenes, which could only occur by somatic mutations because the dominant oncogenic phenotype would result in the gestational death of the embryo if it were acquired from the germline. So, for the first time, a recessive mutation conferring an inherited increased risk of neoplasia could be envisioned. The finding of deletions on chromosome 13q14 in both familial and sporadic retinoblastomas [110],[111] supported the Knudson hypothesis and lead to the eventual cloning of the first tumor-suppressor gene, the retinoblastoma gene, RB.[112],[113] and [114]

The retinoblastoma gene encodes a 105 kDa protein product, pRb. The nuclear phosphoprotein, pRb, serves as a negative regulator of cell cycle progression, at least in some specific cell types. RB transcripts are present in all normal tissues examined. [114] In cell lines that lack a functional pRb protein, the restoration of pRb function, by either microinjection of the protein in early to mid-G1 or by transfection of the cDNA, arrests cell growth in the G1-phase of the cell cycle. [115],[116] and [117] This inhibition of cell growth by pRb depends on the sequences necessary for the interaction of pRb with the transcription factor E2F, as well as a number of oncoproteins from human DNA viruses such as E1A, T antigen, and E7 (from adenovirus, simian virus 40 [SV40], and human papillomavirus, respectively). [118],[119],[120] and [121] Binding of pRb to this set of associated proteins occurs at a specific "pocket region" in pRb.

The "pocket region" of RB is also a common site of mutation in many human tumors, and it has been found altered or deleted in nearly all RB mutants from the tumors thus far examined.[111],[122] Inactivation of RB function involves various genetic lesions, including large-scale deletions and splicing mutations resulting in the deletion of an exon.[123],[124] Smaller deletions in the promoter region of RB and point mutations have also been found. [125],[126] Genetic mutations in RB have been demonstrated in several human tumors such as osteosarcomas, bladder carcinomas, prostate carcinomas, breast carcinomas, small cell lung carcinomas, cervical carcinomas, and leukemias.[127]

pRb and the Cell Cycle

Posttranscriptional regulation of pRb involves changes in the phosphorylation state of pRb throughout the cell cycle. [128],[129] During the G0 and G1 phases of the cell cycle, pRb is found in a hypophosphorylated form, which becomes increasingly phosphorylated on serine and threonine residues as the cell cycle progresses. The cell cycle–dependent phosphorylation of pRb may occur in several steps. In primary human T lymphocytes, pRb probably undergoes phosphorylation at discrete residues during three phases of the cell cycle: late G1, S-phase, and again, in G2/M. [128] All phosphorylations of pRb are on serine-threonine residues; to date, no evidence exists for phosphorylation on tyrosine residues in pRb. [129],[130] As the cells emerge from mitosis and enter into the G1-phase again, or become senescent in G0, pRb is dephosphorylated back to its hypophosphorylated form, possibly by pp1 phosphatase. [131] The viral oncoproteins and the transcription factor E2F bind specifically to hypophosphorylated pRb.[118],[119],[120] and [121] Microinjection studies show that hypophosphorylated pRb is the physiologically active form; [115] it exhibits the growth-suppressive function that can be inactivated in G1 by phosphorylation or by dimerization with viral oncoproteins to allow DNA replication.

The specific kinase(s) responsible for the *in vivc* phosphorylation of pRb is/are currently not known. Several Cdks have been found in association with pRb *in vivc* in a region similar to "the pocket." The A, B, D, and E Cdks as well as the recently discovered Cdc2-related kinase PITALRE (now known as Cdk9), [132] phosphorylate pRb *in vitro*.[68],[84],[116],[133],[134] and [135] Considering the timing of phosphorylation of pRb, as well as the peak activity intervals of the Cdks and their interactive abilities, it seems plausible that pRb is phosphorylated by the D-type–dependent kinases in early G1, cyclin E–Cdk2 at the G1/S transition, and by the cyclin A–Cdc2 complex at the G2/M transition. After completion of the cell cycle, cells generated by the mitotic process again display hypophosphorylated pRb caused by specific phosphatase activities. The Cdk inhibitors further guarantee the stringent timing of the activity of the Cdk complexes on pRb. [136] Because Interleukin 2 is stimulatory and TGF-b is inhibitory to cyclin E–Cdk2 activity, this offers one possible route by which exogenous growth-regulatory signals influence pRb and the cell cycle machinery. [20],[69]

Phosphorylation of pRb by the D-type–dependent kinases may play a key role in overriding the G1 cell cycle arrest of pRb. Microinjection of cyclin D antibodies into RB +/+ cells but not into the RB -/- tumor cell line, SAOS-2 (human osteosarcoma), blocks entry into S-phase. [38] This reaction suggests that pRb may indeed be the key substrate for the D cyclins. Several cell lines harboring mutated, or pRb inactivated, by the expression of the oncoprotein SV40 large T antigen, exhibit an enhanced expression of the specific cyclin D–Cdk4 kinase inhibitor, p16. [23] Additionally, cell lines, which fail to express functional p16, are resistant to the growth-suppressive effects of ectopic pRb expression. [117] This resistance reflects the cooperative effort and codependence of p16 and pRb in regulating cell cycle progression, as shown in Figure 7.2.

pRb Cellular Targets

Functioning as a transcriptional regulator through the modulation of the activity of several transcription factors, pRb exerts its growth-suppressive effects. pRb binds directly to the transcription factor ATF-2 and enhances its activity. [137] ATF-2 is thought to be involved in the expression of TGF-b. In this example, pRb may actually upregulate the expression of TGF-b and thereby lead to growth suppression through the expression of this growth inhibitor. As discussed previously, TGF-b would in turn disrupt and inactivate the cyclin D–Cdk4 complexes, leading to the release of the Cdk inhibitor p27 and the effective inhibition of cyclin E–Cdk2 (Figure 7.3). This process would prevent the phosphorylation of pRb and thus serve as a positive feedback loop to block progression into S-phase.

The transcription factor E2F, first identified as a DNA-binding protein required for E1A-mediated induction of the adenovirus E2 promoter, binds to hypophosphorylated pRb in the "pocket region" during the G0 and G1 phases of the cell cycle. [15],[63],[118],[138],[139] E2F binding sites are located in the promoters of multiple growth-promoting and growth-responsive genes such as c-*myc, c-myb,* dihydrofolate reductase (DHFR), thymidine kinase (TK), thymidine synthetase, DNA polymerase alpha, RB, the gene for the Rb-related protein p107, cyclin A, cyclin D1, cdc2, and E2F-1 itself. [15],[140],[141] The heterodimer of pRb-E2F is thought to sequester the active form of E2F and in effect block the transactivation of genes, whose products are necessary for DNA synthesis. [63],[141] The inhibition of transactivation potential of E2F-1 by pRb may occur by targeting a repressor domain to the transcription complex or by physically blocking the interaction of E2F-1 with a separate component of the transcription complex.[142] Association with the viral oncoproteins or the phosphorylation of pRb releases E2F in its functional form, which is then able to promote the transcription of genes required for S-phase entry and completion. The adenovirus early region 1 transforming proteins not only liberate the active form of E2F but also stabilize the protein by inhibiting targeted proteolysis of the transcription factor. [143]

Recently, four E2F-related proteins (E2F-2, E2F-3, E2F-4, and E2F-5) have been isolated and shown to share homologous domains with E2F; [144],[145],[146] and [147] thus confirming the speculation that an E2F family may exist. E2F binds as a heterodimer to DNA with dimerization partner-1 (DP1) (Figure 7.1).[148],[149] DP1 is actually the patriarch of a family of DP genes with their own protooncogenic properties that are able to dimerize with E2F family members. [150],[151] and [152] Besides the sequestering of E2F by pRb, the activity of the E2F/DP1 heterodimer is further regulated during the cell cycle by phosphorylation of DP1. As the phosphorylation level of DP1 increases, the DNA-binding activity of E2F/DP1 decreases proportionally. [153] Because a cyclin A–binding domain is located in the amino-terminus of E2F-1, cyclin A–Cdk2 is the most likely candidate for the late S-phase phosphorylation of DP1. [154] Moreover, cyclin A–Cdk2 interacts with E2F-1 directly both *in vivc* and *in vitro* and phosphorylates E2F-1, thereby inhibiting the DNA-binding activity of the E2F-1/DP-1 complex. [155] The regulation of transcriptional activity is made even more complex considering the involvement of the Rb-family proteins, p107 and pRb2/p130. The Rb-family is capable of association with the E2F family. This interaction seems to be temporally modulated and varies among family members. Several sources of data suggest that pRb and p107 associate with distinct E2F species. The *in vivc* results demonstrate that E2F-1, E2F-2, E2F-3, and E2F-4 all form complexes with pRb, but E2Fs one through two do not interact with p107. [156] E2F4 and E2F5 were both cloned by their ability to interact with pRb2/p130. E2F4 undergoes complex formation *in vivc* with pRb2/p130 during G0 and G1, then later associates with p107 and pRb in late G1 and S phases as the levels of these regulators increase. [145],[146] and [147],[157] The vast majority of endogenous E2F activity stems from E2F-4. In fact, during

G1 E2F-4 accounts for almost all of the free activity. During S-phase an equal mixture of E2F-4 and E2F-1 constitutes the free E2F activity. [157]

Another important feature of the interaction between pRb and E2F-dependent gene repression is that pRb protects E2F-1 from proteolytic degradation by the ubiquitin-proteasome pathway.[143,158,159] Furthermore, the antagonistic effect of pRb on E2F activity not only blocks transcription of growth-promoting genes but also may be the mechanism by which pRb protects against apoptosis in differentiating cells. Overexpression of E2F-1 induces apoptosis following entry of the cells into S-phase in cells with a wild-type p53 gene, but it favors proliferation in cells null for p53 (p53 -/-). [160,161] Coexpression of pRb with E2F-1 blocks the induction of apoptosis by E2F-1.[160] Additionally, studies involving homozygous disruption of the E2F-1 gene indicate that E2F plays a physiologic role in normal development, more than likely by the induction of apoptosis in a specific set of developing cells. This conclusion comes from the finding that at an early stage of development, mice null for the E2F1 gene show defects in cell types in which apoptosis plays a significant role in their terminal differentiation, such as epithelial cells of the testis and other exocrine glands and T-cells. Later in life these animals develop widespread tumors. [162,163] The stochastic levels of pRb and E2F-1 may prove to be critical not only in regulating cell cycle progression but also in determining cell fate and cellular specialization. Because terminal differentiation invariably involves permanent withdrawal from the cell cycle,[164] and because apoptosis is a constant phenomena in differentiating cells, [165] key proteins regulating such events would be predicted to be multifunctional in nature.

pRb and Cellular Differentiation

In addition to the role of pRb as a checkpoint regulator of the cell cycle, the protein is also implicated in cellular differentiation through complex formation and subsequent modulation of various tissue-specific transcription factors. The retinoblastoma protein is implicated in playing an integral role in adipogenesis, myogenesis, and hematopoiesis.[166] Members of the MyoD bHLH transcription factor family associate with pRb, and the binding of pRb to MyoD is thought to induce activation of muscle-specific genes. In fact, cell lines that lack a functional pRb are unable to undergo myogenic conversion. This ability points to a possible role of pRb in the myogenic activation of MyoD. [167] Similarly, in murine fibroblasts pRb activates CCAAT/ enhancer-binding proteins (C/EBPs), a family of transcription factors crucial for adipocyte differentiation. The C/EBP zinc finger transcription factor and pRb form a complex in the E2F pocket-binding domain of pRb. Furthermore, conversion of fibroblasts to adipocytes by C/EBP transfection requires the presence of a functional retinoblastoma protein. [168] Furthermore, an intact retinoblastoma susceptibility protein family binding domain in SV40 large T-antigen is necessary for deletion mutants of this oncoprotein to block adipocyte differentiation. [169] This requirement further demonstrates that the Rb-family proteins are important in regulating adipocyte differentiation. Evidence directly links pRb with several other transcription factors that are involved in the withdrawal from the cell cycle and the induction of differentiation, [167,170] such as the brahma-related gene 1 (BRG1).

Perhaps the most convincing evidence for the importance of pRb in cellular differentiation and specialization stems from the studies of RB knockout mice. Homogeneous germline disruptions of the RB gene (RB -/-) are lethal mutations, with the mice dying *in utero* by the fourteenth day of gestation and manifesting gross defects in the development of the hematopoietic and central nervous systems.

The heterozygous mice (RB +/-) mature normally until 9 months of age when they develop thyroid and intermediate lobe pituitary tumors. Surprisingly, they show no indication of retinoblastoma. [171,172] The fact that the vast majority of cell division cycles in the RB -/- embryos occur without the presence of pRb suggests that other proteins, possibly the Rb-family members, can complement pRb function, or perhaps the cell can elicit a different signal transduction pathway to regulate the activities of proliferation. These results also point to pRb involvement in neurogenesis and hematopoiesis. The link between pRb and hematopoiesis is supported by recent transcriptional studies indicating that the RB gene plays an erythroid- and stage-specific functional role in normal human adult hematopoiesis, particularly at the level of late erythroid hematopoietic progenitor cells. [173]

Rb-Family

The "pocket region" of pRb is shared by two additional E1A-associated proteins, which has led to the identification of two members of the Rb-family, p107, and pRb2/p130.[117,174,175] All three Rb-family members (also known as pocket proteins) localize primarily to the nuclear compartment of the cell. [114,174,176] A schematic picture of pRb, p107, and pRb2/p130 is shown in Figure 7.4 highlighting the zones of high homology among the family members.

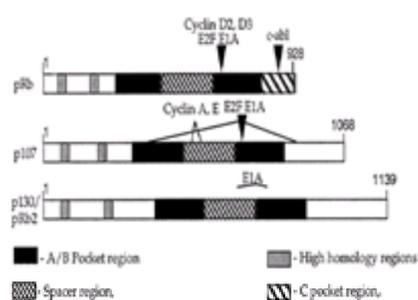

FIGURE 7.4. A schematic representation of the retinoblastoma (RB) family proteins. (From M. Paggi, Baldi A, Bonnetto F, et al., in "Retinoblastoma protein family in cell cycle and cancer," *J Cell Biochem* 1996;62:419, with permission.)

Essentially, the structures consist of (a) the N-terminal portion; (b) the pocket structure subdivided into domain A, spacer, and domain B; and (c) the C-terminal portion, also called domain C. The pocket functional domains A and B are the most conserved and are responsible for most of the interactions involving both endogenous proteins and viral oncoproteins. Amino acid comparisons of the three protein sequences of the Rb-family suggest a closer relationship of pRb2/p130 to p107.[175] Beyond the high structural homology, phylogenetic studies show that pRb is specific to vertebrates; however, p107 and pRb2/p130, which form their own subfamily defined by their homologous spacer region, are common to plants, insects, and vertebrates. [177,178]

Similar to pRb, ectopic expression of p107 and pRb2/p130 is able to suppress the growth of the osteosarcoma cell line SAOS-2. [116,117,121,179] Recent functional studies of p107 and pRb2/p130 indicate that although the Rb-family members may be able to complement each other, the proteins are not fully functionally redundant. Unlike pRb, both p107 and pRb2/p130 form stable complexes with cyclin A, cyclin E and Cdk2 *in vitro* and *in vivo*.[180,181,182,183 and 184] Both p107 and pRb2/p130 undergo cell cycle–dependent phosphorylation similar to pRb. As with pRb, p107 phosphorylation is cell cycle regulated with a high level of hyperphosphorylated p107 present during S-phase and at the G2/M transition. [185] The major complex responsible for p107 phosphorylation is the cyclin D1–Cdk4 complex. [182,186,187] As far as pRb2/p130 is concerned, it displays evident cell cycle changes in phosphorylation, coupled to an extensive microheterogeneity in SDS-PAGE migration pattern. [176,183,188] From a functional point of view, cyclins A, D-type, and E overexpression rescue pRb2/p130-mediated growth arrest in SAOS-2 human osteosarcoma cells. [183] This rescue may result from the cyclins targeting pRb2/p130 for phosphorylation and subsequent inactivation, and/or pRb2/p130 may negatively modulate cdk activity.

Additionally, pRb, p107, and pRb2/p130 all form complexes with specific E2F family members, as detailed previously. [118,145,146,156,185,189] However, the temporal order of complex formation appears to vary. For example, the binding of p107 to E2F is first detected at the G1-S boundary and remains stable throughout S-phase. [185,189] On the other hand, pRb-E2F complexes are found in the G1-phase and then dissociate in late G1. [118,119] The main form of E2F detected in the G0 to G1 phases in primary mouse fibroblasts is E2F bound to pRb2/p130, which is then replaced by p107-E2F complexes in late G1. [188] Therefore, pRb2/p130 is the major negative modulator of E2F activity in quiescent cells.

Similar to the case for pRb and E2F-1, p107 and pRb2/p130 through complex formation with E2F-4 stabilize the protein and protect E2F-4 from targeted proteolysis by the ubiquitin-proteasome pathway. Stabilization of the p107- and pRb2/p130-E2F4 complexes is thought to contribute to maintaining a state of active transcriptional repression in quiescent cells. [143] Unlike E2F-1, E2F-2, or E2F-3, which are constitutively nuclear, E2F-4 and E2F-5 lack a nuclear localization signal. The subcellular localization of E2F-4 is regulated in a cell cycle–dependent manner with high nuclear/cytoplasmic ratios in G0 and early G1, with a progressive increase in cytoplasmic E2F-4 as the cells proceed toward S-phase. [190] Co-transfection studies indicate that cellular compartmentalization of E2F-4 and E2F-5

becomes nuclear by complex formation with p107, pRb2/p130, DP-2, and/or DP-3d.[190],[191] and [192] E2F-4 nuclear accumulation induced by pRb2/p130 and p107 correlates with cell growth arrest, whereas overexpression of E2F-4 with DP-3d stimulates reentry into the cell cycle in previously quiescent cells. This E2F-4/DP-3d reactivation of the cell cycle, however, is efficiently counteracted by overexpression of either p107 or pRb2/p130. [192]

Genetic analysis of mice homozygously deleted for each of the retinoblastoma family members, as well as combined deletions of the p107 and RB genes and targeted disruptions of the RB2/p130 and p107 genes, further demonstrates that the Rb-family proteins have unique but partly overlapping functions that are required for the proper development and maintenance of vertebrate organisms.[171],[172],[193],[194] and [195] The expression patterns of the Rb-family members during early development of wild-type mice correlates well with the tissue-specific damage elicited by the absence of different sets of the Rb-family proteins.[196] Moreover, deletion of different members of the Rb-family results in altered expression patterns of E2F-regulated genes in mouse embryonic fibroblasts (MEF) prepared from embryos of the knockout mice.[197] Severe deregulation of E2F-dependent transcription occurs in RB -/- and p107 -/-; RB2/p130 -/- double mutants, resulting in improper expression of S-phase–promoting and cell cycle–responsive genes such as p107 and pRb in RB2/p130 -/- MEFs, cyclin E in RB -/- MEFs, and cyclin A, b-myb, and E2F-1 in p107 -/-; RB2/p130 -/- MEFs.[197] This expression clearly demonstrates differences among the Rb-family in the transcriptional regulation of distinct genes.

Each of the retinoblastoma family proteins elicit cell cycle growth arrest in a unique manner. The E1A mutant pm928 that binds p107, but fails to bind pRb and pRb2/p130, is able to initiate DNA synthesis, but the transformation property of the oncoprotein is abrogated. [134],[198],[199] This condition implies that pRb2/p130 and pRb may elicit repression of cell cycle progression at similar checkpoints. Growth suppression by pRb requires an intact E1A oncoprotein-binding domain, whereas p107 does not.[116],[117] p107 contains two functional domains that are able to block cell cycle progression independently in a cell type–specific manner. One domain, like pRb, corresponds to the sequences necessary for association with the transcription factor E2F. The interaction domain for cyclin A and cyclin E complexes forms the other. Only the cyclin-binding domain is an active growth suppressor in the cervical carcinoma cell line C33A, which is sensitive to p107-but resistant to pRb-mediated growth suppression.[200] This relationship illustrates an important functional difference between pRb and p107. Additionally, p107 and pRb2/p130, similar to the p21 family of Cdk inhibitors, can inhibit the phosphorylation of target substrates by cyclin A–Cdk2 and cyclin E–Cdk2 complexes through a structurally and functionally conserved kinase inhibitory domain in their N-terminal region. This domain also serves as an independent growth-suppressive domain. [201],[202] and [203] The interactions between p21 and p107 with cyclin–Cdk2 complexes are mutually exclusive. p53-mediated induction of p21 levels in response to DNA damage leads to the dissociation of p107– cyclin–Cdk2 complexes to form p21–cyclin–Cdk2 complexes.[202] Furthermore, p107-E2F complexes dissociate upon activation of the p107-bound cyclin–Cdk kinases.[202] Together, these results suggest that different families of proteins, in a mutually exclusive manner in response to certain signals, can affect cdk activity, thereby regulating macromolecular assembly. Intriguingly, a unique domain of pRb2/p130 within the spacer region also acts as an inhibitor of Cdk2 kinase activity separate from that of p107. Increased expression of pRb2/p130 during various cellular processes correlates with decreased kinase activity of Cdk2. This correlation demonstrates that pRb2/p130 may act not only to bind and modify E2F activity but also to inhibit Cdk2 kinase activity in concert with p21 in a manner different from p107.[201]

Most interestingly, the T98G human glioblastoma cell line, which is resistant to the suppression effect of both pRb and p107, [117] demonstrates a drastic reduction in cellular proliferation upon overexpression of pRb2/p130.[179] This reaction suggests that pRb2/p130 may function in a completely different pathway than that of p107 or pRb, and that certain mutation(s) within the T98G cells predisposes them to be sensitive to the effects of pRb2/p130 but not to those of p107 or pRb. An alternate explanation may be that the three proteins may share functional properties, whereas pRb2/p130 has an additional property that p107 and pRb2 are unable to complement in this particular cell line.

In addition to these differences, no evidence supports the notion that p107 is normally a tumor suppressor. To date no examples of naturally occurring mutations of p107 have been found, despite the testing of several hundred human tumor samples and cell lines. In addition, p107 maps to chromosome 20q.11.2, a region not commonly found to be cytogenetically altered in human neoplasms.[174] Furthermore, the expression of p107 in cell lines derived from retinoblastoma tumors implies that p107 is unable to complement the lack of pRb and to suppress tumor formation.[204] However, pRb2/p130 maps to human chromosome 16q12.2,[205] an area in which deletions have been found in several human neoplasms, including breast, ovarian, hepatic, and prostatic cancers. [205]

The introduction of wild-type pRb2/p130 in HONE-1 cells, a cell line of human nasopharyngeal carcinoma (NPC) that endogenously expresses a genetically altered form of pRb2/p130 at a very low level, causes a significant reduction in cell proliferation and a change in morphology. [179] The HONE-1 cell line expresses the RB gene product with normal size and abundance, and no point mutation has been detected in the common sites for RB mutations.[206] NPC shows no detectable retinoblastoma-susceptibility gene alterations. [206] These recent findings hint to a possible involvement of pRb2/p130 in nasopharyngeal carcinogenesis in the face of a functionally intact RB gene. NPC is a rare disease in most parts of the world; however, the disease has a racial and geographic distribution. The people of Southern China are among those that deviate from the low-risk profile so much that NPC is the most common cancer in the city of Guangzhow (Canton) and constitutes 32% of all cancer.[207],[208] Furthermore, immunohistochemical studies indicate that lack of pRb2/p130 expression plays a role in the formation and/or progression of lung (Table 7.1, Table 7.2, Table 7.3)[209],[210] and endometrial cancer (Table 7.4 and Figure 7.5).[211] Serving as an independent prognostic factor, the expression level of pRb2/p130 is able to predict patient outcome and to identify groups of patients at a greater risk of dying from the cancer. [211] Morever, certain human tumor cell lines of nasopharyngeal and lung cancer harbor genetic mutations in the RB2/p130 gene. [179],[212],[213] and [214] This finding suggests a role for the RB2/p130 gene as a tumor-suppressor gene in human cancer.

TABLE 7.1. RB-FAMILY PROTEINS AND PCNA EXPRESSION IN LUNG CANCER

Expression	pRb/p105	p107	pRb2/p130	PCNA
High	23 (30%)	—	36 (47%)	19 (25%)
Medium	33 (43%)	10 (13%)	7 (9%)	42 (54%)
Low	16 (21%)	64 (83%)	16 (21%)	16 (21%)
Undetectable	5 (7%)	3 (4%)	18 (23%)	—

High = 60% to 100% of positive cells; Medium = 30% to 60% of positive cells; Low = 1% to 30% of positive cells; Undetectable = 0% of positive cells.

TABLE 7.2. EXPRESSION PATTERN OF Rb-FAMILY MEMBERS AND PCNA IN LUNG CANCER

	Tumors			
Score[a]	Squamous	Adenocarcinoma	SCLC[b]	Carcinoid
1	23 (19.5%)	8 (25%)	4 (100%)	
2	55 (46.6%)	18 (56.3%)		
3	40 (33.9%)	6 (18.7%)		4 (100%)

[a] 1, 0% to 10% of positive cells; 2, 10% to 50% of positive cells; 3, 50% to 100% of positive cells.
[b] SCLC, small cell
lung cancer.

TABLE 7.3. Rb2 PERCENTAGE OF EXPRESSION IN LUNG CANCER

Adjuvant Treatment	No. of Cases	pRb2/p130 (%)		P Value
		Positive	Negative	
None	57	97.4%	68.5%	<.01
Radiotherapy	37	86.8%	50.3%	<.05
Chemotherapy	6	66.6%	0	<.01

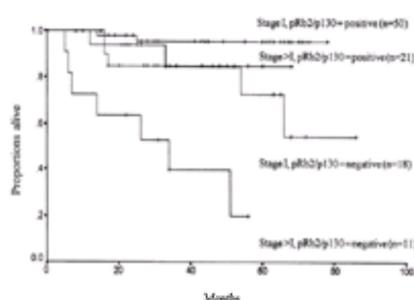

FIGURE 7.5. Probability of survival in 100 patients with endometrial carcinoma (all stages) and pRb2/p130 positive or -negative tumors. (From T. Susini, Baldi F, Howard CM, et al. "Expression of the retinoblastoma-related gene Rb2/p130 correlates with clinical outcome in endometrial cancer," *J Clin Oncol* 1998;16:1091, with permission.)

RB1 AND RB2 IN LUNG CANCER

Lung cancer is one of the leading causes of death related to cancer in the world. The high mortality rates for lung cancer may in part result from the absence of standard clinical procedures for diagnosis of early tumoral stages, in contrast to the screening modalities available for breast, prostate, and colon cancers. [215] Early studies indicated that several distinct chromosomal loci (3p, 9p, 13q, 17p, and others) are implicated in the pathogenesis of lung cancer, suggesting that sequential genetic events may occur during the initiation and progression of lung carcinogenesis. [216],[217 and 218] PRb/p105 (RB1) maps to the chromosomal locus 13q and pRb2/p130 (RB2) on 16q.[114],[205] Recently, frequent allelic losses on chromosomes 2q, 18q, and 22q have been reported in advanced NSCLC. [219] Additionally, frequent novel genetic alterations such as increased DNA copy number at 5p, 1q24, and Xq26 and decreased DNA copy number at 22q12.1–13.1, 10q26, and 16p11.2 have been identified in NSCLC.[220],[221]

In all normal cells, two types of genes—oncogenes and anti-oncogenes (also known as tumor-suppressor genes—are expressed and control cell proliferation and differentiation. Cell growth is stimulated by oncogenes and inhibited by anti-oncogenes. Neoplastic transformation involves loss of growth control caused by defective gene expression either by overexpression of a normal growth-promoting protein or by expression of an abnormal mutated protein that may result in a gain or loss of function. Several oncogenes, such as *c-myc, N-myc,* and *L-myc,* have been identified as potential initiators of lung cancerogenes. [222] On the other hand, loss of anti-oncogene function has also been described in lung cancer. Mutations or deletions of the *RE* gene have been reported in non–small cell carcinomas in greater than 90% of the cases.[223] Likewise, mutations of other tumor-suppressor genes such as p53 have been reported with frequencies as high as 50% in NSCLC and 70% to 80% in SCLC.[222],[223] Moreover, by immunohistochemistry the expression of *p53, pRb/p105, Ras,* and *Bcl-2* have been investigated in a panel of 65 samples of preneoplastic lesions of the bronchial epithelium. The frequency of p53-positive and pRb-negative microscopic fields was directly related to the morphologic grading of the lesions. One of the main patterns found to be correlated with the severity of histopathologic features was characterized by combined p53 hyperexpression and pRb hypoexpression.[224]

Lung cancer arises from a series of morphologic changes that take several years to progress from a normal epithelium to an invasive cancer. During the progression from hyperplasia through metaplasia, to dysplasia, to carcinoma *in situ,* to invasive and finally to metastatic cancer, multiple molecular changes have been noted. The molecular changes include activation of dominant oncogenes as well as loss of recessive growth-regulatory genes or anti-oncogenes. [225] Interestingly, some authors correlated the prognostic significance of the loss of Rb protein either alone, or in combination with *Ras* or p53 mutations in patients with NSCLC. Individuals with the theoretically best pattern of protein expression in their tumors versus those with the theoretically worst pattern of gene expression (i.e., Rb+/ *Ras-* versus Rb-/*Ras+* and Rb+/p53- versus Rb-/p53+) showed a longer period of survival. The correlation between Rb and *Ras* proved to be a better prognostic factor than that of the Rb and p53 status in NSCLCs. In patients affected by squamous cell carcinoma, neither Rb/ *Ras* nor Rb/p53 status was a significant prognostic factor in this cohort. [226]

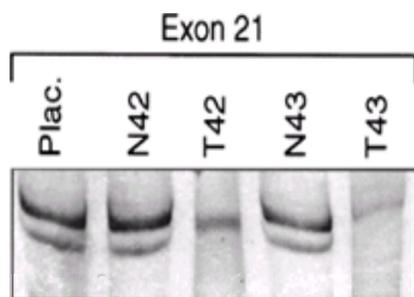
RB2/p130 is the latest member of the Rb-family of proteins to be identified. [175],[181],[184] Immunohistochemic studies of the expression patterns of the Rb family members (pRb/p105, p107, and pRb2/p130) in 235 specimens of lung cancer indicate that pRb2/p130 may play an important role in the pathogenesis and progression of certain lung cancers (Table 7.1, Table 7.2, Table 7.3).[209],[210] The same studies have suggested that *RB2/p130* protein expression inversely correlates with the histological grading and with PCNA expression in different lung cancer histotypes (Table 7.1, Table 7.2, Table 7.3).[209],[210] The characterization of the genomic structure of the *RB2/p130* gene[227] allowed for mutational screening. Different authors reported that the majority of point mutations in the *RB/p105* gene are located in the C-terminal region.[228] Very little is known about the presence of mutations in human cancers in the *RB2/p130* gene instead. In two very recent studies, the *RB2/p130* gene has been found to be mutated in the carboxyl-terminus region in more than 80% of the human lung tumors analyzed, as well as in primary human lymphomas and NPCs by single-strand conformation polymorphsm (SSCP) analysis and direct DNA sequence analysis (Figure 7.6).[213],[214] Interestingly, the vast majority of those lung tumors were adenocarcinomas spanning from poorly to moderately differentiated.


FIGURE 7.6. Representative example of single-strand conformation polymorphyism analysis of exon 21 of the *RB2/p130* gene in primary lung tumors compared to the normal genomic DNA extracted from peripheral blood of the corresponding patient, indicating that the mutations found in the tumors were somatic. (From P.P. Claudio, et al. "Mutations in the retinoblastoma-related gene RB2/p130 in lung tumors and suppression of tumor growth *in vivc* by retroviral-mediated gene transfer," *Cancer Res,* [*in press*], 1999.)

As a model to study carcinogenesis, mice are among the most suitable. Mice develop lung tumors with a similar histology and molecular features to peripheral adenocarcinomas in humans. Additionally, mice are an easy and firmly established model to grow tumors *in vivc* and to study different delivery systems suitable for human gene therapy. The advantage of this model system is that events early in tumorigenesis can be studied at the molecular level. Decreased expression of p15, p16, Rb, cyclin D1, Apc, Mcc, and Gjal occur during tumor formation in both rodents and humans. [229]

Gene therapy models in different types of cancers using viral vectors to deliver either a functional p53 or pRb have been attempted. [230,231,232,233,234,235,236 and 237] In a recent study, using a tetracycline-regulated gene expression system to control the expression of *RB2/p130* in JC virus-induced hamster brain tumor cells, it was demonstrated for the first time that *RB2/p130* could be used to inhibit the growth of such tumors *in vivo.* Induced expression of pRb2/p130 in this *in vivc* study brought about a 3.2 fold or 69% reduction in tumor mass in *nude* mice. [238]

The effects of expressing pRb2/p130 *in vivc* in a lung adenocarcinoma cell line were also analyzed using a retroviral delivery approach. [213] Retroviruses are among the most efficient vector systems for transducing genes into mammalian cells, and they have been successfully used to deliver therapeutic genes into humans. [232,239] The requirement for host cells to actively divide to allow viral genes to integrate into the host genome [240] may be advantageous for cancer gene therapy. This requirement would limit exogenous gene delivery to rapidly proliferating cancer cells while sparing delivery to other nonproliferating cells within the effected organ.

It has been recently shown that *in vivc* retroviral transduction of the *RB2/p130* gene in established tumors, derived from injection of the lung adenocarcinoma cell line H23 grown subcutaneously in *nude* mice, greatly reduced the tumor mass. The average tumor weight of the excised tumors transduced with *RB2/p130* was over 12 fold smaller compared to those transduced with retroviruses carrying the puromycin (*Pac*) resistance alone or the *Lac-Z* gene. [213]

Functional inactivation of tumor-suppressor gene products by way of interaction with viral oncoproteins of DNA tumor viruses represent another mechanism of tumorigenesis. Such a scenario has been proposed for the oncoprotein of simian virus 40, the SV40 large T antigen (Tag) that targets and inactivates cell cycle regulatory proteins such as the Rb-family and p53, leading to transformation of human cell lines *in vitro,* and producing tumors *in vivc* in rodent models. [241,242 and 243] Even though mesotheliomas are among the most aggressive human cancers, alterations of important cell cycle "controllers," such as the Rb-family genes, have never been reported in these tumors. However, SV40-like sequences have been detected in 86% of archival specimens of mesothelioma; furthermore, SV40 Tag was isolated from frozen biopsies of human mesothelioma that retained its ability to bind each of the Rb-family proteins: pRb/p105, p107, and pRb2/p130. [242] This finding raises the question of whether the tumorigenic potential of SV40 Tag in some human mesotheliomas may stem from its ability to interact with and thereby inactivate several tumor- and/or growth-suppressive proteins.

The absence of mutations in Rb-family proteins and the unusually high level of expression of pRb, pRb2/p130, and p107 in the mesothelioma specimens may be explained by the physical association of these proteins with SV40 Tag, which should lead to their functional inactivation. All members of the Rb gene family share the ability to interact physically with certain oncoproteins of DNA tumor viruses. These viral oncoproteins compete with the E2F family of transcription factors for binding to the Rb-family proteins. [244] Release of the E2F family members from the pocket structure leads to the induction of genes needed to proceed through the cell cycle. The finding that p53, a well-characterized tumor-suppressor gene, is also a target of SV40 Tag, [241,245] further supports the model of viral transformation via the binding of the viral oncoproteins to a specific region of cell growth-suppressor genes.

A paradigm is forming that the removal or inactivation of functional tumor-suppressor proteins such as pRb/p105 or pRb2/p130 by way of tumor viral oncoproteins, as is the case in SV40 large T antigen–associated mesothelioma, [242,245] or by way of genetic alteration as is the case in lung cancer, [124,213,215,217,218,222,223,225,246] may be a critical event in the malignant transformation of a cell.

Considering the impact of lung cancer in terms of morbidity and mortality on the Western world, [247] it is possible to suggest that *RB1* (pRb/p105) and/or *RB2* (pRb2/p130) in combination with *p53, Ras,* and other cell cycle regulatory genes, may serve as valuable tools in establishing the molecular diagnosis and/or prognosis of lung cancer. Additionally, identification of mutations within these tumor-suppressor loci in lung cancer could have possible implications on guiding and designing standard as well as novel therapeutic regimes.

CONCLUSION

The prototypic tumor-suppressor gene *RE* is mutated in several human tumors, and numerous studies are now beginning to identify their role in cancer development, as well as in normal cell physiology. In cell lines that lack a functional pRb protein, the restoration of protein function suppresses the cells' neoplastic properties. [115,116] These data have led to the exploration of the possibility of replacement of the wild-type *RE* gene as a clinical treatment for human cancers. [231,232 and 233,235,236 and 237,248,249,250 and 251]

The fact that transforming oncoproteins such as SV40 Tag must maintain an intact Rb-family binding domain (LXCXE domain; L = Leucine, X = any amino acid, C = Cystein, B = Glutamine) to transform *RE* -/- cells indicates that p107 and/or pRb2/p130 are also strategically important targets for SV40 Tag-mediated transformation and implicates them as putative tumor-suppressor genes. [252] In support of an involvement of the *RB2/p130* gene in human cancer as a tumor-suppressor gene, it maps to human chromosome 16q12.2, an area in which deletions have been found in several human neoplasias including breast, ovarian, hepatic, and prostatic cancers. [205] Intriguingly, differential expression of pRb2/p130 in human endometrial cancer, where the expression level of pRb2/p130 inversely correlates with tumor grade and prognosis, has been detected. [211] These findings have significant clinical implications involving prognosis and implementation of therapeutic strategies. Immunohistochemic data examining the expression of the Rb-family proteins in 235 patient samples of lung carcinoma suggest an independent role for the reduction or loss of pRb2/p130 expression in the formation and/or progression of lung carcinoma Table 7.1, Table 7.2, Table 7.3. [209,210] Additionally, different groups have detected mutations in the *RB2/p130* gene in human cell lines of small cell and adenocarcinoma [212] as well as patient tumor specimens. [213] This finding suggests that functional inactivation of one or more of the Rb-family genes by genomic mutation or by transforming oncoprotein may provide the cell with a growth advantage resulting in tumor formation.

Additionally, it has recently beer shown that the induction of pRb2/p130 expression is growth suppressive to tumor formation *in vivo.* [213,238] This data predicts that *RB2/p130* gene therapy may serve as a beneficial therapeutic alternative for cancer and lays the foundation for exploring this avenue of research in addition to other gene therapeutic models that are under current investigation. [253]

In summary, pRb2/p130 is proving to be a complex multifunctional protein that is directly linked to the cell cycle machinery by its Cdk-inhibitory activity. Furthermore, the fact that induction of pRb2/p130 expression or overexpression by retrovirally delivered pRb2/p130 inhibits tumor growth *in vivo,* [213,238] along with the mapping of the *RB2/p130* locus to a region altered in several human neoplasms, [205] immunohistochemic data indicating an independent role for pRb2/p130 in the development and/or

progression of human lung (Table 7.3)[209],[210] and endometrial cancer (Table 7.4 and Figure 7.5),[211] and the identification of mutations in the *RB2/p130* gene in human tumor cell lines[212] and primary tumors,[213],[214] strongly supports the hypothesis that *RB2/p130* is a tumor-suppressor gene as well as RB1/p105.

THE ROLE OF THE *FHIT* GENE IN THE PATHOGENESIS OF LUNG CANCER

MARIA-LUISA VERONESE
GABRIELLA SOZZI
KAY HUEBNER
CARLO M. CROCE

Lung cancer is a major cause of mortality worldwide, and despite progress in early detection and treatment, the overall survival rate has not improved significantly during the past two decades.[1] A direct association between lung cancer and smoking is well known, being first observed 55 years ago by Ochsner and DeBakey[2] and subsequently confirmed by epidemiologic studies.[3,4] Lung tumors that develop in nonsmokers account for only 5% to 10% of all lung cancers.[5,6] Although the relationship between carcinogen exposure and tumorigenesis has long been recognized, the molecular events resulting in lung cancer have been defined only recently. Lung cancer, similar to other cancers, results from the sequential accumulation of specific genetic changes. These changes involve deletions of the short arm of chromosome 3 (3p), inactivation of tumor-suppressor genes *TP53, CDKN2,* and *RB,* deregulated expression of *EGER* and *HER2/neu* oncogenes, and alteration in expression of proteins involved in apoptosis control, such as Bcl2, as well as point mutations in *KRAS2* and amplification of *myc* oncogene family members (see also Chapter 4, Chapter 5, Chapter 6, Chapter 7, Chapter 23).[7] Definition of the genetic alterations and the associated alterations in biologic behavior of lung cancer will undoubtedly aid in the design of novel therapies, as well as in early diagnosis and prevention of the disease.

Evidence linking exposure to carcinogens in cigarette smoke and specific genetic alterations of the bronchial tissue is accumulating. In particular, deletions of loci on the short arm of chromosome 3, which have been recognized as early events in lung tumor development, seem to be preferential targets of tobacco smoke carcinogens.[8,9] We have shown that the *FHIT* gene at chromosome 3p14.2 plays a critical and early role in lung carcinogenesis.[10] Interestingly, this gene that spans more than 1.5 Mb of DNA contains the most inducible of the constitutive fragile sites of the human genome, *FRA3B,* a common target of rearrangements in lung carcinogenesis.

In this chapter we examine the importance of the 3p14.2 region and the *FRA3E* fragile site in lung cancer. We summarize previous studies on the cloning and characterization of the *FHIT* gene and the investigation of the Fhit protein and its biologic function. We also describe the biallelic alterations of the *FHIT/FRA3B* locus in human cancers, methods to detect these alterations, and our theories about the mechanisms involved in deletion. Finally, we discuss the role of *FHIT* in lung tumors and the clinical implications of its loss of function.

THE GENE

The Short Arm of Chromosome 3 and the FRA3B

Chromosomal deletions and loss of heterozygosity (LOH) involving the short arm of chromosome 3 (3p) are often detected in carcinomas of the lung, head and neck, kidney, stomach, breast, cervix, and ovary.[11,12,13,14,15,16 and 17] At least four distinct regions—3pl12, 3p14, 3p21, and 3p24–25—have been identified by LOH studies, suggesting the presence of tumor-suppressor genes involved in the pathogenesis of several epithelial neoplasia in these regions. The von Hippel-Lindau gene (*VHL*) at chromosome 3p25 was isolated several years ago.[18] This gene is responsible for some familial kidney carcinomas, is inactivated in a large fraction of sporadic renal cancers, but does not seem to be involved in lung cancer.[19] A gene at chromosome band 3p14.2 has been sought for many years because this region is the site of a balanced chromosome translocation, t(3;8)(p14.2;q24), associated with familial clear cell renal carcinoma.[20] This translocation is also known to be close to an interesting genetic landmark, *FRA3B,* the most inducible of the constitutive or common human chromosomal fragile sites.[21,22]

Fragile sites are specific chromosome regions that reveal specific cytogenetically detectable gaps or breaks when cells are exposed to certain chemicals, for example inhibitors of DNA synthesis such as aphidicolin, and are divided into two classes, common and rare.[23,24] Common fragile sites are highly conserved during evolution, are induced by agents that perturb DNA replication, and have been implicated in interchromosomal and intrachromosomal rearrangements, deletions and translocations in hybrid cells, and plasmid and viral integration.[25,26,27 and 28] Expression of fragile sites can also trigger gene overexpression, suggesting their possible role in oncogenic amplification during tumorigenesis.[29] The coincident chromosome location of common fragile sites, characteristic cancer breakpoints, and genes involved in tumor development has suggested that fragile sites could be involved in specific chromosomal rearrangements in malignant diseases, or harbor oncogenes or tumor-suppressor genes that are altered in the process of carcinogenesis.

Interestingly, *FRA3B,* the most inducible constitutive fragile site, is located at 3p14.2 and is expressed after exposure of cultured cells to diverse carcinogens, including benzo[*a*]pyrene diol epoxide, the ultimate carcinogen of benzo[*a*]pyrene, a major constituent of tobacco smoke.[28] In addition, homozygous deletions within the *FRA3B* in primary lung cancers have been shown to correlate with exposure to cigarette carcinogens and asbestos.[9] Understanding the structure of the *FRA3E* could provide clues to the mechanism of fragility. We sequenced approximately 800 kb of the 3p14.2 region containing the *FRA3E* locus and precisely located the homozygous deletion breakpoints of numerous cancer cell lines, including those derived from lung cancers.[22,30,31] The *FRA3E* locus has a low content of Alu repeats and is abundant in LINE repeats over 1 kb in length, mostly of the L1 subtype; most of the deletion endpoints in tumor-derived cell lines involve L1 repeats greater than 1 kb in length or long terminal repeats (LTRs).[22,30,31]

This finding suggests that homologous recombination between L1 sequences or LTRs can result in internal deletions within the *FHIT* gene in response to carcinogen-induced double-strand breaks at the *FRA3E* fragile region. The breakpoints are induced by agents such as aphidicolin, an inhibitor of DNA polymerase a and d apparently occurring in regions of the highest DNA flexibility, confirming a relationship between fragility and DNA flexibility, as suggested by Mishmar et al.[32,33] Thus double-strand breaks occurring in regions of high flexibility, which could result in cell death, may be rescued by homologous recombination involving LINE 1 elements or LTRs, leading to deletion of the intervening DNA sequences.

Cloning and Characterization of the *FHIT* Gene

The definition of the region of hemi- and homozygous loss at 3p14.2 within YAC clone 850A6, telomeric to the t(3;8) translocation, in cancer-derived cell lines, facilitated the cloning of the *FHIT* gene, a portion of which was included in the homozygously deleted region.[34,35] We constructed a cosmid contig covering this common deleted region, the t(3;8) translocation and the *FRA3B* region, and identified and cloned the *FHIT* gene. Individual cosmids were used in exon-trapping experiments, and primer extension was used to obtain a 5' extended product from the initial trapped *FHIT* exon 5. A full-length cDNA was characterized and the genomic structure determined. The 1.1-kb *FHIT* cDNA consists of 10 small exons and is distributed over a genomic locus of greater than one megabase. The protein

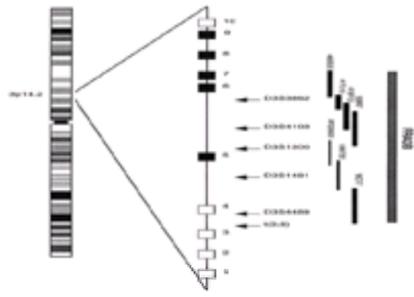
coding region begins in exon 5 and ends in exon 9 (Figure 8.1).


FIGURE 8.1. The *FHIT* gene at 3p14.2 contains the *FRA3E* fragile site, a region of approximately 800 kb that is often involved in deletions in a variety of human cancers, including lung cancer. The *FHIT* gene spans well over 1 Megabase of DNA and consists of 10 exons, of which five are coding (*black boxes*). It encodes a mRNA of 1.1 kb and a protein of 16.8 kD. The position of 3p markers on the *FHIT* map is described, as well as the position of the 3p break involved in the t(3;8)(p14.2;q24) translocation in a family with renal cell carcinoma. The BAC contig we have used to sequence the entire *FRA3E* region is described on the right of the figure; AF020503 and U66722 are Genbank accession numbers for published sequences.

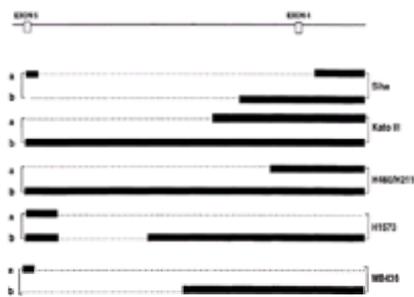
We characterized deletions in numerous cancer-derived cell lines and observed that homozygous deletions can occur in several discontinuous segments within the *FRA3B/FHIT* locus and often involve loss of specific *FHIT* exons (Figure 8.2).[36] The common deleted region originally defined in tumor-derived cell lines often involves exon 5.[35,36] The first three 5' exons of the gene are centromeric to the t(3;8) break, an observation that is consistent with the involvement of *FHIT* in the development of familial clear cell renal carcinoma because one copy of the gene is disrupted by the translocation.[35] Further characterization of the complex homozygous deletions revealed that they are often the result of overlap of independent deletions of the two *FRA3B/FHIT* alleles.[22,36] For example, a stomach carcinoma–derived cell line, AGS, exhibited three separate regions of homozygous deletions, including exon 3, a portion of intron 4, and exon 5.[36] The Kato III cell line showed independent biallelic deletions resulting in absence of Fhit protein, and the Siha cervical carcinoma cell line exhibited a small homozygous deletion in intron 4, also the result of overlap of biallelic deletions.[36,30,31] Figure 8.2 illustrates portions of *FHIT* alleles missing within the gene in some cancer-derived cell lines.


FIGURE 8.2. Biallelic *FHIT* deletions involving the *FRA3E* fragile site in human tumor-derived cell lines. Five cell lines derived from cervical cancer (Siha), gastric cancer (Kato III), lung cancer (H460/H211, H1573), and breast cancer (MB436) were studied for alterations of the *FHIT* gene. The DNA junctions associated with the deletions were sequenced by inverted PCR as described by Mimori et al. (From Mimori K, Druck T, Inoue H, et al. Cancer specific chromosome alterations in the constitutive fragile region. *FRA3B. Proc Natl Acad Sci USA* 1999;96:7456, with permission.) As shown in the figure, the region between intron 3 and exon 5 is involved in deletions in these cell lines. In the gastric cancer cell line, Kato III, the deletion in the allele b occurred past exon 5. In the lung carcinoma H460/H211, the deletion of the allele b is outside the region shown. The black bars represent the undeleted portions of alleles.

Northern blot analysis indicated that *FHIT* is expressed at variable levels in all normal human tissues tested, as a 1.1-kb mRNA. The highest levels have been detected in epithelial tissues. Initial studies of primary gastrointestinal tumors, compared to their normal counterparts, using reverse transcription-polymerase chain reaction (RT-PCR) showed a mixture of apparently normal size transcripts and aberrant transcripts in the tumor tissues, with complete absence of the full-length product in some tumors.[35] Sequence analysis of these short abnormal transcripts revealed that regions between exons 4 and 9 were missing, whereas mRNA from matched normal tissue did not exhibit alteration. Several studies later reported presence of similar aberrant transcripts in mRNA from some normal cells, such as white blood cells, raising the question of the cancer-specificity of the alterations initially detected.[37,38] Such transcripts in normal cells are, however, faint and not reproducible, suggesting that such transcripts in normal cells are artifacts. Numerous experiments have shown consistent, reproducible, and abundant aberrant *FHIT* transcripts in cancer cells, supporting the original observation that detection of abnormal *FHIT* RT-PCR products indicates the presence of *FHIT* genomic alterations.

The genetic alterations to the *FHIT* gene, usually involving independent deletions within both alleles, rather than point mutations, are probably the result of the particular location of the *FRA3E* fragile region within the *FHIT* gene, rendering it more susceptible to deletions than point mutations. When antibodies recognizing the Fhit protein became available, we demonstrated a good correlation between DNA and RNA alterations and the absence of the expression of the Fhit protein in tumors.[36] Initial studies in gastric cancer cell lines showed that absence of *FHIT* mRNA by Northern blot analysis and presence of aberrant RT-PCR products were associated with absence of Fhit protein.[39] Immunohistochemic analysis showed absence of Fhit protein in gastric carcinomas and strong *FHIT* expression in the normal epithelial cells within the same tissue sections.[39]

Similar results have been reported in lung cancer, breast cancer, cervical cancer, pancreatic cancer, and clear renal cell carcinoma.[40,41,42,43 and 44] Of particular interest is the finding that Fhit protein was absent in low-grade, low-stage clear cell renal carcinomas, whereas higher grade and stage tumors displayed a mixture of Fhit-positive and -negative cancer cells.[44] These results suggest that the *FHIT* gene plays a role during the early steps of tumor development in the low-grade renal carcinomas and is associated with progression in the high-grade tumors. Subsequent studies in lung cancers showed Fhit inactivation in preneoplastic lesions,[10] in line with the observation that loss at 3p14/*FHIT* is the earliest LOH event observed in preneoplastic lung lesions,[45,46] and showing that complete Fhit loss is a very early event in the development of lung cancer.

THE PROTEIN

The Fhit Protein and the HIT Family

The *FHIT* gene encodes a polypeptide of 16.8 kD that consists of 147 amino acids that show 52% identity and 69% similarity to a core region of 109 amino acids of the diadenosine 5', 5'''',P4-tetraphosphate (Ap$_4$A) hydrolase from the fission yeast *Schizosaccaromyces pombe*.[35,47,48] This latter enzyme catalyzes the *in vitro* hydrolysis of dinucleoside polyphosphates, with Ap$_4$A as the preferred substrate. Both the Fhit protein and the *S. pombe* Ap$_4$A are members of the Histidine Triad (HIT) protein family. HIT proteins are characterized by four conserved histidines, three of which form a histidine triad sequence that, together with a distinct protein fold, binds nucleotides (Figure 8.3).[48,49] Although *FHIT* also cleaves Ap$_4$A efficiently, biochemical studies and site-directed mutagenesis analysis demonstrated that the Fhit protein could be classified as an Ap$_3$A hydrolase on the basis of its *in vitro* enzymatic activity and that all three conserved histidines are required for full activity (Figure 8.3).[50] Structural analysis and sequence comparison linked Fhit to Hint (triad nucleotide-binding protein) proteins, whose most conserved residues mediate nucleotide binding.[51,52] The HIT motif forms part of the phosphate-binding loop of Hint proteins. Thus Fhit is a member of the HIT family involved in nucleotide

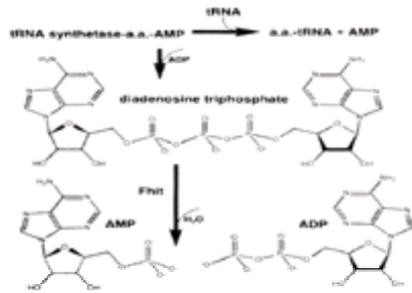
metabolism. Interestingly, Fhit substrates, Ap$_4$A and Ap$_3$A, accumulate in human cultured cells as a consequence of toxic stress or interferon induction, suggesting a possible involvement of Fhit in signaling responses to cellular stress. [53,54]


FIGURE 8.3. Fhit encodes an Ap$_3$A hydrolase. Diadenosine triphosphate (Ap$_3$A) is a product of the tryptophan tRNA synthetase. Ap$_3$A is cleaved by Fhit into AMP and ADP. As mentioned in the text, Ap$_3$A is found to be elevated in a variety of human cancers.

Biologic Function of Fhit

As mentioned previously, Fhit is a mammalian member of the HIT family of proteins. Insight into the enzymatic function of Fhit came from its similarity to the yeast enzyme, Ap$_4$A hydrolase, and our data have shown that Fhit has Ap$_3$A hydrolase activity. [50] However, the *in vitro* enzymatic activity of Fhit did not suggest a biologic function for Fhit. Because established cancer cell lines can be positive or negative for Fhit expression, and because Fhit-negative cell lines and their Fhit-positive DNA transfectants grow well *in vitro,* Fhit expression did not seem to alter the ability to grow in culture. [55] This experiment is not conclusive, however, because the Fhit-expressing clones are selected for constitutive Fhit expression. In addition, the pattern of Fhit expression did not correlate with any phase of the cell cycle.

To analyze Fhit biologic function, several cancer cell lines, including lung, kidney, and gastric, were transfected with *FHIT* cDNA.[55] The number of colonies obtained after transfection with the *FHIT* vector was lower compared to transfection with the empty vector, and only a few of the selected colonies expressed Fhit, suggesting that overexpression *FHIT* was selected against. The lung cancer clones expressing exogenous Fhit exhibited a longer doubling time in liquid medium than the parental Fhit-negative H460 cells and formed fewer colonies in soft agar. The Fhit-expressing gastric (MKN74 *FHIT* and AGS*FHIT*) and kidney (RC48*FHIT*) cancer clones did not show changes in the *in vitro* growth pattern compared to the negative parental cells. *In vivo* experiments conducted by inoculating Fhit-expressing clones of each cell line, as well as empty-vector transfected clones, into nude mice showed that the expression of Fhit in the clones suppressed their tumorigenicity *in vivo*.[55] Thus the expression of Fhit strongly affects the ability of cells to form tumors *in vivo.*

Evidence is also accumulating that binding to diadenosine triphosphate regulates the activity of Fhit. In particular, transfectants with a mutant form of Fhit that binds diadenosine polyphosphates well but does not cleave them are unable to form tumors in nude mice or to form tumors of reduced size. [50,55,56] This finding indicates that Fhit binding with a dinucleotide polyphosphate is important for tumor-suppressor activity and that the Fhit-Ap$_3$A complex may send the tumor-suppression signal. Similarly, activated Ras p21, a nucleotide-binding protein, exerts its tumorigenic action by decreasing guanosine triphosphatase (GTPase) activity. [57] Because the GTP-bound form of Ras stimulates cell division, oncogenic-activating mutations of Ras lead to cellular transformation. X-ray crystallography provided an attractive model of the structural consequences of *Fhit*-substrate binding, reminiscent of the conformational change of GTP-bound Ras, which results in activation of mitogenic effectors.[56] Two diadenosine polyphosphate substrates fill the positively charged cleft of the Fhit dimer in its empty form and convert it to a bulging electronegative surface. It is possible that the tumor-suppressing effectors of Fhit recognize this change in protein appearance, interact with the Fhit-substrate complex, and are activated.

Fhit and Apoptosis

To gain insight into the biologic mechanisms underlying Fhit overexpression in lung cancer cells, we studied H460/*FHIT* clones overexpressing Fhit for proliferation, apoptosis, and cell cycle profiles. [58]

We focused on the lung cancer cell line H460 and on H460/*FHIT* clones transfected with a *FHIT*-FLAG expression vector under control of a CMV promoter. Endogenous wild-type *FHIT* mRNA transcript and protein are undetectable in the H460 cells. Only a few stable Fhit-expressing clones were isolated after transfection of H460 cells with pRC-CMV/*FHIT,* suggesting that constitutive Fhit overexpression negatively affects cell growth. In contrast, in 293 adenovirus 5 transformed human kidney cells, which express endogenous Fhit, enforced Fhit overexpression does not affect cell growth, as reflected in the high yield of rescued colonies and the high number of Fhit expressors among them.[55] Analysis of apoptosis by *in situ* TUNEL assay (TdT mediated dUTP Nick End Labelling) revealed a high rate of apoptosis-induced DNA strand breaks in stable H460/*FHIT* clones. *In situ* results were confirmed by FACS can analysis, which showed an apoptotic rate of 44% to 47% compared to a 15% level in the control H460 cells. No significant changes in Bcl2, BclX, and Bax protein expression levels were observed in the transfected clones as compared to the control H460 cells, whereas a two-fold increase in Bak protein levels was noted. [58] An increased level of p21^{waf} protein, paralleled by an upregulation of p21^{waf} transcripts, was also found in Fhit-expressing clones compared to H460 parental cells. No differences in p53 levels were observed in the same cells, suggesting a p53-independent effect. [58]

These data suggest that the observed growth-inhibitory effect in Fhit-expressing H460 cells could be related to apoptosis and cell cycle arrest, and link the tumor-suppressor activity of Fhit to a proapoptotic function. Interestingly, it has been reported that apoptosis in human cultured cells is associated with a decrease of free Ap$_3$A levels,[59] suggesting that Fhit, through binding with Ap$_3$A, is involved in induction of apoptosis.

A recent paper from J. Roth's group strengthens the observation of Fhit involvement in apoptosis, with relevant *in vitro* and *in vivo* experiments.[60] In this study an adenovirus-*FHIT* vector was used to study the effect of Fhit expression in several cancer cell lines, including H460, and normal human bronchial epithelial cells. Transient overexpression of exogenous Fhit resulted in cell growth inhibition of tumor cell lines, associated with induction of apoptosis and alteration of cell cycle processes. Moreover, the tumorigenicity of the highly tumorigenic H1299 lung cancer cells transduced by Ad-*FHIT* was eliminated *in vivo.* Together, these results suggest that the *FHIT* gene functions as a tumor-suppressor gene.

ROLE IN CANCER

Detection of *FHIT* Gene Alterations

The characterization and sequencing of the *FHIT* gene and the *FRA3E* fragile region facilitated the detection of *FHIT* rearrangements in primary cancers and cancer-derived cell lines. [30,31,35] Alterations at the *FHIT* locus are characterized by deletions, including homozygous deletions, of coding exons, intronic deletions, deletions involving one coding exon in one allele and another coding exon on the other allele, multiple discontinuous regions of deletion in some cell lines, and deletions affecting the 5' untranslated exons, such as exons 3 and 4. [22,36] The effect of all these alterations is the loss or severe reduction of expression of Fhit protein.[22,36] The pattern of alterations characteristic of the *FHIT* gene in cancer cells is different from that of other tumor-suppressor genes, and for this reason the involvement of *FHIT* in human cancer has been slow to be accepted, that is, since *FHIT* is not p53.

Analysis of the levels of *FHIT* transcripts in cases with complex deletions within the *FHIT* gene presents a challenge; *FHIT* mRNA is not abundant and its detection requires poly A$_+$ RNA, which is usually not available from primary cancers. Therefore, *FHIT* expression has often been studied by RT-PCR. Cancer-derived cell lines and primary tumors exhibited different sized transcripts, ranging from apparent normal to short products, or absence of products. [36] Short abnormal transcripts were often detected in cell lines with defined deletions, consistent with the suggestion that aberrant products reflect DNA lesions. [22,36] Several laboratories observed similar

short *FHIT* products in normal cells and normal *FHIT* transcripts in cancer cells and argued against the tumor-specificity or relevance to tumor development of these abnormalities.[37,38] Such aberrant transcripts in normal tissues are, however, not consistent from one experiment to another and may be artifacts of the amplification process. Extensive analysis of many tumors revealed that abnormal *FHIT* transcripts are consistently detected and much more common in cancer tissues, indicating that although the RT-PCR assay has pitfalls and must be interpreted with caution, aberrant *FHIT* amplification products often indicate DNA damage.

The availability of antiserum against the Fhit protein allowed the demonstration of the abundant expression of Fhit protein in normal epithelial tissues and its absence in tumors.[39,40,41,42,43 and 44] Western blot analysis showed that cancer cell lines with *FHIT* DNA deletions or aberrant transcripts lacked Fhit protein; cancer cell lines with no *FHIT* DNA or RNA alterations expressed normal Fhit protein; and cancer cell lines with a mixture of normal and aberrant *FHIT* products exhibited reduced levels of Fhit expression.[36] Even more exciting were the results of immunohistochemic analysis of cytologic preparations from cancer cell lines and tumor sections. Nine of eleven lung cancer–derived cell lines, 73% of primary small cell lung cancer (SCLC) tested, lacked Fhit protein expression, and near concordance was observed between RNA alteration and protein expression.[40] Similar results were obtained by analyzing cervical cancers.[42] Seventy percent of cervical carcinomas showed reduction or lack of Fhit expression, whereas the normal cervical tissue in the same section showed normal Fhit expression. Again, a correlation existed between Fhit expression and DNA or RNA alterations.

Thus immunohistochemic methods are useful in determining the relevance of Fhit in tumorigenesis and are the best way to assess the level of Fhit involvement in a clinical setting.

FHIT Abnormalities in Human Cancer

The *FHIT* gene is inactivated in a wide range of solid tumors, including breast cancer, head and neck cancer, gastrointestinal and esophageal cancer, renal cancer, cervical cancer, and lung cancer. Analysis of numerous cell lines derived from tumors of the gastrointestinal tract, as well as from other sites, demonstrated a correlation of DNA lesions at the *FHIT* locus with aberrant RT-PCR products and altered *FHIT* protein.[36] The most common type of alterations were deletions and/or rearrangements within the gene. In addition, the same study showed that Fhit protein may be reduced or absent, even in absence of detectable DNA or RNA alterations, suggesting the usefulness of Western blot analysis and immunohistochemistry in assessing the level of Fhit involvement.

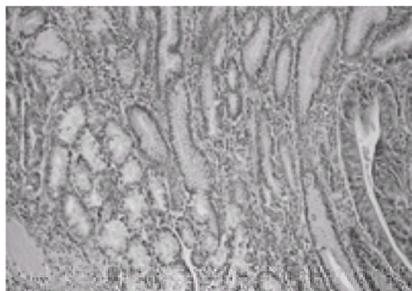
Baffa et al.[39] analyzed 32 primary adenocarcinomas of the stomach and 8 gastric cancer–derived cell lines using RT-PCR, Southern analysis, Western blot analysis, and immunohistochemistry. Four of the eight cell lines and eighteen of the primary gastric cancers (56%) showed deletions or rearrangements within the *FHIT* gene, together with absence of the wild-type transcript and Fhit protein (Figure 8.4). Although not statistically significant, there was a trend toward a higher frequency of Fhit immunonegativity in intestinal-type carcinoma (76%), which is thought to develop from carcinogenic exposure, compared with the diffuse-type adenocarcinoma (50%). Thus results of this study were consistent with the hypothesis that abnormal *FHIT* transcripts result from carcinogen-mediated DNA damage leading ultimately to Fhit inactivation. Another study involving 40 matched normal and gastric cancer tissues using PCR single-strand conformation polymorphism (SSCP) and sequencing revealed the presence of a missense mutation in exon 6 in a signet ring cell adenocarcinoma.[61]


FIGURE 8.4. Immunohistochemistry of a gastric adenocarcinoma for expression of Fhit protein. As shown in the figure, the normal gastric epithelial cells stain strongly positive for Fhit, whereas the adenocarcinoma cells are completely negative (From Croce C, Sozzi G, Huebner K. Role of FHIT in human cancer. *J Clin Oncol* 1999;17:1618, with permission.) (See Color Figure 8.4.)

The discovery that the t(3;8) chromosome translocation was associated with hereditary renal cancer in a large three-generation family was the first suggestion that the 3p14.2 region could be involved in kidney cancer. The *FHIT* gene is interrupted by this translocation and is likely to play a role in renal tumor development. An extensive analysis of renal cell carcinomas of different subtypes showed a variable spectrum of Fhit expression from the almost 100% strongly positive oncocytomas through mostly positive papillary renal carcinomas to the predominantly negative clear cell carcinomas.[44] Loss of *FHIT* protein in clear cell renal carcinomas agrees with previous studies showing LOH of markers within the *FHIT* gene in more than 80% of this subtype of kidney tumor.[62]

A high frequency of LOH at 3p14 was demonstrated in head and neck cancers,[63,64] which have been recognized to be associated with tobacco and alcohol use,[63,64] and interestingly, in oral dysplastic lesions at the precancerous stage.[65,66] Virgilio et al.[67] analyzed 26 head and neck cancer–derived cell lines for *FHIT* alterations by Southern blot analysis, RT-PCR, and interphase fluorescence *in situ* hybridization (FISH). Homozygous deletions within the *FHIT* gene were observed in three cell lines, aberrant transcripts were detected in 55% of them, and FISH analysis revealed the presence of more than one cellular population lacking portions of *FHIT* alleles in 65% of cell lines. Mao et al.[68] reported LOH at 3p14.2 in 81% of 16 head and neck cancer cell lines and abnormal *FHIT* expression in 45%.

Interstitial deletions of the short arm of chromosome 3 have been repeatedly detected in breast carcinomas by LOH and cytogenetics, and the minimal common deleted segment was 3p14.[69,70 and 71] Similar deletions were also found in hyperproliferative breast disease and *in situ* ductal carcinoma, suggesting that 3p alterations are probably early events in breast carcinogenesis.[72,73] Analysis of a series of breast cancer cell lines and primary tumors revealed *FHIT* alterations, mainly consisting in aberrant transcripts, in approximately 30% of cases.[74] Involvement of *FHIT* in breast tumor development was confirmed by analysis of three benign proliferative breast disease samples with cytogenetic rearrangements of chromosome 3p14.[75] The level of *FHIT* expression was either reduced or absent by RT-PCR analysis in samples with atypical hyperplasia, consistent with the hypothesis of a role for the *FHIT* gene in the early steps of tumorigenesis. Another study tested the level of Fhit protein expression in a group of 29 primary breast tumors in the normal and tumor epithelia of the same patients and in a second group of 156 primary breast carcinomas.[41] This analysis found that more than 60% of the breast cancers displayed reduced or absent Fhit protein and that Fhit inactivation was associated with a poorly differentiated phenotype.[41]

Greenspan et al. analyzed 7 cervical carcinoma cell lines and 35 primary cervical carcinoma by RT-PCR, Northern blot analysis, and immunohistochemistry.[42] Six of seven cell lines and 68% of primary tumors exhibited aberrant *FHIT* transcripts, and the same cases displayed markedly reduced Fhit protein by immunohistochemic analysis. Conversely, nonneoplastic squamous and glandular epithelium revealed strong Fhit positivity.

Finally, a study analyzing 19 pancreatic cancer cell lines and 21 primary tumors by RT-PCR, Western blot analysis, and immunohistochemistry found that 42% of the cell lines and 62% of the primary cancers displayed *FHIT* inactivation.[76]

In summary, these studies provide strong evidence that the *FHIT* gene is involved in a variety of epithelial tumors and that abnormalities in this gene are among the most common genetic changes occurring in human cancers; these studies also represent the first molecular evidence linking the instability of fragile sites to cancer. Of particular interest is the finding of *FHIT* alterations in the earliest stage of tumorigenesis and their association with carcinogen-induced tissue damage.

FHIT Alterations in Lung Cancer

Analysis of primary lung tumors for abnormalities of *FHIT* expression by RT-PCR showed that 80% of SCLCS and 42% of non–small cell lung cancers (NSCLCS)

exhibited aberrant transcripts.[77] The absence of *FHIT* exons 4 or 5 through 8 was the most common abnormality detected by sequencing these altered transcripts.

Eleven lung cancer cell lines were studied by Southern blot analysis, RT-PCR, Western blot analysis, and immunohistochemistry. [40] Southern blot analysis using cDNA and specific cosmid probes covering large intronic regions of *FHIT* revealed deletions or rearrangements involving exon 3, exon 4, intron 5, and a more distal region surrounding exon 6 in three cell lines. One cell line showed a homozygous deletion in intron 5. RT-PCR analysis showed complete absence of *FHIT* transcripts in three cell lines and a mixture of abnormal transcripts lacking exons 3 or 4 through 8 or 9 in two cell lines. Both normal-size and aberrant transcripts were present in six cell lines, and only two showed the wild-type transcript only. Western blot analysis revealed that indeed 9 of the 11 lung cell lines did not produce Fhit protein and immunocytochemistry displayed a clear cytoplasmic immunostaining in the two cell lines expressing Fhit. These data confirmed that immunohistochemistry is the simplest assay to investigate the involvement of the *FHIT* gene in lung tumors. Indeed, absence or reduction of Fhit protein expression was observed in cancer cell lines and tumors for which DNA or RNA alterations were not detected.

We have investigated 474 NSCLCs for the expression of Fhit by immunohistochemistry and found that 73% of tumors were negative (Table 8.1; Figure 8.5), as were approximately 85% of dysplastic lesions (Table 8.2).[10] Fhit inactivation was significantly more common than p53 (46%), Egfr (50%), and Bcl2 (19%) overexpression, and was an independent biological marker. Notably, absence of Fhit protein was not related to p53 overexpression, thus indicating that Fhit and p53 inactivation represent independent biological pathways in lung cancer.

| | Fhit Reactivity | | | % Fhit | |
	+	−	Total	negative	P-value
Squamous cell carcinoma	31	202	233	87	<0.01
Adenocarcinoma	84	112	196	57	<0.01
Large cell carcinoma	31	14	45	69	<0.01

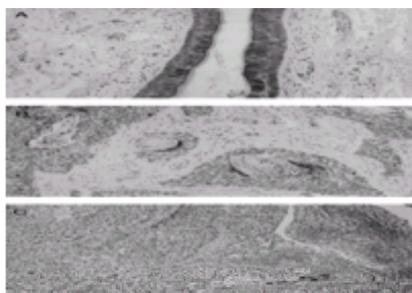
TABLE 8.1. LOSS OF Fhit EXPRESSION IN DIFFERENT HISTOLOGIC TYPES OF NON–SMALL CELL LUNG CANCER


FIGURE 8.5. Loss of Fhit expression in human non–small cell lung carcinoma (hNSCLC). As shown in **(A)**, all cells of the normal bronchus stain positively with the anti-Fhit antibody. On the contrary, NSCLCs are negative for Fhit expression **(B,C)**. (From Croce C, Sozzi G, Huebner K. Role of FHIT in human cancer. *J Clin Onco* 1999;17:1618; Sozzi G, Pastorino U, Moiraghi L, et al. *Cancer Res* 1998;58:5032, with permission.) (See Color Figure 8.5.)

| | Fhit Expression | | | |
	+	−	Total	% Fhit Negative
Dysplasia	3	17	20	85
Carcinoma in situ	0	25	25	100

TABLE 8.2. LOSS OF Fhit EXPRESSION IN BRONCHIAL DYSPLASIA

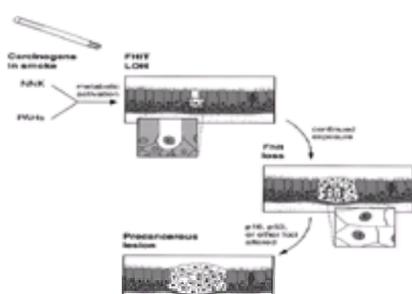
In the same study, a larger fraction of squamous-type carcinomas were Fhit negative compared with adenocarcinomas (87% versus 57%), whereas the other histotypes (large cell carcinoma, mucoepidermoid carcinoma) displayed an intermediate value (69%). Interestingly, adenocarcinomas had a strong association between the pattern of Fhit expression and the level of cell differentiation; positive immunostaining was shown in the more differentiated cells and weaker protein expression in the less differentiated areas of the tumor. Of relevance is the loss of Fhit expression in the earliest stages of the neoplastic process, indicating that Fhit loss is a very early event in lung carcinogenesis, as illustrated in the cartoon shown in Figure 8.6. This finding is particularly important because the highest frequency of Fhit loss of expression is observed in the squamous type of lung cancer, which is associated with bronchial dysplastic lesions. In fact, positive Fhit immunostaining was observed in 326 hyperplastic bronchial mucosa and in 78 squamous metaplasia lesions; however, in several cases of incomplete metaplasia, Fhit immunostaining was weaker then in normal bronchus. Modulation of Fhit expression was observed in the bronchial lesions of increasing grade, occurring in 34 patients. A progressive loss of Fhit protein expression occurred in moderate and severe dysplasia lesions, whereas the mild dysplasia analyzed showed positive immunoreactivity. Negative immunostaining was observed in all of the 25 (100%) *carcinoma in situ* (CIS) lesions. Overall, 85% of dysplastic lesions and 93% of all the precancerous lesions analyzed showed negative Fhit immunostaining.


FIGURE 8.6. Tobacco smoking causes loss of function of the *FHIT* gene. Carcinogens present in tobacco smoke cause deletion in a *FHIT* allele. Continued exposure causes deletion in the second allele, leading to loss of Fhit expression. *FHIT* alterations and then mutations in p16, *p53,* and other loci cause precancerous lesions (bronchial dysplasia), some of which will later evolve into frank carcinomas. (From Huebrev K, Sozzi G, Brenner C, et al. *FHIT* loss in lung cancer: diagnostic and therapeutic implication. *Adv Oncology* 1999;15:3, with permission.) (See Color Figure 8.6.)

Of interest, p53 overexpression and loss of Fhit protein expression were concordant in these lesions. However, the frequency of Fhit-negative, high-grade preinvasive lesions (dysplasia and CIS) was significantly higher than that of p53 overexpression (93% versus 55%) and reflected that observed in tumors of the squamous type. Thus the level of sensitivity of Fhit immunostaining is higher than that achieved by p53 immunoreactivity in precancerous lesions. These findings reinforce the hypothesis that Fhit may act as a "gatekeeper" in the lung carcinogenetic process, and the similar temporal sequence of Fhit and p53 alterations in lung carcinogenesis points to a role for both pathways in lung carcinogenesis.

We also found that loss of Fhit expression was significantly more common in tumors occurring in smokers (75%) than in those of nonsmokers (39%), which was also true in the subset of adenocarcinoma patients (Table 8.3). These results, together with other evidence discussed in the next section, indicate that Fhit alterations preferentially occurred in the tumors of heavy smokers and were not correlated with p53 mutations. Fhit expression did not seem to correlate with prognosis of squamous tumors, consistent with the role of Fhit in the initiation of the tumorigenic process rather than in the progression to invasive and metastatic disease.

| | Fhit Expression | | | % Fhit | |
	+	–	Total	Negative	P-value
Nonsmokers	14	9	23	39	<0.01
Smokers	115	336	451	75	<0.01

TABLE 8.3. SMOKING AND LOSS OF Fhit EXPRESSION

Tomizawa et al.[78] also found that Fhit loss correlated with the squamous cell subtype of lung cancer and smoking history but indicated poorer prognosis for patients with stage I NSCLC. This study also concluded that Fhit protein expression could be a marker of aggressiveness in stage I NSCLC. Although differing in several aspects, these two studies agree on important points: A larger proportion of squamous lung cancers showed Fhit inactivation; loss of Fhit protein expression was associated with a less differentiated morphology, especially in adenocarcinomas, and the *FHIT* gene is a preferential target of tobacco carcinogens.

A very recent study (Tseng JE, Proceedings AACR 1999, abstract #1228, page 184) investigated whether loss of Fhit expression is associated with prognosis in stage I NSCLC. Fhit levels were determined by immunohistochemistry in 86 specimens; 52% of NSCLC samples lacked Fhit immunostaining and 48% showed at least moderate staining. Loss or reduced staining was observed in multiple areas of preneoplastic lesions and even normal-appearing bronchial epithelium. However, Fhit expression status was not associated with disease-free survival or overall survival. The lack of association between Fhit expression and prognosis in NSCLC in this study may reflect the occurrence of alterations in the *FHIT* gene at an early stage in lung carcinogenesis.

The common loss of Fhit in early-stage NSCLC and preneoplastic lesions suggests a role for Fhit in initiation of lung cancer and indicates that assessment of Fhit protein could be an important aspect of screening programs (see also Chapter 23).

FHIT/FRA3B Alterations and Smoking Habits

We undertook molecular analysis of microsatellite alterations within the *FHIT* gene and *FRA3E* in lung tumors from heavy smokers and in tumors developed in never-smokers to seek genetic damage attributable to tobacco smoking.[8] LOH affecting at least one locus of the *FHIT* gene was observed in 41 out of 51 tumors in the smokers group (80%) but in only 9 out of 40 tumors in the nonsmokers (22%) (p = 0.0001). These findings suggest that the *FHIT* gene is a preferential target of carcinogens in tobacco smoke and indicate the possibility of using LOH at *FHIT* and *FRA3E* as early molecular indicators of damage related to tobacco smoke in screening high-risk individuals, such as those belonging to the heavy smokers category. Accordingly, Nelson et al.[9] observed homozygous deletions of *FHIT* exons in 13 of 30 (43%) microdissected primary lung cancers. These authors also observed an association of *FHIT* exon deletion with smoking duration and asbestos exposure.

Lung cancer is directly linked to smoking, and genetic changes similar to those observed in tumors can be detected in the normal bronchial epithelium of smokers or previous smokers. The association between LOH at 3p14.2 alleles and smoking history was investigated by many authors, and common agreement exists that deletions at the *FHIT/FRA3B* locus are early and common events in lung carcinogenesis and are associated with smoking history.[8,45,46] Mao et al.[45] analyzed DNA microdissected from bronchial biopsies from 54 current and former smokers for LOH at three different loci within or near candidate lung tumor–suppressor genes (3p14, 9p21, and 17p13). Overall LOH tended to be more common in current smokers than in former smokers (82% versus 62%), but the difference was not statistically significant, indicating that cigarette smoke induces genetic alterations in the bronchial tissue that persist after smoking cessation. Current smokers, however, showed a higher frequency of loss at the 3p14 locus than former smokers, a finding that was attributed to reversal of squamous metaplasia following smoking cessation.

In a similar study, Wistuba et al.[46] obtained multiple biopsies from current smokers, former smokers, and nonsmokers without cancer. Fifteen microsatellite markers were used to assess LOH at five chromosomal arms. Eighty-six percent of subjects with a history of smoking demonstrated LOH in at least one biopsy specimen, whereas none of the nonsmokers showed genetic alterations. In addition, LOH at 3p and 9p was more common than LOH at other chromosomal loci.[46]

Overall, these studies highlight the linkage between tobacco smoking and genetic alterations that initiate the process of carcinogenesis in the bronchial epithelium, and are followed by the accumulation of additional mutations during the neoplastic process leading to invasive and metastatic cancer. The studies also agree that deletions at chromosome 3p14.2 are common and early events in the carcinogenesis, being detected in precancerous lesions, and that *FHIT* is a preferential molecular target of carcinogens contained in tobacco smoke. Consistent with this finding is the low frequency (20%) of LOH at 3p14.2 in lung tumors from subjects who had never smoked.[5,6] Thus the discovery that *FHIT* inactivation is an important determinant in lung tumorigenesis and represents an early step during the neoplastic process provides the basis for molecular approaches in screening, diagnosis, prognosis, and, possibly, treatment.

Diagnostic and Therapeutic Implications

As mentioned previously, lung cancer is the leading cause of cancer-death among men and women worldwide, and smoking is the single biggest risk factor. Because the diagnosis is often reached when lung cancer is at advanced stages, efforts to significantly decrease mortality, including new therapeutic approaches and early diagnosis, have been relatively unsuccessful. So far sputum cytology or screening by radiography, as means of early detection, have proved unsatisfactory.[79]

The studies discussed previously have clearly shown that, similarly to other epithelial tumors, lung cancer evolves throught a multi-step process over time. The occurrence of these sequential genetic changes, which we are beginning to characterize and understand, can provide the basis for novel molecular diagnostic

approaches.

Thus although alterations of almost every chromosome can be observed in lung cancers, deletions at chromosome 3p are commonly detected in both SCLC and NSCLC and in the earliest preneoplastic lesions of the bronchial epithelium. [10,77,78] As the malignant transformation progresses, mutations of p53, p16 inactivation, and mutations and deregulated expression of Ras, Egfr, Her2/neu, Bcl2, and Myc oncoproteins can be demonstrated. [7] In addition, LOH at multiple chromosomal loci and microsatellite instability occur at various frequencies in NSCLC and may serve as clonal markers for cancer detection. [7] The possibility of using such genetic markers for early detection of lung cancer has been suggested primarily for tissue biopsies [45,46,80,81] and exfoliated cells in sputum and bronchoalveolar lavage. [82,83,84 and 85] Assessment of the level of Fhit protein in biopsy or cytologic specimens from smokers and former smokers could be included in screening programs to identify high-risk patients and to provide markers for prevention regimens.

Of particular interest is the presence of genetic alterations, mostly involving LOH at 3p14.2, in the respiratory mucosa of smokers, even in the absence of recognizable preneoplastic lesions. These changes gradually accumulate with duration of smoking and persist after smoking cessation, suggesting that the risk of developing lung cancer never returns to that of nonsmokers.

Despite pronouncements to the contrary, [86,87 and 88] evidence is accumulating that the *FHIT* gene is a critical determinant in lung tumorigenesis and that it could be a long-awaited link between chromosomal fragile sites and cancer. The characterization of the *FHIT/FRA3B* locus is therefore likely to provide important means for the screening, diagnosis, and prognosis of lung cancer.

Because *FRA3E* is constitutively fragile, it might be supposed that this locus would be equally vulnerable to carcinogens in all individuals. However, polymorphisms that could confer increased fragility and susceptibility to lung cancer in certain subjects may be present within the *FRA3E* locus. The complete sequence of *FRA3E* may allow for definition and eventual screening of individuals for cancer risk. Moreover, knowing that a specific genetic alteration defines a true cancer risk factor and that it is easily detectable, could reinforce smoking cessation programs by providing a powerful screening tool.

Recent studies have demonstrated the possibility of detecting genetic alterations in plasma or serum DNA from patients with various cancers. In a recent study, [89] we looked for microsatellite alterations at the *FHIT/FRA3B* locus and other genomic loci in circulating plasma DNA of 87 stage I–III NSCLC and 14 controls. Sixty-one percent of the NSCLC patients showing allele shift and LOH in tumor samples also displayed a microsatellite change in plasma, irrespective of tumor size and stage, suggesting that circulating tumor DNA is present in early phases of lung tumor development.

Of interest, plasma DNA abnormalities were detectable in 43% of pathologic stage I and in 45% of cases with tumors up to 2 cm of maximum diameter. These findings highlight new prospects for early tumor detection by noninvasive screening procedures based on the analysis of genetic changes in plasma.

Finally, a long-term goal of research strategies in lung cancer is to directly modify lung cancer cells in order to restore the function of an altered gene product that suppresses the malignant phenotype. Candidate genes for replacement are those that are commonly altered in human cancers, inactivated in early phases of carcinogenesis, and/or involved in relevant cellular biochemic and biologic pathways. If we could identify the earliest genetic changes that initiate the process of malignant transformation, we might be able to detect these changes in premalignant lesions and develop novel therapeutic approaches to eliminate premalignant cells. The overall high frequency and precocity of Fhit loss in lung carcinogenesis and its role in controlling apoptosis prompt FHIT gene replacement as a gene therapy approach for early lesions accompanying lung carcinogenesis.

TELOMERASE IN LUNG CANCER

FULVIO LONARDO
JOAN ALBANELL

A distinguishing biological feature of tumor cells is their ability to undergo unlimited cell divisions. The discovery that the enzyme telomerase plays a crucial role in immortalization has constituted a major advance in the biology of cell transformation and has offered insights into the pathogenesis of lung cancer. Further, it has highlighted the clinical relevance of telomerase activity as an important molecular marker of lung cancer and a potential target of therapy.

BIOLOGY OF TELOMERES AND TELOMERASE

Structure

Telomeres are DNA-protein complexes located at the end of linear chromosomes, made up of multiple repeats of the oligomeric sequence 5'-TTAGGG-3' which can be up to 15 kbases long[1] and are associated with specialized nucleoproteins.[2] In the absence of telomerase activity, telomeres shorten with each cell division (end-replication problem). Telomerase is an RNA-dependent DNA polymerase (reverse transcriptase) specialized in the synthesis of telomeric repeats, an activity which cannot be carried out by conventional DNA polymerases.[3,4 and 5] Telomerase is composed of an RNA component and multiple associated proteins.[2] It is a unique polymerase in that its integral RNA component provides its own template for the synthesis of oligomeric repeats. Studies in *Tetrahymena* show that, in addition to acting as a template, this RNA component is endowed with regulatory functions, affecting the affinity of RNA binding to the catalytic protein and the fidelity of transcription.[6,7] Cloned constituents of human telomerase include an RNA component named hTR[8] and two associated proteins: hTERT (also named TP2 or hEST2),[9,10] endowed with polymerase activity,[11] and a telomerase-associated protein with unknown function, named TP1.[12] The presence of homology between the TP2 component, the yeast homologue EST2, retroviral reverse transcriptases, and transposons,[5,13] in regions that are crucial for its polymerase activity,[11] points to a common evolutionary origin of these molecules. Reconstitution studies *in vitro* have shown that the minimal core complex still capable of telomerase activity is constituted by the RNA and the TP2 reverse transcriptase components.[14]

Tissue Expression

The availability of molecular probes has allowed the study at the cellular level of correlations between expression of telomerase constituents, proliferation, and differentiation, in both normal and neoplastic tissues. This availability has also allowed the study of how expression of single telomerase components affects telomerase activity by allowing a comparison between cellular expression of telomerase components through *in situ* hybridization and immunohistochemistry and telomerase enzymatic activity assessed by the TRAP assay (see *infra*). Thus Yashima and colleagues[15] have found that, by *in situ* hybridization, hTR expression is predominantly found in proliferating, undifferentiated tissue during embryogenesis. In contrast, differentiation is accompanied in most tissues by decreased or absent expression. In adult tissues, expression is restricted to actively dividing cells of gonads, lymphoid tissue, and epithelia. These include primary and secondary spermatocytes; ovarian follicular cells and oocytes; follicular center cells of lymphoid follicles; basal cells of respiratory epithelia and of keratinized and nonkeratinized squamous epithelia, including the skin; and intestinal crypt cells. In the normal lung, hTR is expressed in the basal cells of bronchi and in bronchioles.[15,16] An exception is provided by the presence of weak positivity for hTR in differentiated, nonproliferating ganglion cells in normal tissue, ganglioneuroblastomas, and ganglioneuromas.[17] These studies show a general correlation between hTR expression, telomerase activity, and proliferative potential in normal tissues. Studies on the cellular localization of hTR in histologically preneoplastic lesions of the cervix, bronchi, and breast (see *infra*) also point to a direct correlation between hTR expression and proliferation. In addition, they highlight an indirect correlation with differentiation. Thus cervical dysplastic lesions, while showing a cellular redistribution of hTR positivity, also reveal that the lowest levels of positivity are found in the superficial, differentiated component of the dysplastic epithelium.[18] Studies on germ cell tumors also point out an inverse correlation between differentiation and hTR expression. Differentiated tissue within ovarian germ cell tumors and mature testicular teratomas lacks detectable hTR expression by *in situ* hybridization.[19] In contrast, germ cell cancers and immature teratomas show telomerase activity.[20] Such an inverse correlation between telomerase activity and differentiation in germ cell tumors is supported by *in vitro* and *in vivo* studies.[20,21]

Use of reverse transcripture chain reaction (RT-PCR) has shown that hTR is also present in somatic tissues, although at much lower levels than in cancers and gonads.[8] Analyses of the tissue distribution of hTR conducted by Northern blot (NB) have generally revealed a wider tissue distribution than those conducted by *in situ* hybridization. Thus Feng and co-workers found by NB that hTR was expressed in tissues such as brain and lung that are respectively negative or positive only in a small cell population. *In situ* hybridization, although less sensitive, offers the advantage of precisely localizing subsets of cells positive for hTR. Furthermore, a correlation exists between the presence of hTR and telomerase activity[16,22] when this is detected by the latter technique but not by NB.[23]

The chromosomal site where the gene for hTR resides has been mapped to chromosome 3q26.3. Interestingly, this region is frequently overexpressed in head and neck squamous cell carcinomas,[24,25] raising the prospect that increased levels of hTR found in tumors may be secondary to gene amplification.

These data highlight that telomerase activation is usually accompanied by upregulation of hTR levels. However, data exist supporting the view that control of levels of the hTERT component is the key element in regulating telomerase activity. Thus, immortalization is accompanied by upregulation of this component, and differentiation by its down-regulation;[10] and introduction of this component extends the recipient's cell life span.[26] Further evidence of an important role of this component in carcinogenesis is suggested by the frequent amplification of the 5p chromosome in approximately 70% of non–small cell lung carcinomas (NSCLC),[27,28] where the EST2 gene resides at 5p.33. A comparative analysis by RT-PCR of all three components of human telomerase components in renal cell carcinomas reveals that the expression of hTERT is a critical determinant of telomerase activity in this cancer. Here, TP1 and hTR mRNA were constitutively expressed both in tumor and in normal tissue. In contrast, the expression of hTERT was found to be limited to cancer and correlated with telomerase activity.[29] Recently, the finding by immunohistochemistry of hTERT protein in colonic crypt cells, known to represent the proliferative component of this epithelium, further confirms the important role of this component in regulating telomerase activity.[30]

Another mechanism of regulation of telomerase activity may be operating through telomerase inhibitors.[8,23] An inhibitor of telomerase activity has been demonstrated to reside on the short arm of chromosome 3 at 3p.21.2–3p21.3.[24,31] This region frequently undergoes loss of heterozygosity in NSCLC[32] and has tumor suppressive ability *in vitro*,[33,34] thus raising the prospect that it may act as a tumor suppressor gene *in vivo*. This hypothesis awaits further confirmation by a detailed mapping of the genes involved in the deletion.

The TRAP Assay

Telomerase activity was originally detected by the visualization of the direct enzymatic products generated by cell extracts in the presence of a synthetic primer and labeled nucleotides. The subsequent introduction of a different method of cell lysis (detergent-mediated lysis versus hypotonic shock) and, most important, of a

polymerase chain reaction (PCR) step in the technique greatly enhanced the sensitivity of the telomeric repeat amplification protocol (TRAP) assay.[35] The oligomeres generated in the reaction, instead of being immediately separated and visualized by electrophoresis, are first used as templates in a PCR reaction, which allows their exponential amplification. The typical TRAP product appears as a "ladder" composed of multiple bands of increasing length, each differing from the other by 6bp, spanning the entire length of the gel. Telomerase activity is quantified by measuring the intensity of the generated bands, normalized for background activity. This modified technique is reported to be able to detect 10^{-4} telomerase-positive cells in a mixed cell population. The high sensitivity of the TRAP assay, in conjunction with the differential expression of telomerase activity in normal versus cancer tissue, constitutes the premises for its potential clinical use as a marker of cancer, as discussed later. Recently, the development of an *in situ* version of this assay has been reported in the Japanese literature.[36]

Function

Telomeres have multiple functions. Telomere integrity is crucial for maintenance of chromosomal stability, and for preventing chromosome fusions, translocations, and nondisjunctions.[37] Telomere shortening constitutes an end point of oxidative stress, thus controlling ageing. Genetically transmitted human diseases characterized by early aging, such ataxia telangiectasia, and Down's syndrome, have all been described as showing accelerated telomeric attrition and a reduced proliferative life span.[24] A large body of evidence, briefly reviewed here, further highlights that telomerase activity can control the cell's life span, and its deregulation constitutes a key event in cell transformation.

In vivo, differentiated cells do not proliferate and are constantly replaced by new cells. Examples of replicating cells include bone marrow stem cells, neck cells of the intestinal crypts, and basal cells of squamous epithelia. The extended proliferative potential of these cells allows for the generation of differentiated elements able to carry out specialized biological functions but incapable of division. It has long been known that *in vitro,* primary cell lines undergo senescence after a limited, set number of cell passages.[38] In contrast, immortal cell lines have an unlimited proliferative potential. Advances in our knowledge of the interactions between telomerase, telomeres, and cell proliferation have shed new light on the molecular basis of this process. Namely, a host of data suggest that telomere length constitute the cell's clock to monitor the number of cell divisions it has gone through and that there is a correlation between telomere length, telomerase activity, and proliferative potential.

A progressive shortening of telomeric ends takes place with each cell division in mortal cells lacking telomerase activity, with a loss of approximately 50 bp per division for cultured human fibroblasts, until a critical telomere length is reached. When cells reach this point (named Mortality Stage 1) they stop proliferating and undergo senescence.[35] Senescence is characterized by the inability of the cell to express transcription factors crucial in allowing progression into G1, such as c- *fos* and members of the E2F family, in addition to overexpression of the cyclin-dependent kinase inhibitors p21 and p16.[37] Whereas this model implies a link between telomere length, transcription factors, and kinase inhibitors in controlling cell cycle progression, the molecular details of this mechanism are unknown. It has been hypothesized that a short telomere may trigger a DNA damage response through a "sensor" molecule, and *p53* is a candidate for this role.[40] Alternatively, a short telomere may directly bind transcription factors or indirectly repress the transcription of regulatory genes as a consequence of tridimensional changes in the DNA structure.[37]

Oncogene activation or tumor-suppressor gene inactivation allows somatic cells to bypass cell senescence, extending their life span. In particular, *p53* and Rb are thought to have a crucial role in controlling this checkpoint.[41] With continuing cell divisions, telomeres become progressively shorter, until a critical length is reached and cells undergo a second crisis (Mortality Stage 2). Further proliferation and cell survival at this stage are critically dependent on the presence of telomerase activity, which appear spontaneously *in vitro* in rare tumor clones which become immortal.[1,39]

Activated lymphocytes are an exception among normal cells in that they express telomerase activity.[42,43] This has important clinical bearings, limiting the role of telomerase as a molecular marker of cancer (see *infra*).[44] As for its biological relevance in the context of the presented model, it has been shown that lymphocytes lose telomeric DNA with cell proliferation, in spite of the presence of this telomerase activity.[43] These data highlight that low-level telomerase activity present in rare somatic cells is not sufficient to overcome the end-replication problem.

In contrast to mortal cells, germ cells and a great majority of spontaneously immortalized human cancer cell lines and human tumor specimens exhibit telomerase activity at a level sufficient to stabilize telomerase,[45,46] and have unlimited proliferative potential.

These data prompt a model envisioning progressive telomere shortening as a crucial factor determining cell senescence. This process is counterbalanced by telomerase activity which, by stabilizing telomere length, allows cells to undergo unlimited cell divisions. In tune with this model, telomerase activity is found in immortal cell lines but not in mortal ones *in vitro. In vivo,* it is restricted to cells with unlimited life span, including gonads, tumors cells,[39,46] and renovating cell subsets within differentiated epithelia.[15,39,47] This proposed association between unlimited life span and telomerase activity has been further confirmed by several *in vitro* data. The reverse transcriptase component of human telomerase has the ability to expand the recipient's cell life span when introduced in telomerase-negative retinal pigment and foreskin fibroblasts,[26] and its message is upregulated during immortalization.[10] Furthermore, transfection of the immortal HeLa cell line with an antisense to the RNA component of telomerase results in loss of telomeric DNA and cell death.[8]

However, it should be stressed that the control of senescence is multifactorial. Thus four sets of genes acting as complementation groups were revealed by cell hybrids to control senescence.[37] Further, inactivation of crucial tumor-suppressor genes such as *p53*[40] and Rb is crucial in allowing continuing cell proliferation and transformation, despite critically short telomeres.[37] Particularly, it has been proposed that *p53* may act as a "sensor" of telomere length. According to this model, *p53* deficiency allows cancer cells to escape the growth arrest that telomere shortening induces in normal cells by upregulation of wt *p53*.[40] Unrestricted cell proliferation can occur in rare cases in the face of absent telomerase activity by alternative mechanisms of telomere lengthening.[48]

Studies show that papilloma virus's E6 and E7 and SV40 constitute a convenient experimental model for the study of the molecular pathways of immortalization and have shed further light on this mechanism. It was previously assumed that papilloma virus–mediated immortalization depended entirely on the combined inactivation carried out by E6 and E7 of *p53*[49] and Rb.[50] In contrast, it has recently been demonstrated that the minimal requirement for immortalization of human keratinocytes or mammary epithelial cells is constituted by the combination of telomerase activation carried out by E6 and E7-induced Rb/p16 inactivation, and that *p53* inactivation is dispensable.[51] Further highlighting the multifactorial nature of cell transformation, cells transfected with the enzymatic component of telomerase hTERT have extended life span but are nontumorigenic.[52,53] In contrast, it has been shown that the transformed phenotype can be reproduced by the transfection of an activated *RAS* and a large T in addition to hTERT.[54]

These data highlight that acquisition of telomerase activity may constitute an obligatory step for the acquisition of an unlimited life span, but cooperation with other molecules is required to achieve immortalization and cell transformation. The molecular details of the interrelationships between telomerase activation and deregulation of other cell cycle–controlling molecules remain largely uncharacterized.

TELOMERASE IN LUNG CANCER

Telomerase in the Pathogenesis of Lung Cancer

The noninvasive lesions associated with the development of lung carcinoma are well characterized for squamous cell carcinoma both at the morphological[55] and at the molecular level (reviewed in Colby[56]). Increasing molecular alterations have been described as occurring in these lesions, paralleling their increasing histological grades. These include alterations in cyclins D1 and E,[57] EGFR, and *p53*,[58] and loss of heterozygosity at loci at chromosomes 3p, 9p-21 and 5q.[56,59] Only one study has addressed the timing, within this histological continuum, of telomerase deregulation. Yashima and colleagues studied the cellular distribution of the RNA component of human telomerase (hTR) in normal, preneoplastic, and invasive carcinoma. They found a correlation between hTR positivity as detected by *in situ* hybridization, and telomerase activity as detected by the TRAP assay. In normal lung, hTR expression is restricted to small bronchioles (23%) and the basal cells of bronchi (26%).[16] In contrast, virtually all preneoplastic lesions show deregulated expression (20 out of 22). This is two-fold. First, a cellular redistribution of hTR is present. Thus, while positive only in the basal layer in normal bronchial mucosa and in the basal and parabasal layer in hyperplastic lesions, in dysplasia it becomes expressed throughout the entire thickness of the epithelium. A similar redistribution is also observed in cervical dysplasia.[18] This phenomenon reproduces the redistribution of epidismal growth factor receptor (EGFR) positivity observed in bronchial dysplasia by immunohistochemistry.[56] Second, low-level telomerase activity appeared in dysplasia. This was severalfold lower than that detected in invasive carcinoma; however carcinoma *in situ* (CIS) in the vicinity of invasive carcinoma had

telomerase levels comparable to those of invasive carcinoma. Similar results were obtained in studies of preneoplatic lesions of the breast [22] and cervix uteri.[18]

Overall, these data highlight that increasing histological grades are associated with increasing telomerase activity and hTR expression in histological models of preneoplasia (see also Chapter 23). Because in these sites, including the bronchus, increasing proliferative rates are associated with increasing histological grades, [59] these data also highlight an association between telomerase activity and proliferative rate. The positivity of the basal bronchial layer in normal and hyperplastic conditions for hTR is further in tune with this association, because this cell type is believed to play a crucial role in the turnover of the bronchial mucosa. [60] An intriguing association is also evident in this cell type between telomerase positivity and positivity for EGFR. [58] Interestingly, the basal cells of the skin, which are assumed to play the same role in the epithelium, are also reported to be positive for telomerase activity. [47]

These observations seem further to indicate out that progression to invasive carcinoma is marked by a progressive increase in the *level* of telomerase activity rather than by its *acquisition.* Were this model confirmed, it would justify the employment of telomerase inhibitors as prevention agents to arrest the progression of preinvasive bronchial lesions to overt cancer in patients with bronchial dysplasia. This group of patients is rarely detected clinically yet comprises the target of early lung cancer detection screening programs.[61]

The view that invasive adenocarcinomas arise from noninvasive proliferative lesions of small bronchioles and alveoli, termed atypical alveolar hyperplasia (AAH) (see also Chapter 26) is substantiated by a large body of experimental and morphological evidence (reviewed in Colby [56]). Only one study has studied telomerase activation in these lesions. Yashima and colleagues found that, although 23% of small bronchioles were positive for telomerase, the six samples of AAH examined were all negative. Yet overt invasive adenocarcinomas (*infra*) frequently express telomerase activity. Furthermore, AAH lesions of different nuclear grades exist, and the occurrence of molecular alterations such as *p53* accumulation has previously been shown to increase with nuclear grades in these lesions for *p53*.[62] However, the nuclear grade of the lesions analyzed was not commented on in this small series. Thus further studies are needed to address the timing of telomerase activation in the pathogenesis of lung adenocarcinoma.

Telomerase in Invasive Lung Cancer

The data from the three major studies performed so far on telomerase in lung cancer are provided in Table 9.1. The incidence of telomerase positivity in NSCLC in these series ranges from 80%[63,64] to 85% [84 of 99],[65] compared with a range of positive expression in normal tissue of 0%[65] to 7.7%.[64] Only Hiyama and associates have also analyzed small cell carcinomas (SSC)[63] finding telomerase activity in all 11 cases examined. No significant differences in telomerase activity have been found in these series between squamous cell carcinomas, adenocarcinomas, and large cell undifferentiated carcinomas. In these series, the bronchioloalveolar carcinomas category has been incorporated with adenocarcinomas or within a third miscellaneous group. [64] However, in view of the distinctive clinical and pathological features of this histological type, [66] it would be intriguing to find out if its incidence of telomerase positivity is different from that of ordinary adenocarcinoma. A positive correlation between high telomerase activity and high pathological (TNM) stage has been reported in the only study analyzing the association between telomerase and clinical-pathological features in lung cancer (Figure 9.1).[65] This study confirms the association between telomerase activity and stage which has also been repeated in gastric[67] and breast cancer[68] and leukemias[69] but not in renal cell carcinoma, [70] highlighting the importance of telomerase as a molecular cancer marker in these malignancies.

Author	Cases Analyzed	Overall Positivity	Adenocarcinomas	Squamous Cell Carcinoma	Other Histotype
Wu et al.	100	80%	83% (n = 54)	79% (n = 44)	83% (n = 12)[a]
Hiyama et al.	136	84%	79% (n = 63)	88% (n = 52)	83% (n = 18)[b]
Albanell et al.	99	85%	86% (n = 54)	85% (n = 38)	86% (n = 7)[c]

[a] Includes large cell carcinoma, bronchioloalveolar carcinoma, poorly differentiated carcinoma NOS.
[b] Include adenosquamous (4/5 positive) large cell (12 positive), carcinoid (1/1 positive) and Small Cell Carcinoma (11/11 positive).
[c] Includes only large cell carcinoma (n = 7).

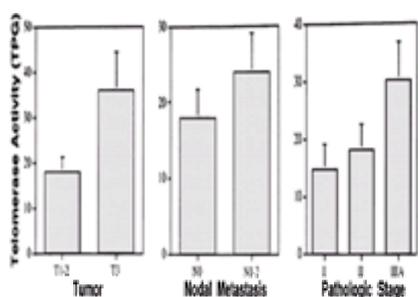
TABLE 9.1. REPORTED DISTRIBUTION OF TELOMERASE POSITIVITY IN RESECTED LUNG CANCER


FIGURE 9.1. Telomerase activity (average total product generated [TPG] +/- standard error of the mean [SEM]) was associated with tumor size and extension of the primary lesion (left pane, two-sided P = 0.03), the presence of lymph node metastasis (middle panel, two-sided P = 0.05), and pathologic TNM stage (right panel, two-sided P = 0.01) in non–small cell lung cancer. (From Albanell J, Lonardo F, Rusch V, et al. High telomerase activity in primary lung cancers: association with increased cell proliferation rates and advanced stage. *J Natl Cancer Inst* 1997;89:1609, with permission.)

A positive correlation has also been found between high telomerase activity and proliferative rate, determined by immunohistochemical stain for Ki-67, a nuclear antigen expressed only in proliferating cells. [71] This latter finding is in agreement with the demonstrated role of telomerase in the control of cell proliferation. However, though associated with proliferation, as discussed before, the expression of telomerase is likely to reflect immortality and therefore to constitute a more meaningful parameter than the proliferative rate as assessed by traditional pathological markers.

No associations were found by Albanell and associates [65] between the level of telomerase activity and tumor histological grade or the amount of lymphocytes infiltrating the tumor. This latter analysis was prompted by the reported [fcpositivity of activated lymphocytes for telomerase, [42] a finding that, as discussed later, hinders the use of this test in molecular staging. [72]

Albanell and associates[65] found that telomere lengths were not significantly different in groups with low, moderate, and high telomerase activity and were not associated with pathological stage. Furthermore, in 34 cases, telomere restriction fragments (TRFs) were determined in both tumor samples and adjacent normal tissue, revealing mean TRFs reduced in the tumor in 18% of cases and elongated in 6%. Peak TRFs were similar in tumor and normal tissue in 68% of cases, reduced in 24%, and elongated in 9% of cases. These data are in agreement with others, showing that many tumors have mean telomerase length similar to those of adjacent normal tissue.[68,70,73,74] They are also in agreement with *in vitro* data showing that in tumor-derived cell lines there is no association between telomerase activity and telomere length. [65]. Thus, telomere length alone is unlikely to be a predictor of cell immortality. [75]

Though these data point out that telomerase activity is associated with tumor progression, not much is known about the specific molecular deregulation underlying such process. Interestingly, a statistically significant association between *p53* positivity and presence of telomerase activity has also been found in NSCLC. [64] Further correlative studies are needed to define whether telomerase activation is significantly associated with deregulation of other cell cycle–controlling molecules and their

nature.

TRAP Assay as a Molecular Test of Lung Cancer?

The widespread positivity of telomerase in human tumors, including lung cancer, and its infrequent positivity in nonneoplastic tissues have prompted investigations on its value as a molecular marker of cancer. These studies have addressed the value of positive telomerase activity in cytological specimens as a diagnostic test of cancer, as well as in lymph node tissue in patients with known cancer, for the purpose of molecular staging. The first line of investigation has been pursued in several organ systems, including the upper and lower aerodigestive system. Califano and colleagues [76] have studied oral rinses from 44 patients with head and neck SCC and found telomerase activity in 14 of them, in contrast to 1 of 22 rinses from control patients without cancer. Both primary tumor and oral rinses were analyzed in 19 cases. A positive telomerase activity in the primary tumor was detected in 17 of 19 samples. Among these 17 telomerase-positive cases, activity was detected in both tumor and oral rinses in seven cases and only in the primary tumor in ten cases; no case showed telomerase activity only in oral rinses. [76] Thus, in this setting, the utility of telomerase as a cancer marker is severely hindered by its low sensitivity.

Three studies have addressed the role of detection of telomerase activity in cytological specimens in the diagnosis of lung cancer. The combined results, showing telomerase activity in benign versus neoplastic cases, are shown in Table 9.2. The reported rates of telomerase positivity in bronchiolaveolar lavage fluids from cancer patients ranged from 44% (14 of 34), [77] to 82% (29 of 37), [78] (18 of 22), [79] with an overall positive percentage of 65% (61 of 93). In contrast, a study of the incidence of K RAS, p53 mutations, and microsatellite alterations and methylations of the p16 gene in bronchoalveolar lavage fluid from patients with lung cancer yielded a sensitivity of only 53% in the diagnosis of cancer. [72] The positivity for telomerase activity detected in cytological specimens from nonneoplastic pulmonary disease was of seven of 128 in the series by Hiyama and colleagues including four of 106 bronchoalveolar lavage fluids, which contained a large number of lymphocytes. [77] Among 21 combined specimens from normal and inflammatory conditions, positive telomerase was found in two cases of sarcoidosis, two cases of tuberculosis, and two normal samples by Arai and associates. [78] Yahata and colleagues [79] found no telomerase positivity in seven normal specimens and only one low-level positivity in 12 nonneoplastic conditions. Two studies compared the sensitivity of telomerase with that of cytology in the detection of lung cancer. Arai and associates [78] found that the TRAP assay detected 29 of 37 clinically proven cancers, versus 24 of 37 for cytology. In the series of Yahata and colleagues [79] telomerase activity detected 18 of 22 cancer cases, cytological examination nine of 22. Interestingly, Yahata and colleagues [79] have combined a traditional TRAP assay with a recently modified *in situ* version of the assay. They found that the sensitivity of the assay significantly improved when both assays were combined.

TABLE 9.2. DISTRIBUTION OF TELOMERASE POSITIVITY IN BRONCHOALVEOLAR LAVAGE FLUID*

These results are particularly intriguing in view of the limited sensitivity of cytology alone [61] and of currently available molecular markers [72] in the detection of lung cancer in cytology specimens. In particular they highlight the possibility that telomerase activity may complement currently available screening tests in the diagnostic workup of suspected lung cancer, a possibility that needs further testing in large clinical cohorts.

Only one study has addressed the role of detection of telomerase activity in the molecular staging of lung cancer. These authors found positivity in eight of nine histologically positive and 26 of 48 histologically negative nodes, including three of four lymph nodes found to contain cancer cells by the p53 plaque assay hybridization. In comparison, assessment of p53 mutations by plaque hybridization revealed positivity in three of three histologically positive and three of 27 histologically negative nodes. Assessment of K RAS mutations revealed positivity in all six histologically positive nodes and in one of 21 histologically negative nodes. It is unlikely that all telomerase-positive, histologically negative lymph nodes harbor metastases, because these patients remained recurrence-free. [44] Furthermore, normal lymph nodes have been shown to contain telomerase activity. [42] These data thus show that the assessment of telomerase activity, while representing a promising molecular marker in the detection of suspected lung cancer, is of little utility in the molecular staging of NSCLC.

SUMMARY

The acquisition of telomerase activity represents a key event in the biology of immortalization *in vitro* and tumorigenesis *in vivo,* including the progression of preneoplastic bronchial lesions. Telomerase activity is an important molecular marker of lung cancer because it is present very rarely in the nonneoplastic lung, while appearing in more than or equal to 80% of NSCLC, where it correlates with tumor pathological stage and proliferative rate. Its assessment may thus help identify lung cancer patients with unfavorable pathological features and, in addition, potentially may assist the clinician in the diagnostic workup of suspected lung cancer. Furthermore, its ubiquitous role in carcinogenesis and its differential expression in normal and tumor cells make it an attractive target for novel therapeutic and/or chemopreventive intervention in overt and/or preinvasive lung cancer.

GROWTH FACTORS

GREGORY P. KALEMKERIAN

Various growth factors and growth factor receptors have been implicated in the pathogenesis and progression of both small cell (SCLC) and non–small cell (NSCLC) lung cancer. Many of these factors and receptors are preferentially expressed by either SCLC or NSCLC cells, and their effects on proliferation are similarly cell-type specific. Growth factors generally act through interactions with specific membrane-associated receptors, resulting in the activation of intracellular signal transduction pathways that carry mitogenic signals to the nucleus where cell cycle activation leads to cellular division. These pathways are also involved in the transmission of survival signals that can maintain malignant clones by interfering with appropriate apoptotic, or cell death, signals. Therefore, the dysregulation of the expression or function of specific growth factors, receptors, or signal transduction mediators can result in uncontrolled proliferation and malignant transformation. Although most growth factors induce proliferation, several growth-inhibitory factors have also been identified. The production of autocrine growth factors by lung cancer cells plays an important role in the establishment and survival of primary tumors and metastatic deposits. Proof of an autocrine growth pathway requires the demonstration of growth factor production, specific receptor expression, and growth factor–mediated proliferation within a homogenous cell population. Growth factors secreted by tumor cells or associated stromal cells can also act in a paracrine fashion by interacting with specific receptors on neighboring cancer cells. Recent advances in our understanding of the specific pathways through which growth factors affect the survival and proliferation of cancer cells has allowed the development of novel, tumor-specific therapeutic strategies.

GROWTH FACTORS IMPLICATED IN SMALL CELL LUNG CANCER

SCLC cell lines (see also Chapter 18) can be categorized into two phenotypic subsets: classic and variant. The majority of SCLC cells exhibit a classic phenotype with a high degree of neuroendocrine differentiation. Variant cell lines are less differentiated and tend to have shorter doubling times and greater treatment resistance. In light of the neuroendocrine nature of SCLC, it is not surprising that a wide variety of neuropeptides and neuropeptide receptors are expressed by SCLC cell lines and tumors. Several of these neuropeptides have mitogenic potential and have been shown to be important mediators of SCLC proliferation (Table 10.1).

Stimulatory Factors/Receptors
Gastrin-releasing peptide/GRP receptor
Neuromedin B/NMB receptor
Vasopressin/V₁ receptors
Bradykinin/B₂ receptor
Gastrin/CCK-B/gastrin receptor
Cholecystokinin/CCK-B/gastrin receptor
Neurotensin/NT receptor
Galanin/Galanin receptor
Insulinlike growth factor I/IGF-I receptor
Stem cell factor/SCF receptor (c-kit)
Transferrin/TF receptor
Interleukin-3/IL-3 receptor
Testosterone/Androgen receptor
Nicotine/Nicotinic acetylcholine receptor

Inhibitory Factors/Receptors
Transforming growth factor β₁/TGFβRII receptor
Opioids-endorphins/Opioid receptors
Somatostatin/SST receptors
Physalaemin

Bifunctional Factors/Receptors
Vasoactive intestinal peptide/VIP receptor
Nerve growth factor/NGF receptors

TABLE 10.1. GROWTH FACTORS AND RECEPTORS IMPLICATED IN SMALL CELL LUNG CANCER

Bombesinlike Peptides

Gastrin-releasing peptide (GRP) is the 27-amino acid mammalian homologue of the 14-amino acid amphibian neuropeptide bombesin. The C-terminal region of these peptides is a highly conserved receptor-binding domain that allows interaction with a family of G-protein-coupled, membrane-associated receptors. Thus far, three mammalian bombesinlike peptide receptors have been identified: GRP receptor (GRP-R), neuromedin B receptor (NMB-R), and bombesin receptor subtype-3 (BRS-3). Significant GRP expression has been reported in bronchial neuroendocrine cells and fetal, but not adult, lung preparations. [1,2] A role for inappropriate GRP expression in lung carcinogenesis was suggested by studies demonstrating that high levels of bombesinlike immunoreactivity (BLI) are present in bronchoalveolar lavage fluid from smokers,[3] and that bombesin and GRP can induce the proliferation of normal human bronchial epithelial cells and classic SCLC xenografts in nude mice.[4,5 and 6]

Initial reports of BLI in SCLC cells led to the finding that most SCLC cell lines and tumors produce and secrete GRP, and that those lacking BLI generally exhibit a variant phenotype.[7,8 and 9] The expression of GRP in SCLC cells is not constitutive, but is regulated by numerous factors, including several proteins found in nuclear extracts of classic, but not variant, SCLC cells that interact with cis-acting regulatory elements in the 5' flanking region of the GRP gene. [10,11] In addition, somatostatin down-regulates BLI in SCLC cells,[12] whereas retinoic acid,[13] vasoactive intestinal peptide,[14] and corticotophin-releasing factor[15] induce the expression of GRP. The

complexity of the GRP signaling system was underscored by the finding that extensive alternate splicing and posttranslational processing of GRP mRNA result in the expression of multiple GRP gene-associated proteins in SCLC cells. [16,17 and 18]

High-affinity GRP-R and NMB-R have been identified on most SCLC cells, whereas BRS-3 is expressed by a smaller subset of tumors. [19,20] In SCLC cells, the binding of bombesin or GRP to these receptors activates several G-proteins that initiate the second messenger cascade by hydrolyzing guanine nucleotides (Figure 10.1). Activated G-protein complexes then activate phospholipase C-b (PLC), which cleaves phosphotidyl inositol 4,5-biphosphate (PIP $_2$) into inositol 1,4,5-triphosphate (IP $_3$) and 1,2-diacylglycerol (DAG). [21,22] IP$_3$ induces intracellular calcium ion mobilization, whereas DAG activates protein kinase C (PKC). [23,24] Mitogen-activated protein kinase (MAPK) pathways, including the c-jun amino-terminal kinase (JNK) and extracellular signal-regulated kinase (ERK) pathways, are activated by both PKC-dependent and -independent mechanisms, culminating in the transcriptional activation of early-response genes (c- *fos,* c-*jun,* c-*myc*), DNA synthesis, and mitosis. [25,26] Neuropeptide receptors have also been shown to activate arachidonic acid signaling pathways, leading to an accumulation of cyclic AMP (cAMP). Further evidence of GRP's role as an autocrine growth factor in SCLC comes from studies in which the monoclonal antibody 2A11, with specificity for the C-terminus of bombesin, blocked GRP:GRP-R binding, inhibited clonal growth of SCLC cells *in vitro,* and induced the regression of human SCLC xenografts in nude mice. [27] The expression of neuromedin B and its receptor, NMB-R, has been identified in some SCLC and NSCLC cells, and exogenous neuromedin B induces clonal proliferation in classic SCLC cell lines. [28,29]

(From Woll PJ. Growth factors and lung cancer. In: Pass HI, Mitchell JB, Johnson DH, Turrisi AT, eds. *Lung cancer: principles and practice,* 1/e, Philadelphia: Lippincott-Raven, 1996:123, with permission.)

Although only a few NSCLC specimens have been reported to express GRP or BLI, [30,31 and 32] most NSCLCs do express either GRP-R or NMB-R, [33,34] and activation of these receptors by bombesin can induce intracellular calcium ion shifts and PKC translocation. [35] However, despite a few reports suggesting that GRP can stimulate the growth of NSCLC cells, most studies have failed to demonstrate any GRP or bombesin-mediated mitogenic effects in NSCLC. [26,36]

GRP has been evaluated as a clinical tumor marker for SCLC, with several trials reporting elevated plasma pro-GRP or GRP concentrations in more than 70% of patients with SCLC, but not in those with NSCLC. [37,38 and 39] In addition, high levels of cerebrospinal fluid GRP were noted in 75% of SCLC patients with carcinomatous meningitis. [40] However, most studies have found that low sensitivity and specificity severely limit the clinical utility of plasma GRP levels in patients with SCLC. [41,42]

Although many other neuropeptides induce biochemical evidence of signal transduction pathway activation, such as mobilization of intracellular calcium ion stores, relatively few have been shown to enhance the proliferation of SCLC cells. [43,44] Among this latter group are vasopressin, bradykinin, cholecystokinin, gastrin, neurotensin, and galanin.

Vasopressin

Vasopressin, a hypothalamic nonapeptide, is a regulator of blood pressure and the adrenal axis, and is the major antidiuretic hormone (ADH) in humans. These physiologic functions are mediated through a family of vasopressin-specific receptors, V $_{1a}$, V$_{1b}$, and V$_2$, which are all expressed by most classic and variant SCLC cell lines.[45] Activation of the V$_{1a}$ receptor results in an increase in cytosolic calcium ion concentrations and activation of PKC and phospholipases C, D, and A $_2$, whereas the V$_2$ receptor acts through cAMP-coupled increases in protein kinase A (PKA). Vasopressin is produced by 67% of SCLC tumors, but not by NSCLC, and is responsible for the syndrome of inappropriate ADH secretion, which causes paraneoplastic hyponatremia in 11% of SCLC patients. [46,47] (see also Chapter 29.) Vasopressin enhances the clonal growth of classic SCLC cell lines, an effect that can be antagonized by synthetic substance P analogues, suggesting that it is an autocrine mediator of SCLC proliferation. [48,49 and 50]

Bradykinin

Bradykinin is a nonapeptide that regulates diverse physiologic processes, including coagulation and nociceptive neurotransmission. Although few lung tumors produce bradykinin, normal lung tissue and many lung cancers do express B $_2$ bradykinin receptors. [51,52] Activation of B$_2$ receptors by bradykinin in both SCLC and NSCLC cells results in cytosolic calcium ion flux and stimulation of growth through a PKCa pathway. [48,53,54] In light of these findings, long-acting, N-terminally-linked bradykinin antagonist dimers containing the novel amino acid, indanylglycine, were developed and shown to inhibit the growth of SCLC cells *in vitro* and in xenograft models through the induction of apoptosis. [55] It has been suggested that the anti-SCLC activity of these bradykinin antagonist dimers and of substance P analogues is caused by discordant signaling. Specifically, these compounds activate or inhibit specific G-proteins, resulting in the activation of JNK pathways without activating PLC or PKC, a signal transduction pattern that can stimulate apoptotic pathways. Additionally, the activity of bradykinin antagonist dimers is synergistic with that of standard chemotherapeutic agents, even in SCLC cells exhibiting a multidrug-resistance phenotype. [56]

Gastrin and Cholecystokinin

Both gastrin and cholecystokinin (CCK) mediate their biologic activity through an identical C-terminal pentapeptide sequence that binds to CCK-B/gastrin receptors and, to a lesser extent, CCK-A receptors. Pro-gastrin is produced and processed by both SCLCs and NSCLCs, [57] but pre-pro-CCK and carboxyamidated bioactive CCK are expressed only by SCLC cells.[58] CCK-B/gastrin receptors are present on most SCLC cells, but are rarely expressed by NSCLC, and only a few lung tumors have been reported to express CCK-A receptors. [59,60] The concurrent expression of gastrin and CCK-B/gastrin receptors in many SCLCs has raised the possibility that they may be components of an autocrine loop. Both gastrin and CCK induce intracellular calcium ion shifts and stimulate proliferation of SCLC cells that possess CCK-B/gastrin receptors,[61] and several CCK analogues have been reported to antagonize CCK-B/gastrin receptor-mediated signal transduction events in SCLC cells.[62,63] CCK also enhances clonal growth through activation of CCK-A receptors in some SCLC cell lines. [64]

Vasoactive Intestinal Peptide

Vasoactive intestinal peptide (VIP) is a 28-amino acid neuropeptide that binds to a transmembrane receptor and activates both G-protein- and cAMP-mediated signal transduction pathways. Expression of VIP occurs in approximately 50% of lung cancers and is a rare cause of paraneoplastic watery diarrhea. [65] The VIP receptor is expressed in normal lung alveoli, as well as by SCLC and NSCLC cell lines. [66] In NSCLC cell lines, VIP stimulates proliferation,[67,68] and a hybrid peptide consisting of the N-terminus of neurotensin fused to the C-terminus of VIP has been shown to antagonize VIP-mediated induction of cAMP and inhibit the growth of NSCLC cells and xenografts.[69] In SCLC cells, VIP induces the secretion of GRP and has been reported to have both growth-stimulatory and -inhibitory potential, the latter of which

is potentiated by an antibombesin monoclonal antibody. [70],[71] and [72]

Neurotensin

Neurotensin is a 13-amino acid neuropeptide that is expressed and processed by most classic SCLC cells, but not by variant SCLC or NSCLC cells. [73],[74] Both neurotensin and the bioactive C-terminal fragment, NT(8–13), bind with high affinity to classic SCLC cells, resulting in the release of calcium from intracellular stores, PKC-dependent activation of ERK pathways, and enhancement of proliferation, suggesting an autocrine growth-stimulatory pathway. [48],[75],[76] and [77]

Galanin

Galanin is a 29-amino acid polypeptide that is widely distributed in neurons and has diverse physiologic functions. In classic SCLC cells, galanin-mediated stimulation of clonal proliferation is associated with increases in intracellular calcium ion concentrations and inositol phosphatase activity, as well as activation of ERK pathways in a PKC-dependent manner. [48],[77],[78]

Tachykinins

The tachykinins are a group of neuropeptides that mediate a diverse range of biologic activities, including pulmonary inflammation and the proliferation of mesenchymal and epithelial cells. Tachykinin receptors, such as the NK1 receptor, have been identified in human bronchial epithelium and are linked to G-proteins that activate PLC signaling pathways. [79] Mammalian tachykinins, including substance P and the neurokinins, induce calcium ion mobilization in SCLC cells, but have little effect on DNA synthesis or proliferation. [80],[81] A peptide with immunologic and biologic homology to the amphibian tachykinin, physalaemin, has been infrequently identified in human SCLC,[82] and picomolar concentrations of physalaemin have been reported to inhibit the growth of both classic and variant SCLC cells. [80]

Therapeutic Strategies Targeting Neuropeptide Pathways

The profound influence of GRP and other neuropeptides on SCLC proliferation has led to a variety of therapeutic strategies targeting relevant growth factor pathways. Thus far, the most extensively studied approaches involve receptor-specific and broad-spectrum neuropeptide antagonists. [83] Numerous peptide analogues of bombesin and GRP have been synthesized and evaluated for anticancer activity in SCLC cells. Among these compounds, short-chain peptides with homology to the C-terminal region of bombesin and GRP, especially those containing reduced peptide bonds, appear to possess the greatest antitumor activity. [84],[85] These analogues interact specifically with GRP-R, competitively blocking bombesin/GRP binding and inhibiting bombesin/GRP-mediated calcium ion mobilization and PIP_2 turnover in classic SCLC cells. [86],[87] Receptor-specific antagonists also down-regulate the expression of GRP-R and epidermal growth (EGF-R) block DNA synthesis, and inhibit basal and bombesin/GRP-mediated proliferation in a cytostatic manner in some SCLC cell lines and xenografts. [88],[89] and [90] However, receptor-specific neuropeptide antagonists are inactive against NSCLC cell lines and SCLC cells lacking expression of bombesin/GRP receptors. [88],[90]

Because the growth and survival of SCLC depends on the combined actions of a variety of neuropeptide growth factors, substantial effort has been directed toward the design of broad-spectrum neuropeptide antagonists. In this light, a variety of substance P peptide analogues have been developed and evaluated for activity in SCLC. These substance P antagonists inhibit neuropeptide-mediated calcium ion mobilization, protein tyrosine kinase activation, and DNA synthesis in SCLC cell lines.[91],[92] In addition, these compounds inhibit the growth induced by multiple neuropeptides, including bombesin/GRP vasopressin, bradykinin, cholecystokinin and others, in SCLC cell lines and xenografts. [83],[93],[94] and [95] Broad-spectrum substance P analogues are generally more potent inhibitors of SCLC growth than receptor-specific neuropeptide antagonists, despite being less potent inhibitors of neuropeptide binding and receptor activation. [83] In addition, the activity of substance P analogues does not consistently depend on the expression of neuropeptide receptors by the target cell, suggesting that these compounds may inhibit basal and neuropeptide-stimulated SCLC growth through unpredicted mechanisms. [81],[96] The activity of full-length analogues, such as [D-Arg^1, D-Phe^5, D-Trp^{7,9}, Leu^{11}] substance P (antagonist D), depends on relatively high antagonist concentrations, a finding that has hampered clinical development. In contrast, some short-chain analogues, such as [Arg^6, D-Trp^{7,9}, N-MePhe^8] substance P(6,7,8,9,10 and 11) (antagonist G) and [D-MePhe^6, D-Trp^{7,9}, Y^{10,11}, Leu^{11}] substance P(6-11) (NY3460), inhibit SCLC growth *in vitro* and *in vivc* at low micromolar concentrations.[50],[97],[98] The activity of antagonist G is additive with that of the tyrosine kinase inhibitor, tyrphostin, [95] and NY3460 has recently been shown to be a potent inducer of apoptosis in some SCLC cell lines. [100] Preclinical evaluation of the metabolism, pharmacokinetics, and toxicity of antagonist G yielded favorable results, and a phase I–II clinical trial is currently underway. [101]

Another therapeutic strategy aimed at interrupting autocrine growth loops in SCLC involves murine monoclonal antibody 2A11 directed against the C-terminal region of GRP. This antibody blocks bombesin-mediated PLC activation and PIP_2 turnover,[87] and inhibits the growth of SCLC cells and xenografts that express at least one bombesin-family receptor. [102] Recently, Kelley and colleagues reported a clinical trial in which monoclonal antibody 2A11 induced a complete response in a patient with relapsed SCLC.[103] An alternate immunotherapeutic strategy involves the fusion of a GRP analogue with a monoclonal antibody directed against the Fc $_1$RI or Fc$_1$RIII cytotoxic trigger molecules on immunologic effector cells. This immunoconjugate binds to SCLC cells that express GRP-R and attracts cytokine-activated monocytes and NK cells that mediate the lysis of the targeted SCLC cells *in vitro*.[104] A similar approach utilizes an immunoconjugate in which the active domains of diphtheria toxin are fused to either GRP (DAB$_{389}$-GRP) or substance P (DAB$_{389}$-SP). Exposure to nanomolar concentrations of DAB$_{389}$-GRP or DAB$_{389}$-SP results in the inhibition of both protein synthesis and proliferation in SCLC cells expressing GRP-R or NMB-R. [105]

Second-messenger molecules can also serve as effective targets for the disruption of autocrine growth factor pathways. The recognition of the importance of protein phosphorylation in neuropeptide-mediated proliferative signal transduction pathways has led to studies evaluating the antitumor activity of kinase inhibitors. Several tyrosine kinase inhibitors, including the tyrphostins and genestein, inhibit basal and neuropeptide-mediated SCLC growth at low-micromolar levels, with the induction of p53- and bcl-2-independent apoptosis (see also Chapter 6) at higher concentrations. [92],[99] The serine/threonine kinase, p70^{s6k}, is constitutively active in classic SCLC cells and is involved in neuropeptide-mediated mitogenesis. Rapamycin, an immunosuppressant that inhibits p70^{s6k} phosphorylation and activation, induces the dephosphorylation of p70^{s6k} and inhibits basal and galanin-stimulated proliferation in classic SCLC cells. [106]

Neutral endopeptidase (CD10/NEP, CALLA, EC 3.4.24.11) is a cell surface metalloproteinase that regulates growth factor–mediated proliferation by hydrolyzing and inactivating many neuropeptides, including GRP, neurotensin, and bradykinin. A possible role for CD10/NEP in lung carcinogenesis has been suggested by the finding that cigarette smoke not only induces neuropeptide production but also inhibits CD10/NEP expression, leading to a dramatic increase in the concentration of neuropeptide growth factors in the bronchial epithelium of smokers. In addition, although CD10/NEP is highly expressed by normal airway epithelial cells, CD10/NEP mRNA and protein levels are low or absent in most SCLC and NSCLC tumors and cell lines. [107],[108] In cultured NSCLC and human bronchial epithelial cells, the expression of CD10/NEP is inversely related to that of proliferating cell nuclear antigen (PCNA), [109] and the inhibition of CD10/NEP activity potentiates neuropeptide-induced signaling and cellular growth. [107],[110] *In vitro* studies have shown that recombinant CD10/NEP inhibits neuropeptide-mediated calcium ion mobilization, DNA synthesis, and proliferation in most SCLC and NSCLC cells, but that this activity requires prolonged exposure to high concentrations of CD10/NEP.[107],[108],[110] *In vivo,* high doses (10 mg/kg/day) of CD10/NEP administered intraperitoneally reversibly slowed the development of subcutaneous classic and variant SCLC xenografts in nude mice, but had no effect on large, established xenografts. [108]

Somatostatin

The somatostatins physiologically inhibit the secretion of many amine and peptide hormones and growth factors. As such, they can act as growth-inhibitory factors for a variety of normal and malignant cell types that rely on autocrine growth factors. The activity of somatostatin is mediated through specific membrane-associated receptors, SST-R1 and SST-R2, that are expressed by a variety of cancers. These receptors are linked to G-protein signaling pathways that inhibit cAMP production and calcium ion influx and activate tyrosine phosphatases, thereby interfering with a range of proliferative signaling pathways. [111] Somatostatin expression has been detected in approximately 25% of SCLC cell lines and tumors, but is rare in NSCLC, [112],[113] and [114] and 15% of patients with SCLC have elevated plasma levels of somatostatin.[115] In addition, functional somatostatin receptors have been identified on most SCLC, but few NSCLC, cell lines and tumors. [116],[117] and [118] Somatostatin inhibits VIP-induced autocrine growth factor release in classic SCLC cells, [119] but has no effect on the growth of Lewis lung carcinoma cells with an NSCLC phenotype.[120] In light of the short half-life of natural somatostatins, several long-acting analogues with somatostatin agonist activity have been developed (e.g., octreotide, BIM 23014C, RC-160). These analogues inhibit the proliferation of some SCLC and NSCLC cells and xenografts in a cytostatic manner that is additive with cisplatin.[121],[122] and [123] Mechanistically, somatostatin agonists have been reported to inhibit growth factor–stimulated MAPK activation and to down-regulate EGF-R and

IGF-I-R expression.[90,124] However, their anticancer activity does not correlate with the expression of known somatostatin receptors, or with the inhibition of calcium ion influx or cAMP production.[90,121,124] Clinical trials of octreotide have reported only one partial response in a total of 22 patients with SCLC. [121,125] Although the antitumor activity of somatostatin analogues has been disappointing, they have been effective in blocking hormone secretion and alleviating paraneoplastic syndromes associated with a variety of neuroendocrine tumors. The presence of somatostatin receptors in most SCLC tumors has also led to interest in the use of radiolabeled analogues for detection and staging; however, the clinical utility of such imaging studies is severely limited by low sensitivity in detecting metastatic foci. [126,127]

Nerve Growth Factor

High-affinity receptors for nerve growth factor (NGF) have been identified in a subset of SCLC cells but not in NSCLC. [128,129] However, the biologic effects of NGF on SCLC remain unclear. One study found that NGF stimulated *in vitro* growth of several SCLC cell lines in a specific manner that was inhibited by anti-NGF antibodies and the tyrosine kinase inhibitor, genestein, [129] but a conflicting report suggested that NGF inhibited basal and nicotine-mediated SCLC proliferation and tumorigenicity.[130]

GROWTH FACTORS IMPLICATED IN NON–SMALL CELL LUNG CANCER

The factors and receptors involved in the regulation of NSCLC proliferation have also been identified as growth mediators in many other epithelial tumors (Table 10.2). The frequent dysregulation of these pathways in NSCLC and other malignancies suggests that they are important determinants of neoplastic growth and rational targets for novel anticancer strategies.

Stimulatory Factors/Receptors
Epidermal growth factor/EGF receptor (c-erbB-1)
Transforming growth factor α/EGF receptor (c-erbB-1)
Platelet-derived growth factor/PDGF receptor
Insulin-like growth factors I & II/IGF-I receptor
Parathyroid hormone-related peptide
Vasoactive intestinal peptide/VIP receptor
Transferrin/TF receptor
p185^HER2 (HER2/neu)

Inhibitory Factors/Receptors
Transforming growth factor β₁/TGFβ-RII receptor
Interleukin-6/IL-6 receptor
Tumor necrosis factor α/TNFα receptor

Bifunctional Factor/Receptor
Amphiregulin/EGF receptor (c-erbB-1)

TABLE 10.2. GROWTH FACTORS AND RECEPTORS IMPLICATED IN NON-SMALL CELL LUNG CANCER

Epidermal Growth Factor Receptor and Its Ligands

EGF-R, a transmembrane receptor with tyrosine kinase activity encoded by the c- *erbE*-1 oncogene, can be activated by several ligands, including EGF, transforming growth factor a (TGFa), and amphiregulin. Both EGF and TGFa induce mitogenic signals through EGF-R, whereas amphiregulin is a bifunctional growth factor with both stimulatory and inhibitory potential. Normal lung tissue and many NSCLC tumors express EGF-R, TGFa, and amphiregulin, but most studies have failed to demonstrate significant expression of EGF-R or its ligands in SCLC. [131,132,133 and 134] Rusch and colleagues reported overexpression of EGF-R and TGFa relative to normal bronchial epithelium in 45% and 61% of NSCLC tumors, respectively, with co-overexpression in 38%. [135] In contrast, amphiregulin was underexpressed in 63% of tumors, with simultaneous EGF-R overexpression and amphiregulin underexpression in only 21%. Although EGF was not detected in any tumors in this study, another report noted overexpression of EGF in 50% of lung adenocarcinomas. [136] Studies demonstrating that the growth of NSCLC cell lines is enhanced by EGF or TGFa and inhibited by monoclonal antibodies directed against EGF-R or TGFa suggest that these molecules participate in autocrine or paracrine loops in NSCLC.[137,138 and 139] Treatment of NSCLC cell lines with exogenous EGF results in rapid autophosphoylation of EGF-R followed by activation of MAPK pathways, including the ERK and JNK pathways, with subsequent enhancement of proliferation. [140,141] Inhibition of JNK pathways with specific antisense oligonucleotides blocked EGF-induced growth, whereas inhibition of ERK activity had no effect on proliferation, suggesting separable MAPK signaling pathway functions. [141]

A role for TGFa in lung carcinogenesis has been suggested by reports that TGFa enhances tumorigenicity in lung epithelial cells expressing EGF-R and p185 ^HER2.[142] In addition, increased expression of TGFa has been associated with malignant transformation of SV-40 immortalized human bronchial epithelial cells (BEAS-2B) induced by tobacco-specific N-nitrosamines or cigarette smoke condensate. [143] Although some reports have noted an association between EGF-R expression and drug resistance, lymph node metastases, and shortened survival, [144,145] most studies have failed to demonstrate any prognostic significance for the expression of EGF-R or its ligands, [135,146,147] suggesting that these factors modulate local tumor growth without affecting tumor progression or metastatic potential. However, in lung adenocarcinomas the expression of TGFa or EGF appeared to portend a poorer prognosis in patients whose tumors also expressed EGF-R, but not in those with EGF-R-negative tumors.[136] In a recent study of 195 patients who underwent resection of a stage I–III NSCLC, multivariate analysis revealed that lymph node involvement, high microvessel counts and overexpression of amphiregulin correlated with poor prognosis, whereas overexpression of EGF-R, TGFa, and p185 ^HER2 did not.[148]

EGF-R-mediated proliferative pathways have become popular targets for experimental therapeutic interventions in NSCLC. A variety of anti-EGF-R monoclonal antibodies have been shown to block the binding of TGFa or EGF to EGF-R, and to inhibit EGF-R activation and the proliferation of NSCLC cell lines and xenografts.[138,149] The growth-inhibitory activity of anti-EGF-R monoclonal antibodies can be augmented by combining them with GM3, an anti-tyrosine kinase ganglioside that further suppresses the activation of EGF-R. [150] Clinical trials have found that anti-EGF-R monoclonal antibodies localize to EGF-R-expressing lung tumors, down-regulate EGF-R tyrosine kinase activity *in vivo,* and have minimal toxicity.[151,152 and 153] Anti-TGFa monoclonal antibodies also inhibit the proliferation of NSCLC cell lines.[154] In addition, the experimental anticancer agent, suramin, can interfere with the binding of EGF or TGFa to EGF-R and can inhibit growth factor–induced DNA synthesis and proliferation in NSCLC cells. [139,155] TGFa-PE40, a recombinant fusion protein consisting of TGFa and a 40kD cytotoxic fragment of *Pseudomonas* exotoxin A that was designed to target EGF-R-expressing tumor cells, partially inhibited the growth of NSCLC colonies and xenografts, and its cytotoxicity was associated with the expression of EGF-R. [156,157] An EGF-R deletion-mutant with unique peptide sequences, EGF-R type III, has been identified in up to 16% of NSCLCs, but not in normal lung tissue, suggesting that it may serve as a tumor-specific therapeutic target. [158,159] Strategies targeting the signal transduction pathways downstream of EGF-R are also being developed. Genestein, a naturally occurring tyrosine kinase inhibitor, abrogates EGF-induced receptor phosphorylation and MAPK activation and induces apoptosis in NSCLC cells. [140] Finally, the high level of expression of EGF-R in NSCLC cells has been exploited to develop an efficient gene therapy delivery system in which the gene of interest is fused to EGF. This EGF-DNA conjugate specifically targets EGF-R-expressing cells, resulting in efficient heterologous expression of the delivered gene. [160]

HER2/neu

The *HER2/neu* (c-*erbB*-2) oncogene encodes p185^HER2, a transmembrane growth factor receptor with tyrosine kinase activity that shares significant sequence homology with EGF-R (see also Chapter 4). Overexpression of p185^HER2 occurs in 25% to 60% of NSCLC tumors and cell lines but not in SCLC. [161,162] However, unlike the case in breast cancer and other tumors where gene amplification is the primary mode of *HER2/neu* dysregulation, gene amplification is rare event in NSCLC. [163,164] Studies with transgenic mice and immortalized human bronchial epithelial cells have suggested that although overexpression of p185 ^HER2 appears to be involved in the development of neoplastic lung lesions, it is not sufficient for malignant transformation. [165,166] Transfection experiments have also shown that p185^HER2 overexpression results in increased invasiveness and metastatic potential in NSCLC cells. [167]

P185^HER2 has become a common target for novel therapeutic strategies because of reports that have identified an association between *HER2/neu* overexpression and advanced-stage disease or shortened survival in patients with NSCLC. [162,168] High levels of p185^HER2 expression also appear to correlate with chemoresistance, and the treatment of p185^HER2-overexpressing NSCLC cells with the tyrosine kinase inhibitors tyrphostin AG825 and emodin suppressed p185 ^HER2 activation and

increased sensitivity to cisplatin, etoposide, and doxorubicin. [169,170 and 171] Similarly, the inhibition of p185 [HER2] expression through the transfection of a *HER2/neu* antisense-containing vector suppressed growth and tumorigenicity of *HER2/neu*-expressing NSCLC cells. [172] A murine monoclonal anti-p185 [HER2] antibody conjugated to gelonin, a potent ribosomal inhibitor, was also found to be a potent selective inhibitor of p185 [HER2]-positive NSCLC cell growth. [173] The significant clinical activity of Herceptin a humanized monoclonal antibody targeting p185 [HER2], as a single agent and in combination with chemotherapy in patients with breast cancer, has led to substantial interest in applying this approach to patients with NSCLC. [174,175]

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) is a chemotactic and growth factor for normal mesenchymal and endothelial cells. Most NSCLC cell lines and tumors express the PDGF A and B subunits, whereas SCLC cells do not. [176,177] The available data on PDGF-receptors (PDGF-R) in lung tumors is less clear, with conflicting reports of frequent or rare expression in NSCLC. [177,178 and 179] Most studies agree that coexpression of PDGF and PDGF-R is uncommon in lung cancer and that PDGF does not appear to mediate an autocrine proliferative effect. However, PDGF-R is highly expressed in stromal and endothelial cells within and around lung tumors, suggesting that tumor-derived PDGF may act in a paracrine manner to stimulate the development of tumor stroma and/or angiogenesis. [178]

Parathyroid Hormone-Related Protein

A large percentage of squamous cell carcinomas of the lung produce parathyroid hormone-related protein (PTHrP), which is responsible for the clinical syndrome of paraneoplastic humoral hypercalcemia. [180,181] The expression of PTHrP is enhanced by TGFa and is associated with increased proliferation in some squamous cell lung cancer cell lines, suggesting an autocrine pathway. [182] PTHrP may also act as an autocrine regulator of differentiation in bronchioloalveolar carcinoma cells. [183]

OTHER GROWTH FACTORS IMPLICATED IN LUNG CANCER

Insulinlike Growth Factors

Although insulin is essential for the serum-free propagation of SCLC and NSCLC cells in culture, it is probably not an important mediator of lung cancer growth in humans. The insulinlike growth factors, IGF-I and IGF-II, are polypeptides that share structural homology with insulin and mediate embryonic development, growth, and differentiation primarily through interactions with a high-affinity IGF-I-R membrane-associated receptor with tyrosine kinase activity. [184] A second receptor, IGF-II/M-6-PR, binds both IGF-I and IGF-II with a low affinity, but appears to lack intracellular signaling activity. The biologic activity of the IGFs is regulated by interactions with at least six IGF-binding proteins, IGF-BP1–6. The IGFs are predominantly produced in the liver and exert physiologic autocrine and paracrine effects in most organs, including the lung. Secretion of a precursor-form of IGF-II by some tumors is a rare cause of paraneoplastic hypoglycemia. A role for the IGF pathways in carcinogenesis is supported by the finding that the overexpression of IGF-I-R induces IGF-dependent cellular transformation. [185]

Nearly all lung cancer cell lines and tumors express both types of IGF receptors, [186,187,188 and 189] and IGF-I-R mediates the invasiveness and metastatic potential of Lewis lung carcinoma cells. [190] Although IGF-I is expressed by most SCLC and NSCLC cell lines and tumors, few lung cancer cells actually secrete IGF-I. [191,192 and 193] In contrast, IGF-I is secreted by lung fibroblasts and can stimulate the proliferation of both SCLC and NSCLC cells *in vitro,* suggesting that IGF-I affects lung cancer growth in a paracrine, rather than an autocrine, manner. [189,192,194,195] IGF-II, which is expressed and secreted by most SCLC and NSCLC cell lines, [191,196] preferentially binds the active IGF-I-R instead of IGF-II/M-6-PR [197] and is a more potent mitogen than IGF-I in NSCLC cells, [198] suggesting that IGF-II participates in an autocrine growth pathway in NSCLC. In addition to its effects on tumor cell growth, recent studies have noted that IGF-II also promotes the proliferation of vascular endothelial cells. [199] The potential pathophysiologic role of the IGFs in SCLC is less clear because both IGF-I and IGF-II preferentially bind to membrane-associated IGF-BP2, rather than IGF-I-R, without inducing proliferation in SCLC cells. [198] The IGF-BPs are differentially expressed by SCLC and NSCLC cell lines, but conflicting reports on individual IGF-BP expression and our lack of understanding of their specific functions make it difficult to explain their possible role in lung cancer. [191,198,200,201] Studies evaluating the potential use of IGFs or IGF-BPs as tumor markers have found that although plasma levels of IGF-I are not elevated in patients with lung cancer, 93% of patients with SCLC or NSCLC have elevated plasma concentrations of IGF-BP. [202]

The apparent importance of the IGF-I-R signaling pathway in lung cancer led to the development of an IGF-I-R-antisense-containing adenoviral vector that inhibits the proliferation of NSCLC cells and improves survival in mice with human NSCLC xenografts. [203] Other potential therapeutic approaches targeting the IGF pathway that have been shown to inhibit the growth of NSCLC cells include aIR-3, a monoclonal antibody specific for IGF-I-R, [204] and distamycin A derivatives that block the binding of IGF to IGF-I-R. [205]

Transforming Growth Factor b

The transforming growth factor b (TGFb) family consists of several growth factors and receptors with pleiotropic effects on growth and differentiation in normal and malignant cells. The TGFb-receptors (TGFb-RI, -RII, and -RIII) are serine/threonine kinases that induce p21 [WAFI] expression and cell cycle arrest. In normal tracheobronchial epithelial cells, TGFb inhibits growth and regulates normal mucoepithelial differentiation. [206] The dysregulation of TGFb pathways has been implicated in the pathogenesis of lung cancer, and the role of TGFb as an autocrine tumor suppressor is supported by the finding that the development of urethane-induced pulmonary adenomas in A/J mice is preceded by the down-regulation of TGFb-RII expression. [207] In addition, transgenic mice expressing a dominant-negative mutant TGFb-RII exhibit a higher frequency of lung and breast tumors after carcinogen exposure than nonengineered controls. [208] Most SCLC and NSCLC cell lines and tumors express TGFb, primarily as TGFb. [209,210 and 211] TGFb$_1$ inhibits the growth of SCLC and NSCLC cells and xenografts, [212,213] and can enhance the cytotoxicity of DNA-damaging agents, such as gamma irradiation and cisplatin. [214] TGFb$_1$ also increases the motility and invasiveness of NSCLC cells *in vitro*[215] and suppresses IL-2-dependent T-lymphocyte proliferation, [216] suggesting a role for TGFb in lung cancer progression and immunosuppression, respectively. Although many lung cancers express TGFb-receptors, [209,210] TGFb-RII expression is often suppressed, and resistance to the growth-inhibitory effects of TGFb is associated with the loss of TGFb-RII expression. [213,217,218] It has been suggested that TGFb may be a useful prognostic factor in lung cancer because patients with NSCLC whose tumors express high levels of TGFb or have concordant expression of TGFb and p21 [WAFI] (i.e., both high or low) appear to have better survival rates than patients with low TGFb or discordant expression. [219,220]

Opioids and Nicotine

The discovery of opioid and nicotine responsive signaling pathways in lung cancer cells led to important insights into the potential role of the dysregulation of growth factor pathways by tobacco carcinogens in the development of lung cancer. Both SCLC and NSCLC cells express natural opioids, including b-endorphin and enkephalin, along with high-affinity d, k, and m opioid receptors. [221,222] Proopiomelanocortin, the precursor of b-endorphin, is produced by one-third of SCLCs and two-thirds of pulmonary carcinoids. [223] Opioid agonists act as negative regulators of lung cancer growth, and exposure to nicotine abrogates the tumor-suppressive activity of autocrine opioids. [222] In some SCLC cells, b-endorphin enhances proliferation through activation of atypical opioid signaling pathways. [224]

Pulmonary neuroendocrine cells and tumors, including SCLC, express neuronal-type nicotinic acetylcholine receptors (nAChR) that regulate cation flux directly and through interactions with voltage-sensitive calcium channels. [225,226] These receptors can be activated by nicotine or nicotine-derived N-nitrosamines, such as NNK, resulting in increased proliferation of normal and malignant neuroendocrine cells, suggesting that chronic nicotine exposure may play a role in the promotion of pulmonary neoplasms.[227,228 and 229] In a Syrian hamster model, the mitogenic effect of nicotine plus elevated pCO$_2$ on pulmonary neuroendocrine cells was blocked by nAChR antagonists,[230] and the combination of nicotine or NNK and chronic hyperoxia, which induces emphysematous lung injury, resulted in neuroendocrine lung tumors.[231] In SCLC cells, nicotine has been shown to alter the balance between cellular proliferation and death by activating MAPK and PKC growth-stimulatory pathways and by inducing the expression of bcl-2, an inhibitor of apoptosis. [232,233] In addition, nicotine-mediated proliferation in SCLC cells is associated with increased expression of serotonin, a neuropeptide that stimulates SCLC growth through an autocrine mechanism, suggesting that both nicotinic and serotonergic receptors are potential targets for therapeutic or chemopreventive interventions. [234]

Hepatocyte Growth Factor

Hepatocyte growth factor (HGF), the ligand for the receptor product of the c-*met* protooncogene, is a physiologic mediator of angiogenesis, cellular motility, and

invasion. HGF is expressed by normal bronchial epithelial cells and most NSCLC tumors but is rarely produced by SCLC cells. [235,236 and 237] C-*met* is expressed in nearly all SCLC and NSCLC cell lines and tumors, but overexpression relative to normal bronchial epithelium has been demonstrated in only 25% to 50% of NSCLC specimens.[235,236,237 and 238] Conflicting studies have reported that HGF can either enhance or inhibit the proliferation of NSCLC and SCLC cells, with growth stimulation occurring through calcium-independent pathways.[239,240,241 and 242] In contrast, HGF consistently potentiates the *in vitro* motility and invasiveness of lung cancer cells and normal bronchial epithelial cells, [239,241] suggesting that the HGF-c-*met* pathway may mediate lung cancer progression rather than proliferation. In support of this concept, high levels of HGF and c-*met* expression have been identified as negative prognostic factors in patients with resected early-stage NSCLC. [243]

Sex-Steroid Hormones and Receptors

The finding that women with lung cancer have better stage-specific survival than men has led to the study of sex-steroid hormones and their receptors in lung cancer. Androgen-receptor (AR) expression has been reported in most NSCLC and a few SCLC cell lines, and testosterone can stimulate the growth of AR-expressing SCLC cells.[244,245] Progesterone receptors are expressed in many NSCLC samples, but not in SCLC.[245,246 and 247] Although most NSCLC cell lines and tumors exhibit estrogen-receptor (ER) immunoreactivity,[248,249] recent studies have shown that this reaction is primarily caused by the expression of p29 ER-related protein or type II estrogen-binding sites, and that very few NSCLCs actually express ER. [246,247,250] Nevertheless, tamoxifen, an anti-estrogen, inhibits the growth of NSCLC cells in culture,[251] and the intensity of p29 expression is directly associated with poor survival in women, but not men, with NSCLC. [250]

Transferrin

Iron is required for cellular proliferation, and transferrin—a glycoprotein that transports iron through interactions with transferrin receptors—is an essential factor for the *in vitro* growth of both SCLC and NSCLC cells in serum-free media.[252,253] Transferrin is produced by normal lung cells in culture and can act in a paracrine fashion to support tumor cell growth.[254] The expression of transferrin receptors, which are found in more than 75% of NSCLC tumors, is associated with increased mitotic activity and poor prognosis.[255,256] In addition, transferrin has autocrine growth-stimulatory activity in SCLC cell lines that express both transferrin and transferrin receptors.[257,258]

CYTOKINES IMPLICATED IN LUNG CANCER

Hematopoietic Growth Factors

The hematopoietic growth factors were initially characterized based on their ability to stimulate the growth and differentiation of specific subsets of hematopoietic progenitor cells. Subsequently, these factors have also been found to influence the biologic properties of some normal and malignant epithelial cells. The expression of granulocyte colony-stimulating factor (G-CSF) and its receptor have been reported in a small subset of SCLC and NSCLC cell lines and tumors. [259,260] In contrast, granulocyte-macrophage colony-stimulating factor (GM-CSF) is produced by both normal bronchial epithelial cells and about one-half of NSCLC cell lines, and several NSCLC and SCLC cell lines express GM-CSF receptors. [261,262] Exposure to G-CSF or GM-CSF enhanced *in vitro* proliferation in at least 10 lung cancer cell lines, mostly of the small cell phenotype. [259,262,263,264 and 265] However, these cytokines are not likely important activators of lung cancer cell proliferation because the growth of most SCLC and NSCLC cell lines is not affected by exposure to G-CSF or GM-CSF. [261,266,267 and 268] Interestingly, both GM-CSF and interleukin-3 (IL-3) stimulated the growth of one SCLC cell line *in vitro,* but they failed to affect the growth of these cells in an *in vivo* xenograft model.[269] Despite the concerns raised by some of these studies, numerous clinical trials have not revealed any adverse consequences resulting from the use of G-CSF or GM-CSF in patients with SCLC.

Cytokines can influence cellular properties other than proliferation. GM-CSF has been shown to enhance the *in vitro* invasiveness and *in vivo* metastatic potential of murine Lewis lung carcinoma cells through activation of PKA pathways.[270] In addition, GM-CSF increases the production of matrix metalloproteinases in human squamous cell lung carcinoma cells, and both GM-CSF and G-CSF can enhance the *in vitro* invasiveness of human NSCLC cells.[261,271] Macrophage-CSF (M-CSF, CSF-1) and its receptor, CSF-1R, the product of the c-*fms* oncogene, mediate normal macrophage invasiveness. In NSCLC cells expressing CSF-1R, M-CSF increases basement membrane invasiveness *in vitro.*[272] However, the expression of heterologous M-CSF in human squamous and SCLC cell lines decreased hematogenous and lymphatic metastases in *in vivo* xenograft models,[273] and treatment of mice bearing subcutaneous Lewis lung carcinoma transplants with M-CSF results in fewer pulmonary metastases. [274] The effect of M-CSF on metastasis may be immune-mediated, as suggested by a study in which the pretreatment of mice with irradiated Lewis lung cancer cells that were engineered to express heterologous M-CSF resulted in the inhibition of tumor formation after subsequent injection of untreated Lewis lung cancer cells.[275]

Lymphokines

The proliferation of most lung cancer cell lines appears to be unaffected by interleukins (IL-1, IL-2, IL-3, IL-4, IL-6) and interferons (IFNa, IFNb, IFNg). [266,267,276] However, IL-3 can stimulate the growth of some SCLC cell lines that express IL-3 receptors, and it can partially inhibit the cytotoxic effects of cisplatin and doxorubicin.[267,277] In addition, IL-6 inhibits and anti-IL-6 antibodies enhance the proliferation of some NSCLC cells that express IL-6 and IL-6 receptors, suggesting an autocrine growth-inhibitory loop. [278] The finding that NSCLC cells are less sensitive to the inhibitory effects of IL-6 than are normal bronchial epithelial cells also suggests that escape from autocrine IL-6 control may be involved in lung carcinogenesis. Finally, TNFa and IL-1b, which are induced by retinoic acid, can inhibit the growth of lung cancer cells *in vitro,* and the inhibitory activity of TNFa can be potentiated by IFNg. [266,279]

Stem Cell Factor and *c-Kit*

Stem cell factor (SCF), a growth and differentiation factor that affects multiple hematopoietic lineages, and its receptor, the product of the c-*kit* oncogene, are coexpressed by at least 70% of SCLC cell lines and tumors[235,280,281] and constitute an autocrine loop that can cooperate with other growth factor pathways in SCLC. [282] In contrast, c-*kit* is not expressed by normal bronchial epithelial cells, [281,283] and only 15% of NSCLC tumors coexpress SCF and c-*kit*.[284] SCF mediates both proliferation and chemotaxis in SCLC cells that express c-*kit,* suggesting that the c-*kit* pathway is a rational therapeutic target. [284,285] Antisense oligonucleotides targeting c-*kit* and SCF inhibited the growth of NSCLC cells that coexpress c-*kit* and SCF.[286] In addition, infection of SCLC cells that express c-*kit* with a c-*kit* antisense-containing adenoviral vector significantly inhibited cellular proliferation. [287] Krystal and colleagues demonstrated that AG1296, a tyrosine kinase inhibitor that is relatively selective for c-*kit,* induced apoptosis in SCLC cells that coexpress c-*kit* and SCF.[288] These investigators also reported that activation of kit by SCF enhanced the activity of lck, a src-family tyrosine kinase, and that treatment of SCLC cells with PP1, a lck-selective inhibitor of src-family kinases, antagonized SCF-mediated proliferation and inhibition of apoptosis. [289]

CONCLUSION

Recent advances in our understanding of the signaling pathways that regulate the survival and proliferation of both small cell and non–small cell lung cancer have allowed the development of a wide variety of therapeutic strategies designed to specifically target various components of these pathways, including growth factors, growth factor receptors, and second messenger molecules (Table 10.3). Although the ultimate clinical utility of these approaches has yet to be determined, future advances in the prevention and therapy of cancer will depend on further research aimed at expanding our knowledge of the cellular and molecular determinants of the malignant phenotype.

Growth Factor–Targeted
Anti-growth factor (GRP, TGFα) monoclonal antibodies
Anti-growth factor (GCF) antisense oligonucleotides
Neutral endopeptidase
Inhibitory growth factors (TGFβ, SST analogues)

Receptor–Targeted
Receptor-selective neuropeptide antagonists (GRP, bombesin analogues, bradykinin antagonist dimers CCK analogues)
Broad-spectrum neuropeptide antagonists (substance P analogues)
Anti-receptor (IGF-I-R, EGF-R, p185^{neu}) monoclonal antibodies (Herceptin)
Anti-receptor (c-kit, IGF-I-R, p185^{neu}) antisense oligonucleotides/gene therapy
Immunoconjugates (GRP analogue; anti-FC, Ricin monoclonal antibody)
Growth factor: toxin fusion proteins (GRP diphtheria toxin, TGFα-PL exotoxin A)
Receptor-selective tyrosine kinase inhibitors (anti-c-kit, anti-EGF-R, anti-p185^{neu})
Growth factor: receptor (IGF, IGF-I-R) binding inhibitors (cblastomycin A derivatives)
Growth factor (EGF): DNA conjugate gene therapy delivery system

Signal Transduction Pathway: Targeted
Tyrosine kinase inhibitors (tyrphostins, genestein, PP1)
Serine/threonine kinase inhibitors (rapamycin)

(parentheses) indicate examples under preclinical or clinical development

CURRENT CONCEPTS OF ANGIOGENESIS RELATED TO PRIMARY LUNG CANCER

YASUHIKO OHTA
YOH WATANABE

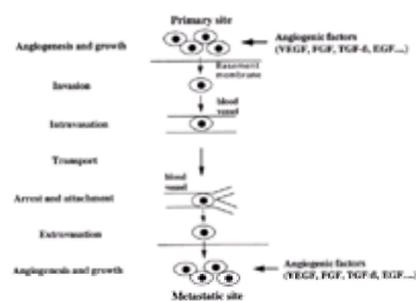
As a route for nutrients, oxygen, and metastasis, blood vessels are an integral component of malignant solid tumors. Angiogenesis is the phenomenon of the development of new blood vessels from preexisting blood vessels (Figure 11.1). Development of metastases includes many steps, among which are angiogenesis and growth of tumor cells in the primary site, followed by invasion, intravasation, transport, arrest, attachment, and extravasation. The same series of steps, including angiogenesis and growth, should occur at the metastatic site. Theoretical simulations have led us to believe that tumors with rich vascularization are likely to have faster growth and higher risk of distant metastasis compared to those with poor vascularization. Tumor angiogenesis is of particular interest not only as a promising prognostic indicator but also as a target for possible innovative therapeutic interventions against tumor growth and metastasis. Folkman has been foremost in the concept that tumor growth is angiogenesis-dependent and that the acquisition of an angiogenic phenotype clearly has a decisive meaning in the development of tumor cells.[1,2] His hypotheses were first substantiated when he proved that tumors grown in isolated perfused organs without proliferating blood vessels were limited to 1 to 2 mm^3, but expanded rapidly after vascularization in an *in vivo* model system.[3]


FIGURE 11.1. Schematic sequential steps of the metastatic cascade.

Among the many reported angiogenesis-associated factors, vascular endothelial growth factor (VEGF) is the most powerful endothelial cell-specific mitogen that is associated with tumor neovascularization. This novel angiogenic stimulator has a peculiar background in that it was originally detected as a vascular permeability factor in malignant ascites fluid in 1983[4] To date, two definite VEGF receptors, kinase insert domain-containing receptor (KDR)/Flk-1 and fms-like tyrosine kinase 1(flt-1), have been identified in its signal transduction pathways. [5,6,7 and 8] Several factors that are related to the regulation of VEGF expression have also been identified. Transforming growth factor (TGF)-b, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF), which are all angiogenesis stimulators, appear to be major stimulants of VEGF expression. [9,10] Recent studies have also revealed a connection between mutant *p53,* mutations in the H-*ras* or K-*ras* oncogene, and *Src* oncogene and the stimulation of VEGF expression in tumor angiogenesis. [11,12,13 and 14] These results suggest that VEGF participates in the key role of tumor angiogenesis. In this chapter, we highlight VEGF/vascular permeability factor expression in primary lung cancer, outlining clinical implications that are just being realized. The areas that are covered include (a) intratumoral microvessel density and its clinical implications in primary lung cancer, (b) tumor angiogenesis and VEGF expression in lung cancer, (c) the association of VEGF expression with metastasis, (d) assessment of lymphatic vessel density in tumor tissue and its association with VEGF family expressions, (e) other angiogenesis-associated agents that appear to take part in the progression of lung cancer, and (f) inhibition of angiogenesis for cancer treatment.

NEOVASCULARIZATION ASSESSED BY INTRATUMORAL MICROVESSEL DENSITY IN PRIMARY LUNG CANCER—ITS CLINICAL IMPLICATIONS

In primary lung cancer, Macchiarini et al. first observed a relationship between neovascularization of tumors in early stages and metastasis in 1992. [15] In this study, neovascularization was assessed by counting microvessels by using anti-Factor VIII (FVIII) immunohistochemistry in the most vascularized "hotspot" area. In 1994, Yamazaki and colleagues found that microvessel density similarly assessed by FVIII was positively correlated to the relapse of patients with lung adenocarcinoma after resection. These authors also suggested that intratumoral microvessel counts were associated with the aggressiveness of the tumor. [16] Since then, many reports have assessed the impact of intratumoral microvessel density on the prognosis in primary lung cancer, and some researchers have found that intratumoral vascularity has a close relationship to poor prognosis in the assessment of overall survival or disease-free intervals. [17,18,19,20,21 and 22] However, not all studies agree with the concept of microvessel density as prognostic in lung cancer. [23,24 and 25] This inconsistency may partly be a result of the lack of homogeneity of experimental methods and/or conditions, heterogeneity of angiogenesis in samples used, and the character of markers mostly used for the detection of endothelial cells that recognize both blood and lymphatic vessels.

Harpole et al. studied 275 consecutive non–small cell lung cancer (NSCLC) patients with stage I disease using anti-FVIII immunohistochemistry and found an increased positive correlation between microvessel density and poor outcome of the patients. [18] Giatromanolaki et al. studied 134 NSCLC patients with stage I–II diseases using both anti-FVIII and anti-CD31 antibodies, also revealing a positive correlation with poor prognosis. [20] Duarte et al. also found a significant association between vascularization assessed by anti-FVIII antibody and cancer-related mortality rate in 106 patients with stage I NSCLC. [22] Ohta, using 104 randomly selected stage I NSCLC patients with or without recurrence for a follow-up period of at least 5 years, reported that the mean microvessel density in tumors with recurrence was significantly greater than that in tumors without recurrence (18.2 ° 10.5 versus 8.5 ° 5.0, p < 0.0001). [26] Vascularity may be able to reduce the risk of recurrence of lung cancer with curative resections in early stages. The limitations of FVIII analysis are well described. FVIII antigen is not necessarily expressed in all endothelial cells and is actually consumed by the endothelium of newly formed capillaries. In addition, the endothelial cells from microvessels are inferior to those from macrovessels in the expression of Weibel-Palade bodies, which store factor VIII antigen. [27]

Research using other antibodies has confirmed a similar significant association between intratumoral microvessel density and prognosis. For example, using anti-CD34 monoclonal antibody (which has a higher specificity compared to anti-FVIII), Fontanini reported that microvessel count was an independent prognostic indicator among 195 patients with stage I–IIIA NSCLC. [21] Conventional wisdom, therefore, implies that direct counting of microvessels, which is mainly based on immunohistochemical staining for endothelial cells, will define the risk of recurrence and outcomes for lung cancer patients who undergo potentially curative

operations.

TUMOR ANGIOGENESIS AND VEGF EXPRESSION IN PRIMARY LUNG CANCER

Molecular cloning has found four VEGF alternative spliced transcripts from the single VEGF gene on chromosome 6p21.3; that is, VEGF121, 165, 189, and 206. Although the longer forms, designated as VEGF189 and 206, are mostly cell-associated and have vascular permeation ability, VEGF121 and 165, which are translated from shorter transcripts, are efficiently secreted and promote mitogenesis of endothelial cells. [28] A positive correlation between VEGF expression and microvessel density has already been observed in a variety of tumors. [23,29,30 and 31] Michenko and colleagues have found that VEGF is associated with the mechanisms underlying the induction of angiogenesis by hypoxia. [32] According to the study, which used primary cultured vascular cells, the number of both endothelial cells and pericytes increased significantly under hypoxic conditions, along with an increase of mRNAs coding for the secretory forms of VEGF (VEGF121 and 165). VEGF receptors KDR and flt-1 were found to be constitutively expressed in endothelial cells, but only flt-1 mRNA was expressed in pericytes under hypoxic conditions. [33] Secretory forms of VEGF seem to be involved in tumor angiogenesis not only through autocrine mechanisms but also through paracrine systems. As a tumor increases in size with resulting ischemic change, angiogenic mechanisms may be influenced.

The significance of each spliced variant of VEGF is not yet clear. Using the quantitative reverse transcription-PCR (RT-PCR) method, we previously examined the VEGF mRNA expressions in primary lung cancer tissues. [34] Human lung cancer cell lines (PC-6, PC-10, QG-56, and QG-96) all had secretory forms of VEGF mRNA, and large amounts of the secretory forms of VEGF mRNAs were also found in resected lung cancer tissues independent of histologic subtypes (71.4% in total). VEGF121 mRNA expression levels also correlated with patient outcomes. Although the sample scale was small, VEGF121 gene expression levels were associated with poor prognosis in patients in the early stages of lung cancer. In patients who underwent a curative operation at stage I of the disease (n = 17), the median survival of the VEGF high-expression group was 8 months, and that of the VEGF low-expression group was 151 months. The 3- and 5-year survival rates of the high-expression group were 50.0% and 16.7%, respectively, and those of the low-expression group were 90.9% and 77.9%, respectively. Further, among eight cases of long-term survival beyond 5 years, seven cases had low or no VEGF121 mRNA expression. In contrast, among 18 cases with VEGF121 mRNA overexpression, 17 cases died because of recurrence. These data imply that gene expressions of the secretory forms of VEGF mainly pertain to cancer cells and have an important role in lung cancer progression.

According to the results of another study using 90 randomly selected primary lung cancer patients without distant metastasis, [35] the percentage of positive cases for each spliced variant in tumors (T) and surrounding normal lung tissue samples (N) was 84.3% in T and 66.7% in N for VEGF121, 76.5% in T and 56.9% in N for VEGF165, and 47.1% in T and 7.8% in N for VEGF189. Among the four alternatively spliced variants, although VEGF121 and 165 were the dominant types in both lung cancer tissue and surrounding normal lung tissue, VEGF189 appeared to be dominant only in tumor tissue. The mean relative intensities of VEGF121 mRNA expression (VEGF121/b-actin) in tumor (T) (20.2 ° 5.2) was significantly higher than that in normal (N) (3.5 ° 1.1, p = 0.0024). In addition, if tumors were classified as high or low VEGF121 expression group relative to the mean value of densitometry index in N, the percentage of high-expression cases was 65.0% in T, whereas only 10.9% in N. These results reveal that the secretory form of VEGF, VEGF121, is overexpressed in lung cancer tissue compared to surrounding normal lung tissue. Moreover, overexpression of VEGF is found in adjacent normal lung tissue in advanced stages, including pleural involvement. [35] The association of VEGF with pleural dissemination, however, needs further definition.

If VEGF is involved in tumor angiogenesis through both autocrine and paracrine systems, then the expression in normal lung tissue may participate in the mitogenic activity in tumor angiogenesis. Although the meaning and significance of each alternatively spliced variant of VEGF remains unclear, the majority of studies support the importance of VEGF121 isoform for the progression of lung cancer. Regarding the role of VEGF121 in tumorigenesis, it has been found that transfection of this isoform into a human breast carcinoma cell line promotes tumor growth and angiogenic response. [36] Although VEGF189 expression is not as high as that of VEGF121, its specific expression in tumors suggests that VEGT 189 may be involved in tumor progression. The specific upregulation of the VEGF189 isoform in confluent cultures compared to sparse monolayers has been found in colon cancer cell lines, [37] implying a potential role for the isoform in cellular interaction. [38,39] In colon cancer patients, VEGF189 isoform has also been found to be correlated with liver metastasis. [40]

Lung alveoli (together with adrenal cortex, renal glomeruli, and cardiac myocytes) are rich in VEGF expression. [41] This particular condition may promote malignant development in patients with lung cancer. Strong VEGF expression in tumors seems to predict a poor outcome in lung cancer patients. [23,34,42,43 and 44] VEGF expression levels have been assessed chiefly by the immunohistochemistry using antibodies that recognize multiple VEGF spliced variants at a time. In 1995, Mattern et al., in a study of 204 patients with primary NSCLC, demonstrated a trend that patients with VEGF-positive tumors had worse prognoses than those with VEGF-negative tumors. [23] They also reported that the proliferating cell nuclear antigen (PCNA) labeling index significantly increased with increasing VEGF expression, but that no association existed between PCNA labeling index and tumor vascularity. These findings imply that VEGF may participate in tumor progression and development through at least two separate mechanisms; that is, as a growth factor for tumor cells and as a mitogen for vascular endothelial cells. [45] Data have also demonstrated that VEGF expression, based on immunohistochemic staining methods, was an independent prognostic indicator in lung cancer patients. [43,44]

Limited data exist regarding serum VEGF protein levels in lung cancer patients, and high VEGF expression levels in serum have been associated with poor outcomes in these patients. [46] Recent studies have also shown that serum VEGF is produced by megakaryocytes and platelets *in vitro,* and its concentrations are correlated with platelet counts. [47,48]

ASSOCIATION OF VEGF EXPRESSION WITH LYMPH NODE METASTASIS

Two routes are involved in the development of lymph node metastasis. An anatomic route involves the blood circulation to the lymphatic hilum, in which tumor cells in the blood can be transported and arrested in the lymph nodes. An increasing number of tumor cells in the blood may result in a high frequency of nodal involvement, and tumor angiogenesis may be involved in nodal metastasis via this medium. The second route involves a direct invasion of tumor cells into lymphatic vessels. In tumors with an increase in newly formed lymphatic vessels, both preexisting lymphatic and neolymphatic vessels may be the route for lymph node metastasis. If the neolymphatics develop from preexisting lymphatic endothelium as do blood vessels, the number of preexisting lymphatics should affect the lymphatic density. Although this neolymphatic route is hypothetical, it implies that tumor angiogenesis as well as lymphangiogenesis may be involved in lymph node metastasis formation. The study on neovascularization of lymphatics in tumors has just begun to be explored and no conclusive data have been reported. Consistent with this hypothesis, however, are previous data that indicate a relationship between microvessel density and lymph node metastasis, using antibodies that recognize both blood and lymphatic microvessels. [49,50] This area of study is controversial, however, with minimal data supporting the mechanism. [16,23]

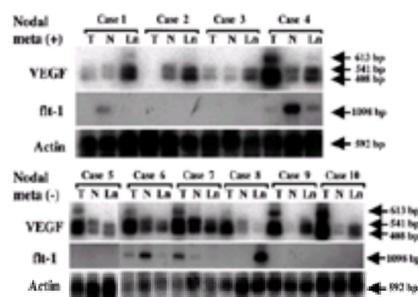
A correlation between VEGF expression and lymph node metastasis in primary lung cancer has been documented. [35] Primary lung cancer tissue and surrounding normal lung from 90 patients without distant metastasis had the intensity of VEGF mRNA expression levels calculated by the sum of the relative intensities of both the tumor tissue and corresponding adjacent normal lung tissue using quantitative RT-PCR analysis. A trend to higher VEGF mRNA expression levels occurred in patients with nodal metastasis (23.2 ° 39.9, n = 35) than in those patients without nodal metastasis (8.8 ° 17.9, n = 55) (p = 0.051). When stratified by nodal status, the VEGF expression levels had a tendency to increase with the progression of nodal status [N1, 12.0 ° 14.9 (n = 7); N2, 21.2 ° 36.2 (n = 21), and N3, 40.5 ° 66.1 (n = 7)]. Moreover, VEGF expression could be detected in lymph nodes. Ten lymph nodes (four nodes positive and six nodes negative), together with the corresponding primary lung tumors and surrounding normal lung tissue, were simultaneously examined. To obtain an exact diagnosis of nodal micrometastasis, keratin 19 mRNA expression was also investigated by using the RT-PCR technique along with histologic examination. VEGF expression levels in metastatic lymph nodes were conspicuously higher than those in the primary site, and all the expression levels from nodes without metastases were lower than those of the primary tumors (Figure 11.2). These results suggest that tumor cells with high VEGF expression may metastasize selectively to nodes. VEGF expression within lymph nodes, although a small sample scale renders the meaning inconclusive, may imply the existence of another function of VEGF for the development of nodal metastasis independent of the proliferation of endothelial cells. In fact, Gabrilovich and colleagues recently reported a potential role for VEGF in allowing tumor cells to avoid the induction of an immune response.[51]


FIGURE 11.2. RT-PCR analysis of VEGF mRNAs in lymph nodes (*Ln*), correspondent lung cancer tissue (*T*), and adjacent normal lung tissue (*N*). Among the 10 lymph node samples, 4 from node-positive patients were metastatic (samples 1–4) and 6 from node-negative patients were nonmetastatic (samples 5–10). This assessment of lymph node metastasis was done by histopathologic examination using enzyme-histochemistry staining and the RT-PCR method for the detection of keratin 19 mRNA as a sensitive assay for the micrometastasis. Other receptors (flt-4 and KDR) could not be found in this study. (From Ohta Y, Watanabe Y, Murakami, et al. Vascular endothelial growth factor and lymph node metastasis in primary lung cancer. *Br J Cancer* 1997;76:1041, with permission.)

ASSESSMENT OF LYMPHANGIOGENESIS AND ITS CONNECTION WITH VEGF FAMILY

Partly because of the difficulties in making exact distinctions between blood and lymphatic microvessels and because of the lack of suitable *in vivo* or *in vitro* model systems for the study of lymphatic endothelial cells, little information is available about the phenomenon of "lymphangiogenesis" in tumors; that is, the neovascularization of lymphatic vessels in tumors. As previously detailed, this phenomenon is not well documented, and its existence is controversial. In human primary cutaneous melanoma, de Waal et al. recently reported the lack of lymphangiogenesis in tumors even in the presence of extensive hemangiogenesis based on the results of a differential immunohistochemic double-staining method. [52] It was concluded from this study that hemangiogenesis might indirectly enhance lymphatic invasion as the driving force behind tumor expansion. Despite the infrequent observation of lymphatics inside the tumor, the expanding cutaneous melanoma tumor mass appeared to facilitate entrapping of lymphatics in tumors and the invasion of tumor cells into lymphatics at the site of the subepidermal lymphatic plexus. Other reports have suggested the existence of the specific pathways involved in the formation of lymphatics separately from those of hemangiogenesis. [53,54,55 and 56] Among the VEGF family members, the function of VEGF type C (VEGF-C) appears to extend to the lymphatic systems, where it serves as a ligand for fms-like tyrosine kinase 4 (flt–4). [53,54]

The correlation between VEGF-C expression levels and microlymphatic vessel density in malignant pleural mesothelioma has been recently examined. [57] An attempt was made to discriminate lymphatics from blood vessels using an enzyme-histochemistry assay for 5'-nucleotidase (5'-NA). [58] The activity of the enzyme is higher in lymphatic endothelial cells compared to that in blood capillary endothelial cells, and as such is used to discriminate lymphatics from capillary endothelial cells after adequate inhibition of its activity. [59,60,61, and 62] Among 54 malignant pleural mesotheliomas, significant positive correlations were found between VEGF-C and flt-4 gene expression levels that were assessed by semiquantitative RT-PCR analysis ($p = 0.0018$, $r = 0.67$). Further, the association between microlymphatic vessel density and VEGF-C expression levels was especially strong ($p < 0.0001$, $r = 0.63$). The correlation of microlymphatic vessel density with flt-4 expression levels was also confirmed ($p = 0.0164$, $r = 0.64$). The microlymphatic vessel density, however, within mesothelioma tumor tissue had no impact on nodal metastasis. Instead, the expression of VEGF had a tendency to be greater in node-positive than in node-negative patients, suggesting its association with nodal metastasis independent of the number of lymphatics in malignant pleural mesothelioma tumors. In addition, flt-4, which was originally described in lymphatic endothelium, [63,64] was highly expressed in malignant pleural mesothelioma tissues, in human malignant mesothelioma cell lines, and in normal pleural tissue samples. Although the role of flt-4 in mesothelioma is not well known, flt-4 expression was confirmed in normal mesothelial cells. [65] These results suggest a possibility that VEGF-C has some role for the autocrine growth of mesothelioma cells.

VEGF-C is actually expressed in a variety of human tumors, [66] and its family members encompass VEGF-B, [67] VEGF-C, [63,68] and VEGF-D. [69,70] The significance of these VEGF-associated factors as novel stimulators for vascular endothelial cells and/or lymphatic ones needs to be further studied to elucidate their connections with proliferation of lymphatic endothelium and lymph node metastasis.

The relationship between microlymphatic vessel density in tumors and the capacity of tumors to develop lymph node metastasis has been studied using the microlymphatic vessel density (MLD) method in SCID mice injected subcutaneously with various human tumor cells (PC-14, DLD-1, OST, and MNNG/HOS). Subcutaneous regional lymph nodes and lungs were dissected when the primary tumor volume reached 2 cm^3. As a result, lymph node metastases were detected in mice injected with PC-14, and primary PC-14 tumors had high MLD (15.3_7.6). Tumors with no lymph node metastasis had low MLD (DLD-1, 0 and MNNG/HOS, 0) except for OST (13.5_6.0). Moreover, an interesting contrast was found between PC-14 and MHHG/HOS tumors in that, while PC-14 tumors developed lymph node metastasis, all MNNG/HOS tumors developed lung metastasis, paralleling the contrast of the relatively high MLD in PC-14 tumors to low MLD in MNNG/HOS tumors. DLD-1 developed no lymph node metastasis or lung metastasis, and this cell line had low MLD. On the other hand, OST tumors developed no lymph node metastasis despite relatively high MLD. These findings suggest that high microlymphatic vessel density is not necessarily associated with nodal involvement, although some tumors appear to have a tendency to develop lymph node metastasis when they are rich with lymphatic vessels.

OTHER ANGIOGENESIS-ASSOCIATED AGENTS THAT ARE RELATED TO THE PROGRESSION OF LUNG CANCER

Of the nine fibroblast growth factors (FGFs), FGF-2 (bFGF) is the leading candidate for being a stimulator of angiogenesis. The functions of FGF-2 include vascular endothelial and smooth muscle cell proliferation, capillary tube formation, and chemotaxis of endothelial cells. A recent study also suggests an antiapoptotic effect of FGF-2 via induction of Mdm-2 with the subsequent inhibition of p53 function and via down-regulation of bcl-2. [72,73] In NSCLC the potential role of bcl-2 in suppressing tumor angiogenesis has been reported. [74] There have been suggestions of an association between FGF-2 and VEGF; [75,76,77 and 78] however, clinical investigations using resected tumor specimens have not necessarily disclosed a significant association between them. [31,34] The significance of bFGF as a prognostic indicator still needs to be defined in lung cancer. In breast carcinoma, low expression of bFGF is reportedly associated with a poor prognosis. [79] In lung cancer, one report found a significant correlation between bFGF expression and patient survival, [80] whereas another did not. [81]

Platelet-derived endothelial cell growth factor (PD-ECGF)/thymidine phosphorylase is also an angiogenesis stimulant and promotes tumor cell growth. [82,83] PD-ECGF expression has been observed in a variety of human tumors, including NSCLC cell lines. [84,85] In NSCLC patients, tumors with PD-ECGF overexpression have reportedly been associated with poor prognosis. [86,87]

Interleukin 8 (IL-8) is one of the most studied chemokines that stimulate angiogenesis. The production of IL-8 has been confirmed in NSCLC cell lines and in resected NSCLC specimens alike, and it appears to act as a promoter of human NSCLC tumor growth through angiogenesis activation. [88,89] A study using human glioma cell lines suggested that the paracrine control of tumor angiogenesis by IL-8 was independent of that by VEGF/bFGF. [90]

Thrombospondin (TSP) is a matricellular glycoprotein that is secreted by a variety of cells, including tumor cells. [91,92] Among the five structurally different members (TSP-1–5) of the TSP family, TSP-1 and -2 have a molecular architecture similar to angiogenesis inhibitors. Recent data suggest that TSP-1 may also function as an angiogenesis stimulator. [93,94] For example, a domain analysis has revealed that TSP-1 possesses binding sites for avb3 integrin and TGF-b, which are both proangiogenic. [93,95,96] In addition, the role of TSP-1 seems to be multifunctional and to be associated with adhesion, chemotaxis, and proliferation of endothelial cells. [93] Further, recent studies have also suggested that *p53* can down-regulate TSP-1 expression, [97] raising the possibility that inactivation of *p53* may induce transcriptional activation of TSP-1 in affected tumors. In primary lung cancer, although little information is available on the role and clinical implications of TSP, a recent study suggested an inhibitory role of TSP-2 in angiogenesis and progression of NSCLC. [98]

TABLE 11.1. THE EFFECT OF ANTIANGIOGENIC AGENTS ON LYMPH NODE METASTASIS

Candidates for Antiangiogenic Cancer Treatment

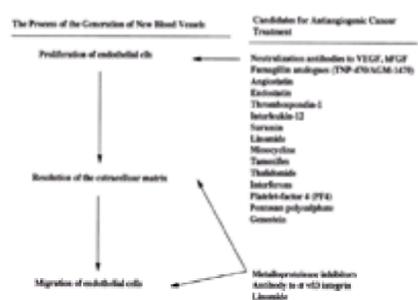
Antiangiogenic therapy is being used as a new anticancer "dormancy therapy" to promote stabilization or shrinkage of disease. The process of new blood vessel generation is divided into multiple major steps; that is, (a) proliferation of endothelial cells, (b) resolution of the extracellular matrix, and (c) migration of endothelial cells.[99] Several antiangiogenic agents or drugs are expected to be feasible for cancer therapy that targets these angiogenic steps (Figure 11.3). For inhibition of the first step, neutralization antibodies to angiogenic factors (VEGF, bFGF), antiangiogenic agents [fumagillin analogues (TNP-470/AGM-1470), interleukin-12, suramin, linomide, minocycline, tamoxifen, thalidomide, interferons, platelet-factor 4(PF4), pentosan polysulphate, genestein, etc.], and angiogenesis-inhibitory factors (angiostatin, endostatin, thrombospondin, etc.), are representative agents so far.[100] For the second and third steps, metalloproteinase inhibitors, antibody to avb3 integrin, and linomide are also potential candidates.[100] Some of these agents (e.g., linomide, PF4, pentosan polysulphate, neutralization antibodies to VEGF, metalloproteinase inhibitors, fumagillin analogues, interleukin-12, thalidomide, and so on) are already in clinical trials.[100,101]


FIGURE 11.3. Candidates for antiangiogenic cancer treatment.

Inhibition of Angiogenesis for Cancer Treatment by Targeting VEGF and its Receptors

VEGF itself may be a potential molecular target for the treatment of lung cancer. Using *in vivo* model systems, inhibition of VEGF function has successfully controlled tumor growth, dissemination, and distant metastasis by a variety of anti-VEGF agents such as neutralizing anti-VEGF antibodies, anti-sense VEGF cDNA, and soluble VEGF receptor.[102,103,104,105,106,107 and 108] Kim first demonstrated the effectiveness of a monoclonal antibody against tumor cells having VEGF expression in 1993.[102] Human sarcoma cells injected into nude mice were inhibited by the administration of anti-VEGF antibody A.4.6.1. The monoclonal antibody had no direct inhibitory effect on tumor cell growth *in vitro,* suggesting the importance of the inhibition of paracrine VEGF mechanisms from both host and tumor cells in order to control tumor angiogenesis and tumor progression. In addition to antibody cocktails that recognize all VEGF-spliced isoforms, those antibodies to VEGF121 secretory form alone can also inhibit tumor growth and metastasis. Asano found that a neutralizing monoclonal antibody to VEGF121 could inhibit the growth and formation of spontaneous lung metastasis of human sarcoma HT-1080 cells subcutaneously inoculated into nude mice.[109]

Targeting of VEGF receptors also serves as a possible therapeutic intervention to inhibit tumor angiogenesis and tumor growth.[110,111] A clinical investigation of colon cancer found that upregulation of VEGFR-2 (KDR) was associated with metastasis[31] and that inhibition of angiogenesis by blocking VEGFR-2 (KDR) prevents tumor cell invasion.[111] These results suggest a mutually close relationship between VEGF and tumor invasion, and that anti-VEGF therapy may have a direct therapeutic influence against cancer invasion or metastasis together with antiangiogenic effects for tumor angiogenesis.

The timing of the antiangiogenesis therapy may be important, as suggested by Yoshiji.[112] No growth inhibition of human breast carcinoma T-47D cells was observed when anti-VEGF treatment was started for tumors that had reached a certain size (820 mm^3) despite the observation of significant inhibitory effects for smaller tumors. This correlation suggests that VEGF may not be the crucial angiogenic factor for larger tumors or that angiogenic factors may alternatively be changed and superseded by other factors after the suppression of VEGF. If VEGF is essential at the initial phase of tumor development and angiogenesis, the practical usage of anti-VEGF treatment may then be most expected for the control of micrometastasis.

The Effect of Antiangiogenic Drugs on Tumor Growth, Distant Metastasis, and Lymph Node Metastasis

Antitumor or antimetastatic activity with antiangiogenic therapies have been documented in a variety of metastatic model systems using various antiangiogenic drugs. Most of the experimental studies have reported inhibitory effects for bloodborne distant metastases, such as liver and lung metastases, and few comments have been made on possible therapeutic effects for lymph node metastasis. Because nodal involvement is one of the most important factors influencing the survival of surgical patients with primary lung cancer, the effects of antiangiogenic drugs on lymph node metastasis need to be clarified.

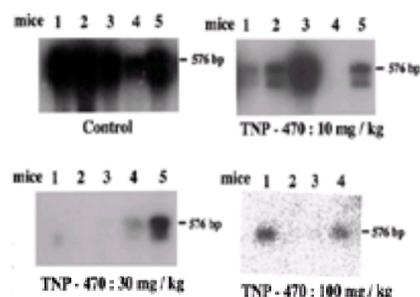
Ohta assessed the inhibitory action of a semisynthetic analogue of fumagillin, TNP-470/AGM-1470, on lymph node metastasis in a metastatic model system using athymic nude mice.[113] In this study, lymph node metastases were detected by PCR and Southern blotting for human b-globin-related sequence. After mice were injected subcutaneously with human fibrosarcoma HT-1080 cells, various amounts of the antiangiogenic agent (10, 30, and 100 mg/kg) were injected subcutaneously every other day beginning seven days after tumor inoculation. Five weeks after tumor inoculation, DNA was extracted from axillary and inguinal lymph nodes. Antitumor effects on the primary sites were seen only in the 100 mg/kg treatment group. Lymph node metastases were detected in all mice in the no treatment group, and the incidence of lymph node metastasis in treated mice was 2/4 mice (100 mg/kg), 2/5 mice (30 mg/kg), and 4/5 mice (10 mg/kg). Further, the inhibition ratios of lymph node metastasis were 82.3% in 10 mg/kg, 97.2% in 30 mg/kg, and 97.5% in 100 mg/kg, respectively, implying that antiangiogenic treatment can be useful in inhibiting nodal metastasis (Figure 11.4). In the literature, Mu has also observed an almost complete inhibition of metastasis to lymph nodes in mice with murine ovarian carcinoma cells by administering an angiogenesis-inhibitory fumagillin analog, FR118487.[114] A similar inhibitory action of TNP-470/AGM-1470 against lymph node metastasis in breast cancer cell lines and rat fibrosarcoma cell line has also been reported.[115,116] Other studies have reported variable results on lymph node metastasis with antiangiogenic agents.[117,118]


FIGURE 11.4. Effects of TNP-470 (10, 30, and 100 mg/kg) on lymph node metastasis of HT-1080 cells. TNP-470 was subcutaneously injected every other day from 1 week after tumor inoculation on mice. Mouse lymph nodes were then dissected at 5 weeks after tumor inoculation. Following extraction of DNA from dissected lymph nodes, specific detection of human b-globin gene in metastasized human tumor cells in nude mice (576 bp) was performed by the PCR technique and analized by Southern blotting. (From Ohta Y, Watanabe Y, Tabata T, et al. Inhibition of lymph node metastasis by an anti-angiogenic agent, TNP–470. *Br J Cancer* 1997;75:512, with permission.)

The fumagillin analogues have been shown to inhibit *distant metastasis* and tumor growth via inhibition of tumor angiogenesis.[119,123] TNP-470/AGM-1470 inhibits the growth of human umbilical vein endothelial (HUVE) cells in a biphasic manner, cytostatic and cytotoxic.[123] Exposure to TNP-470 arrests HUVE cells in G0/G1 phases, and this cytostatic inhibition may be the mechanism for the antiangiogenic activity.[124,125 and 126] In addition, other studies have suggested a variable effect of the agent on the host immune system, involving B-cell proliferation in the presence of T-cells.[127,128]

Safety of Antiangiogenic Drugs for Cancer Treatment in Practical Usage

In *in vivo* experimental model systems, the treatment by a combination of antiangiogenic drugs has been found to be more effective compared to that by only a single agent. In addition, a combination therapy using both antiangiogenic agents and cytotoxic anticancer drugs has also been shown to have a greater effect than that using only cytotoxic anticancer drugs.[129,130 and 131] These results offer implications about the practical usage of the antiangiogenic agents for cancer treatment to achieve optimal therapeutic effects.

Most angiogenesis inhibitors appear to have less toxicity and no drug resistance, making for an advantageous contrast to conventional cytotoxic anticancer drugs. These merits give credence to the permanent or long-term administration of these drugs to sustain the stabilization of the cancer or to continue to inhibit the development of metastasis. So far, although drug-induced side effects should be carefully investigated in a long period of dosage, no major side effects have been reported from results of phase I clinical studies using antiangiogenic agents for cancer treatment. Reversible neurologic side effects have been reported to be the dose-limiting toxicity[132] of fumagillin analogue TNP-470. Among 18 patients in the phase I trial[132] with recurring or metastatic squamous cell carcinoma of the cervix, one patient had a complete response and three patients had stable disease. A phase I clinical trial using orally administered pentosan polysulphate in patients with advanced cancers revealed no major side effects.[133]

Antiangiogenic Therapy and Micrometastasis

Via the biomolecular or immunohistochemical techniques for the detection of the specific biologic marker for cancer cells, such as cytokeratin fragments, it has been found that tumor cells are present in some distant organs such as bone marrow, peripheral blood circulation, and lymph nodes in a significant proportion of various cancer patients, including lung cancer, even if any distant metastasis cannot be detected by conventional clinical examinations.[134,135,136,137,138,139,140,141 and 142] Importantly, a recent study also showed worse postoperative outcomes of such patients and their trend toward recurrence after curative operations.[134,139,140,141 and 142] These findings suggest a necessity to take some steps for patients with micrometastasis before the manifestation of the occult disease. In patients with NSCLC, the percentage of the patients with micrometastasis of bone marrow has been reported to be 21.9% to 59.7% in total.[139,140 and 141] If stratified by pathologic stages, its rates were reported to be 29% in stage I or II and 46% in stage III.[140] For lymph node micrometastasis, 63.0% of NSCLC patients were revealed to have micrometastasis despite negative studies based on the conventional examination using hematoxylin and eosin stained slides.[138,142] Folkman previously proposed an interesting theory that is related to the clinical patterns of metastasis.[143] According to the theory, the duration of metastatic disease-free interval after operation depends on "the switch to the angiogenic phenotype as a net balance of positive and negative regulators of blood vessel growth." The antiangiogenic therapy may theoretically improve the survival of the patients with micrometastasis after curative resection of the primary site by keeping the micrometastatic cells in the dormant state. Exploitation of this strategy will require the proper selection of patients and greater assessment to determine the phenotype of cancer cells with potential metastatic ability as a function of short or long periods after operation.

RADIATION BIOLOGY

ROBERTO PACELLI
FRANCIS J. SULLIVAN
MURALI CHERAKURI
JAMES B. MITCHELL

The study of the effects of ionizing radiation on biologic tissue has contributed greatly to the management of cancer patients. Techniques first developed and described by radiation biologists have elucidated much important information in the understanding of basic cellular biology and the response of biologic tissues to therapeutic agents. Lung cancer is an enormous therapeutic challenge to the clinician. The following chapter is intended as a summary of key radiation biologic contributions to our understanding and management of this disease. By no means is it intended to be an exhaustive treatise on this important topic. Many fine textbooks and reviews fulfill this need. These texts have been liberally referenced as appropriate throughout the chapter. The reader requiring a more detailed review is encouraged to review these texts.

THE CHEMISTRY OF RADIATION BIOLOGY

Introduction

The transfer of energy from radiation to an absorbing medium can cause either excitation or ionization of the component molecules. If the energy of the incident radiation is sufficient to eject an electron from the outer orbital of an atom or molecule, then the incident radiation is defined as ionizing radiation. Ionizing radiation releases energy sufficient to exceed bond energies of many chemical bonds (5 eV) and thereby break them. Radiation that causes excitation without ionization has wavelengths in the UV/visible region.

Both electromagnetic radiation and particulate radiation such as alpha-particles, protons, and neutrons can cause ionization. X-rays that are produced extranuclearly and gamma-rays that are produced intranuclearly are two forms of electromagnetic radiation that possess sufficient energy to cause ionization of atoms or molecules. Electromagnetic radiation and particulate radiation, which have high energies, are slowed down in the absorbing medium by interacting with the electrons of the component molecules with characteristic dependence on linear energy transfer (LET). LET is defined as the energy lost from the charged particle per unit length of the absorbing medium it traverses and has units of KeV/µ m (kilo electron Volts/micrometer). Generally, particulate radiations have higher LET. However, for a given type of radiation, LET is inversely proportional to the energy of the radiation. LET values for typically used radiation are Cobalt 60 gamma-rays: 0.2; 150 MeV protons: 0.5; 250 kV x-rays: 2.0; 10 MeV protons: 4.7; and 2.5 MeV alpha-particles: 166.

Photons of ionizing radiation are absorbed by two processes depending on their energies and the chemical composition of the absorbing material. At high photon energy, characteristic of therapeutic radiation, the *Compton scattering process* is important. In this process, the x-ray photon interacts with and ejects an electron whose binding energy is negligible compared to the photon energy. On collision, part of the photon energy is given as kinetic energy to the ejected electron. The x-ray photon with the diminished energy continues, deflected from its original path, to cause subsequent ionization. After the initial collision, in place of an original x-ray photon, an ejected electron and a scattered photon of diminished energy appear. In the second process, the *photoelectric process,* the x-ray photon interacts with a strongly bound orbital electron and transfers all of its energy to it. Part of its energy is utilized to overcome the binding energy of the electron to release it from the orbital, and the remaining energy is converted to the kinetic energy of the ejected electron. In diagnostic radiology, where lower energy x-rays are used, the photoelectric process dominates. The absorption of the radiation through Compton scattering is independent of the atomic number of the component molecules of the absorbing material, whereas the energy absorption by the photoelectric process is proportional to the cube of the atomic number of the absorbing material. Hence, in diagnostic radiology (low-energy x-rays), the photoelectric process predominates, and a greater extent of the energy is absorbed by the bone that contains atoms with high atomic number (e.g., calcium). This reaction provides the sharp contrast between bone and soft tissue necessary for diagnostic evaluation. In the case of high-energy therapeutic radiation, the absorbed dose is the same in the bone, muscle, and soft tissue. However, in both cases, the energy of the photon is converted into the kinetic energy of the fast electron, leading to ionization events.

Direct and Indirect Effects

Particulate radiation such as alpha-particles, neutrons, and protons, which have high LET values, cause direct ionization by disturbing the atomic structure of

molecules of the absorbing material, thereby causing chemical and subsequent biologic changes. On the other hand, when x-rays are absorbed in biologic material, they can directly ionize a critical site (direct effect) or interact with other molecules to produce reactive radicals, which can subsequently damage critical biologic molecules (indirect effect). The chemical nature of the free radicals produced by indirect effects depends on the abundance of chemical species in the absorbing material.

Because 80% of biologic matter is composed of water, the effect of radiation on water molecules is important in understanding the indirect effects causing damage to critical molecules, which eventually lead to biologic damage. The two major effects of radiation on water molecules are excitation and ionization and are described below.

$$H_2O \rightarrow H_2O^{+\cdot} + e^- \ (\text{ionization}) \tag{1}$$
$$H_2O \rightarrow H_2O^\cdot \ (\text{excitation}) \tag{2}$$

The electron e^- becomes solvated by the surrounding water molecules and is called the solvated electron (eq. 3), which can also produce H-atoms (eq. 4).

$$e^- + (H_2O)_n \rightarrow e_{aq}^- \tag{3}$$
$$e_{aq}^- + H^+ \rightarrow H\cdot \tag{4}$$

The H_2O^+ produced by ionization (eq. 1) is strongly acidic and loses a proton to the surrounding water molecules to give the hydroxyl radical $\cdot OH$.

$$H_2O^{+\cdot} + H_2O \rightarrow \cdot OH + -OH \tag{5}$$

The water molecule in the excited state (H_2O^*) can also homolyze to produce H-atoms and $\cdot OH$ radicals.

$$H_2O^* \rightarrow H\cdot + \cdot OH \tag{6}$$
The H-atoms and OH radicals should be distinguished from the protons (H+) and the hydroxide ion (-OH). H^+ and ^-OH both have their outer orbital electrons completely paired up without any free electrons, unlike for H-atoms and $\cdot OH$ radicals.

All these free-radical species react with each other within the spur (regions of high local concentrations of ionization products) or diffuse into the bulk of the solution. Solvated electrons (e_{aq}^-) can react with protons to produce H-atoms. Recombination reactions of all the water radiolysis products in the spur are described below.

$$H\cdot + H\cdot \rightarrow H_2 \tag{7}$$
$$e_{aq}^- + e_{aq}^- \rightarrow H_2 + 2\ ^-OH \tag{8}$$
$$\cdot OH + \cdot OH \rightarrow H_2O_2 \tag{9}$$

The primary radicals can also be converted to water in the spurs

$$H\cdot + \cdot OH \rightarrow H_2O \tag{10}$$
$$e_{aq}^- + \cdot OH \rightarrow\ ^-OH \tag{11}$$

The initial ionizing events leading to primary lesions are completed in less than 10^{-10} sec. The transfer of energy from the primary species to cause lesions on biologically important molecules such as DNA and to cause genetic or metabolic alterations is completed in less than 10^{-6} sec (1 μ sec). All the above recombination reactions that occur in the spur after the initial ionizing event are practically diffusion controlled and hence are very efficient. However, considerable quantities of the radicals formed escape the spur and can be intercepted by critical biologic targets or radical scavengers. The scavenging efficiency of a given radical depends on the rate constant of reaction of the scavenger with the radical and the scavenger concentration. All the primary radical species produced by ionizing radiation are highly reactive and abstract H-atoms or add to various target molecules, causing chemical modification.

The radiochemical yields are expressed in terms of G-values. G-value is defined as the number of molecules damaged or formed per 100 eV of absorbed energy. The G-values for the various products of water radiolysis produced by 250 kV x-radiation are as follows: $e_{aq}^- = 2.63$; $\cdot OH = 2.72$; $\cdot H = 0.55$; $H_2 = 0.45$; $H_2O_2 = 0.68$. The concentration of individual species produced by 10 Gy radiation can be derived by multiplying the G-value with 1×10^{-1}. The concentration of $\cdot OH$ radicals produced by irradiating water to a radiation dose of 1 Gy is $2.72 \times 10^®$ M.

The formation of single-strand breaks in the DNA of cells is a linear function of the dose of irradiation of the DNA solutions. For double-stranded 10^6 dalton DNA, the efficiency of single-strand breaks is 0.2–0.3 breaks/100 Gy, whereas for isolated chromatin particles, the value is $0.5–1.5 \times 10^{-2}$.[1,2] Are these ages or rations example, 1.5×10^{-2} or 1.5×10^{-2}. The dependence of double-strand breaks in double-stranded DNA and isolated chromatin depends on the radiation dose in a complex manner. At a dose of 100 Gy, the yield of double-strand breaks in a 10^6 dalton DNA molecule is $3–9 \times 10^{-2}$. The same value for chromatin is $0.6–1.7 \times 10^{-4}$.[3] As discussed later, a total body dose of 4.5 Gy may be lethal to a human, despite efficient chemical DNA repair mechanisms, whereas much larger doses are required for detectable DNA damage in isolated DNA and chromatin *in vitro*.

Cellular Targets in Radiation Biology

DNA is considered to be a critical target for damage induced by ionizing radiation either by direct or indirect processes. [4] However, in therapeutic radiology utilizing high-energy x-rays, damage mediated by H·, e_{aq}^- and $\cdot OH$ radicals (indirect effects) are important. The rates of reactions of H·, e_{aq}^-, and $\cdot OH$ radicals with free nucleic acid bases and ribose have been determined, which give information about the relative efficiencies of attack by the primary species. Based on the rate constants, the site of attack of e_{aq}^- is exclusively the *base components* of various monomeric nucleic acid compounds. H-atom also attacks heterocyclic bases rather than the sugar moiety. Approximately 20% of the $\cdot OH$ radicals react with the sugar moiety. Because the product of reaction among the primary radical species with DNA is still a radical, it must further react before converting into a stable and chemically modified state. This process can occur via radical reactions in three mechanisms: (a) unimolecularly, (b) bimolecularly with other radicals, and (c) bimolecularly with another molecule. For the *in vivc* situation, the radical-molecule reaction (c), particularly with oxygen or a drug, is the relevant pathway.

DNA adducts of OH radicals are considered to be the most damaging. The damage has been found to be DNA-DNA cross-links, base damage, sugar damage leading to DNA single-strand breaks, as well as base release. Model studies of irradiated aqueous aerobic solutions of DNA have revealed (a) unaltered bases and their radiation-induced oxidation products that are released by the rupture of the N-glycosidic bond and (b) altered bases attached to DNA. The main site of OH radical attack on pyrimidines is the 5, 6 double bond leading to ring saturation. In the case of purines, OH radical attack has been suggested to mediate scission of the bond between C-8 and N-9 atoms in the imidazole ring. In the case of halogenated pyrimidines (e.g., 5-bromouracil), a uracilyl radical is formed by splitting the C-Br bond, presumably by both direct effects as well as by reaction with solvated electrons. This radical is highly reactive and can abstract an H-atom from neighboring sugar moiety. This process induces a DNA strand break as well as a uracil moiety into the DNA.

Although 20% of the OH radicals react with the sugar moiety, scission of the sugar-phosphate bond (leading to strand breaks) and release of unaltered bases can be induced by sugar radicals. It has also been proposed that radicals on base moiety can lead to strand breaks by radical transfer to sugar moiety.

Radiation Repair and Sensitization

In addition to enzymatic repair of DNA lesions caused by radiation, chemical repair can be accomplished by reducing agents, the most abundant being *reduced*

glutathione as shown in the simplified model. If TH is the critical radiobiologic target

$$TH + (x\text{-}rays) \longrightarrow T\cdot + H^+ \text{ (radical formation)}$$ [12]

The radical site on the target can be fixed by O_2 or chemical radiosensitizers, leading to subsequent base modification or strand breaks.
$$T\cdot + O_2 \longrightarrow TOO\cdot \text{ (damage fixation)}$$ [13]
$$T\cdot + S \longrightarrow TS$$ [14]
$$(S = \text{sensitizer, e.g., nitric oxide or nitroxides})$$

However, glutathione can compete with the damage fixation reaction by chemical restitution by donating an H-atom.

$$T\cdot + GSH \longrightarrow TH + GS\cdot$$ [15]
The GS· radical is an extremely weak oxidant and may not mediate further damage and forms disulfides

GS. + GS. ® GSSG
Lipid Peroxidation

Cellular membranes can also be damaged by radiation-induced lipid peroxidation. The initiating event is the radiation-induced formation of a radical on the membrane lipid. The radical formation can be caused by H-atom abstraction by ·OH radicals among other radiation-induced reactive intermediates.

$$RH + \cdot OH \longrightarrow R\cdot + H_2O$$ [16]

Reaction of the radical species (R·) with oxygen produces the *lipid peroxyl* radical

$$R\cdot + O_2 \longrightarrow ROO\cdot$$ [17]

The lipid peroxyl radicals are very unstable and form lipid hydroperoxides by reaction with other lipids by abstracting an H-atom.

$$ROO\cdot + RH \longrightarrow ROOH + R\cdot$$ [18]

Reaction (16) is the initiating reaction in the lipid peroxidation process. After this reaction, a chain reaction is set up in the system in the presence of dissolved oxygen (reactions 17 and 18). Thus a significant amount of damage can be induced through a single initiating reaction through the process of lipid peroxidation and may also contribute to radiation-induced cytotoxicity by inducing membrane damage. The lipid peroxidation *can be inhibited by the use of antioxidants* that scavenge the initiating radical species such as ·OH radicals or by terminating the chain reaction by acting as radical acceptors. Natural antioxidants such as vitamin E are purported to terminate chain reactions by terminating reactions 17 and 18.

Importance of Free Radicals in Biology and Medicine

Generation of free radicals in biologic systems in the normal course of metabolism and abnormal states has gained increasing attention in recent years to explain several aspects of human disease processes, such as inflammation, mutagenesis, carcinogenesis and cancer, atherosclerosis and postischemic reperfusion injury of cardiac tissue, Alzheimer's disease, and Parkinson's disease.[5] In addition, free-radical intermediates in the metabolism or activation of anticancer drugs are being recognized (Adriamycin, Mitomycin C, Streptonigrin, Neocarzinostatin, etc.). In most of the cases where radicals are generated naturally by biochemical processes in the normal metabolic pathways, or in the presence of xenobiotic agents capable of generating free radicals by enzymatic processes, the radical species are similar in chemical nature and reactivity to those generated by radiolysis. Of more direct relevance to lung cancer, some of the detrimental effects of cigarette smoke have been attributed to free-radical damage, (see also Chapter 3).

CELL DEATH AND VIABILITY

Biologic tissue must possess the ability to either repair or reproduce itself in order to maintain function and the health of the organism throughout natural life span. A tumor owes part of its malignant potential to the ability of cells to reproduce in an uncontrolled way and thus grow and invade local tissues and even metastasize throughout the body. One of the most important consequences of exposing biologic tissue (and its component cells) to ionizing radiation is the loss of the cell's ability to reproduce and thus the ultimate death of the cell. Cell death is the main cause of the early and late toxic effects of radiation on normal tissues and the reason that radiation may be used to sterilize human tumors.

Such cell death must be defined. It is to be distinguished from the intuitive concept we have of death: that is, complete, instantaneous, and irreversible loss of *all* function. Although super-high doses of radiation (in the region of several hundred gray [Gy]) certainly cause such a death to occur as surely as though the cell were physically crushed, lower radiation doses (several hundred centigray [cGy]) exert no such obvious effect. In fact, the vast majority of such irradiated cells appear morphologically normal and continue to perform complex biologic functions including protein and DNA synthesis. They may even be able to pass through a limited number of mitoses and give rise to some progeny. However, in terms of the continued health of that biologic tissue, a proportion of these cells lose their ability to sustain indefinite reproduction and die at the next or subsequent mitosis, or give rise to progeny incapable of reproduction. The cell's ability to sustain indefinite reproduction and to produce "clones" of itself is referred to as its *clonogenic* potential. For many tissues, the greater the proportion of clonogenic cells damaged by ionizing radiation, the greater the perturbation on the function of that tissue. In normal tissue as well as tumors, a variable proportion of cells are clonogenic; their number is decreased by ionizing radiation. Thus both normal tissues and tumors may be damaged by radiation. In studying these biologic effects, therefore, it is particularly important to be able to determine a cell's sensitivity to loss of reproductive or clonogenic potential. Several methods have been devised to assess cell viability *in vitro* and *in vivo.* These tools are potent not only in radiation biology but also in studying the effects of other cytotoxic agents such as chemotherapy. Before examining these tools individually, the concept of the *survival curve* is explored.

IDEALIZED RADIATION DOSE-RESPONSE CURVES AND MODELING

A single cell that has retained its clonogenic viability is capable of reproducing multiple clones of itself, which may be visualized as discrete colonies in tissue culture flasks or petri dishes. This type of assay, first described by Puck and Marcus in 1956[4] provides *in vitro* evidence of clonogenic viability. Samples of normal tissues as well as tumors can be disaggregated physically and with proteolytic enzymes such as trypsin into single-cell suspensions. These cells may be seeded into culture flasks under aseptic conditions at 37°C with medium appropriate to support growth for 1 to 2 weeks. Viable cells attach to the plate and grow to form colonies that may be stained and counted. The number of single cells seeded may be counted using an automated cell counter, and therefore the *plating efficiency (PE)* for each cell suspension may be calculated. Typically, only 50% to 90% of the cells form colonies (PE = 50% to 90%) even in the absence of any cytotoxic agents. Some loss inevitably occurs due to handling or failure to accurately determine the exact numbers of cells seeded or colonies counted. Plating efficiencies may therefore be compared, in the absence of any cytotoxic agent (controls) and in the presence of various doses of the cytotoxic agent to be tested. For example, a population of such clonogenic cells may be divided into several samples, and each sample maybe exposed to increasingly larger doses of radiation. The numbers of colonies formed in each plate is expressed as a percentage of the control plate (surviving fraction, SF), and survival curves generated. To increase accuracy, samples are plated in triplicate, and results are expressed as mean values with appropriate standard deviations.

Conventionally, the results are plotted on semiogarithmic coordinates, with the doses of the test agent expressed linearly on the ordinate (x-axis), and the logarithm of the SF on the abscissa (y-axis). A smooth curve is drawn between the experimental points, allowing for the uncertainty of each point. The shape and slope of the curve then become important characteristics defining the response of these cells and by inference, the biologic tissues from which they derive, to the cytotoxic agent

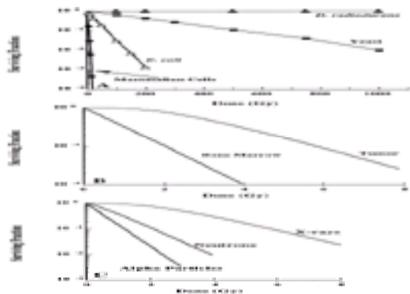
tested. Radiation survival curves may vary according to the biologic system studied (e.g., bacteria, yeast, mammalian cells), the inherent x-ray sensitivity of different mammalian cell types, and the type of radiation (e.g., x-rays, neutrons, a particles) as shown in Figure 12.1. Figure 12.1A illustrates the vast range of sensitivities among different biologic species. In particular, note how sensitive mammalian cells are when compared to other species. Figure 12.1B shows that in humans, a significant difference in radiation sensitivity may exist between normal tissue and malignant cells. This difference may be exploited for therapeutic gain, and at times may be a potential problem in terms of normal tissue toxicity. For example, bone marrow toxicity may be a significant problem when irradiation fields encompass a large quantity of bone marrow. An inability to repair the effects of densely ionizing radiation (a particles) when compared to sparsely ionizing radiation (x-rays) is illustrated in the differential response of mammalian cells to these types of radiation in Figure 12.1C.


FIGURE 12.1. Radiation dose response curves for **(A)** different species, **(B)** typical human bone marrow and tumor, and **(C)** different types of radiation of varying LET.

Various mathematical functions may be used to represent these survival curves, and biophysical models have been proposed to account for their shape and characteristics. Mathematical modeling can provide values of the SF over the range of radiation doses studied. Less accurately perhaps, these mathematical models suggest biophysical theories as to how the cell might be killed. For example, surviving fractions that fall exponentially with increasing dose suggest a "single-hit, single-target" theory, where each particle traversing a cell may produce a lethal event. The total number of lethal events therefore increases in direct proportion to the dose. Although these models can provide useful guidelines in predicting biologic responses, none is precise enough to be truly representative of the complex response of living tissues to radiation. It is worthwhile, however, to examine "reference" radiation survival curves utilizing X- or g-rays given over a short time under well-oxygenated conditions. *Exponential* ("straight") survival curves, as well as survival curves with *initial shoulders* ("curved") are described, and three of the many mathematical models used to predict responses in this dose range are outlined.

Exponential Survival Curves

The relationship between the surviving fraction (SF) and the radiation dose (D) is given by the mathematical equation

$$SF = e^{-\alpha D}$$

where a is a constant and e is the base of the natural logarithm

We now define a specific dose, the mean lethal dose (D_0), which reduces the SF to 37% of the initial cell number.

Thus when $D_0 = 1/a$

$$SF = e^{-D/D0}$$
$$\log SF = -\alpha(D)$$

This equation is now in the form of a general equation [y = m(x)], describing a line with a slope m. On semilogarithmic coordinates, this plots a "straight" line with slope

$$m = -\alpha \text{ or } -1/D_0$$

Thus D_0 becomes an important comparative number when evaluating radiation sensitivity of cells or tissues. D_0 is the dose (on an exponential curve, or portion of a curve) that reduces the surviving fraction of the cells to 37% of the number present prior to irradiation. Further, because D_0 is inversely related to a ($D_0 = 1/a$), the slope of the line (-a) provides a visual demonstration of the sensitivity of the tissues irradiated. The steeper the slope, the more sensitive the tissue, and the smaller the D_0. It now becomes possible to compare at a glance the radiation sensitivity of cell populations or tissues that fit an exponential modeling curve when irradiated. Furthermore, because no shoulder (or flat portion) is present on this curve, no dose exists, however small, which will not bring about some cell kill. This distinction from survival curves with initial flatter portions or "shoulder" as described below is important.

Survival Curves with an Initial Shoulder

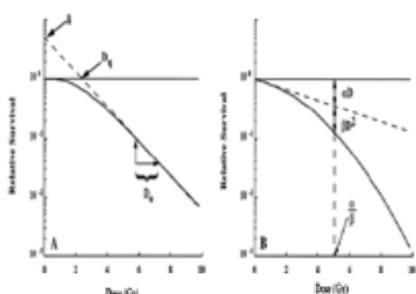
Mammalian cells irradiated with x- or g-rays generally show some curvature or "shoulder" in the initial (or low-dose) segment of the survival curve. Often, although not invariably, at higher radiation doses the curve becomes straight with a constant exponential slope downwards as shown in Figure 12.2A. Because the initial curved portion cannot be described by a line equation with a single slope, as is true of the exponential lines, the concept of a mean lethal dose (D^0) cannot be used to define radiation sensitivity at low doses in mammalian survival curves. This concept is particularly important because daily doses of radiation used in the clinic (150 to 200 cGy) often fall in this low-dose region of the curve. Two other parameters, the *extrapolation number* ($\bar{n}$) and the *quasi-threshold dose* (D_q) are used to characterize the width of the initial shoulder. These parameters become important when attempting to characterize the sensitivity of mammalian cells to the radiation dose fraction sizes used in cancer treatment. Extrapolation of the terminal "straight" portion of the mammalian curve back to the point at which it intersects the abscissa, defines $\bar{n}$. Thus when $\bar{n}$ is large (10.0 to 15.0), the survival curve has a broad shoulder, and when $\bar{n}$ is small (1.2 to 2.0) the shoulder is narrow. The dose point at which the same extrapolated line intersects the dose axis at SF = 1 defines the quasi-threshold dose (D_q). The quasi-threshold dose may be thought of as that dose below which no measurable effect of the radiation on cell killing occurs. Both parameters define the size of the initial shoulder and may define the cell's ability to repair sublethal radiation damage (see following). The three parameters D®, D_q and $\bar{n}$ are linked together by the equation:


FIGURE 12.2. Idealized radiation dose-response curves. **A:** exhibits survival parameters based on the multitarget, single-hit model. The terms extrapolation number ($\bar{n}$), quasi-threshold dose (D_q), and mean lethal dose (D_0) are defined in the text. **B:** shows a survival curve based on the linear-quadratic model. Note how the curve has

an initial slope and lacks a terminal "straight" or exponential portion. The a/b ratio, or the dose at which the linear and quadratic components of cell killing are equal in this example, is ~l5Gy.

$$\log_e \ (\bar{n}) \ = \ D_q / D_0$$

Doses at or around the D_q on the curved portion of the curve are interesting in that each incremental increase in dose produces a proportionally larger (as opposed to equivalent) effect on cell kill. This response suggests that cell death may be resulting from an accumulation of effects on critical targets, where individual "hits" are ineffectual or sublethal but become lethal when added together. Alternatively, the cell may be less efficient at repairing sublethal damage when it accumulates. Several mathematical models have been proposed to fit such "shouldered" survival curves. Three of the more popular models are further described.

Single-Hit Multitarget Model

In this model, as opposed to a single critical target, the cell is theorized to have multiple (n) targets, all of which must be inactivated before the cell is killed. The cell surviving fraction (SF) in this model is given by the equation:

$$SF \ = \ 1 \ - \ (1 \ - \ e^{-D/D0})^n$$

Thus when n = 1, as in the single-hit model, the equation solves to SF = $e^{-D/D0}$ as shown previously. Furthermore, as the dose (D) gets larger, then SF tends toward $n(e^{-D/D0})$, which is an exponential line with slope $-1/D_0$ intercepting the ordinate at the extrapolation point ($\bar{n}$). Note also that this curve starts out with zero initial slope, which infers zero mortality from small radiation doses. This property does not with most experimental results and is further discussed in following sections.

Quadratic Model

Cell death in this model is caused by the addition of two independent "hits" on a single critical target, from two separate radiation-induced particles. The mean number of lethal events is proportional to the square of the dose, so the SF is given by the equation:

$$SF \ = \ e^{-\beta D^2}$$

Here b is a constant relating to the probability of a dose of radiation producing a sublethal event. Note that this equation also plots a line with zero initial slope. Thus the "single-hit multitarget" and "quadratic" models are probably not accurate when dealing with the response of mammalian cells to small doses of radiation. One further model is described to address this important point.

Linear-Quadratic Model

This model assumes that cell killing was two components. One component is proportional to the given dose (D), and the second is proportional to the square of the given dose (D^2). The equation that plots this survival curve is

$$SF \ = \ -e^{\alpha D - \beta D^2}$$

Here a and b are constants of proportionality. The components of cell kill proportional to the dose and square of the dose are equal when

$$\alpha D \ = \ \beta D^2$$
$$D \ = \ \alpha / \beta$$

Expressing this relationship in words, the linear and quadratic components of cell killing are equal at a dose equal to the a/b ratio. Such a curve is shown in Figure 12.2B. It has an initial slope (a), so it is perhaps a better predictor of the response of mammalian cells to low doses of radiation. However, such a curve continuously curves downward with increasing dose, which does not correlate well with the exponential ("straight") response to larger radiation doses in actual experiments.

Thus no single mathematical model accurately fits experimentally observed cell survival across a broad range of radiation doses. The linear-quadratic model is a useful representation of the data, however, because it has only two adjustable parameters and is accurate in the range of doses used in daily standard fractionated radiation therapy.[6] This model is often used when predicting the biologic effect of altering radiation-dose fractionation schemes and comparing them to standard (180–200 cGy per day) treatment regimens. The coefficients a and b relate to the two modes of cell killing, and the a/b ratio thus gives an indication about the relative importance of each. When a is large relative to b, the a/b ratio is high and the survival curve slopes steeply and near exponentially. Early-reacting normal tissues and tumors tend to have high a/b ratios. When b is large relative to a, the curve starts out with a shallow slope and a broad shoulder. This response is typical of late-reacting normal tissues. a/b ratio is a dose expressed in Gy; a is expressed in Gy^{-1} and b in Gy^{-2}.

Predictive Assays

In vitro assays of radiosensivity are important tools in radiobiology with the potential to guide clinical practice. If *in vitro* assays of radiosensitivity truly reflect *in vivo* radiosensitivity, then such assays may prove to be of considerable help in predicting those patients who are potentially curable with radiation, and those perhaps requiring more aggressive multimodality treatment. Several candidate factors, including hypoxia, clonogenic cell number, and intrinsic tumor cell radiosensitivity, have all been tested as potential predictive assays in this context. One assay, the fraction of cells surviving a dose of 2 Gy (SF 2Gy) has recently received much attention. The observation was originally made by Fertil and Malaise[7] and Deacon et al.[8] that the radiosensitivity of cell lines derived from human tumors was characteristic of tumor type, and that tumors more difficult to cure in the clinic produced cell lines that are more resistant to low doses of radiation *in vitro*. The technique involves disaggregating tumor cells enzymatically, attaching cells as single-cell suspensions to tissue culture plates, irradiating the cells typically over dose ranges of 0.5 to 6.0 Gy, incubating the irradiated cells in culture medium for up to 2 weeks, then assaying for surviving fraction. The data derived are typically fitted to the linear-quadratic modeling described previously and survival curves are generated. From these curves, the SF 2 Gy may be derived. Several preliminary reports are now available comparing clinical local control with SF 2Gy, and in at least some instances, a correlation is emerging. This assay has problems, however,[10] and as yet no consensus has been reached as to whether it will prove clinically useful enough to be routinely used.

REPAIR OF RADIATION DAMAGE

If cells could successfully repair all radiation damage, then ionizing radiation would produce no lasting biologic effect. Fortunately for the radiation oncologist, absolutely radioresistant cells do not exist. Biologic tissues clearly possess a differential ability to accumulate and repair radiation damage. Irradiated cells can be shown to behave differently *in vivo* versus *in vitro*. Malignant cells often fail to adequately repair accumulated radiation damage that is effectively repaired by normal tissue. An understanding of radiation damage and repair is helpful in exploiting the differential response of normal tissues and tumor cells, and thus the effective use of radiation in the treatment of cancer. Two operationally defined terms, *sublethal damage repair* (SLDR) and *potentially lethal damage repair* (PLDR) have been coined to account for the observation that cells can survive radiation under certain conditions. Although these terms were originally defined in an abstract way, without reference to the molecular or subcellular entities experiencing the actual radiation damage, a wealth of experimental data now exists to support the concepts, and perhaps to allow for the design of therapeutic strategies in the treatment of cancer.[11]

Potentially Lethal Damage Repair

It was found that by altering a cell's environment following radiation, a proportion of the radiation injury could be obviated. This phenomenon was observed both in

normal tissues and tumors, and it suggested that a component of radiation damage is repairable under certain environmental conditions and irreparable in others. *In vitro,* allowing cells to remain in a density-inhibited state (plateau phase) for several hours postirradiation, or incubating them in a balanced salt solution instead of culture medium, leads to improved survival indicative of PLDR. Similar conditions may be mimicked *in vivo.* For example, mouse thyroid or mammary cells may be irradiated *in situ,* then transplanted into a fat pad for survival assay. If the transplant is delayed several hours, then enhanced survival is seen, which is thought to be caused by PLDR.[12] The hypothesis underlying such observations is that a *proportion of radiation damage may be repaired if cells are somehow prevented from attempting the complex process of mitosis and cell division for a period following the radiation.* This theory may then be of relevance to both normal tissues and tumors.

Normal tissues are often in a resting (nondividing) state akin to plateau-phase cell cultures *in vitro.* Tumors under certain conditions (e.g., nutritional impairment, hypoxia, etc.) may be unable to cycle a proportion of their cells through mitosis and thus create PLDR efficiently. The exact relevance of PLDR in the clinic is uncertain. No good evidence supports a differential in PLDR between normal and malignant tissue, so it is difficult to define a method to exploit this phenomenon in the clinic.[12] It is noteworthy that the *quality* of the radiation is important in PLDR. It has been shown that PLDR does not occur following densely ionizing (high-LET) irradiation, such as neutrons, but can be shown in the same cells irradiated with sparsely ionizing (low-LET) irradiation, such as ^{50}Co g-rays.[13] The relevance of this finding in terms of the mechanism of such repair is unknown.

Sublethal Damage Repair

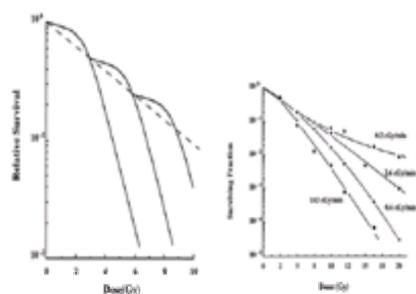
As discussed previously, the survival curve for mammalian cells irradiated *in vitro* has a characteristic shape (Figure 12.2A). The initial portion of the curve is shallower, sweeping downward in a continuously curving "shoulder" of varying magnitude and extent. The terminal portion has a steeper slope and falls "exponentially." The general interpretation of the initial shoulder region is that a proportion of the radiation damage is being repaired and therefore not producing lethality. After sufficient radiation damage has been accumulated, each additional dose causes exponential cell kill. Although these lower radiation doses are not producing exponential cell kill, they are causing "sublethal" damage, which the cell appears capable of repairing under appropriate conditions. The association between the initial shoulder on the survival curve and SLDR has been well established. [14] Bacterial cells genetically deficient in repair enzymes, such as (rec-) *E. coli*, have exponentially falling survival curves with no shoulder (Figure 12.1A). Herein lies one of the most important observations in radiobiology: Mammalian cells exposed to smaller doses of radiation (i.e., in the initial "shoulder" region) can repair proportion of the radiation damage ("sublethal damage") given sufficient time and nutrients. *A* proportion of the cells irradiated, however, will sustain lethal damage and will not survive. Adding a second small dose of radiation reproduces exactly the same initial curve, and kill the same proportion of the remaining cells (Figure 12.3). The survival curve for multifractionated irradiation can be generated by joining these curves as shown. Theoretically, this curve approaches an exponential decline, with a uniform albeit *shallower* slope than seen with acute single-dose exposures. The broader the shoulder, the greater the capacity for repair. In general, the survival curves of late-reacting normal tissues have such "shoulders." Thus multifractionated radiation schedules, using small doses per fraction, tend to spare late reactions in normal tissues.


FIGURE 12.3. Theoretical survival curves illustrating the effect of repeated administration of 3 Gy doses of radiation to a population of mammalian cells. Because of the cells' capacity to repair sublethal damage caused by these doses, a proportion of the cells survive each time, giving rise to the shoulder. The net effect of such fractionation yields an exponentially falling curve (*dotted line*) much shallower than when single doses are used (*solid lines*). Thus the "sparing" effect of radiation dose fractionation.

Evidence for this important phenomenon was first provided in the classic studies of Elkind and Sutton. [15] In a series of experiments comparing the lethality of a large single dose of radiation with the same total dose, split into two smaller fractions and separated by a time interval (fractionated irradiation), it was shown that the split dose produced *less* lethality.[16] The interval between the two fractions allows SLDR. The half-time for this repair has been estimated at 0.5 to 1.5 hours depending on the cells studied.[14] The *fading-time* has been defined as the time taken for this repair to decay to an undetectable level (e.g., less than 5%). Thus one can calculate that in acute-reacting cells, including most tumors, where SLDR is less developed (e.g., less than 20%), the fading-time would be three to four hours for acute effects. In late-reacting normal tissues, where sublethal damage repair may be significant (50%), the fading-time may be on the order of 5 to 6 hours for late effects. As a direct consequence of these observations, clinical studies using altered radiation-dose fractionation (e.g., hyperfractionation) have usually incorporated a time interval of at least 6 hours between fractions to avoid severe late normal tissue reactions. [17] Such studies involving patients with head and neck cancers,[18] as well as small cell lung cancer (SCLC)[19] have generally shown equivalent to improved local control rates with acceptable long-term toxicities. Just as has been observed in the case of PLDR, sublethal damage is significant for low-LET radiation, including x-rays, but is insignificant following neutron-beam irradiation. [12]

Dose-Rate Effect

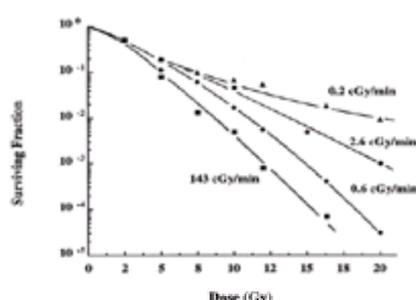
The sparing effect of fractionating a radiation dose over time has been explained by the SLDR in those cells whose survival curve is characterized by an initial "shoulder" (e.g., late-reacting normal mammalian tissues). As shown previously, it is a feature of low-LET irradiation (i.e., X- and g-rays) and is not seen for high-LET irradiation (i.e., neutrons, a-particles, etc.). Stated a different way, a given single dose of radiation tends to spare normal tissues if it is protracted over time. Dose fractionation is one example of protracting the treatment time to spare such tissue. A second example is provided *by slowing the rate* at which a single continuous dose is given. This process is referred to as the *dose-rate effect.* This effect has been demonstrated *in vitro* as well as *in vivc* and is an important radiobiologic tenet underlying effective administration of radiation in the clinic. Reducing the dose-rate at which certain cell lines are irradiated *in vitro* shows a progressive sparing effect, most marked between 1 to 100 cGy/min as shown in Figure 12.4.[20,21] and [22] Tremendous variability exists among differing cell lines irradiated at varying dose-rates *in vitro,* depending on their ability to accumulate and create SLDR. [12] Furthermore, little if any additional effect is seen at rates above 100 cGy/min. However, over a range of dose rates between 0.3 to 1.6 cGy/min, a paradoxical "inverse" dose-rate effect is observed (Figure 12.4); the survival curve becomes steeper once again as cell-cycle effects increase the radiation sensitivity and outweigh the effect of SLDR. [21] Of course, similar to fractionating radiation doses, little benefit would be gained in altering dose-rates in the clinic, if the lower dose-rates also spared tumor cells. Fortunately, data suggest that tumor cells do not show the same response to altered dose-rates as to normal tissue.[12] The EMT6 mammary sarcoma and the KHT sarcoma in the mouse show much less sparing effect to reduced dose-rates than normal tissues.[23,24] Thus we may begin to exploit the differential response of normal and malignant cells to varying radiation dose-rate.


FIGURE 12.4. Radiation dose-response curves for human S3 HeLa cells exposed to varying dose-rates of continuous radiation. Note that as the dose-rate is lowered,

a greater proportion of the cells survive. Note also the paradoxic increased killing at 0.6 cGy/min, which is caused by cell cycle blockade. At this dose-rate, the cells are selectively blocked at G2/M, a more radiosensitive phase of the cell cycle. (From Mitchell JB, Bedford JS, Bailey SM. Dose-rate effects in mammalian cells in culture III. Comparison of cell killing and cell proliferation during continuous irradiation for six different cell lines. *Radiat Res* 1979;79:537, with permission.)

The dose-rate effect has proven to be important in the response of both normal lung and lung tumors to radiation. Clinical and experimental studies have clearly shown a marked sparing effect in the lung as a result of fractionating radiation doses. [25,26] and [27] *In vivc* assays in the mouse model showed a sparing effect of low dose-rate irradiation in terms of the development of radiation pneumonitis. [28] Histologic comparison of radiation reactions in the lungs of mini-pigs exposed to 750 cGy total body irradiation revealed a quantitative effect on the lungs with higher dose-rates (25 cGy/min) when compared to lower dose-rates (5 cGy/min). [29] Radiation pneumonitis in humans has been shown to correlate not only with absolute dose within the lung [30] but also with dose rate. [31] Experience with wide-field irradiation, including hemibody and total body irradiation, estimates that a dose of 930 cGy at 50 cGy/min is equivalent to 1,100 cGy at 10 cGy/min. Protocols using total-body irradiation for marrow transplant have sought to avoid lung toxicity by limiting the dose-rate to the lungs to the region of 10 cGy/min. [32]

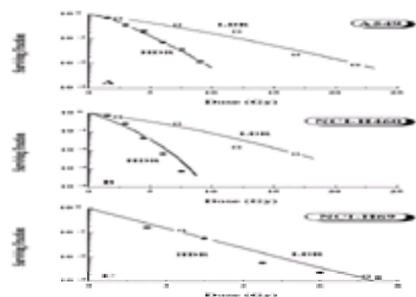
Limited data exist on radiation dose-rate effects in lung carcinoma cells in culture. When clonogenic survival alone is used as an end point, sparing effect of dose-rate reduction may be expressed as a dose-reduction factor (DRF). [33,34] This factor is defined as the ratio of doses required to reduce clonogenic survival (for example to 1%), at low and high dose-rates. A series of four lung cancer lines so studied showed DRFs ranging from 1.19 to 1.57. No clear correlation between the overall radiation sensitivity of these lines and the DRF could be seen. [34] However, the more radiosensitive SCLC lines showed significantly more residual DNA damage (double-strand breaks), suggesting a failure of these cells to produce SLDR even at low dose-rates, whereas the more resistant non–small cell lung cancer (NSCLC) lines showed significantly less residual DNA damage, in keeping with efficient repair at low dose-rates. Lung carcinoma lines in culture exhibit a marked heterogeneity in response to varying dose rates, as shown in Figure 12.5.[35] Although NSCLC lines (NCI-H460 and A549) show increased survival at low dose-rates, the SCLC line (NCI-H69) shows no such variation in response.


FIGURE 12.5. Radiation dose-response curves for three human tumor cell lines as a function of dose-rate (HDR = 100 cGy/min, LDR = 1 cGy/min). **A:** A549, adenocarcinoma. **B:** NCI-H460, adenocarcinoma. **C:** NCI-H69, small cell. The non–small cell lines have shouldered survival curves and exhibit a dose-rate sparing effect, whereas small cell carcinoma has an exponential curve, and survival is unaffected by altering dose-rate. (From Sullivan FJ, Carmichel J, Glatstein E et al. Radiation biology of lung cancer. *J Cell Biochem* 1996;24:152, with permission.)

These findings suggest a possible strategy for improving the therapeutic outcome in SCLC. A reduced dose-rate (1 to 5 cGy/min) in SCLC would effect cell killing equivalent to standard/high dose-rate irradiation (100 to 200 cGy/min), with less toxicity to normal tissue (e.g., lung and esophagus). This strategy has been recently brought to clinical trial at the National Cancer Institute (NCI), and early tumor responses are encouraging, with a suggestion of less acute toxicity. Should tumor response rates be equivalent to standard radiation responses, with less acute toxicity, this might allow for the possibility of escalating the total radiation dose and/or treating greater tumor volumes.

RESPONSE OF NORMAL TISSUES TO RADIATION

The differential response of normal tissue and tumors underlies the successful use of ionizing radiation in treating cancer patients. In order to predict the likelihood of sterilizing a tumor and protecting the surrounding normal tissues, we must have some method of assaying radiation effects *in vivc* as well as *in vitro.* Here the biologic end points of relevance are altered structure or loss of function of a tissue or organ. When considering the radiotolerance of tissue, the critical targets may be thought of as functional subunits, and the tolerance of the tissue is related to the number as well as the radiosensitivity of such units. Biologic tissue consists of a heterogenous population of living cells, interacting in a complex fashion. Clinical effects of radiation are not predictable solely on the basis of cell kill but on a host of interrelated variables that may be difficult to accurately quantitate. It is recognized, however, that death of critical cells or functional subunits may contribute significantly to loss of function of the tissue or organ. Thus clonogenic assays that can quantitate cell death *in vivc* may predict functional impairment within tissue. This process is particularly dramatic in tissues consisting of cells that are proliferating rapidly as part of their normal function (e.g., bone marrow, gastrointestinal mucosa, testis, skin, hair follicles). Clonogenic assays can be used to construct dose-response curves reflecting the radiosensitivity of such tissues. The dose required to see a measurable effect on the function of such a tissue is termed the *threshold dose* and may be quite low, depending on the intrinsic radiosensitivity of the individual cells.

A second strategy for estimating radiation effects in tissues relies on loss of observed function (including death of the animal) with increasing radiation dose. Such assays have been described for normal lung, skin, and spinal cord tissues among others. The following sections discuss the tolerance of various organs and biologic systems to irradiation. The concept of radiotolerance needs to be further defined. Individual variability makes medicine an inexact "science." Nothing better exemplifies this concept than the tolerance of human tissue to ionizing radiation. Extrapolating *in vitro* and animal data to humans is a risky business. Nonetheless, this process and the collective (and often empiric) observations of clinicians in the practice of radiotherapy, guide us in treating patients. Ideally, one would like to know the tolerance of the whole body and each organ system (e.g., respiratory, gastrointestinal, neurologic, etc.) to both single doses as well as fractionated irradiation. In practice, these data are not completely available. For some situations, the only available information is the dose of irradiation that is known to kill 50% of animals tested. Such lethal dose (LD$_{50}$) data are available from a variety of sources for different animal models as well as organ systems. [36] The most widely utilized measure of radiotolerance in the human is the tolerance dose (TD) system described by Rubin et al. [37] This system assesses a percentage risk of a complication occurring within a given time interval after treatment. The TD5/5 represents a 5% risk of severe complication within 5 years. This percentage is usually taken as the minimal tolerance dose. The TD50/5 represents a 50% chance of severe reaction within 5 years. These doses are limited in that they make no allowance for patient age, nutritional status, or the presence of other important factors such as prior surgery, chemotherapy, or irradiation. Recent attempts have been made to review accepted normal tissue tolerance levels with respect to the influence of volumes irradiated. [38] It should be borne in mind that these doses are only guidelines and may be overridden in certain clinical situations. For example, it may be perfectly reasonable to expose a patient to a higher than usually considered acceptable risk of radiation injury if the clinical situation warrants intervention, if no reasonable alternative is available and if the patient is fully informed and accepts such risk. In general, however, clinicians prefer not to exceed quoted doses, especially in an environment dominated by fear of litigation. These data are provided, together with experimental models where available, and clinical information for each body system.

Cell Death in Tissue: Necrosis and Apoptosis

The classic observation by Kerr et al. in the early 1970s of a distinct mode of cell death, distinguishable histologically and in other ways from necrosis, paved the way for a fascinating series of observations concerning a genetically programmed cell death. [39] *Apoptosis,* or *programmed cell death* (PCD) has since been reported as a consequence of a bewildering variety of stimuli and may be important in several disease states. [40,41] *Cellular necrosis* is a consequence of environmental insults such as hypoxia, toxins, complement attack, hyperthermia, viral lysis, and so on, and follows a relatively well-defined morphologic and biochemical path (Table 12.1). Apoptosis, on the other hand, shows morphologic features quite distinct from necrosis. The original description by Kerr was "shrinking necrosis" (Table 12.2).

- Early plasma membrane changes leading to a loss of K⁺ influx of Ca⁺⁺ and Na⁺
- Acidosis
- Osmotic shock caused by uptake of water
- Blebbing of the cell surface
- Clumping of chromatin and nuclear pyknosis

These changes are accompanied by:
-Activation of mitochondrial phospholipase
-A loss of oxidative phosphorylation
-A drop in ATP production and a loss of synthetic and homeostatic capability
-Random DNA degradation by lysosomal enzymes

TABLE 12.1. FEATURES OF CELLULAR NECROSIS

- Cell-to-cell contact breaks down early
- Loss of cellular features such as microvilli and desmosomes
- Distinct margination and blebbing of chromatin
- Chromatolysis involving the activation of endonuclease, the chromatin is cleaved into nonfunctional fragments of 180 to 190 base pair DNA (laddering)
- The cell ruptures into several membrane-bound spheres (apoptotic bodies) and is phagocytosed by neighboring cells or macrophages

TABLE 12.2. FEATURES OF APOPTOSIS

Although the final pathway of both processes has similarities, the triggering events are very distinct. PCD is a highly active process requiring energy (ATP) and signaling factors including calcium[42] essential for the activation of specific endonucleases.[43] A burst of cellular protein and RNA synthetic activity always precedes PCD, and inhibition of endonuclease activity, such as by protein inhibitors (actinomycin-D, cycloheximide), blocks apoptosis. This process is not true of necrosis, which is accompanied by a loss of protein synthesis and a decline in oxidative phosphorylation that is not affected by actinomycin D.

Apoptosis has been shown following irradiation in several systems.[44,45,46 and 47] The intriguing phenomenon of interphase death in lymphocytes following irradiation suggested a role for apoptosis.[48,49 and 50] The rapidity of onset of this mode of death (6 to 7 hours)[44] offers perhaps a more appealing explanation for the well-known ability of radiation to induce measurable and rapid shrinkage in certain tumors,[51] and early acute reactions in normal tissues, than mitotic-linked death. Attempts are currently underway to link apoptosis in the causation of acute radiation effects in the clinic.

"Acute" and "Late" Radiation Reactions

The effects of ionizing radiation on biologic tissues can be usefully considered in two categories. Those occurring during or immediately following the course of radiation are considered "acute" or "early," whereas those occurring months to years after completing therapy are termed "chronic" or "late." The exact chronology of these events is not strictly defined, and some authors have preferred the terms "acute," "subacute," "chronic," and "late," depending on the time of observation.[52,53] We will define "acute/subacute" effects as those occurring during and up to 6 months, and "late" effects as those occurring from 6 months to several years from treatment. These terms are important not only in understanding the pathophysiology of radiation effects, but also in counseling patients receiving radiation therapy in the clinic.

Acute Effects

As noted previously, reproductive cell death is thought to be the most important consequence of radiating biologic tissue. The *threshold dose* is that which kills a sufficiently large proportion of the cells so that a measurable effect may be observed in the tissue. Actively cycling cells are particularly sensitive to the effects of ionizing radiation and undergo mitotic-linked death when attempting reproduction. It follows, therefore, that tissues composed predominantly of actively cycling cells (e.g., bone marrow, gastrointestinal mucosa, skin, and rapidly growing tumors) are most susceptible to cell kill, and furthermore manifest a measurable radiation effect relatively quickly after doses in excess of the threshold dose.[54] Such tissues in which active cell division is required to maintain the function of the organ are often referred to as *acutes reacting tissues.* It is further true that loss of a cell destined to undergo differentiation along multiple lines, such as a pluripotent stem cell in the bone marrow, also results in loss of all potential progeny, and therefore exerts a greater biologic effect than loss of a relatively well-differentiated cell, such as a late normoblast or mature myelocyte.[14] The radiation sensitivity of each tissue thus depends to a great extent on the number and cell cycle kinetics of these target or stem cells.

Nonetheless, measurable effects of radiation can sometimes be encountered in a matter of hours, too fast to be easily explained by cells attempting to undergo mitosis. The link between apoptosis (PCD) and radiation has been recently established as described previously. The rapidity of apoptotic cell death (hours) is a more appealing explanation for rapid onset "acute" radiation reactions and may well be an important component of such events. This correlation has not as yet been definitively shown. In addition to actual cell death, it should further be borne in mind that the body's reaction to acute injury of any kind, including inflammatory response, hyperemia, edema, release of chemotactic, and other factors, also underlies the acute radiation reaction.[55] Such effects are important in the body's homeostasis and repair of radiation injury to normal tissues. In practice, virtually all patients undergoing therapeutic irradiation experience acute symptoms caused by radiation injury to normal tissues in the irradiated field. These symptoms range in severity from insignificant to severe and at times life-threatening. Acute reactions are usually rapidly repaired and completely reversible. The vast majority resolve within 4 to 6 weeks of completing the course of therapy. These effects are further elaborated by individual body system in following sections.

Late Effects

In contradistinction to acute radiation effects, "late" effects differ in time course and natural history from acute reactions. The onset is usually several months following completion of therapy, and they are generally irreversible. The degree to which a late side effect of radiation is clinically important is highly variable. Although patients treated with modern radiation technique almost invariably experience self-limiting acute effects that are clinically apparent, the occurrence of clinically significant late effects is far less common. The occurrence of an acute reaction is not necessarily predictive of subsequent late reactions. The pathologic hallmarks are *fibrosis, atrophy, vascular damage,* and less frequently *necrosis.* Although the exact cause of late effects is debatable, it seems likely that a combination of *direct* cytotoxicity on tissue stem cells, allied to *indirect effects* from damage to microenvironmental supporting tissues (e.g., vascular and lymphatic systems) is important.

Tissues particularly at risk for late reactions are generally those with slow cellular renewal and long cell cycle times. Reduction in the number of stem cells[56] and loss of reproductive ability in those remaining have both been implicated in the genesis of late reactions. The slower proliferation rate and longer cell cycle times (months to years) account for the delayed onset and gradual manifestation of these effects. For example, it has been shown that the turnover time of normal tissue endothelium in the mouse is estimated to be 20 to 2,000 times longer (47 to 23,000 days) than tumor cells derived from the same animal (2.4 to 13 days).[57] In addition, loss of vascular endothelial and other supporting stromal cells along with growth and regulatory factors may also play a role.[58] Although the latent interval between radiation and late effects shortens with increasing total radiation dose,[59] the severity of these effects worsens with increasing radiation dose-fraction size. It has been suggested that stem cells in late-reacting tissues may have a better capacity to repair damage from smaller fraction of radiation, possibly related to the

prolonged cell cycle times, than early-reacting stem cells.[58]

The following sections detail the response of those normal tissues most often irradiated in the radiation management of lung cancer. The skin, gastrointestinal tract, and bone marrow are early-reacting tissues, whereas the spinal cord and lung are late-reacting.

Skin

Skin is a complex structure comprising an epidermis and dermis. The epidermis contains keratinocytes, dendritic cells, melanocytes, Langerhans cells, and hair follicles. It is regenerated from proliferative units in the basal layer. The epidermis is a rapidly proliferating (acute-reacting) body tissue. The dermis is a dense connective tissue containing fibroblasts, sebaceous glands, and lymphovascular channels, which play a major role in the radiation response. It is considered a slowly proliferating (late-reacting) tissue. Thus the full spectrum of normal tissue reactions, both acute and chronic, are easily seen in the skin and are a common feature of clinical radiotherapy.

Clinical Features. The acute and chronic skin reactions are listed in Table 12.3. The hallmark of acute damage is *erythema,* which appears in three phases.[58] Erythema is the result of keratinocyte damage in the epidermis and dilatation of superficial blood vessels in the dermis. The phases are early (within 24 hours of a single dose of 4.5 to 5.0 Gy) lasting 2 to 3 days; main erythematous reaction (appearing within 8 days of a single 8 to 10 Gy dose) peaking within 8 days; and a third phase, which sometimes develops 6 to 7 weeks following a course of irradiation and lasts 2 to 3 weeks. Marked erythema is seen to conform exactly to the irradiated portal. Intermediate doses of irradiation (10 to 12 Gy single dose) produce *dry desquamation* within 1 month. High (15 Gy single-dose) or tumoricidal fractionated doses kill all basal cells and expose the underlying dermis. Serous weeping from the exposed dermis is termed *moist desquamation.* Very high doses of irradiation result in epidermal necrosis with separation of the epidermis from the dermis and bulla formation. Melanocytes are located in the basal layer of the epidermis at a 1:10 ratio to the keratinocytes and produce melanin, which pigments human skin and hair.[60] Stimulation of the melanocytes after irradiation may produce increased melanin, which may be deposited in the dermis and appear as increased *pigmentation.* Higher doses may kill melanocytes and cause depigmentation. Altered pigmentation is a feature of both acute and chronic radiation injury.[61] Actively growing hair follicles are particularly radiosensitive. It has been estimated that as many as 86% of scalp follicles are in the anagen phase at any point in time,[61] thus hair loss and pigment change is a feature of radiation skin injury. The extent of loss and subsequent recovery is a function of radiation dose. Permanent *alopecia* may result from high doses. Added insult from chemotherapy may also affect recovery. Late radiation changes produce atrophy, hyperkeratosis, fibrosis, telangiectasia, and marked reduction in resistance to subsequent injury (infection, surgery, chemotherapy, etc.). Reduction in dermal fibroblasts, and cross-linking of collagen result in loss of elasticity.[58] Altered sweat gland function is particularly important in patients receiving total electron skin therapy for diseases such as mycosis fungoides. Increased risk of *carcinogenesis* is most marked in children and patients receiving low doses of radiation (2 to 10 Gy). Low doses are thought more likely to induce mutations, whereas high doses sterilize irradiated skin. The Radiation Therapy Oncology Group (RTOG) and European Organization for Research and Treatment of Cancer (EORTC) have defined clinical grading criteria for skin injury due to radiation.[62] These grading systems are useful for ensuring uniformity in reporting radiation toxicities.

Acute	Chronic
• Erythema	• Atrophy
-early phase	• Thickening/fibrosis
-main phase	• Telangiectasia
-postirradiation phase	• Sebaceous gland dysfunction
• Dry desquamation	• Impaired sweating and
• Moist desquamation	temperature control
• Bulla formation	• Altered pigmentation
• Altered pigmentation	• Altered hair growth and color
• Altered hair growth	• Necrosis
and color	• Carcinogenesis
• Impaired wound healing	• Impaired wound healing

TABLE 12.3. CLINICAL FEATURES OF RADIATION SKIN INJURY

Radiobiologic Features. Since the earliest observation of radiation-induced skin changes by Freund in 1897, an immense amount of radiation biology has been learned by the study of various skin model systems. Both clonogenic and functional assays have been described, and much important time dose fractionation (TDF) information has been applied to radiation treatment strategies. The following section outlines the model systems used and lists the basic radiobiologic information derived.

Clonogenic Assays. Classic studies by Withers provided *in vivo* clonogenic data for radiation reactions in mouse skin.[63,64 and 65] Data deriving from these experiments are shown in Table 12.4.

• Single dose	D_0 = 1.35 Gy (mouse skin) Range tested 8 to 25 Gy (Withers)
• Quasi-threshold dose	D_q = 3.5 Gy (mouse skin)
• Rate of loss of basal (stem) cells = 2.6% +/− 0.2% per day (pig skin) following single and	
fractionated doses (Bernstein)	
• Repopulation: Usually at 1 week postirradiation. Following modest dose, from the hair	
follicles and high dose from the edge of the irradiated area.	
• α/β ratios (X-rays): α/β (Gy) (Tubiana)	

Acute desquamation	9.4 to 21
Epilation (anagen)	7.7
Epilation (telogen)	5.5
Late effects	3.0

TABLE 12.4. SKIN: BASIC RADIOBIOLOGIC PARAMETERS

Functional Assays. Classic observations by Strandqvist[66] on 280 patients undergoing skin irradiation at various TDF schedules attempted to define isoeffect curves for the irradiation of human skin. Further work by Ellis[67,68] and Fowler et al.[69,70 and 71] brought to light the importance of number of fractions used as well as the overall treatment time. The observation of acute and long-term effects on the skin of rodents as well as pigs has provided invaluable information regarding skin tolerance and the effects of fractionation. Pig skin is remarkably similar to human skin in many respects. Fowler derived a scale of acute reactions to irradiation.[69] The acute and long-term reactions were found to correlate well with those observable in humans. The expense of the pig model led to the development of similar models in rodents, and scales of acute and long-term reactions have proven reproducible in these studies.[36]

Gastrointestinal Tract The vast majority of patients irradiated for lung cancer receive an obligatory radiation dose to the esophagus. The anatomic proximity of this organ to the lung and mediastinum make this treatment unavoidable. Anatomically, the entire length of the gastrointestinal (GI) tract shares common generalized structural features. From superficial to deep, the major subdivisions are mucosa, submucosa, muscularis mucosae, muscularis propria, subserosa, and serosa (in part only). The mucosa of the esophagus is lined with nonkeratinizing stratified squamous epithelium. The mucosa and submucosa are surrounded by the muscularis propria, composed of striated muscle in the superior portion and smooth muscle inferiorly. The esophagus does not uniformly have a surrounding serosa.[72] The major acute reactions in the gut are typically a result of the effects of irradiation on the superficial layers (mucosa and submucosa). The late effects of irradiating the gut tend to produce full-thickness effects.

Clinical Features. Acute radiation esophagitis is a common accompaniment of radiation treatment in lung cancer. The epithelium of the esophagus is a moderately

radiosensitive acute-reacting tissue. Large single doses are seldom if ever administered to the esophagus in clinical practice, so relatively little information exists on the acute reaction to such doses in the human. In a rat model, doses of 30 Gy produced submucosal edema at 4 days, necrosis of the basal epithelium at 6 days, intraluminal sloughing at 10 days, and re-epithelialization beginning at 14 days and complete at 20 days. [73] Even fractionated radiation produces mucosal injury. Symptoms include dysphagia and odynophagia, usually beginning in the second to third week of therapy. Symptoms generally increase in severity throughout the treatment course and subside within 1 to 2 weeks after completing therapy. The severity varies from mild, responsive to simple analgesics, to severe, requiring narcotic analgesia and parenteral support. The radiation tolerance of the esophagus is generally accepted as 60 to 65 Gy in 6 to 7 weeks at standard fractionation. [72] The late effects of radiation damage in the GI tract develop at 12 to 24 months following treatment. Gut mobility is reduced, and wall thickening, induration, and fibrosis occur. Ulceration may lead to perforation. Mesenteric thickening and fibrous adhesions are common, and subacute/acute bowel obstruction may occur. The likelihood of adhesions is increased by prior surgery and chemotherapy. The incidence of late complications to the small bowel increases after fractionated doses in excess of 40 to 45 Gy to large volumes. Smaller volumes of small bowel will likely tolerate doses of 45 to 55 Gy. The radiation tolerance of the colon and rectum is greater, and doses of 55 to 70 Gy are generally tolerated to small-volume fields. [58]

Radiobiologic Features. Both clonogenic and functional assays have been described for the GI tract, reflecting measures of both acute and late radiation gut injury.

Clonogenic Assays. Normal jejunal mucosa include villi and crypts. Stem cells divide rapidly, repopulate the crypts, and differentiate as they move up through the villi, to be eventually sloughed off into the lumen. They can be used as the basis for a clonogenic assay. Irradiating mouse jejunum initially denudes crypts (sensitive stem cells) and leaves villi (resistant differentiated cells) unscathed. Eventually the villi also disappear because of a lack of replacement cells from the irradiated crypts. Graded doses of total-body irradiation in mice (11 to 16 Gy) sterilize varying proportions of the crypt stem cells. Three to four days later the mice are sacrificed, and histologic sections of the jejuni are made to count the number of regenerating crypts per circumference. [36] Such assays like the one described by Withers [74,75] can yield information on gut radiation response as shown in Table 12.5. The late effects of radiation on the esophagus include a reduction in the number of capillaries, submucosal fibrosis and stricture of the lumen.

• Single dose	D_0 = 1.2 to 1.3 Gy (mouse gut) Range tested 9 to 16 Gy)
• Quasi-threshold dose	D_q = 4.0 to 4.5 Gy (mouse gut)
• α/β ratio (X-ray)	
	α/β Gy (Tubiana)
Acute effects (jejunum)	7.1 Gy
Late effects (bowel)	3.0 to 5.0 Gy
Functional Assays:	
• In vivo esophageal toxicity	$LD_{50/28}$ = 27 Gy

TABLE 12.5. GASTROINTESTINAL: BASIC RADIOBIOLOGIC PARAMETERS

Functional Assays. Acute esophageal radiation reactions have been studied *in vivo*. [36] Thoracic irradiation in air-breathing mice denudes the esophagus in 6 to 10 days and kills a proportion of the treated animals by 28 days. Those animals surviving at 28 days eventually go on to die from radiation pneumonitis. The early deaths are attributed to radiation esophagitis, and thus LD50/28 may be calculated reflecting acute radiation esophagitis (Table 12.5). Such experiments provide useful information on the effects of different types of radiation and fractionation, as well as chemosensitization data, but are not useful for determining dose-response information.

Lung The radiation response of normal lung is critically important in considering the radiation biology and management of lung cancer, and this subject is also discussed in detail in Chapter 13. The lungs are generally considered among the late-reacting tissues, but both "acute" as well as "late" clinical reactions are well described following irradiation. In addition, the lungs are susceptible to damage from certain chemotherapeutic agents (bleomycin, cyclophosphamide, nitrogen mustard, procarbazine, etc.), and such effects must also be considered in the treatment of lung cancer patients.

Anatomy. The lung consists of two physiologically distinct sections with separate functions in respiration. [76] The *respiratory tract,* which conducts air from the trachea to the terminal bronchioles, and the *acinar units,* containing the alveoli that actually perform the gas exchange. At least five cell types occupy the alveoli: epithelial cell (type 1 and 2 pneumocytes), endothelial cells, macrophages, and interstitial cells. Type 2 pneumocytes are a proliferating population of cells that produce, store, and secrete surfactant. They are the progenitors of type 1, membranous pneumocytes. After radiation, the type 2 pneumocytes, which are relatively radiosensitive, swell and release surfactant into the interstitial spaces and alveoli. This reaction is a marker for early radiation injury in the lung.

Clinical Features. Two clinical syndromes, histologically distinct and chronologically separate, are described following irradiation of the lung. *Radiation pneumonitis* occurs 1 to 3 months following a course of radiation and is characterized by either asymptomatic pulmonic infiltrates on radiographic evaluation or a clinical syndrome of cough, fever, and shortness of breath. [58] The infiltrate on chest x-ray (or CT scan) characteristically corresponds to the radiotherapy treatment portal. The syndrome is generally self-limiting, but may require treatment with corticosteroids, and in severe cases, intensive ventilatory support. [77] If steroids are used, they must be cautiously withdrawn to avoid recrudescence of the syndrome. Pathophysiologically, damage to type 2 pneumocytes is believed to cause loss of surfactant, alveolar collapse, and interstitial edema. [76] *Pulmonary fibrosis* occurs as an inevitable consequence of the acute pulmonary reaction to radiation, whether or not the patient has shown evidence of acute radiation pneumonitis. The onset is generally 6 to 12 months after irradiation, and it is irreversible. Alveolar wall sclerosis, obliterative vasculitis, interstitial fibrosis, lung volume loss, and pleural thickening have been described. [77] Arterial hypoxia and a restrictive defect may be seen on pulmonary function testing. The functional impact of these reactions on the patient is largely related to the amount of lung irradiated, the total dose used, and the dose per fraction.

Radiobiologic Features. The lack of clear evidence as to the nature of the critical target cells following irradiation, coupled with the slow cell cycle times of those implicated (type 2 pneumocytes cell cycle time of 1 to 2 months[58]), means that no reliable clonogenic assay can assess lung radiosensitivity *in vitro*. [76] Thus we must rely on *in vivo* functional or histological end points for such assessments.

Functional Assays of Lung Radiation Response. The ultimate test of function of a vital organ after radiation is survival. LD$_{5c}$ estimates have been described by Phillips et al. [25] Animals surviving the first wave of death (80 to 180 days) exhibited a second phase of damage at 6 to 12 months. This phase is thought to relate to radiation fibrosis. Dyspnea, manifested by increased breathing rate, can also be quantitated in animals to assess lung damage. [76] Airtight total-body plethysmography allows for a noninvasive test that can be sequentially applied to a single animal at intervals post irradiation. [76] Respiratory rate climbs rapidly with doses exceeding 11 Gy in association with radiation pneumonitis at 14 to 24 weeks and fibrosis at 52 weeks. [36] Other functional end points, such as arterial blood gas analysis, have also been described in this context. Most experimental systems involve whole lung irradiation, and as such are not totally representative of the more common partial lung irradiation used in the clinic. Table 12.6 summarizes the quantitative data derived from these and other assays, as well as from clinical observation of the occurrence of lung damage following partial or whole lung irradiation. Although differing estimates of lung tolerance are quoted depending on the author and system used, the figures quoted in Table 12.6 are useful guidelines in the clinic.

Species	Treated Volume	Dose Tolerated
• Mouse	Whole lung	12 to 13 Gy ($LD_{50\text{-}90}$)
• Man	Whole lung	6 Gy (threshold dose)
• Man	Whole lung	8 Gy ($TD_{5/5}$)
• Man	Whole lung	10 Gy ($TD_{50/5}$)

Fractionated doses*:		
• Mouse	Whole lung	47 Gy ($LD_{50\text{-}90}$)
• Man	Whole lung	22 to 24 Gy ($TD_{5/5}$)
• Man	Whole lung	26.4 to 28.8 Gy ($TD_{50/5}$)
• Man	Partial lung	45–50Gy (volume dependent)

* 200 cGy/day five days a week.

TABLE 12.6. LUNG: RADIOBIOLOGIC PARAMETERS AND TOLERANCE DATA

Heart Portions of the heart often receive substantial doses of radiation that are unavoidable with current techniques. In the radiation management of the lymphomas, especially Hodgkin's disease, and certain carcinomas, including lung and breast, this radiation effect may be clinically relevant and at times life-threatening. Both acute and late effects are seen, and all anatomic structures of the heart are vulnerable. The radiotolerance of the heart is not clearly defined. Furthermore, as techniques assessing cardiac function have become more sensitive, it appears that probably no radiation dose to the heart is not accompanied by some measurable decrement in function. A useful rule of thumb in the clinic is that 60% of the volume of the heart appears to tolerate 40 Gy at standard fractionation, whereas 40% of the heart generally tolerates doses up to 60 Gy. This statement is empiric and imprecise. It must also be remembered that preexisting cardiac conditions are common and may be important in altering the radiotolerance. Similarly, chemotherapeutic agents (e.g., anthracycline drugs) may greatly affect cardiac function in this context.

Acute pericarditis may appear a few weeks to several years following radiation. Features include fever, tachycardia, substernal pain, and a friction rub. Pericardial effusion and even tamponade may occur, with radiographic and electrocardiographic changes typical of these syndromes. Approximately one-half of the cases are self-limiting, whereas the remainder progress to chronic pericarditis of varying clinical significance. Most patients will have received doses in the 40 to 50 Gy range in 4 to 6 weeks to substantial portions of the heart. The incidence of significant pericarditis rises with doses in excess of 50 Gy in 5 weeks. [79] Chronic pericarditis occurs from 6 months to several years following radiation. The clinical syndrome comprises chronic restrictive changes with associated cardiac fibrosis and effusion. Clinical features are those of constrictive pericarditis, effusion, and ultimately progressive cardiac failure. Antecedent history of acute pericarditis is only elicited in approximately 50% of patients.

Myocardial dysfunction occurs because of vascular damage and progressive fibrosis and thickening of the myocardium. Coronary artery stenosis and occlusion is a particularly significant component of radiation injury to the heart. With mature follow-up now available from earlier studies using radiation therapy in diseases such as Hodgkin's disease and breast cancer, comes the realization of the importance of cardiac toxicity caused by radiation in clinical practice. Early trials of chest wall radiation in patients with breast cancer actually revealed a decrement in survival on the irradiated arm. It is now appreciated that this outcome was caused by excess cardiac deaths. Important causative factors included poor choice of radiation fields (internal mammary node groups), lower energy equipment, and higher daily doses (>2.5 Gy). With attention to proper technique, cardiac injury is no longer being encountered, and more recent trials are beginning to show a trend toward improved survival. [80] Likewise, long-term follow-up of patients treated with radiation for Hodgkin's disease are now also showing markedly increased rates of various cardiac injuries including myocardial infarctions. [81] Factors implicated again include higher total doses and dose per fractions used. The recent development of sophisticated cardiac pacemaker devices, and the frequent coexistence of lung cancer in patients fitted with them has highlighted the occurrence of pacemaker malfunction caused by ionizing radiation. Guidelines are now being drawn to avoid clinical problems in such patients. [82] Careful attention to these factors is therefore warranted in the radiation management of the lung cancer patient.

Hematopoietic Tissues The sensitivity of hematopoietic tissues is perhaps the single most important factor limiting the dose of cytotoxic therapies in the clinic. The requirement for rapid reproduction of the cellular elements in blood to maintain homeostasis (gas exchange, immune protection, and coagulation) calls for a prodigious clonogenic output and therefore renders this tissue especially sensitive to ionizing radiation and myelotoxic chemotherapies. An exhaustive discussion on this topic is beyond the scope of this chapter, but key points are highlighted as they apply to the management of lung cancer patients.

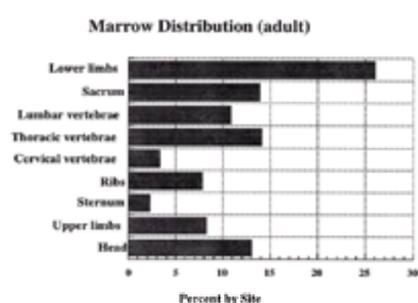
Anatomy and Physiologic Features. The bone marrow may thus be regarded as a single organ with structural organization for hematopoiesis. [58] Given the quantitative importance of radiation volume in terms of toxicity, the location of active marrow within the adult skeleton becomes a key issue (Figure 12.6).[83]


FIGURE 12.6. A graphic representation of the distribution of active bone marrow in the adult skeleton. Note that more than 80% of active marrow in health is in the axial skeleton, with approximately 30% in the vertebral bodies. (From Ellis, Thames HD, Withers HR, Peters LJ, et al. Changes in early and late radiation responses with altered dose fractionation: implications for dose-survival relationships. *Int J Radiat Oncol Biol Phys* 1982;8:219, with permission.)

Clinical Features. When functional bone marrow is included in the radiation portal, an inevitable loss of stem cells occurs. The greater the volume of marrow, the greater the loss. Clinical effects are thus most easily observed following total-body irradiation (TBI). However, limited-field irradiation can cause measurable marrow toxicity, especially when significant amounts of the axial skeleton and pelvis are irradiated (Figure 12.6). Prior or concomitant myelotoxic chemotherapies can also aggravate the situation. Changes in peripheral blood counts may not mirror cytotoxic damage in time or extent because compensatory mechanisms may mask the marrow toxicity, and the life cycle of mature cellular elements in the blood may be sufficiently long (e.g., red cell = 120 ± 30 days) so as to obscure the effect on the marrow. As always, *stem cells are most sensitive to radiation, whereas the more mature and differentiated cells are relatively resistant.* Following a TBI dose of 30 cGy, peripheral lymphocyte counts fall in humans.[58] Doses of 3 to 8 Gy cause profound lymphopenia, followed by granulocytopenia, thrombocytopenia, and anemia. The nadir in counts occurs at 2 to 3 weeks, and death occurs in a proportion of cases. A measure of bone marrow toxicity from radiation is the LD50/30 for animals and LD50/60 for humans. This measure is the dose that kills 50% of those irradiated at 30 days (animals) and 60 days (humans). The LD50/60 for humans is variously quoted at 3 to 4 Gy.[38] Death occurs as a consequence of infection or bleeding. The higher the dose, the deeper and more prolonged the nadir. [58] It should be stressed that with modern medical support, including empiric broad-spectrum antibiotics, transfusions, and marrow "rescue," patients may survive whole-body doses up to 8 Gy. Above 10 Gy the patient will likely die from gastrointestinal toxicity. Following *partial marrow* irradiation, compensatory hyperplasia in the unirradiated marrow usually maintains peripheral blood counts. With doses greater than 30 Gy, hemopoiesis rarely returns to normal in the irradiated volume. However, if substantial portions of the marrow are irradiated, regeneration occurs to a greater extent within the irradiated field, probably because of intense humoral stimulation needed to recover.[56] Typically, when hypoplasia occurs following partial-marrow irradiation, platelet counts are the slowest to recover.

Radiobiologic Features. Clonogenic assays are available to assess the radiation sensitivity of bone marrow *in vivo.* The classic work of Till and McCulloch using supralethally irradiated mice (9 to 11 Gy), in whom marrow is infused following increasing exposure to radiation, has yielded much valuable information on the radiosensitivity of hematopoietic tissue. [84] The spleen is assayed for the number of colonies, each representing a pluripotent stem cell surviving the test irradiation

dose. These and other studies have confirmed that hematopoietic tissue is an acute-reacting and relatively radiosensitive tissue (Table 12.7).

TABLE 12.7. HEMATOPOIETIC TISSUE: BASIC RADIOBIOLOGIC PARAMETERS*

Central Nervous System The proximity of the spinal cord to the lung and mediastinal nodes makes it virtually impossible to avoid obligatory irradiation of this critical structure. The tolerance of the cord is therefore of paramount importance in the radiation management of the lung cancer patient. Nervous system tissue is a classic example of late-reacting tissue, and although acute toxicities can occur, the major concern is avoidance of a catastrophic late sequela—myelopathy.

Anatomy. Neurons are terminally differentiated cells that do not undergo cell division. As such, they are relatively resistant to radiation. However, important stromal support tissue, including Schwann cells, oligodendrocytes, and vascular endothelium, are susceptible. Damage to Schwann cells and oligodendrocytes is thought to cause loss of the myelin sheath, a protective support tissue. Demyelinization is implicated in the early radiation injury to the cord.

Clinical Features. Although a long-held belief states that the tolerance of the spinal cord varies according to the anatomic segment irradiated, objective evidence supports this belief.[85,86] The factors associated with the development of cord injury are principally dose (total and fraction size[87]) and volume. When greater than 10 cm of cord is irradiated, most clinicians do not exceed total doses of 45 to 50 Gy at standard fractionation (1.8 to 2.0 Gy/day). It is also important to realize that other factors, such as concomitant chemotherapy, may also reduce the tolerance of the cord to radiation.[88] *Early reversible myelopathic syndromes* may appear within a few weeks following cord doses of 50 to 60 Gy. *Lhermitte's syndrome* is characterized by an acute episode of demyelination, with symptoms of "electric shock" or "tingling" in the spine, aggravated by tilting the head (the "barber's chair sign"). This syndrome is generally self-limiting and is not associated with the inevitable development of permanent myelopathy. *Late radiation injury* to the spinal cord is a potentially catastrophic event that can usually be avoided by adhering to doses and fractionation schedules considered "safe." The most common cause of late radiation injury in clinical practice is overdosage at the junction of two abutting radiation fields. The onset is 6 months to 4 years from the end of treatment. The incidence is hard to determine because irradiated patients often do not survive their cancer long enough to be at risk for such damage. Although dose and fractionation are clearly extremely important, the occurrence of myelopathy with doses considered within "tolerance," indicates that other factors must be involved. Demyelinization and atrophy of the cord is visible on MRI scanning, and histologic evidence of absent glial cells, necrosis, infarcts, and hyaline degeneration may be seen microscopically.[58] Clinically, a Brown-Sequart syndrome evolves and is generally irreversible.

Radiobiologic Features. Just as is true in the case of the late-reacting tissues of the lung, no useful clonogenic assays can detect the slowly dividing normal tissues of the central nervous system (CNS). However, several useful animal models provide information on tolerance of the spinal cord and the effects of fractionation. The rat model with atrophy and dysfunction of the hind limbs has been used to study different fractionation schedules and the effects of reirradiation.[89,90] The potential protective effects of hyperbaric oxygen have been assessed in the mouse.[91] Other models utilize the guinea pig[92,93] rhesus monkey,[94] and the dog.[95]

MODIFICATION OF RADIOSENSITIVITY

Biological Aspects

In 1961 Terasima and Tolmach showed that cells vary in their radiosensitivity as a function of their position in the cell cycle.[96] In general, the ordering of radiosensitivies from the most resistant to the most sensitive response with respect to phases in the cell cycle are as follows: late S, early S, early G1, late G1, G2, M.[97] The difference in radiosensitivity from a cell in late S-phase versus mitosis is on the order of 2.5 to 3.0 fold. It is impressive that the same cell would vary so much in radiosensitivity as it simply traverses the cell cycle. Little is known as to why this happens. Possible explanations may be differential repair capacities, inability to appropriately arrest in critical phases of the cell cycle for repair, or changes in the biophysical nature of DNA as cells progress through the cell cycle. Presently this area of research is fruitful now that several molecules (in particular, the cyclins) have been discovered that are important in controlling movement through the cell cycle.[98,99 and 100]

Considerable radiosensitization could be achieved in a population of cells if they could somehow be synchronized into radiosensitive phases of the cell cycle such as G2, M, or the interface of G1 and S-phase. Radiation exposure (either acute exposures or continuous low dose-rate irradiation) has long been known to impose cell cycle blocks, in particular, in the radiosensitive G2-phase of the cell cycle.[21,101] Recent information identifies increased levels of mitotic cyclins as key biochemical events initiating mitosis. In HeLa cells, cyclin B mRNA and protein levels have been shown to increase in G2 and to decrease after division is completed. Cyclin B protein binds to cdc2, resulting in histone kinase activity, which is necessary for the initiation of mitosis. Radiation has been shown to alter levels of cyclin B and thus may interfere with the progression of cells from G2 to mitosis.[102] Indeed, continuous irradiation at low dose-rate has been shown to become much more efficient with respect to cell killing once cells are blocked in G2.[21]

Likewise, several drugs impose cell cycle blocks and have been used as radiation sensitizers.[103] Two examples are hydroxyurea (HU), evaluated many years ago, and more recently, paclitaxel (taxol). HU blocks cells at the G1/S-phase interface, is cytotoxic to cells in S-phase, and inhibits radiation damage repair.[104] If HU is exposed to cells for a time equivalent to the total cell cycle time, then cells in S-phase are killed and cells that were in G2, M, and G1 are synchronized at the G1/S-phase interface. When HU is removed, this cohort of cells moves synchronously through the cell cycle, and the cells become more radiosensitive as they move into G2 and M. This observation has been shown for *in vitro* cell cultures,[105,106 and 107] but it has been more difficult to demonstrate *in vivo.* Nonetheless, HU has been extensively evaluated in the clinic as a potential radiation-sensitizing drug.[108,109,110,111,112,113,114,115,116,117 and 118]

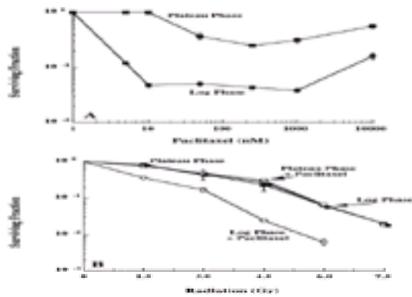
Paclitaxel binds to microtubules, possibly at a site on b-tubulin,[119] and interferes with normal microtubule structure and function. The effects of paclitaxel on nuclear microtubules probably account for most of the cytotoxicity manifested by the drug. Nuclear microtubules become shortened and form numerous abnormal spindle asters as paclitaxel-treated cells enter mitosis.[120] Normally, only two spindle asters appear in cells during mitosis, and these cells facilitate the separation of chromosomes before cell division. The abnormal microtubule asters that arise in mitotic cells following paclitaxel exposure do not contribute to cellular division. Indeed, paclitaxel markedly prolongs the duration of mitosis.[121] In order for paclitaxel to exert cytotoxicity, cells must be moving through the cell cycle because cells in plateau phase are resistant to paclitaxel (Figure 12.7A).[122] Long-term treatment of cells with relatively low concentrations of paclitaxel results in radiosensitization of log-phase cells, but no radiosensitization is observed for cells exposed to paclitaxel and subsequently irradiated (Figure 12.7B).[123] This radiosensitization is most likely caused by the paclitaxel-mediated G2/M block in the cell cycle.[123,124 and 125] In clinical trials, paclitaxel alone has exhibited activity against several malignancies, including ovarian,[126] breast,[127] head and neck,[128] and NSCLC carcinomas.[129] Combination of paclitaxel with radiation may have utility in lung cancer treatment given paclitaxel's activity alone in lung cancer and its ability to block cells in radiosensitive phases of the cell cycle.


FIGURE 12.7. Cytotoxicity of paclitaxel (taxol) in V79 cells. **A:** illustrates the cell cycle specificity of paclitaxel. Because paclitaxel interferes with microtubule function during mitosis, actively cycling cells are much more sensitive. **B:** shows that paclitaxel sensitizes log-phase (cycling) but not plateau-phase (resting) cells to radiation. (From Liebmann JE, Cook JA, Fisher J, et al. Cytotoxic studies of paclitaxel (Taxol) in human tumour cell lines. *Br J Cancer* 1993;68:1104, with permission.)

Physical Aspects

The response of cells and tissues depends on the type of radiation used. [130],[131] Examples of different types of radiation include x-rays, electrons, protons, neutrons, a-particles, and heavy-charged ions (e.g., C, Ne, Ar). As a photon or charged particle moves through cells or tissue, it transfers its energy randomly. The average energy lost per unit of track length of the photon or charged particle is referred to as LET. The radiation response of cells and tissues depends on the LET. In general, as the LET increases, the effectiveness of radiation increases and the dependence on oxygen (see following) decreases. [53],[132] For example, cell killing for a given dose of radiation is greater for neutrons and a-particles (LETs, 2-10, and 100-200 kev/μ, respectively) than for x-rays (LET, 1 kev/μ) (Figure 12.1C). The use of high LET for cancer treatment carries several potential advantages over conventional x-ray treatment, including improved dose distribution, enhanced radiosensitization of hypoxic cells, and less radiation damage repair. [53] Despite these potential advantages, the use of high LET has not become a mainstay in clinical radiotherapy. Some problems reside in unacceptable normal tissue toxicities observed with high-LET treatments and simply the cost and complexity involved in maintaining such sophisticated equipment.

Chemical Aspects

The inherent radiosensitivity of cells and tissues can be influenced by several chemical approaches and manipulations, which is important for at least two reasons. First, modifying the radiosensitivity by specific agents of known mechanisms of action can provide information about how radiation damage is registered and repaired. Second, selective modification of radiosensitivity, for example, in tumor as opposed to normal tissue, could provide therapeutic possibilities. In radiation oncology the major goal is to develop a treatment that affords a therapeutic gain; that is, enhanced tumor response without increased damage to surrounding normal tissue. It is well established that, for most tumors, increasing the radiation dose results in improved local control. [133],[134],[135],[136] and [137] Ideally, the use of *tissue-specific radiation sensitizers or protectors* could result in an effective increase in the tumor radiation dose. For example, if a tumor-specific radiation sensitizer enhanced the effectiveness of radiation by a factor of 1.5, a delivered dose of 10 Gy would actually be equivalent to 15 Gy. Likewise, a specific radiation protector of normal tissue would allow for more radiation dose to be delivered to the tumor without enhancing normal tissue damage. Much research has gone into the development of both radiation sensitizers and protectors as a means of improving the local control of tumors by radiation, and examples of major classes are discussed in following sections.

RADIATION SENSITIZERS

Oxygen

Perhaps the most efficient radiation sensitizer is molecular oxygen. Oxygen has long been known to enhance the effectiveness of radiation (x-rays) in killing cells in culture by a factor of 2 to 3 compared to when irradiation is conducted under oxygen-free conditions. [138] In other words, if cells are irradiated in an hypoxic (<0.5% oxygen) as opposed to aerobic (~20% oxygen) environment, they are two to three times more resistant to the cytotoxic effects of radiation. When comparing the radiosensitivity of cells in aerobic versus hypoxic conditions, radiobiologists use the term oxygen enhancement ratio (OER), thus the OER for mammalian cells exposed to x-rays is 2.0 to 3.0. As discussed previously, it has been postulated that radiation produces carbon-centered radicals (most likely in the cellular DNA) that can react with molecular oxygen (a diradical molecule) to yield a lesion that is toxic and if not repaired results in death of the cell. [139] Under hypoxic conditions very few, if any, oxygen-related lesions are formed, and hence less cell killing results.

A major research effort has been directed toward the potential problem of the presence of viable hypoxic cells within tumors. In 1955 Thomlinson and Gray published a landmark study, which hypothesized that the presence of hypoxic cells in tumors may limit the effectiveness of radiation therapy. [140] This theory was based on the observation that tumor biopsy material taken from lung cancer patients contained distinct regions of viable tumor always near or surrounding blood capillaries. With increasing distances from the capillaries, regions of necrosis were noted. These observations prompted Thomlinson and Gray to make a series of calculations regarding the maximum distance oxygen could diffuse through actively metabolizing tissue. The distance obtained from their calculations was between 150 to 200 μ M. Actual measurements of their biopsy material revealed that viable tumor cells extended approximately 150 to 200 μ M from the capillaries; beyond this distance, evidence for necrosis was apparent. Thus Thomlinson and Gray hypothesized that a gradient of oxygen concentrations may exist as a function of distance from capillaries and that tumor cells located at 150 to 200 μ M, although still viable, are in an environment of extremely low oxygen concentrations. Such cells would be considered resistant to radiation, and thus their presence could limit the effectiveness of radiation cancer treatment. Considerable creditability was given to this hypothesis from the findings of Powers and Tolmach,[141] who showed quantitatively using a rodent tumor model that viable radiobiologically hypoxic cells exist *in vivo.* The experiments of Powers and Tolmach are not amenable to the study of hypoxic cell presence in human tumors, and thus scientists have assumed their presence in human tumors and sought means to eliminate them.

Only recently has technology been available to determine if, in fact, hypoxic cells are present in human tumors. When oxygen electrodes are directly inserted into tumors and many readings are taken as the electrode is tracked through the tissue, regions within the tumor have been recorded as having low oxygen levels (<10 mm Hg). The presence of hypoxia has been demonstrated in various tumor types, including head and neck carcinomas [142] breast carcinoma,[143] malignant brain tumors,[144] and cervical cancer.[145] Regional hypoxia has also been observed using noninvasive positron emission tomography of [18F]fluoromisonidazole for prostate and SCLC.[146] As more experience is gained with *in situ* oxygen measurements of tumors, it may be possible to select patients prior to therapy whose tumor has a significant hypoxic fraction and use approaches targeted at this radioresistant compartment.

To address the problem of hypoxic cells in tumors, radiobiologists and radiotherapists for the past 30 years have actively pursued various approaches to sensitize hypoxic cells to radiation. The goal of this research is to identify an approach that will reduce the OER from ~3.0 to 1.0; that is, hypoxic cells will have the same response to radiation as aerobic cells. Use of high LET radiation (i.e., neutrons) has been proposed because hypoxic cells exhibit less radioresistance under hypoxia to neutrons (OER = 1.7) than to x-rays.[138] The use of neutrons in clinical radiotherapy has not yielded significant improvement in tumor response, and because of the cost of constructing and maintaining a clinical neutron facility, this option is not likely to be explored extensively. The use of hyperbaric oxygen has been evaluated both experimentally and clinically. The idea here is to force oxygen into hypoxic regions of tumors using hyperbaric oxygen (100%). This approach has shown some degree of hypoxic radiosensitization in rodent tumors, [141] but the results in the clinic have not been impressive, primarily because of low patient accrual because of the problems associated with multiple treatments (~20 to 30) at hyperbaric oxygen levels.

Another approach that has received more attention is the development of chemicals that would not be metabolized like oxygen but could diffuse into hypoxic regions in tumors and sensitize hypoxic cells to radiation. [147] A class of compounds known as *nitroimidazoles* was identified to have such characteristics. [147] These compounds were shown not to radiosensitize aerobic cells; however, at concentrations of ~1mM, hypoxic cells were radiosensitized (OER = 1.6). The mechanism of hypoxic cell radiosensitization by nitroimidazoles is unknown; however, it is hypothesized that they have similar electron affinity to that of oxygen, and under hypoxic conditions can react with carbon-centered free radicals produced by radiation, and hence like oxygen "fix" the damage on important biological molecules crucial for survival. Two nitroimadazoles have been introduced into clinical radiotherapy trials; misonidazole and SR-2508. Clinical evaluation of misonidazole was complicated by

dose-limiting normal tissue toxicities, namely, peripheral neuropathy. [148] SR-2508 was synthesized specifically to circumvent this problem; however, clinical trials to date have not shown it to be an effective sensitizer. [149,150]

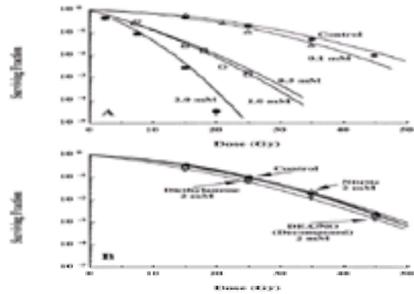
More recently, a new approach at radiosensitizing hypoxic cells has been identified. Nitric oxide (NO) has been unexpectedly found to be an important bioregulatory molecule synthesized throughout the animal kingdom. [151,152,153 and 154] NO has a wide variety of physiological functions, including cardiovascular effects, neurotransmission, smooth muscle relaxation, bronchodilation, and immunologic potentiation. [153,154] The use of NO gas in animals (or humans) as a hypoxic cell radiosensitizer is problematic because breathing high concentrations of NO gas can damage lung tissue, and pharmacologic delivery of adequate concentrations of gaseous NO to distant solid tumor sites is not possible. Recently, a series of compounds called NONOates [(R $_1R_2NN(O)(NO)$], which are amine derivatives of dimeric NO, have been shown to release NO in a predictable manner at physiologic conditions. [155] As shown in Figure 12.8, NO released from NONOates radiosensitize hypoxic cells. [156,157] Such agents may have utility in the treatment of lung cancer.


FIGURE 12.8. Radiation dose-response for Chinese hamster V79 cells exposed to radiation under hypoxic conditions in the absence or presence of **(A)** varying concentrations of the nitric oxide–releasing agent DEA/NO, or **(B)** 2 mM of nitrite, diethylamine, or decomposed DEA/NO. This study suggests that active nitric oxide is responsible for the sensitizing effect. (From Mitchell JB, Wink DA, DeGraff W, et al. Hypoxic mammalian cell radiosensitization by nitric oxide. *Cancer Res* 1993;53:5845, with permission.)

The view that the presence of hypoxic cells in human tumors may limit the effectiveness of radiation treatment is not uniformly agreed upon in the radiation community. The reason for this disagreement resides in the manner in which radiation is delivered to tumors and the phenomenon of tumor reoxygenation. Using a rodent tumor model, van Putten and Kallman demonstrated that following a multifraction course of radiation treatment, the hypoxic fraction remaining at the end of radiation treatment was the same as the hypoxic fraction before treatment. [158] From these studies, van Putten and Kallman concluded that reoxygenation of hypoxic regions must have occurred during the fractionated course of radiation treatment. If no reoxygenation of hypoxic cells had occurred, then the proportion of hypoxic cells would have increased by the end of the fractionated radiation treatment. The fact that the hypoxic proportion remained the same during (and at the end of) treatment was interpreted to mean that for each radiation dose, aerobic cells were killed and the oxygen used by these cells was now diverted to reaerate hypoxic cells. The time course for reoxygenation in experimental tumor models varies widely among experimental rodent tumors ranging from 6 to 24 hours. [138] Thus with repeated daily exposures of radiation, reoxygenation of hypoxic regions should occur, along with killing of aerobic cells, with the net result after 20 to 30 radiation fractions being eradication of the tumor mass. If this correlation were true, then fractionated radiation therapy would not be greatly influenced by the presence of hypoxic cells. Technologic advances in the area of tumor oxygen measurements in human tumors allow for evaluation of the role of tumor hypoxia response and whether tumor reoxygenation during fractionated treatment adequately eliminates this potential problem.

Chemotherapy

As mentioned previously and covered in more detail in Chapter 15, the combination of chemotherapy and radiation may offer potential advantages with respect to tumor radiosensitization. Yet another practical aspect of combined modality therapy often arises in the clinical setting, involving whether chemotherapy-resistant cells are also radiation-resistant or vice versa, or whether previous treatment with one modality produces resistance to a different modality. These concerns have been partially addressed in cell culture studies, and considerable controversy exists. In general, chemotherapy-resistant cells are not radioresistant, [85,159,160,161 and 162] however, in some instances this is not the case. [163,164]

Does radiation treatment result in altered sensitivity to chemotherapy? Some *in vitro* reports indicate that prior radiation exposure increased drug resistance. [165,166,167 and 168] Hill et al. has reported that multiple fractions of radiation were able to induce the multidrug-resistant (MDR) phenotype in Chinese hamster ovary cells. [169] After radiation, these cells showed increased resistance to the vinca alkaloids, VP-16, adriamycin, and cisplatin; this resistance was reversed by the use of verapamil. Interestingly, these cells did not show amplification of the p-170 gene or of the p-170 mRNA; however, the cells did show an increased expression of the p-170 protein. The drug resistance induced using the radiation treatments was not as high as drug resistance produced by continuous low-dose exposure to colchicine. It should be noted that these interesting *in vitro* observations suggest that radiation could lead to changes in inherent cellular sensitivities (as a result of genomic alterations) to subsequent chemotherapy, but other possibilities certainly exist. For example, radiation treatment could alter the tumor vascular supply, tumor bed, and other physiological determinants that could compromise the delivery of the drug to the clonogenic tumor cells in the tumor. Careful work at both the cellular and tissue level will be required to work out these complexities; nonetheless, combined modality therapy remains an important research area in the laboratory and the clinic.

RADIATION PROTECTORS

As detailed previously, the successful treatment of human lung cancer with radiation is often limited by normal tissue complications. The anatomic location of lung tumors place several vital normal tissues at risk for radiation damage. If normal tissue could be protected selectively as opposed to tumor, more radiation dose could be delivered to the tumor with the expectation of greater tumor control with no or little additional damage to normal tissue. At the surface this task seems formidable; however, if blood flow is compromised to the tumor (this would be true if tumor hypoxia exists), a "window" of opportunity might open to deliver a radioprotector to normal tissues (well perfused) before appreciable quantities reach and the tumor. Alternatively, if a radioprotector could be developed such that it could be inactivated by tumor as opposed to normal tissues by virtue of differential metabolism, advantages might be expected.

Radioprotectors are classified in several categories. Some radioprotectors protect by *scavenging radiation-induced free radicals* and/or *donating reducing equivalents to oxidized molecules.* Others protect by *altering physiologic functions* that interfere with the effects of radiation, such as agents that cause vasoconstriction and hypoxia. This class of protectors actually reduces blood flow to normal tissues, such as bone marrow, rendering the tissue hypoxic. Because hypoxic cells are less responsive to the effects of radiation, the net result is radioprotection. Lastly, some radioprotectors act by *enhancing the recovery and/or repair of normal tissues.* Examples of these protectors include cytokines and hemopoietic growth factors.

Aminothiol Radioprotective Agents

The search for radioprotectors began in the 1940s when Patt et al. found that sulfhydryl compounds afforded protection against whole-body irradiation in rodents. [170] The dose modifying factor (DMF) for these experiments was ~1.7. Subsequently, Bacq et al. found that cysteamine also protected animals from whole-body radiation. [171] The mechanism(s) by which these sulfhydryl compounds protect appears to involve their ability to scavenge radiation-induced free radicals and/or to donate reducing equivalents to oxidized molecules, although more recent studies suggest that induction of bone marrow hypoxia could also account for some of the protection. [172] These discoveries prompted the U.S. Army to sponsor the synthesis and screening of compounds to identify relatively nontoxic and potentially more effective radioprotectors. [173] From this massive screening effort, a thiophosphate compound, S-2-(3-aminopropyl- amino) ethylphosphorothioic acid (WR-2721), emerged. WR-2721 showed substantial and selective protection of normal tissues in murine models. [174,175,176 and 177] Yuhas et al. showed that WR2721 could protect normal tissues but did not protect tumor. [176] Subsequent studies established the basis for this observation to be slower penetration of WR2721 into tumor tissue than normal tissues. [177] Phase I studies of WR2721 defined the maximally tolerated dose under different treatment schemes. [178,179 and 180] Recent clinical trials has shown that WR2721 (amifostine) has been quite effective in protecting against radiation-induced normal tissue toxicities without reducing antitumor efficacy in NSCLC [181] and

head and neck cancer.[182]

Nitroxides as Radiation Protectors

Recently, a new class of radioprotectors, the nitroxides, has been described. [183],[184] and [185] Nitroxides are stable free-radical compounds that afford radioprotection both *in vitro*[183] and *in vivo*.[184] Tempol protected V79 cells against radiation in a dose-dependent fashion (Figure 12.9A), whereas, the reduced form of Tempol (Tempol-H), the hydroxylamine, did not provide aerobic radioprotection (Figure 12.9B). Likewise, although Tempol was rapidly reduced to the hydroxylamine (inactive radioprotector) *in vivo* (Figure 12.10A), significant radioprotection was observed in animals (DMF = 1.3) if irradiation was conducted within 10 minutes after drug administration. Figure 12.10B shows that the same concentration of Tempol administered to tumor-bearing mice receiving local tumor irradiation did not influence tumor response.[186] To identify a mechanism for the apparent differential protection of the hematopoietic system (Figure 10A) and tumor tissue, pharmacologic studies were carried out. The percentage of oxidized compound (nitroxide) was approximately 2-fold greater in the bone marrow compartment, compared to RIF-1 tumor at the time of irradiation. Greater bioreduction of Tempol occurred in the RIF-1 tumor. Such a result may provide at least a partial explanation for the absence of tumor radioprotection because it previously had been demonstrated that the oxidized form of Tempol is the active radioprotector. These preliminary data imply that a potential difference exists between normal and tumor tissues with respect to bioreduction.

FIGURE 12.9. *In vitro* radioprotection of V79 cells with the nitroxide Tempol. **A:** Increasing concentrations of Tempol provide increasing aerobic radioprotection in a clonogenic assay. **B:** The reduced form of Tempol (Tempol-H) provides no radioprotection. (From Mitchell JB, DeGraff W, Kaufman D, et al. Inhibition of oxygen-dependent radiation-induced damage by the nitroxide superoxide dismutase mimic, Tempol. *Arch Biochem Biophys* 1991;289:62, with permission.)

FIGURE 12.10. A: An LD $_{50/30}$ curve of whole-body radiation in C3H mice. Tempol injected intraperitoneally protects them against whole-body radiation. Data adapted from Hahn, et al. Tempol, a stable free radical, is a novel murine radiation protector. *Cancer Res* 1992;52:1750, with permission. **B:** Radiation tumor-control curves for animals treated in the absence or presence of Tempol. Closed circles: Tempol-treated mice; open circles: PBS-treated mice. No statistical difference existed between the two curves (p = 0.54). The calculated TCD$_{50/30}$ values for Tempol-treated and PBS-treated mice were 36.7 and 41.8 Gy, respectively. No statistical difference existed between these values (p = 0.32). The error bars represent one standard error above and below the value shown. (From Hahn SM, Sullivan FJ, DeLuca AM, et al. Evaluation of tempol radioprotection in a murine tumor model. *Free Radic Biol Med* 1997;22:1211, with permission.)

CELLULAR PROPERTIES OF HUMAN LUNG CANCER CELLS AND THEIR RESPONSE TO RADIATION

The clinical variability in response among the different histologies of lung cancer to cytotoxic agents probably has many causes. One approach toward unraveling this complex issue has involved a systematic study of inherent properties of tumor cells that might be important in governing response to a particular treatment modality. Studies have focused on three main areas: (a) the human tumor stem-cell assay; (b) established permanent *in vitro* human tumor cell lines; and (c) xenografts of human tumors grown in athymic nude mice.

Human Tumor Stem-Cell Assay

This process involves the disaggregation to a single-cell suspension of tumor cells obtained at biopsy, exposure to cytotoxic substances, and assessment of cloning or colony-forming capacity in medium made semisolid by the addition of agarose. [187] This study allows the potential of tailoring patient therapy based on the sensitivity of their own cells *in vitro*. Unfortunately, at present, major problems with the assay limit its usefulness. These problems include long assay times, the low yield of growth from tumor biopsy specimens, difficulty in obtaining true single-cell suspensions from solid tumors, and low cloning efficiencies, ranging from 0.001% to 0.1%.[188],[189] A further disadvantage is the admixture of both normal and tumor cells in most specimens. [190] Improved culture media, as well as techniques to circumvent these issues, is required before this assay will become clinically useful.

Radiation Sensitivity of Lung Cancer Cell Lines

As noted previously, the use of cell lines to establish radiation sensitivity dates back to the classic work of Theodore Puck, who used the cervical carcinoma cell line (HeLa) to report the first mammalian x-ray survival curve.[4] Over the past decade or more, numerous investigators have reported on the *in vitro* radiation response of human tumor cell lines for various malignant conditions. [191],[192],[193],[194],[195],[196],[197],[198],[199] and [200] In the same time period, it has been estimated that more than 1,000 continuous human cell lines have been established from lung cancer biopsy specimens. [201] The major advantages of using established human cell lines for such assays include the availability of large numbers of cells to perform survival, biochemic, cytogenetic, and molecular studies, as well as reproducibility and generally acceptable cloning efficiencies.[198] NSCLC cells generally adhere to culture flasks and plate in monolayers and thus lend themselves easily to clonogenic assay. [202] In contrast, SCLC lines have been more difficult to establish and tend to aggregate and float in culture, making clonogenic assays more difficult. [203],[204] Furthermore, SCLCs tend to clone inefficiently, especially newly established classic lines from untreated patients. Thus other assays, including dye exclusion techniques, [205] tritiated thymidine uptake,[206] radiolabeled glucose utilization, [207] and automated image analysis of crystal violet-stained cells, [208] have been evaluated as alternatives to the classic clonogenic assays. A semiautomated colorimetric assay has proven a reliable nonclonogenic alternative, allowing for rapid sensitivity screening of lung cancer cells to cytotoxic agents including chemotherapy[209] and radiation.[210] Such studies have confirmed a heterogeneity of *in vitro* response, which parallels the behavior of these diseases in the clinic. To illustrate this property, the radiation survival curves for established cell lines of six different histologic types of lung cancer are shown in Figure 12.11A. The most striking feature observed among these curves is the variation in the initial shoulder as well as the terminal slope of the different lines, indicative of a differential cell survival. The mean surviving fraction at 2 Gy, thought to be a reliable indicator of radiation sensitivity, is displayed in Figure 12.11B and demonstrates the heterogeneous response among the differing histologies. A summary of the radiation survival curve parameters for selected lines evaluated from the NCI lung cancer cell panel,[211] as well as the work of other investigators, confirms this heterogeneity and suggests that the response of lung cancer cell lines can be considered in three groups. Group 1 includes "classic" SCLC lines with D $_0$s in the range of 0.51 to 1.4 Gy and extrapolation numbers ($\bar{n}$) in the 1 to 3.3 range. These

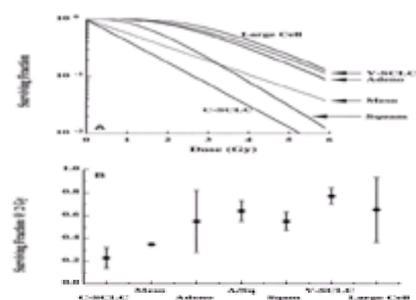
lines were clearly the most radiosensitive. Both NSCLC and "variant" SCLC lines could be considered as belonging to Group 2, with D_0s of 0.8 to 0.91 Gy and rather large $\bar{n}$ values of 5.6 to 14.0. Group 3 consists of the adenocarcinoma lines, with D_0s in the 0.97 to 1.3 Gy and $\bar{n}$ of 1.3 to 3.0. Somewhat surprisingly, mesothelioma cell lines tested appeared radiosensitive with low $\bar{n}$ in the 1.0 to 1.8 range and D_0 1.3 to 1.86 Gy, whereas the clinical experience with this tumor would suggest a more radioresistant response.


FIGURE 12.11. A: Radiation dose-response curves for six different types of human lung cancer cell lines. In this assay, small cell carcinoma is the most radiosensitive, a finding often reproduced in the clinic. **B:** Mean surviving fraction at 2 Gy for seven different types of human lung cancer cell lines, confirming the relative sensitivity of small cell *in vitro*. (From Carmichael J, DeGraff WG, Gamson J, et al. Radiation sensitivity of human lung cancer cell lines. *Eur J Cancer Clin Oncol* 1989;25:527, with permission.)

Therefore, the question may be asked: Is the intrinsic radiation-sensitivity values ($\bar{n}$, D_0, SF 2Gy) of these cell lines generally predictive of clinical responsiveness or curability? Weichselbaum and his colleagues in studies of cell lines from various malignancies found little or no correlation, [192] whereas the data from the studies of lung cancer lines appear predictive. [198,199,211] Classic SCLC is definitely responsive to radiation treatment in the clinic, although it is rarely cured because of its capacity for systemic spread. [212] Variant SCLC and NSCLC are clinically less responsive to radiation. Cell lines from responsive SCLC patients are characterized by low $\bar{n}$ values (1.0 to 3.3) and low SF 2 Gy values, whereas cell lines from variant SCLC or NCSLC tend to have larger $\bar{n}$ values (5.6 to 14) and higher SF 2 Gy values. A large shoulder on the survival curve (or high $\bar{n}$ value) implies a considerable capacity for SLDR, and thus a greater cell survival. Additionally, for a clinically relevant radiation dose of 2 Gy, the surviving fraction is usually greater for those cell lines having a higher $\bar{n}$ value. [211] The absence of a shoulder on the SCLC cell lines has important dose-rate implications discussed previously.

Xenografts

Almost 100 years ago, Livingood described a spontaneously occurring papillary mouse tumor in a mouse lung. [213] Chemically and transgenically induced primary lung tumors in mice share many of the morphologic, histologic, and biochemic features of human NSCLC. [214] For example, when a *ras* oncogene is transfected into SV-40 transformed human bronchial epithelial cells, and injected into a nu/nu mouse, adenocarcinoma of the lung results. [215] These models therefore offer the ability to study premalignant lung lesions, as well as models of lung tumor progression. *In vitro* clonogenic assays of human heterotransplants have been developed with cloning efficiencies ranging from 0.3% to 35%[216] Reasonable correlations have been reported between *in vivo* tumor responses to chemotherapy and observed responses in the clinic. [217] More recently, xenograft models have been utilized in the assessment of novel therapeutic strategies, including radiolabeled monoclonal antibody treatments in SCLC.[218] This approach has been relatively underutilized, and further work is warranted. [214]

MOLECULAR ASPECTS OF RADIATION SENSITIVITY AND RESISTANCE

Human lung cancer is a complex disease resulting from a series of inherited and somatically occurring defects in several critical genes. The genetic changes include mutations, deletions, and amplification of genes coding for proteins involved in fundamental regulatory functions such as signal transduction, nuclear transcription, cell cycle regulation, and apoptosis. Although such genetic alterations are fundamental to many aspects of lung carcinogenesis and may provide the basis for a rational approach to primary and secondary prevention, many attempts have been made to relate molecular features to prognosis and/or to response to radiotherapy and chemotherapy. Can specific genetic alterations be shown to be associated with radiation resistance? The data are not consistent on this question. This section intends to briefly review the major molecular biologic advances in lung cancer made during the last few years and relate such information to clinical oncology. Particular effort is made to interweave these advances with our understanding of radiation biology.

p53

p53 gene mutation is the most common genetic alteration found in human cancers (see also Chapter 6).[219] *p53* is a tumor-suppressor gene linked to control of gene expression, cell cycle arrest at G1 by activation of p21 (an inhibitor of cyclin-dependent kinases) and GADD45 (an effector of growth arrest and DNA repair), and control of cell proliferation and apoptosis. [220] In lung cancer, *p53* is mutated in up to 80% of SCLC and 50% of NSCLC.[221] Fujino et al. showed p53 alterations to correlate with poorer prognosis in surgically resected NSCLC patients. [222] Moreover, their study demonstrated that the *p53* status was a strong predictor of survival in p21-ras negative patients. In fact, patients with altered expression of *p53* had a 43% five-year survival rate as compared to 87% in those patients without *p53* mutation.

A correlation between *p53* status of the tumor and response to gamma radiation or adriamycin *in vivo* has been demonstrated. It was found that the loss of *p53* function in tumors growing in immunocompromised mice was associated with resistance to both ionizing radiation and adriamycin treatment. [223] The loss of *p53* function probably suppresses the apoptotic signals that are activated chemically or physically by antineoplastic agents. Consistent with this view, Chang et al. have shown that transfection of a normal *p53* gene into cell lines with *p53* mutations restores the normal G1 checkpoint and the apoptotic pathway and sensitizes the cells to radiation.[224] However, it is not clear at present exactly how *p53* influences radiosensitivity. No relationship has been found between radiosensitivity and *p53* status among 24 head and neck cancer cell lines. [225] Likewise, abrogation of *p53* function by HPV16 E6 gene does not influence radiosensitivity. [226] More recently, a relationship between the ataxia telangiectasia (AT) gene product and *p53* activation in response to ionizing radiation has been shown. [227] The relationship between AT and *p53* suggests a potential mechanism underlying the exquisite susceptibility of AT patients to ionizing radiation and provides yet another instance of the importance of *p53* in determining the radiosensitivity of a cell.

Ras

Ras (K-*ras*, homologous to Kirsten murine sarcoma virus oncogene; H-*ras*, homologous to Harvey murine sarcoma virus oncogene; and N-*ras* isolated from a neuroblastoma cell line) codes for a 21 kilodalton protein (p21) with high homology to G-proteins that function in signal transduction and cell proliferation (see also Chapter 4). Point mutation at codon 12, 13, or 61 of the *ras* gene confers transforming potential to p21.[221] Although virtually absent in SCLC, mutated *ras* genes are found in approximately 20% of *in vivo* NSCLC tumors and NSCLC-derived cell lines. *Ras* mutations are more commonly found in adenocarcinoma (~30%) than in squamous and large cell carcinoma (~10%). A negative prognostic correlation in surgically resected NSCLC patients has been found for ras gene mutation or overexpression.[228] As noted previously, combining information about *p53* and *ras* status is helpful in more accurately defining the subset of patients at risk and possibly, in the future, defining the best choice of treatment modality. [222]

When mutated *ras* genes were transfected in murine fibroblast cell line NIH3T3, resistance to ionizing radiation was conferred. The implication of this acquired radiation resistance is that *ras* has an important function in the response to the physicochemical insult of ionizing radiation. [229] McKenna and colleagues, using a primary rat embryo cell (REC) model, suggested that transfection of H-*ras* oncogene alone conferred little alteration in radiation resistance, whereas the presence of a co-transfected cooperating oncogene (v-*myc*) induced a dramatic increase in radioresistance.[230,231 and 232] It was further suggested that increased radioresistance may be caused partly by cell cycle perturbation. The transfected cells had a more prolonged G_2 than sensitive cell lines.[233] A similar finding was reported by Su and Little when human fetal fibroblast cells were transfected with activated *ras* oncogene and or simian virus 40 T-antigen. [234] However, these results need to be interpreted with

caution because transfection of REC and human cell lines with nononcogenic DNA sequences alone (pSV2neo, encoding only for neomycin resistance) and subjecting them to subsequent clonal selection, can also yield clones with increased resistance to radiation. [235] Likewise, considerable heterogeneity in radiation response exists among different clones of the NIH 3T3 cells as used by Sklar, such that when *ras, raf,* and *myc* genes were transfected, no clear modification of radiation sensitivity was attained when compared to the nontransfected parent lines. [236] Harris et al. used a temperature-sensitive rat kidney epithelial cell containing k-*ras* and found *increased* radiosensitivity with *ras* activation.[237] More recently, human tumor cell lines with mutations in H- or K-*ras* genes were radiosensitized after treatment with prenyltransferase inhibitors that prevent posttranslational modification of *ras,* required for its activity. [238] The use of prenyltransferase inhibitors in radiation oncology is presently undergoing phase I clinical trials.

ErbB 2

erbB 2 gene encodes a transmembrane glycoprotein receptor having homology with the epidermal growth factor receptor (see also Chapter 4). *ErbB 2* has a constitutive tyrosine kinase activity that is pivotal in the protein's function in growth regulation. [239] *ErbB 2* has been shown to confer the transformed phenotype to murine fibroblasts NIH3T3 *in vitro,*[240] and overexpression of *erbB 2* has been shown in lung cancer.[241] Immunohistochemic expression of *erbB 2* was detected in approximately 50% of lung adenocarcinomas.[242] As in the case with p53, *erbB 2* expression along with K-*ras* mutation has been associated with a poorer prognosis in lung adenocarcinoma patients.[243] Although *erbB 2* has not yet been defined as a treatment determinant in lung cancer, in early-stage breast cancer it has been shown that the presence of the *erbB 2* oncogene, p53 status, and the number of positive lymph nodes correlate with response to adjuvant chemotherapy and radiotherapy. [244]

Myc

Myc, a phosphoprotein with transcriptional regulatory activity, is involved in the control of development and growth of the normal cell (see also Chapter 5). C-Myc, of cellular origin and homologous to the *v-myc* oncogene of the avian myelocytic leukemia virus, has been found to be overexpressed in several neoplasms. Although overexpression of myc family genes: c-*myc,* n-*myc* (from neuroblastoma), and l-*myc* (from lung), has been found in approximately 20% of SCLC, being more common in pretreated patients, it is an uncommon finding in NSCLC. The presence of myc has been associated with more aggressive malignant behavior and poorer prognosis.[245] Transfection of c-*myc* into a human melanoma cell line has been shown to confer increased sensitivity to ionizing radiation. Interestingly, the opposite effect was found when myc was co-transfected with ras in the same cell line. [246]

Retinoblastoma

Retinoblastoma (RB) tumor suppressor gene product is a nuclear protein that in the dephosphorylated form acts negatively on cell cycle progression and holds the cell in the G_0-G1 phase (see also Chapter 2, Chapter 7). In a normal cell, Rb is phosphorylated by a complex cyclin D1-CDK4 (cyclin-dependent kinase 4) to allow the progression of the cell cycle to mitosis. This mechanism is complemented by p16, a product of cdkn2 gene, that inhibits the phosphorylation of RB by the complex cyclin/CDK. P16 expression is upregulated by the phosphorylated form of RB, the result of which is a feedback-type control. RB, cyclin D1, and p16 constitute the RB pathway. Alteration of any part of the pathway seems to play an important role in NSCLC tumorigenesis. In fact, loss of Rb was found in 42 of 101 (41.6%) NSCLC specimens, and disturbances in expression of at least one of the three components of the Rb pathway were found in 91 of 101 (90%) NSCLC specimens. [247] In other studies, altered *RE* gene has been found in 32% of NSCLC patients and 13% of SCLC primary tumors.[248] The absence of the Rb mRNA transcript was common in SCLC specimen and cell line.[249]

Correlation between expression of Rb and sensitivity to carboplatin and VP-16 has been shown in NSCLC cell lines. [250] In this study, the cell lines having higher expression of *RE* gene were more sensitive to the antineoplastic drugs. Interestingly, an inverse correlation was found for radiosensitivity in an *in vitro* study on non-Hodgkin's lymphoma cell line and in a clinical study on patients with bladder cancer. Both of the latter studies, in fact, show a negative correlation of Rb expression with response to radiation. Rb overexpression appeared to be associated with more resistance to ionizing radiation in an *in vitro* model.[251] Consistent with this study, a better response rate to radiotherapy was found in patients whose tumors were immunohistochemically negative for Rb protein. [252]

BCL2

BCL2 gene is an oncogene that was first identified in follicular lymphoma in which a translocation resulted in overexpression. [253] The BCL2 protein is an inhibitor of programmed cell death or apoptosis.[254] BCL2 overexpression is very common in SCLC (~75%)[255] and is found in approximately 25% of NSCLC, where it has been proposed as prognostic factor.[256] However, a study of 427 NSCLC cases showed BCL2 expression not to be an independent prognostic factor.[257] A recent study suggests that BCL2 expression may be a favorable prognostic indicator in some subgroups of patients, such as those having stage IIIa disease. [258] *In vitro* studies have associated BCL2 overexpression with radiation resistance.[259] Transgenic mice ubiquitously overexpressing BCL2 are more resistant to the lethal bone marrow effects of ionizing radiation, and lymphocytes that survive radiation in wild-type mice show higher levels of BCL2 expression. [260]

The evolving paradigm regarding tumorigenesis and ultimate treatment offers a vision of genetic determinism. However, at this time, our molecular biology knowledge is not yet at the level to provide general deterministic views with regard to therapeutic decisions. What may be required is a genetic determination of an array of expressed mRNAs, which will hopefully enable a better understanding of the complex relationship of a particular oncogene or tumors suppressor gene to other expressed genes within an individual tumor. Certainly, our technology is moving in that direction. It is assumed that as our knowledge grows, the role of oncogenes and tumor-suppressor genes in the context of tumor physiology will not only affect tomorrow's radiotherapy decisions, but will also define how to weave radiobiologic principles with molecular biology to arrive at optimal, curative therapy.

SUMMARY

This chapter has summarized the major areas of radiobiology as they relate to lung cancer. Future advances in the management of this disease will likely emerge from continued basic and applied research. Particularly exciting are the recent advances in molecular biology and their application to the understanding of the pathogenesis and treatment of lung cancer. Radiation continues to be one of the most active agents in the management of this disease. As the field of radiation biology incorporates novel molecular techniques, further advances will likely ensue.

TREATMENT-RELATED LUNG DAMAGE

ELIZABETH L. TRAVIS
RITSUKO KOMAKI

Radiation therapy is an integral part of the treatment and management of lung cancer. More than 50% of patients with lung cancer receive radiation at some point during the management of their disease. Because these patients generally require the treatment of a large volume of lung to high doses, definitive radiotherapy of lung cancer requires the use of total doses that result in late sequelae. These late sequelae were observed as early as the 1920s, less than two decades after the discovery of x-ray.[1] The two phases of lung damage—radiation pneumonitis and radiation fibrosis—were first described in 1925 by Evans and Leucutia, who divided the damage into these now well-recognized sequelae of lung irradiation.[2] Although almost a century of studies in patients and experimental models has provided a wealth of information on these two potentially fatal complications, we remain unable totally to circumvent these untoward reactions. Both pneumonitis and fibrosis continue to limit the effective use of radiation in the treatment of malignant tumors of the lung.

Despite the fact that only three years have passed since the first edition of this book was published, significant advances have been made in understanding the genetic regulation and molecular basis of radiation-induced lung damage. In addition, the radiation dose-volume effect in mouse lung has been clearly defined, with substantiation of the experimental findings by clinical studies. As 3D conformal therapy has become the norm for treating lung cancer, new methods of estimating the risk of pulmonary injury from dose-volume histograms and normal tissue complication probability models have been developed. The goal of this chapter is to update the information specifically in these areas as well as to present new data regarding the development of quantitative and easily accessible markers of lung damage and predictive assays of pulmonary radiosensitivity.

In this chapter all the data, unless otherwise stated, will be from studies on normal nondiseased lungs, although preexisting lung disease in patients may have a significant impact on the effects of radiation or drugs on response.

DAMAGE VERSUS MORBIDITY

Damage and morbidity are terms which are frequently interchanged but, although related, they actually reflect different concepts. In clinical practice, the radiation oncologist accepts some structural lung damage, either pneumonitis or fibrosis, because of the large functional reserve of this tissue. Functionally, the whole organ does not fail if some part of it is destroyed. Morbidity is a clinical term that describes how an individual patient feels and/or how well a specific organ functions. The morbidity of treatment is determined by many factors, including the damage incurred by the tissue, the impact of this damage on organ function, and the impact of both of the above on the patient's well-being and lifestyle. Because of the functional reserve of the lung, structural damage is not necessarily reflected in clinical morbidity as assessed by whole-lung function.

The dissociation between damage and morbidity in the lung reflect the organization of those anatomical units responsible for lung function.[3] Morbidity is a reflection of two parameters: (a) the survival of sufficient numbers of cells to maintain tissue function, and (b) the organization of these cells into units that carry out tissue function. The spatial relationship between these functional subunits differs between tissues and is a critical determinant of the relationship between damage and any resultant morbidity. Anatomically, the lung is a system of branching ducts and accompanying blood vessels that ultimately terminate in the alveoli, the site of gas exchange. The functional subunit in the lung is most likely the acinus, which is structurally well defined, beginning at the ramification of the terminal bronchiole to the respiratory bronchioles and terminating in the alveolar sac, each of which bears numerous alveoli. Each acinus is a self-contained entity independent of its neighbor. It is suggested that the destruction of one acinus will have no measurable effect on lung function in a normal healthy lung and that functional damage, particularly total lung function, will be manifested only when a critical number of these units are destroyed. A useful analogy is a strand of Christmas tree lights arranged in parallel. When one burns out (damage), none of the others are affected and the overall effect is not diminished, that is, the damage is below the threshold of the human eye to distinguish it (no morbidity). However, when sufficient numbers of lights burn out such that this is noticeable (the threshold for damage in the human eye is now exceeded), the overall effect is diminished (morbidity occurs).

Many assays are available to quantify radiation-induced morbidity and damage in the lungs of experimental animals and in patients. In humans, regional pulmonary function tests or radiographic evidence of pneumonitis and fibrosis can be quantified, providing a scoring system for damage.[4,5,6,7,8,9,10,11,12 and 13] In rats and mice, the experimental animals most commonly used to study radiation and drug-induced lung injury, measurements of regional lung function are difficult and pulmonary function tests most often assess total lung function, a measure of morbidity.[14,15,16,17 and 18] Whereas in patients structural damage can be quantified by noninvasive methods, for example CT scans, assessment of such damage in small experimental animals is most often performed on autopsy specimens. In this chapter, clear distinctions will be made between damage and morbidity and the assessment of each.

RADIATION-INDUCED LUNG DAMAGE

Pathophysiology of Radiation-Induced Lung Injury

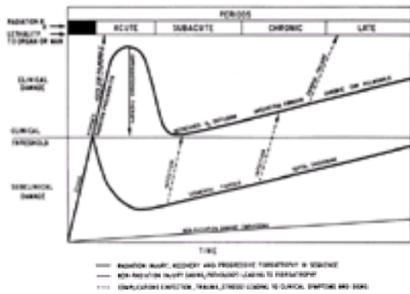
Radiation damage in the human lung has four well-described clinical phases: a phase of acute injury termed radiation pneumonitis, a subacute phase, a chronic phase characterized by lung fibrosis, and a late phase (Figure 13.1).[19,20,21,22 and 23] Two of these phases of damage are clearly separated in time; pneumonitis occurs from three to six months after the beginning of treatment, while fibrosis occurs from one year onward. Both pneumonitis and fibrosis have been well defined histopathologically under controlled conditions in animals. However, because animals can be studied at predetermined times after irradiation, an earlier phase of damage that is asymptomatic has been defined—the latent phase.[19,22,24] Thus radiation lung injury consists of distinct phases characterized by differences in time of expression after irradiation and distinct histologic and/or molecular changes.


FIGURE 13.1. The clinical course of radiation induced pulmonary damage consists of four phases, each having distinct pathologic and clinical signs and symptoms. These changes are dependent on dose, as depicted in the upper curve (high dose) and the lower curve (low dose). The changes in the acute phase after high doses are those generally associated with radiation pneumonitis, while those occurring during the chronic and late phase are associated with pulmonary fibrosis. After low doses, the pathologic changes are subtle, consisting mostly of interstitial fibrosis which is usually not sufficiently severe to cause clinical symptoms. (From Rubin P and Casarett GW, eds, *clinical radiation pathology,* W.B. Saunders Company, 1968; 459, with permission.)

Latent Phase

The weeks to months preceding the overt appearance of radiation pneumonitis is referred to as the "latent" period because no overt histopathologic, radiographic, or clinical signs and symptoms of radiation damage can be observed. In most cases, overt pulmonary reactions are not expressed either clinically or histologically in human and animal models for the first three months after irradiation, regardless of the volume of lung irradiated, although in humans, damage may be expressed as early as two months after initiation treatment. Although no changes can be observed at the light microscopic level during this "latent" time, electron microscopy reveals degranulation and loss of Type II cells with attendant loss of surfactant, loss of basal laminar proteoglycans resulting in swelling of the basement membrane, and transudation of proteins into the alveolar spaces indicating increased capillary permeability and suggesting a loss of endothelial cells within the first month after whole-lung irradiation.[20,22,23] Endothelial cells themselves become vacuolated and pleomorphic and may slough, leading to denudation of the basement membrane and changes in capillary permeability.[25] Although these changes are dose-related and diffuse throughout the lung, they are not in themselves sufficiently severe to result in death during this time. Deaths do not occur before there is overt histologic damage.

It had been generally accepted that a series of biochemical events was occurring during this latent phase that ultimately culminated in the overt expression of damage in the next phase of lung injury, pneumonitis, although none had been identified. The advent of new molecular techniques and tools has shown that dramatic changes do occur during this period and, depending on the dose, may resolve or may progress to the next phase of radiation pneumonitis, which produces overt signs and symptoms. These molecular changes in the lung will be discussed later in this chapter.

"Classical" Pneumonitis

Structural changes in the lung appear within the first six months after irradiation of all or part of the lung of humans or experimental animals, resulting in diffuse alveolar damage.[1,19,22,24] Although this phase of damage occurs relatively long after lung irradiation, histologically it is an acute effect which is characterized by a prominent inflammatory cell infiltrate consisting of macrophages, lymphocytes, and mononuclear cells in the air sacs and in the pulmonary interstitium, the latter of which is normally devoid of cells.[3,19,20,21,22,23 and 24] The neutrophil is not a dominant cell in this inflammatory cell infiltrate in animal models. Although loosening and widening of the interstitium indicates interstitial edema, only after high doses is edema observed in the air spaces. When the whole of both lungs is irradiated in humans or experimental animals, the damage is diffuse and, if sufficiently severe, can be fatal.

This acute phase of damage in the lung is generally referred to as pneumonitis, a term that usually refers to an inflammatory reaction in the lung caused by local growth of bacteria, fungi, or parasites. In such situations, the cellular infiltrate contains polymorphonuclear leukocytes, a cell type rarely found in the "sterile" inflammatory infiltrate in the irradiated lungs of experimental animals. When present, these cells are indicative of a superimposed infection and the cause of death is unclear, that is, radiation or infection or both. Perhaps a more appropriate term for this phase of diffuse alveolar damage following lung irradiation is "alveolitis," which pathologically refers to an inflammatory reaction not caused by a microorganism.[26] Although an inflammatory cell infiltrate in the interstitium and the air sacs is a prominent component of radiation alveolitis, the relative contribution of these inflammatory events versus direct tissue injury from radiation in the pathogenesis of this syndrome is unclear.

In mice, pneumonitis begins at three months after radiation is administered and persists for up to six months, with the majority of deaths occurring between four and five months. The latent time for the appearance of damage is dose-dependent, appearing sooner after high doses than after low doses. To account for the dose-dependent difference in latent time and to include all responders in the assay, the standard time for scoring deaths from pneumonitis is between three and seven months in animal experiments. Techniques used to quantify this phase of lung damage in experimental animals include functional assays such as breathing rate[14,15,18] and CO uptake,[16] CT scans,[17] quantitative morphometry,[24,27] and of course, lethality from the syndrome.[3] These assays provide steep dose-response curves from which estimates of effect dose for a given severity of injury can be obtained. Generally, the Effect Dose 50 (ED50) or lethal dose that kills 50% of the population (LD50) is used. Estimates of the LD50 for radiation pneumonitis occurring between three and six months after whole-lung irradiation in mice range from 9 to greater than 16 Gy in mice, depending on the mouse strain. In the clinic, the use of large single doses to the upper-half body or the whole body has provided dose-response data for radiation pneumonitis in humans. Using incidence of pneumonitis[28,29,30 and 31] or computed tomographic (CT) scans[9,32] to quantify the increase in lung density in patients, the shape of the resultant dose-response curves for lung damage in humans is similar to those for mice. The ED50 for pneumonitis in humans, 9 to 10 Gy, is within the range of LD50s for pneumonitis measured for different mouse strains, although on the low end of the range. Although treatment of lung cancer can involve irradiation of large volumes of lung, rarely is the whole lung irradiated, and thus fatal pneumonitis occurs infrequently. However it is estimated that at least 5% to 15% of irradiated patients will develop clinical signs of pneumonitis, with an even higher proportion, 50%, showing lung changes consistent with pneumonitis on computed tomographic scans.

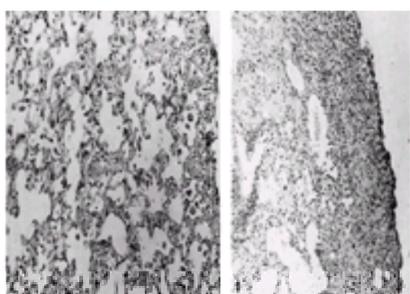
The diffuse alveolitis described above had been considered characteristic of the acute phase of radiation-induced lung damage in humans and animals, but histopathologic differences between mouse pneumonitis and human pneumonitis could not be explained. For example, a characteristic histologic finding in irradiated human lung is the presence of hyaline membranes. Unlike in mice, which do not develop fibrosis during the pneumonitis phase, focal areas of fibrosis have been reported in patients within the first month or two after lung irradiation, the time generally associated with the infiltrative, exudative lesions of radiation pneumonitis. These discrepancies between mice and humans have been partially resolved by the recent studies of Sharplin and Franko[27] that showed that the pathologic lesion of the acute phase was dependent on the strain of mouse used. For example, mice of the C3H and CBA strains showed a classical diffuse alveolitis (pneumonitis) with no evidence of fibrosis, while the C57B16 strain exhibited protein-rich edema, hyaline membranes, and focal fibrosis, with few of the changes characteristic of pneumonitis (Figure 13.2). These data indicate that the choice of mouse strain is critical in studies of radiation lung damage; mouse strains used to study pneumonitis would be different from those chosen to study fibrosis.


FIGURE 13.2. Characteristic changes in the lungs of C3Hf/Kam (**A**) mice and C57/BL6 (**B**) mice after equivalent single doses of radiation or cobalt-60 gamma rays to the whole thorax. The C3H mouse was sacrificed at 3.5 months because of overt signs of severe respiratory distress; the C57 mouse was sacrificed at 5 months. The lungs of the C3H mouse show a classic radiation alveolitis (pneumonitis), while the lungs of the C57 mouse show collapsed atelectatic alveoli with collagen superimposed—alveolitis is not a feature.

Intermediate Phase

If the dose is low or if less than a critical volume of lung is irradiated, the acute pneumonitis phase resolves. Although little data on this phase are available in patients, it has been characterized in irradiated mouse lung. [24] In those mice that survive the acute pneumonitis phase, lung function, as measured by breathing rate, improves. The lungs are not totally normal however, and foci of foamy macrophages are the dominant finding in the air spaces, along with hyperplasia of Type II epithelial cells. However no deaths occur during this phase of damage. Thus this phase appears to be one of resolution of the early exudative alveolitis.

Radiation Fibrosis

In contrast to the acute alveolitis, the chronic effects of radiation in humans are observed from months to years later, even though biochemical and histologic changes occur months earlier. Pulmonary fibrosis develops insidiously and may stabilize after one or two years. Although numerous studies have attempted to elucidate the mechanism(s) leading to pulmonary fibrosis, the pathogenesis of this late lung response remains elusive and controversial.

Pulmonary fibrosis is the end stage of a complex process of abnormal repair of damage that may be preceded by an inflammatory response dominated by macrophages and lymphocytes. It is generally accepted that radiation-induced lung fibrosis is the repair process that follows radiation pneumonitis, or radiation alveolitis. Fibrosis of the pulmonary parenchyma may occur as a diffuse or focal lesion, but the designation of pulmonary fibrosis is usually reserved for diffuse or widespread multifocal collagen deposition involving the peripheral airspaces. Although frequently referred to as interstitial fibrosis, collagenous thickening of alveolar walls is often a consequence of incorporation of organizing intra-alveolar exudate into the interstitium and subsequent reepithelialization, leading to a revision of alveolar architecture. In fact, it is frequently suggested that severe exudative alveolitis of long-standing duration results in a generalized fibrotic thickening of the alveolar septa. [26,33] Loss of pulmonary function results from focal microcollapse of alveoli and apposition of alveolar walls, leading to irreversible remodeling of pulmonary architecture.

Although data from lung irradiation studies in mice indicate that pneumonitis and fibrosis are directly related, [24,34,35 and 36] other data, also in murine models, show that these two sequelae of lung irradiation can be dissociated from each other, and radiation-induced lung fibrosis can and does occur without a preceding inflammatory event.[37,38 and 39] These studies suggest that this phase of injury may result from different pathogenic mechanisms.

The exact form of lung fibrosis that occurs after lung irradiation has been shown to be dependent on the strain of mouse. In the initial studies of radiation-induced lung damage, mice were terminated at seven months after irradiation, when the pneumonitis phase of damage ended. However, in later studies, mice surviving at seven months were followed for periods of up to a year after thoracic irradiation. When sacrificed, a diffuse thickening of the alveolar septa was observed in these mice that was characterized by collagen deposition.[37,38] The air spaces were clear, and patent and pulmonary architecture was preserved, although the lung was stiff. Recently, Sharplin and Franko[27,40] reported that radiation-induced lung fibrosis in mice is not always manifested as a diffuse thickening of the alveolar septa, but that some strains exhibit atelectasis accompanied by collagen deposition in the collapsed area, resulting in a focal contracted scar. In this form of lung fibrosis, alveolar architecture is obliterated. We too have found a difference in the fibrotic lesions in irradiated mouse lung, with the C57B1/6J mice exhibiting collapsed atelectatic alveoli with superimposed collagen, while the C3H strain shows a more diffuse fibrosis of the alveolar walls and small stellate scars surrounded by patent alveoli. [41] Unlike in the C57B1 mice, where the collagen appears in organized bundles, making it easily distinguishable on light microscopy with collagen-specific stains, the initial deposition of the collagen as fine, wispy fibrils in the alveolar wall of the C3H mouse make this type of fibrosis more difficult to resolve with the light microscope. In addition to distinct histological features, these two forms of fibrosis are distinguished further by the time they appear in the two strains after irradiation. Fibrosis in the C57 strain occurs within the first six months after irradiation, the period during which only pneumonitis is found in the C3H strain. In the latter strain, fibrosis of the alveolar walls does not occur until nine months (or later) after irradiation.

The suggestion from these mouse studies that radiation-induced pulmonary fibrosis may not have a uniform pathogenesis is consistent with the suggestion that there may be three different pathways to lung fibrosis which may be dependent on the toxic agent: *luminal fibrosis,* in which granulation tissue buds into the air spaces; *mural fibrosis,* in which exudate is incorporated into the alveolar walls; and *atelectatic induration,* which involves partial or complete collapse of alveoli and permanent apposition of alveolar walls followed by fibrous tissue proliferation and collagen deposition in the area. [26] Franko and colleagues have suggested from breeding studies in inbred strains of mice that radiation-induced lung fibrosis results from two independent pathways which may involve different genes. [42] Further support for the hypothesis that multiple mechanisms lead to pulmonary fibrosis comes from the colon, in which it has been shown that two distinct types of fibrosis occur after irradiation, possibly as a result of two distinct mechanisms. [43]

Most studies in mice irradiated the whole lung, which is not the standard procedure for treating lung cancer with radiation, where a limited volume of lung is irradiated. Thus the question remains of the relevance of these data from experimental animal models to the treatment of lung cancer in humans with radiation. For example, hemithoracic irradiation in mice and rats does not produce the mortality and morbidity of whole-lung irradiation, due to hypertrophy of the contralateral lung, but the mechanisms of collapse and fibrosis of the irradiated lung may differ from those that occur after whole-lung irradiation. In the kidney, a paired organ like the lung, it was found that nephrectomy one day after bilateral kidney irradiation induces a proliferative response in the remaining irradiated kidney that results in a partial restoration of kidney function compared to that in irradiated nonnephrectomized mice. [44] Although it is important to be aware of these differences between animal experiments with radiation and treatment of humans for lung cancer, the clinical data indicate that similar-appearing damage occurs in humans and in mice after lung irradiation, supporting the use of these animal models for mechanistic studies. Most importantly, the studies in mice that defined a strain dependence for the form and severity of radiation-induced lung fibrosis suggest that this late sequelae of lung irradiation may be genetically regulated. Identifying, mapping, and cloning the gene(s) for radiation-induced lung fibrosis could provide a means to identify "sensitive" individuals in the population before treatment commenced.

The characteristic findings in each of these four phases of lung damage are summarized in Table 13.1.

TABLE 13.1. PRINCIPAL HISTOPATHOLOGIC ABNORMALITIES AFTER IRRADIATION OF THE THORAX IN ANIMALS

Sporadic Radiation Pneumonitis

In humans, anecdotal reports of pneumonitis occurring outside the irradiated area have been reported for a number of years. [45,46,47 and 48] Since one of the characteristic

features of classical radiation pneumonitis is that the damage is confined to the irradiated area, it has been suggested that the clinical and radiologic picture of radiation damage outside the irradiated field represents a hypersensitivity pneumonitis. First suggested by Holt in 1964, [49] this syndrome has been given little attention for two reasons: it occurs rarely, and in most of these cases, the contralateral lung received some dose, although the actual quantity was unknown. Three factors suggest that this clinical syndrome may be different from the classical form of radiation induced lung damage: (a) it affects 10% to 15% of patients; (b) symptoms frequently resolve without sequelae; and (c) it frequently develops earlier than classical pneumonitis, that is within two to six weeks after the completion of therapy. In an extensive study of four breast cancer patients who developed bilateral changes after radiation confined solely to one lung, Gibson and colleagues [50] found that bronchoalveolar lavage (BAL) of the irradiated and nonirradiated lung showed a marked lymphocytosis in both the irradiated and nonirradiated lungs. Gallium scan confirmed these BAL findings, showing increased gallium uptake in both irradiated and nonirradiated lungs. In all four patients prompt symptomatic improvement was seen after corticosteroid administration. Based on these data, these authors concluded that the finding of abnormalities in both the irradiated and nonirradiated fields equally was not consistent with simple direct radiation-induced damage but implied an immunologically mediated mechanism such as a hypersensitivity pneumonitis.

More recently, Morgan and Breit have challenged the idea that bilateral radiation pneumonitis after unilateral lung irradiation is a relatively infrequent occurrence in the practice of radiotherapy. [51] These authors contend that the extreme dyspnea experienced by patients with radiation-induced pneumonitis appears out of proportion to the volume of lung irradiated and cannot be explained on the basis of localized tissue destruction. In a prospective study of 17 breast cancer patients, BAL analysis and gallium scans showed a diffuse lymphocytosis, increased gallium scan uptake, and decreased alveolar volume and vital capacity in both the irradiated and nonirradiated lung. Further analysis of the lymphocyte infiltrate in a patient with clinical radiation pneumonitis showed that these cells were almost exclusively recently activated CD4+ helper T-cells, cells that have been implicated in hypersensitivity pneumonitis after other insults. In a further analysis of these patients plus an additional five patients studied only after they developed clinical features of pneumonitis, these authors found no statistically significant difference between BAL findings on the irradiated and unirradiated sides of the chest either pretreatment or posttreatment and with or without clinical pneumonitis. Although bilateral lymphocytosis was found in 75% of the study population (13 of the 17 patients), only two (10%) of these patients developed clinical features of radiation-induced pneumonitis. Symptoms resolved spontaneously in the other 65% (11) patients. The remaining 25% did not develop subclinical or clinical symptoms. On the basis of these findings, these authors suggest that bilateral involvement of both lungs after irradiation of one lung represents an immune-mediated hypersensitivity pneumonitis which leads to the clinical picture of radiation pneumonitis in only 10% of the irradiated population. Because this syndrome appears to be due to an entirely different pathogenetic mechanism from classical radiation pneumonitis, these authors suggest that this form of radiation-induced lung damage be distinguished from the classical form and be called "sporadic radiation pneumonitis." What distinguishes this type of lung damage from the classical type is that it occurs in an unpredictable manner and involves unirradiated portions of the lung.

At this time, an animal model for sporadic radiation pneumonitis has not been identified. However, in a study of CT changes after irradiation of only the right lung of rats, Geist and Trott observed fluctuations in the radiological density in the shielded left lung of the irradiated rats that were greater than those observed in control rats and parallel to those occurring in the irradiated right lung, similar to the sporadic pneumonitis in humans. [52] In contrast to these data, it has been reported that irradiation of one lung of rabbits resulted in a decrease in the number of alveolar macrophages in only the irradiated lung. The number of alveolar macrophages in the contralateral unirradiated lung was not decreased. [53]

Pathogenesis of Radiation-Induced Lung Damage

Target Cells. It has been hypothesized that killing and depletion of a critical "target" cell by radiation in the lung is the initiating event leading, after a "latent" period, to the late sequelae of pneumonitis and fibrosis. [54] In addition, it has been generally accepted that the expression of radiation damage requires cell division. In tissues like the lung, therefore, in which damage is not overtly expressed for months after treatment is completed, the long latent time was thought to be due to a slowly proliferating target cell population. For these reasons, a major research focus has been to identify the target cell(s) for radiation-induced lung damage, with the intention of protecting this cell from radiation damage and thereby preventing or, at least minimizing, the severity of radiation-induced pneumonitis and fibrosis while not compromising tumor cell kill and tumor control. The two most likely target cells were thought to be the Type II cell [19,55,56,57 and 58] and the vascular endothelial cell. [19,59,60,61,62 and 63] The Type II cell was shown to divide more frequently than other types of lung parenchymal cells; it is responsible for synthesizing, storing, and secreting surfactant, the surface active material that prevents alveolar collapse. The vascular endothelial cell also was a reasonable target cell candidate because it too was believed to divide more quickly than other cell types in the lung. Furthermore, edema is a consistent finding in the interstitium and air spaces after lung irradiation, indicating vascular leakage, which in turn implies radiation-induced killing and depletion of vascular endothelial cells.

Type II Cells as the Target. The first evidence that supported the hypothesis that Type II cells were the target cells for radiation pneumonitis was published in 1982 by Shapiro and associates. [58] These investigators showed that local irradiation of both lungs of mice with a range of single doses of x-rays produced dose-dependent changes in phospholipids in lung lavage fluid and in lung tissue as early as 24 hours after irradiation. These changes persisted for the first four weeks after irradiation, indicating that changes in the function of Type II cells occurred long before tissue damage was manifested at the light microscopic level. Although the relationship of these early events to the later incidence of pneumonitis and fibrosis was unclear, these data were the first demonstration that the latent period was not really quiet or latent at all. These investigators then sought to identify biochemical markers of surfactant that could be assessed in patients early during a course of radiotherapy prior to the onset of clinical and pathologic pneumonitis, with the aim of identifying patients at a high risk of developing severe radiation pneumonitis. [57] Their finding in rabbits that surfactant apoprotein in the serum was an accurate predictor and marker for radiation pneumonitis has led to a clinical trial in lung cancer patients. Blood is collected before treatment, weekly during treatment, and one week after treatment, and surfactant apoprotein is quantitated in the serum. These data will be compared with the incidence and severity of radiation pneumonitis and fibrosis assayed by CT scans every three months after treatment and by chest radiograph at one year.

Endothelial Cells as the Target. The suggestion that vascular damage was the underlying mechanism of radiation pneumonitis and fibrosis was based primarily on the hypothesis that the lung cell most likely to divide soon after irradiation was the capillary endothelial cell. The parenchymal cells, most importantly the Type II cells, were believed to be more slowly dividing than the endothelial cell. This hypothesis was substantiated by the pathologic findings in humans and experimental models that pneumonitis after irradiation was characterized by edema in the air spaces and interstitium, and an inflammatory cell infiltrate. Among the many studies aimed at elucidating the role of the vasculature in radiation-induced lung damage, Ward and colleagues [64,65 and 66] performed comprehensive studies that correlated changes in four parameters of endothelial function, angiotensin-converting enzyme activity, plasminogen activator activity, and prostacyclin and thromboxane production, with histopathologic and ultrastructural changes in rat lungs irradiated with the same doses, as well as changes in one vascular functional assay—arterial perfusion. These studies showed that dose-dependent changes occurred in all endothelial functional parameters and that these functional changes agreed well with pathologic changes in the lungs of these rats. These data suggest that changes in vasculature do occur after lung irradiation, but they do not necessarily implicate the endothelial cell as the target cell.

MOLECULAR BASIS OF RADIATION-INDUCED LUNG DAMAGE

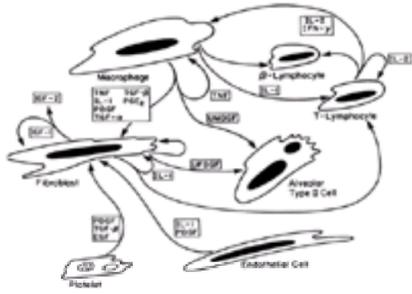
It is obvious that changes in both the pulmonary parenchyma and pulmonary vasculature contribute to radiation pneumonitis and fibrosis, and that these sequelae of lung irradiation arise from a dynamic interaction between different cell types, the major players including both the Type II pneumocyte and the endothelial cell, as well as the fibroblast, macrophages, and lymphocytes, as shown in Figure 13.3.[67,68] However, the concept that one or more target cells are solely responsible for radiation-induced pneumonitis and pulmonary fibrosis has been replaced by the paradigm that it is not only cells but the messages that these cells produce that determine the final outcome. It is now well established that radiation is one of many insults that cause the release of trophic factors that subsequently act through a variety of pathways to produce the end pathologic stage of radiation pneumonitis and fibrosis. [69,70 and 71] These messages are delivered via diffusion of soluble mediators over short distances, which may have been secreted by one population of cells and then act locally upon another population, referred to as paracrine stimulation, or upon the same population, known as autocrine stimulation, or which may involve membrane-associated molecules activating receptors on adjacent target cells, referred to as juxtacrine stimulation. These soluble mediators, or cytokines or growth factors, are currently recognized as playing an important part in stimulating cells to overproduce those extracellular matrix components that characterize fibrosis [69,70,71,72,73 and 74] Following their initial contact with the cell surface, these molecules are postulated to activate intracellular signaling pathways, which in turn lead to activation of a pleiotropic genetic program characteristic of the fibrotic response. This activation is thought to bring about changes in the expression of specific genes that determine the phenotype of cells involved in the healing of lung injury.


FIGURE 13.3. Diagram of hypothesized interaction of different lung target cells and cytokines and growth factors in the development of alveolitis and fibrosis. IGF, insulinlike growth factor; TNF, tumor necrosis factor; TGF, transforming growth factor; IL, interleukin; PDGF, platelet derived growth factor, EGF, epidermal growth factor; PGE, prostaglandin E2; UMDGF, UFDGF. (From King RJ, Jones MB, Minoo P. Regulation of lung cell proliferation by polypeptide growth factors. *Am J Physiol* 1989;257:23, with permission.)

Perhaps the cytokine most frequently associated with lung fibrosis after a number of toxic insults, including radiation, is TGF-b. [73,74,75 and 76] TGF-b has been shown to be an important mediator of tissue damage in a variety of pathologies in which excessive collagen production is a characteristic feature. TGF-b has been shown to stimulate lymphocyte and fibroblast recruitment to the site of damage, to promote fibroblast proliferation, and to stimulate the production of collagen and fibronectin, the net effect being a net increase in extra cellular matrix material which replaces the normal architecture of the tissue. In addition, TGF-b increases the production of Type I plasminogen activator inhibitor, while simultaneously decreasing the production of plasminogen activators, resulting not only in an increase in the production of connective tissue but a decrease in its breakdown, leading ultimately to maturation of this excess connective tissue and scar formation.

Recently, Finkelstein and co-workers [71] have studied the latent period to determine whether changes in early expression of collagen precursors or cytokines, particularly TGF-b, known to be involved in the fibrotic process were expressed before damage was manifested histologically. These investigators used two single doses of radiation to the whole thorax of C57B1/6 mice, a strain known to be sensitive to the fibrogenic effects of lung radiation. The lowest dose used, 5 Gy, is well below the threshold known to induce clinical symptoms and pathologic changes of radiation pneumonitis and fibrosis, while the second higher dose of 12.5 Gy is closer to the reported LD50 for radiation-induced lung damage in this strain, although this dose itself does not cause any deaths from lung damage. The data showed that all three forms of TGF-b mRNA, that is, TGF-b1, b2, and b3, were increased in the lungs of C57B1/6 mice at 14 days, but a consistent dose response relationship was not found. For example, the increase in TGF-b1 was similar after both doses at 14 days; for TGF-b2, an increase was observed only after the higher dose of 12.5 Gy; whereas TGF-b3 was increased only after the lower dose of 12 Gy. Despite these inconsistencies, these data show clearly that after radiation doses that cause no clinical signs nor pathologic changes of radiation lung damage and before the onset of overt lung damage, alterations in expression of at least this fibrogenic cytokine occur which may ultimately lead to the development of chronic fibrosis.

However, just as there is not one target cell that, when depleted, leads to the complex pathologic process known as radiation pneumonitis and fibrosis, it is equally unlikely that the overexpression of only one cytokine initiates and promulgates the fibrogenic process in the lung. It is more likely that the damage, repair, and restructuring of the lung after irradiation as well as other toxic insults is the result of a cytokine network orchestrated by a few key cytokines, such as TNFa and TGF-b. Thus it may be the balance of a few positive profibrogenic cytokines and negative antifibrogenic cytokines generated from the interaction of a number of cytokines constituting these networks that may finally determine the outcome of lung injury and inflammation. Unfortunately, it is not easy to dissect out the role of any of these cytokines in lung damage and repair. However, one approach to determining the role of various cytokines in lung fibrosis is to take advantage of known differences in susceptibility to radiation-induced fibrosis in different inbred mouse strains.

Johnston and colleagues,[77] using the fibrosis-prone C57B1/6 strain and the fibrosis-resistant C3H/HeJ strain, showed that the elevation of mRNA levels of a number of chemokines known to play a role in the recruitment of inflammatory cells to sites of pulmonary damage was not different between the two strains when assessed at eight weeks after irradiation. However, by 26 weeks postirradiation, messages encoding transcripts produced predominantly by macrophages and lymphocytes were elevated only in the fibrosis-prone strain. These data indicate that lymphocytic recruitment and activation are key components of radiation-induced fibrosis, but their role in the pathogeny of this process remains unclear. Thus, despite abundant evidence that expression of a multitude of cytokines is elevated in radiation-induced pneumonitis and lung fibrosis, their actual *in vivo* role and the mechanism of their upregulation remain to be determined. Regardless of our lack of understanding of how these factors mediate damage and repair in the lung, it is now clear that the latent phase preceding the overt expression of radiation damage in the lung is not a quiescent time, but that molecular changes are occurring that may ultimately result in the later clinical and histopathologic picture of pneumonitis and fibrosis. The events that lead to the overt expression of radiation-induced lung damage involve a number of complex cellular and molecular processes, which explains why the nature of both the inflammatory responses and the triggering mechanism that induces the fibrotic response in the lung remain poorly understood.

Table 13.2 summarizes the proposed changes in target cells and growth factors after lung irradiation.

TABLE 13.2. TARGET CELLS AND GROWTH FACTORS ASSOCIATED WITH RADIATION-INDUCED PNEUMONITIS AND FIBROSIS

Time, Dose, and Volume Considerations

Fractionation. The sparing effects of fractionating dose in radiotherapy has been known since the experiments performed on rams' testicles in the 1920s and 1930s. Assuming that the testes were a model of a rapidly growing tumor and the skin of the scrotum was representative of normal tissues, it was found that the ram could not be sterilized by a single dose of radiation without causing extensive damage to the skin, while spreading the dose out over a period of weeks resulted in sterilization without producing unacceptable skin reactions. The basis of fractionation lies in the understanding that dose fractionation spares normal tissue reactions by allowing repair of sublethal damage and repopulation of target cells during treatment while increasing tumor cell kill by allowing reoxygenation and reassortment of cells into more sensitive parts of the cell cycle. [78,79,80,81 and 82] For years, the standard fractionation regimen was doses per fraction of 1.8 to 2.0 Gy over treatment times of four to six weeks. Modification of this conventional treatment schedule by increasing the dose per fraction in the treatment of lung cancer resulted in unacceptable sequelae in tissues such as the spinal cord. However, it was not until the early 1980s that we began to understand the basis for the differences in fractionation sensitivity of normal tissues.

Lung is a *late-responding normal tissue;* that is, damage is not manifested until weeks to months after completion of a standard course of radiotherapy, in contrast to tissues such as intestinal mucosa, which manifests damage during and shortly after the completion of a course of treatment and is an *acutely responding normal tissue.* An analysis of experimental data for a variety of both acutely and late-responding normal tissues by Thames and associates [83] demonstrated a clear and consistent difference between fractionation effects in these two categories of tissues. By plotting the total dose for an isoeffect specific to a variety of tissues versus

the dose per fraction, it was found that the total dose for a given effect in any late-responding normal tissue increased more rapidly as the dose per fraction was decreased than did the total dose for an effect in any acutely responding normal tissue. This pattern was observed consistently in all acutely and late-responding tissues analyzed and suggests that late-responding tissues such as the lung are more sensitive to changes in dose per fraction than are acutely responding tissues. These data imply that decreasing the dose per fraction should spare late-responding tissues such as the lung more than acutely responding tissues as well as the tumor, if tumors respond like acutely responding normal tissues. It has been suggested that the difference in fractionation response for acutely and late-responding normal tissues is due to differences in the repair capacity or shoulder shape of the underlying dose-response curves for these two classes of tissues, that is, the dose-response curve for the late-responding tissues is curvier than that for acutely responding tissues. [83] One way of defining these differences is by the a/b ratio, which derives from the linear quadratic model of cell killing. [83,84,85,86 and 87] Briefly, this model assumes that there are two components of cell killing by radiation; one that is proportional to dose, and the second that is proportional to dose. [2] The a/b ratio then is the dose at which the linear and quadratic contributions to cell killing are equal. For late-responding tissues such as the lung, the dose-response curve bends at lower doses than for acutely responding tissues, and therefore the dose at which the a and b contribution to cell killing is equal is lower in late-responding than acutely responding tissues. In general, the a/b ratio is below 5 Gy for late-responding normal tissues and greater than 5 Gy for acutely responding normal tissues. For the lung, the a/b is about 3 Gy. [81,88,89,90 and 91] In clinical radiotherapy, then, significant sparing of normal lung damage can be gained by decreasing the size of the dose per fraction.

A second factor in the sparing of normal tissues is repopulation of surviving cells during treatment. However, the late response of the lung, that is, weeks to months after completion of treatment, suggests that repopulation does not occur during a conventional four-to-six week treatment schedule. Although retreatment studies in the lung suggest that this may not be totally correct and that repopulation may occur within the first four weeks after irradiation, [92] it remains a general axiom that conventional fractionation schedules extending for six weeks do not allow triggering of proliferation and subsequent repopulation in the lung, a late-responding tissue. Thus, in terms of clinical radiotherapy, prolonging overall treatment time will have little, if any, sparing effect on the lung.

It can be stated, then, that in the lung the size of the dose per fraction is the dominant factor in determining lung damage, while overall treatment time will have little influence. What is more important is that prolonging treatment time may decrease tumor response because of accelerated repopulation of surviving and proliferating tumor cells during treatment. [93,94 and 95]

These radiobiological findings have been translated into the clinical treatment of lung cancer using fractionation protocols that vary from the conventional protocols by reducing the size of the dose and giving more than one fraction per day, while keeping the overall treatment time the same as in traditional schedules. To compensate for the loss of cell killing in the tumor by the reduction in dose per fraction, higher total doses are given. Thus the goal is to hold the lung damage constant by the reduced dose per fraction, but simultaneously increase tumor control by giving a higher total dose. The fractionation schedule most commonly used in the treatment of lung cancer, termed hyperfractionation, gives two doses of 1.2 Gy per day. In initial clinical trials, the total doses given ranged from 60 Gy, the same total dose given in conventional schedules using one fraction of 2 Gy per fraction, to 69.6 Gy. [96,97] The risk of both acute and late effects was found to be acceptable, and there was a dose response for survival, with survival significantly improved in patients receiving the highest total dose. In a second trial, total doses were escalated to a maximum of 79.2 Gy, but this increase in total dose did not result in a significant survival advantage, although lung toxicity was still acceptable. Further clinical trials are underway to test this hyperfractionation protocol against conventional protocols using 2 Gy per fraction alone or combined with systemic radiotherapy.

Volume of Lung Irradiated. It is well accepted by the radiation oncologists that in addition to fractionation, an effective technique to reduce morbidity is to reduce the volume of normal lung irradiated. The advent of 3D treatment planning and conformal radiation therapy allow the use of more than the traditional two to four opposing treatment fields, making it possible to tailor the treatment plan to the individual patient and tumor. However, the dose distributions in these nontraditional plans may be very different from those used in standard two or three field treatments. For example, some plans may deliver a small dose to a larger volume of lung than in opposed fields, making it difficult for the radiotherapist to extrapolate from experience to predict the probability of incurring morbidity. In addition, the lung is a paired organ and has a large functional reserve, thus it is expected that it would exhibit a threshold volume, that is, a subvolume below which irradiation causes no detectable injury, even at very high doses. [3,98,99] However, since most experimental studies had been performed using whole-lung irradiation, neither the threshold volume nor the relationship of volume of lung irradiated, dose, and morbidity were defined.

In the past few years, with the impetus of conformal therapy and questions from radiotherapists regarding the volume response of the lung, experimental studies have been initiated in a number of labs to address these questions. Most of the data for partial lung irradiation have been obtained from hemithoracic irradiation studies in mice and rats. In these studies, single-dose irradiation of only one lung led to dose-dependent increases in one functional assay—breathing rate—but not in lethality (Travis, unpublished observations). The initial increase in breathing rate was followed by a decrease that was suggested to be coincident with compensatory hypertrophy of the unirradiated lung and/or the formation of new alveoli that increased the surface area of the lung. Both breathing rate and lethality are assays of total lung function, both the irradiated half and the unirradiated half, and show clearly that the lung has a large functional reserve. Other studies using blood flow changes in hemithoracic irradiated mice and rats showed that vascular changes in the irradiated lung were similar to those after whole-lung irradiation. [59] Thus this assay of regional function showed no difference after whole-versus partial-lung irradiation.

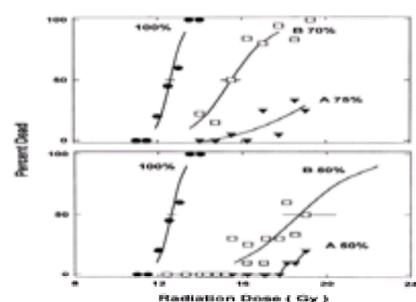
A series of experiments in mouse lung designed to define the relationship of dose and volume to damage assessed histopathologically and morbidity assessed by two tests of total lung function—breathing rate and lethality—has been reported recently. [100,101] In these studies, a range of lung volumes, from 20% to 100%, were irradiated. In addition, matched volumes were irradiated in the base or in the apex of the lung to test the hypothesis that the functional subunits were randomly and homogeneously distributed. Figure 13.4 shows the proportion of dead mice after irradiation of two of the matched volumes in the apex and base of the lung, 50% and 75%. Figure 13.5 shows breathing rate and lethality as a function of the percentage volume of lung irradiated in the apex or the base of the lung. It is clear from these data that for any given volume, the base of the lung is more sensitive than the same volume in the apex, that is, the isoeffect doses for both breathing rate and lethality are lower for all irradiated volumes in the base than in the apex.


FIGURE 13.4. Dose-response curves of lethality after irradiation of two partial volumes of the lungs of C3H mice. 70% to 75% (**top**) or 50% (**bottom**), located in the apex (**A**) or base (**B**) of the lung. The dose-response curve for whole lung is shown for comparison. These data show a clear volume effect. The lethal dose that kills 50% of the population (LD50) for irradiation of 50% in either the base or apex is higher than the irradiation of the larger volume of 75% in these same two sites. In addition, these data show that the LD50 is dependent on the site of the lung irradiated. The isoeffect dose is less for both volumes irradiated in the base than in the apex, suggesting that the base is more sensitive than the apex. These data indicate that the volume effect is dependent not only on the volume of lung irradiated but also on the site of the lung irradiated.
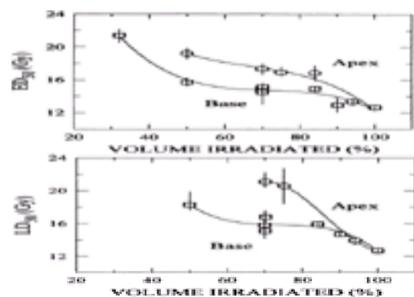

FIGURE 13.5. Breathing rate (ED 50, **top**) and lethality (LD 50, **bottom**) for radiation pneumonitis, plotted as a function of partial volume irradiated in the apex of base of the lung. The curves are second-order regression fits to the data. The curve for irradiation of a range of volumes in the base is consistently displaced below that for irradiation of the same volumes in the apex, that is, the isoeffect doses for both breathing rate and lethality are lower for all volumes irradiated in the base than in the apex. These data show clearly that the base is more sensitive than the same volume in the apex for the induction of radiation pneumonitis. (From Travis EL, Liao Z-X, Tucker SL. Spatial heterogeneity of the volume effect for radiation pneumonitis in mouse lung. *Int J Radiat Oncol Biol Phys* 1997;38:1050, with permission.)

Although the underlying mechanism of this spatial heterogeneity in the response of the mouse lung to radiation is unknown, Travis and co-workers [101] suggested that there is a heterogeneous distribution of target cells or functional subunits in the lung, which is due to the anatomy of the tracheobronchial tree. The alveoli are concentrated in the periphery of the lung, whereas the mid region of the lung is most occupied by conducting airways, which are not involved in gas exchange. Thus the base of the lung is more sensitive because there is a higher concentration of alveoli and fewer conducting airways in this region, whereas a large portion of the mid region of the lung is occupied by large branching bronchi and bronchioles. Boersma [102] suggested that these regional differences in the incidence of pneumonitis could be accounted for by differences in functionality of cells in the base and apex, rather than to a difference in density. Khan and co-workers [103] ascribe these regional differences in the incidence of radiation pneumonitis to differences in the amount of DNA damage sustained by the cells in the apex and the base, that is, the cells in the base sustain more DNA damage than those in the apex when either region is irradiated. Interestingly, this differential in DNA damage between cells isolated from the apex or base of the lung disappears when the whole lung is irradiated. Regardless of the mechanism underlying these regional differences, it is clear that the morbidity of lung irradiation will be related not only to the volume of lung irradiated but to the location of the irradiated subvolume within the lung. Based on these data, then, greater morbidity would be expected when the irradiation portal includes the base than when the apex is included. Also, when using conformal therapy, the data suggest that the volume irradiated in the base be kept as minimal as possible.

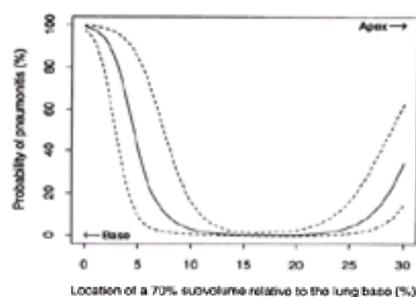
Regardless of the mechanism of the heterogeneity of the lung's response to partial-volume irradiation, these data impact on the use of nonconventional treatment techniques such as 3D conformal radiotherapy and more recently, intensity modulated radiotherapy (IRMT) in the treatment of lung cancer. Both of these latter techniques treat larger volumes of normal lung than conventional treatment techniques, although the normal lung would get a smaller dose. However, the question of whether a lot to a little (conventional treatment) is better or worse than a little to a lot (3D and IMRT), has not been answered. Using the mouse data, Tucker and associates [104] calculated the incidence of pneumonitis for subvolumes of the lung irradiated with a fixed dose. As shown in Figure 13.6, the complication rate varies over the entire range of possible responses, from a 100% incidence after irradiation of the base, to a 0% incidence after irradiation of the mid-lung, with an intermediate incidence after irradiation of the apex. These data indicate that relatively small changes in the location of the irradiated subvolume in lung may correspond to significantly greater changes in the incidence of pneumonitis than moderate changes in either the dose or the size of the irradiated subvolume. Using the mouse data, Tucker and associates found, using a constant integrated dose of 12.7 Gy, that the risk of pneumonitis varied enormously depending on the site of the irradiated subvolume (Figure 13.7), whereas for both the apex and the mid-region of mouse lung, a little to a lot was found to be worse that a lot to a little, provided that the integrated dose, that is, the product of volume and dose, was kept constant. However, a quite different picture emerges for the base, where irradiation of 50% to 70% of the lung is predicted to be worse than irradiation of either larger or smaller subvolumes, again provided that the integrated dose is kept constant. After volumes larger than 70%, the decrease in the probability of pneumonitis occurs because the increase in the number of cells irradiated is more than offset by the decrease in dose required to maintain the constant integrated dose. In terms of the threshold volume, that is, that volume below which radiation causes no detectable injury even at very high doses, the predicted size of this volume depends on the region of lung irradiated and ranges from 10% in the base to 30% to 40% in the apex.


FIGURE 13.6. Effect of subvolume location on response calculated using estimates of cell density in different subvolumes of the lung. The solid curve shows the predicted incidence of pneumonitis in mice after irradiation of a subvolume of fixed size (70%) with a fixed dose (22 Gy), plotted as a function of the location in the lung of the irradiated subvolume. The complication rate varies over the entire range, from a 100% incidence rate after irradiation of the base to a 0% incidence after irradiation of the mid-lung to an intermediate incidence after irradiation of the apex. Dashed curves represent the 95% confidence band around the predicted curve, based on the uncertainty in the estimated cell density parameters. (From Tucker SL, Liao Z-X, Travis EL. Estimation of the spatial distribution of target cells for radiation pneumonitis in mouse lung. *Int J Radiat Oncol Biol Phys* 1997;38:1062, with permission.)
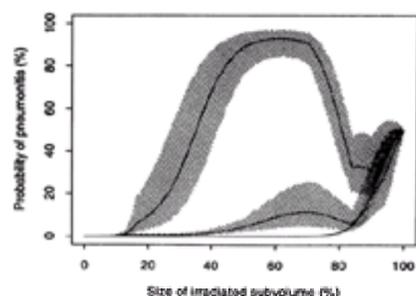

FIGURE 13.7. Predicted incidence of pneumonitis in mouse lung as a function of irradiated volume where the integrated dose (dose × volume) is kept fixed at 12.7 Gy, equal to the whole-lung LD50. The upper, middle, and lower curves represent volumes in the base, apex, or mid-region of the lung respectively. Stippled regions around the curves represent the 95% confidence limits. It is clear that whether a lot to a little is better than a little to a lot is critically dependent on the location of the irradiated subvolume. In the base, the risk of pneumonitis is highest after irradiation of an intermediate subvolume with an intermediate dose, whereas in the apex, a little to a lot is generally worse than a lot to a little. (From Tucker SL, Liao Z-X, Travis EL. Estimation of the spatial distribution of target cells for radiation pneumonitis in mouse lung. *Int J Radiat Oncol Biol Phys* 1997;38:1062, with permission.)

Interestingly, a recent clinical study[105] found that the risk of pneumonitis in patients varied with the location of the irradiated site, exactly as had been observed in mouse lung. In a study of 60 patients treated with radiation and chemotherapy given either sequentially or concurrently for lung cancer, the site of irradiation in the lung was evaluated by dividing the whole lung into three-by-three areas, that is the right and left lung were divided into three equal areas from upper to lower lung field. When the risk of pneumonitis was analyzed by irradiated site, it was found that when the lower lung field was included in the radiation site, the incidence of pneumonitis was 70%, compared with 20% for other sites (p less than 0.01). Multivariate analysis revealed a significant relationship between radiation site and the risk of pneumonitis (p = 0.0096). These data are consistent with the data from the mouse studies, both of which show that irradiated site, the base of the lung, is a treatment factor significantly associated with a higher risk of pneumonitis following CRT.

In contrast to the data from lung function tests, no volume effect was found for damage in the studies of Liao and colleagues.[100] A characteristic pneumonitis was found in all mice regardless of the volume of lung irradiated. These data illustrate the necessity to define whether damage or morbidity is being assessed in both clinical and animal studies, as different answers may be obtained. In addition, these data indicate that tests of total lung function that reflect a summation of the function in the irradiated volume and the function of normal lung in the unirradiated volume will give a different answer from regional lung function tests that assess damage only in the irradiated area.

Quantifying Dose-Volume Relationship in Patients

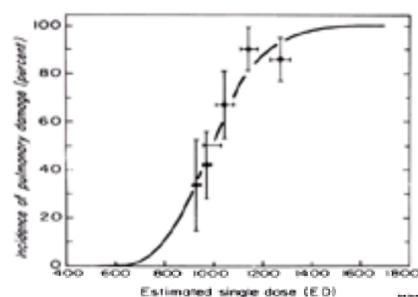
Approximately 50% to 90% of patients who receive lung irradiation will have radiographic or pulmonary function abnormalities following treatment; however, the significance of these changes in terms of morbidity varies from minimal to severe, depending on the volume of lung irradiated. A comprehensive study of radiation pneumonitis after partial volume fractionated irradiation in patients was conducted by Mah and associates.[30] The end point was an increase in lung density within the irradiated volume on CT in the posttreatment period. The estimated single dose equivalent, ED50, was 10 ± 4 ED units, at the low end of the dose range for pneumonitis in various mouse strains (Figure 13.8). However, no information was obtained for the effect of these changes on pulmonary function. More recent studies by Boersma[4,6] and Marks and colleagues[11] in which changes in regional lung function were quantified showed that the dose-effect curves for both functional parameters studied—perfusion and ventilation (Figure 13.9)—were less steep than the dose-effect curve for structural changes as measured by density changes on CT published previously by Mah et al.[9,32] The lack of correlation between CT changes as a measure of structural damage and tests of regional lung function was more clearly observed in one study by Boersma[4] in which all assays were performed in the same patients. These data suggest that lung density may be a different biological end point from perfusion and ventilation, the former representing the late phase of fibrosis, while the functional assays measure the ability of the irradiated lung within that area to perform gas exchange.


FIGURE 13.8. Dose-response curve for the incidence of acute radiation pneumonitis after fractionated radiotherapy of the whole lung in humans. The solid curve is the best fit sigmoid to the data points as determined by probit regression. An ED50 of 1,000 ED units with a standard error of 40 ED units is predicted. Vertical error bars are the standard deviation of the points. (From Mah K, Van Dyk J, Keane T, et al. Acute radiation-induced pulmonary damage: a clinical study on the response to fractionated radiation therapy. *Int J Radiat Oncol Biol Phys* 1987;13:179, with permission.)
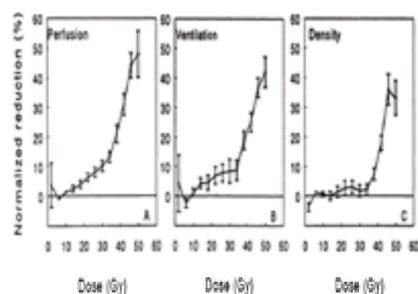

FIGURE 13.9. Dose-incidence curves for perfusion (**A**), ventilation (**B**), and lung-density changes (**C**) greater than 20%, indicating the fraction of patients with average local changes greater than 20%. The solid lines are logistic fits to the data points; the error bars on the points indicate the 68% confidence limits. (From Boersma LJ, Damen EMF, de Boer RW, et al. Dose-effect relations for local functional and structural changes of the lung after irradiation for malignant lymphoma. *Radiother Oncol* 1994;32:206, with permission.)

Numerous studies in the literature describe changes in local lung function using a number of assays, such as those described above and others such as SPECT scanning. However, what is critical in 3D conformal treatment in which both dose and volume are changing is the effect of these changes in regional function and structure on whole-lung function. In other words, as the volume of normal lung irradiated increases, should the dose be decreased, and if so, by how much? Clearly, the correlation of clinical symptoms or changes in whole-lung function is heavily dependent on the volume of functioning lung remaining. What is well accepted is that there is a clear separation between whole organ and regional organ tolerance. The impact of changes in regional lung function and structure on whole-lung function will depend on the dose-volume histogram (DVH).

The most convenient way of expressing this type of information is a DVH which is then used to develop mathematical models that attempt to predict normal tissue complication probability (NTCP). Although NTCP models are useful tools in the treatment planning process, the absolute values of the predicted complication rates must be verified clinically. Because verification of the complication rates predicted from NTCP models requires a large number of patients, Kwa and co-workers,[106] in a large, five-center study of 540 patients, asked the question whether a parameter such as mean lung dose could predict the probability of radiation pneumonitis using doses calculated from 3D treatments. These authors have reported that the mean lung dose, NTD mean, is a useful predictor of the risk of radiation pneumonitis. This parameter is relatively easy to calculate from the 3D dose distribution and is far simpler than NTCP calculation. In addition, there is a good correlation between the mean biological dose, NTDmean, and the mean physical dose, Dmean, both of which have a clear meaning. Thus, until more complex predictive models can be proven to be superior, these authors suggest that calculation of simpler parameters such as the NTDmean may prove more useful for predicting the risk of lung complications when treatment volume is changed.

Intervention in the Pathogenesis of Radiation Pneumonitis and Fibrosis

Although changes in dose-fractionation schedules and information on the effect of irradiated volume on the incidence and severity of radiation pneumonitis and fibrosis have led to advances in the treatment of lung cancer, the challenge is to identify agents that either protect against lung damage or specifically intervene in the pathogenesis of pneumonitis or fibrosis. Although it has been generally thought that interventional techniques would not work, recent studies on the events occurring

during the latent period could prove useful in designing compounds that specifically intervene in these events.

Much information has been obtained at the cellular and molecular level on the biology of connective tissue formation and the pathophysiology of connective tissue diseases. The knowledge that pharmacologic interventions can be specifically targeted at varying strategic points in the life cycle of fibroproliferative processes has broadened considerably the realm of therapeutic modalities that might be investigated to control these processes. Numerous approaches designed to control collagen deposition remain untested in the lung. It would be useful to develop delivery methods that exploit the unique aspects of the lung to overcome the toxicity associated with collagen inhibitors. Collagen degradation, use of steroidal and nonsteroidal anti-inflammatory drugs, and cyclic nucleotides offer opportunities to control the accumulation of extracellular matrix in the lung.

Cytokines. Studies of the events occurring during the "latent phase" of radiation lung injury have shown that a number of these molecules and growth factors are activated during this time, some of which may be exploited interventionally.

Basic Fibroblast Growth Factor (BFGF). A cytokine suggested to be useful in protecting against radiation pneumonitis in mice is the growth factor basic fibroblast growth factor, bFGF. Fuks and co-workers[107,108 and 109] have shown that this cytokine protects against radiation-induced apoptosis in bovine arterial endothelial cells *in vitro*[108,109] as well as against apoptosis in endothelial cells in irradiated lungs of mice. [107] bFGF also protected mice against the lethal effects of radiation pneumonitis.[107] However, neither the time of death nor the histological changes observed were consistent with classical radiation pneumonitis. Hemorrhage and edema in the air spaces was a consistent finding at eight to ten weeks, when the mice were sacrificed because they were moribund. In a separate study giving bFGF after radiation doses to the whole lung that induce a classical pneumonitis, no protection with bFGF was found. [110] Although the reason for the discrepancy between these two studies is not clear, it is possible that the higher doses used by Fuks and co-workers [107] produced "sporadic pneumonitis" whereas the lower doses used in the study by Tee[110] induced a classical pneumonitis. Despite these unresolved differences, these studies do indicate the potential for intervening in these reactions. These studies also indicate our incomplete understanding of the events that occur after chest irradiation.

Interferon g (IFN-g). The rationale for the use of this cytokine in modulating radiation pneumonitis is that IFN-g has been shown to reduce the severity of bleomycin-induced fibrosis in mouse lung [111] and to inhibit acute inflammation.[112,113] Thus, if radiation-induced fibrosis is a sequelae of an acute inflammatory response, that is, pneumonitis, then IFN-g could potentially reduce the severity of lung fibrosis after irradiation. In a study in rats, Rosiello and colleagues [114] showed that IFN-g markedly reduced the neutrophil influx and protein leak into the alveoli after irradiation of rat lung with a single dose of 15 GY, suggesting that prophylactic administration of IFN-g could reduce the severity of radiation pneumonitis in humans. However, long-term follow-up of these animals showed that although IFN-g reduced early inflammatory events in irradiated lungs, the tissue response at 35 days, the end of the study, showed that the number of cells and exudate in the irradiated lungs of the IFN-g-treated rats was not different from that in rats only irradiated. Thus it is unclear whether IFN-g could be useful in modulating either radiation pneumonitis or fibrosis.

Noncytokine Protection. Because radiation damage in the lung is manifested as an alveolitis followed by focal scarring with an attendant increase in collagen, many studies have focused on identifying drugs active against either one or both of these lesions. One of the first drugs to be used clinically was the steroid prednisolone. It was hypothesized to modify radiation pneumonitis by reducing the inflammatory and exudative portion of lung injury, and both animal and human studies showed that prednisolone did protect against the early phase of pneumonitis. However, when drug administration was terminated, the alveolitis reappeared and in mice the LD50 for pneumonitis was not changed.

A second approach of these early studies was to attempt to intervene in the fibrotic process with collagen antagonists. Perhaps the most widely tested was D-penicillamine, a compound shown in experimental studies significantly to inhibit collagen accumulation in rat lung for up to one year after irradiation. [115,116] This biochemical effect was translated into significant improvement in pulmonary function. Although shown to be effective in rats at a concentration that produced no deleterious side effects, D-penicillamine was not widely tested in the clinic, perhaps because its effectiveness required continuous administration.

As more data became available on the different cell types involved in radiation pneumonitis, it became possible rationally to test drugs known to reduce cell killing in these different populations. To determine the role of endothelial dysfunction in the pathogenesis of radiation-induced pneumonitis and fibrosis, Ward and colleagues[64,65 and 66] quantitated markers of endothelial activity—angiotensin converting enzyme (ACE) and plasminogen activator—and correlated these changes with pulmonary perfusion scans and morphologic changes. A time- and dose-dependent decrease in ACE was observed after irradiation of either the whole thorax or hemithorax that was in good agreement with pulmonary perfusion scans. Based on these data, these investigators then sought agents which would protect the endothelial cell, the presumed target, against radiation-induced cell killing. [117,118 and 119] The most promising drug is one that is commonly used in the management of hypertension and congestive heart failure by millions of people—captopril. [120,121] This drug contains a free thiol and is an orally active competitive inhibitor of ACE, the enzyme that metabolizes angiotensin 1 to the vasoconstrictor angiotensin 2 and inactivates the bradykinins. In preclinical studies, captopril has been shown to ameliorate endothelial dysfunction after irradiation and to reduce radiation-induced lung fibrosis in rats. [119,122] Further support for the use of captopril against radiation-induced lung fibrosis is that it reduces age-related and radiation-induced cardiac fibrosis in rats [123] and, in patients, decreases morbidity and mortality from left ventricular dysfunction after myocardial infarction. [124] Captopril has been shown to be effective also in experimental radiation nephropathy by reducing proteinuria, preserving kidney function, and enhancing survival in rats. [125,126 and 127] These promising preclinical studies, coupled with the clinical use of the drug for hypertension, have prompted a clinical trial of captopril in lung cancer patients treated with radiation. Although the mechanism of its protective effect is unknown, studies *in vitro* suggest that captopril acts by inhibiting proliferation of lung fibroblasts. [128]

GENETIC REGULATION OF RADIATION- AND DRUG-INDUCED PNEUMONITIS AND FIBROSIS

A body of data has emerged in this area since the first edition of this book. Clinically, it has been well recognized that there are individual differences in the severity of treatment-related complications, including the severity of radiation-induced pneumonitis and fibrosis after definitive radiotherapy for lung cancer. A recent study by Gears and colleagues[129] of a group of 56 patients with limited small cell lung cancer who were treated with chemoradiotherapy demonstrated patient-to-patient heterogeneity, suggesting that the risk of lung fibrosis is strongly affected by inherent factors that vary among individuals. Although this heterogeneity could be due to a number of factors, mouse studies indicate that at least part of this response may be regulated by genetic factors.

Twenty years ago Steel and co-workers[130] reported an anomalous finding after irradiation of the whole thorax of C57B1 mice. Using a dose range designed to capture the LD50 for radiation pneumonitis previously reported in other mouse strains, they found that the survival time of this inbred strain of mice was significantly prolonged beyond the standard 80 to 180 days reported for radiation pneumonitis in other mouse strains. However the LD50 for radiation pneumonitis was similar in this strain to that reported in other inbred strains, leading them to conclude that the C57B1/6J strain was not more "resistant" to radiation-induced lung damage, but that the survival time was simply prolonged. However, subsequent studies by Down and co-workers[131,132] in a number of inbred mouse strains showed that the incidence of radiation pneumonitis and fibrosis was strain-dependent. Although strain-dependent differences could be due to a number of factors, certainly one possibility is that there is a genetic basis to this strain dependence. Down and co-workers conducted studies on the F $_1$ hybrid of a cross of a sensitive and resistant parent, but no clear-cut genetic dominance for the fibrosing phenotype was found. [132] However, in an in-depth survey of the incidence of radiation pneumonitis and fibrosis in nine inbred mouse strains, Sharplin and Franko [46] showed that the strains could be categorized as fibrosing, nonfibrosing, or intermediate, based on quantitative histological data. Further studies by these authors showed that the crossbreeding of strains with different proneness to fibrosis produced hybrids with the same sensitivity of the least fibrotic parent; the F $_1$ hybrid of a fibrosing and a nonfibrosing strain was uniformly nonfibrosing while a cross of an intermediate with a fibrosing strain produced a hybrid intermediate in its proneness to fibrosis, [133] suggesting that sensitivity to radiation-induced fibrosis is an autosomal recessive trait.

Although the data indicate that radiation-induced fibrosis is under polygenic control, the availability of mapping technologies, a genetic map of the mouse genome, and the existence of over 3000 markers polymorphic for the fibrosis-prone C57BL/6J and the fibrosis-resistant C3H/HeJ inbred strains allow the undertaking of a search for those genes that regulate radiation-induced fibrosis in these two mouse strains. In breeding studies using the C57B1/6J and the C3Hf/Kam inbred strains of mice to produce F$_2$ progeny which were individually genotyped and phenotyped by quantifying fibrosis in the lungs of each mouse, Haston and colleagues [41] have reported one loci on chromosome 17 that segregates with the fibrosing phenotype. This loci, which is within the region containing the major histocompatibility locus (MHC), has also shown by these same authors to be linked to bleomycin-induced lung fibrosis. [134] This same loci has been shown to be linked to susceptibility to ozone-induced lung damage in mice.[135] These data suggest that at least one genetic factor regulating pulmonary fibrosis may be universal and independent of the etiologic, although other loci have been shown to be insult-dependent.

The genetic regulation of pathologic processes in the lung is not without precedent. It is well known that pulmonary inflammation is controlled by genes in the H-2

complex.[136,137 and 138] Mice with an H-2^k loci are high responders (i.e., C3H mice), and those with an H-2^b loci are low responders (i.e., C57B1 mice).[136,138,139] In the studies of Sharplin and Franko[40] and Down and associates,[132] pneumonitis was found to be strain-dependent and related to the H-2 loci, that is an inflammatory cell infiltrate was not a feature of pneumonitis in the highly fibrogenic C57B1 strain, while conversely, an inflammatory cell infiltrate was the most prominent characteristic of the pneumonitis phase in the weakly fibrogenic C3H strain. Although these observations refute the hypothesis that immune-inflammatory processes usually precede fibrosis, they clearly indicate that pneumonitis after irradiation of mouse lung is genetically regulated. However, the strain sensitivity to radiation pneumonitis is exactly opposite that for radiation-induced fibrosis, that is, the C57B1 are highly fibrogenic and the C3H are weakly fibrogenic.

In Sharplin's and Franko's study,[40] lung fibrosis was defined as collagen deposition in the interstitium and air spaces, resulting in contracture and collapse of the alveoli, an obliteration of normal lung architecture, and an attendant loss of pulmonary function resulting in the death of the mouse. The designation of "highly fibrogenic" was based on the number of acini obstructed by this contracted scar; in their studies only the C57 strains met these criteria. Another form of fibrosis characterized by collagen deposited only in the interstitium, a process that maintains alveolar structure, was largely ignored because it was suggested that this lesion alone would not produce sufficient functional impairment to cause death. The strains exhibiting this lesion, that is, CBA and C3H, were considered weakly fibrogenic. Thus the genetic regulation that controls the contracted fibrotic process described by Sharplin and Franko[40] may not be identical to that controlling interstitial fibrosis although there may be overlaps. Contrary to Sharplin's and Franko's suggestion that interstitial fibrosis is not a lethal event, it has been shown previously that interstitial fibrosis in the lung[15,24] and colon[43] can and does cause the demise of both CBA[132] and C3H[15] mice. Thus these lesions may represent two types of fibrosis regulated by different genes or sets of genes. In further studies using a number of inbred strains, Franko and colleagues[42] have also suggested that radiation can elicit two independent mechanisms for the development of fibrosis in mouse lung, one of which is controlled by two autosomal recessive determinants which act additively, the other of which is regulated independently by two additional genes, one of which is X-linked. Thus it is clear that radiation-induced pulmonary fibrosis is genetically regulated at least in part, but the genetics underlying this pathologic process appear to be complex.

Of the nine strains studied by Sharplin and Franko, all the C57B1 strains were found to be high responders, while both the C3H and CBA mice were identified as low responders. Similar strain variations in pulmonary fibrosis after a number of other insults have been reported. Particularly interesting are the data obtained after treatment with bleomycin, another DNA-damaging agent often used to induce lung fibrosis in model systems. The most striking finding after bleomycin treatment is that C57B1 mice were high responders[140,141 and 142] while the C3H strain was weakly fibrogenic,[143] findings remarkably similar to that observed after radiation. These data suggest that genetic factors related to susceptibility to lung fibrosis may operate independently of the etiologic agent.

CONCLUSIONS AND FUTURE DIRECTIONS

Although intervention in the process that results in radiation-induced fibrosis is certainly one way of decreasing the morbidity of thoracic irradiation for lung cancer, this approach would be reactive rather than proactive, and would not necessarily allow for higher tumor control by increasing tumor dose. The ultimate goal is to identify individuals who are at a higher risk of developing treatment-related pneumonitis and fibrosis before treatment begins. Clinically, a wide variation exists in the severity of lung fibrosis exhibited by individual patients treated similarly. These and data in other normal tissues demonstrate that variations in radiosensitivity exist in the same normal tissue cell type from different individuals. However, "tolerance" doses of both drugs and radiation are determined empirically from population averages and may reflect the sensitivity of a genetically determined minority. These data imply then that a majority of patients could be treated with higher doses of either modality without exceeding their individual tolerance to the treatment. One approach to increasing tumor control while maintaining an acceptable level of lung morbidity is to be able to identify those sensitive individuals before treatment begins. Although studies in humans and mice suggest that radiation sensitivity is genetically regulated, none of the genes have been identified. Nonetheless, predictive assays are being developed to individual patients at risk of developing severe late radiation effects, including lung fibrosis.[144,145 and 146]

Radiation-Sensitivity Testing of Cultured Fibroblasts from Patients: Correlation with Tissue Fibrosis

It is now well documented that variations in radiosensitivity can be demonstrated in the same normal tissue cell type from different individuals, suggesting that radiosensitivity is genetically regulated. Data from patients with ataxia telangiectasia (AT) have established not only that these individuals are highly sensitive to ionizing radiation, but that in survival assays, fibroblasts isolated and cultured from AT patients are more radiosensitive by several logs than fibroblasts from unaffected individuals.[147,148,149 and 150] Even in the normal population, a wide range of radiosensitivities is known to exist. If normal tissue radiosensitivity has a genetic component, then the radiosensitivity of cultured cells isolated from individuals should reflect the genetics of the individual. A number of studies have been performed to determine the relationship between fibroblast radiosensitivity as measured by the function of cells surviving a dose of 2Gy (SF 2Gy) (see also Chapter 12) and late tissue damage in patients.[150,151 and 152] Although early studies reported variable results, more recent data suggest that fibroblast radiosensitivity may be a useful predictor of late radiation damage in vasculoconnective tissues. However, the majority of these studies have been performed using skin fibroblasts cultured from breast cancer patients. Fibroblast radiosensitivity as measured by SF2 was compared with both acute and late end points, and although the data do not demonstrate a clear relationship between fibroblast radiosensitivity and chronic skin damage, these data appeared to be promising.[150]

In the case of patients with lung cancer, there are two issues that must be resolved experimentally. First, is there a correlation between lung fibrosis and survival of cultured lung fibroblasts? Also, since it would be difficult to obtain biopsies of normal lung from patients with lung cancer before treatment, the second issue is whether the radiosensitivity of fibroblasts isolated from another tissue, for example skin, from the patient will have a similar radiosensitivity as lung fibroblasts. Both of these questions have been investigated using two inbred strains of mice with documented differences in radiation induced lung fibrosis.

Dileto and Travis[153] determined the radiosensitivity of fibroblasts cultured from the lung and skin of the fibrosis-prone C57B1/6 strain and the fibrosis-resistant C3Hf/Kam strains of mice. In these mouse models, lung fibroblast radiosensitivity was not different as measured by SF2, despite a more than 20-fold difference in fibrosis scores—5.1% and 0.2% in the fibrosis-prone and fibrosis-resistant strains respectively. Similar SF2 values were obtained for skin fibroblasts from the two strains, indicating that the radiosensitivity of fibroblasts isolated from lung and skin of the same strain is the same. These data indicate that the *in vitro* radiosensitivity of lung fibroblasts as assayed by survival at 2 Gy does not correlate with the development of lung fibrosis, at least in the two strains of mice used in the studies of Dileto.[153]

Thus the usefulness of the fibroblast radiosensitivity as measured by SF2 for predicting lung fibrosis remains unclear.

Transforming Growth Factor b

A second approach to identifying "at risk" patients would be to identify the expression of cytokines, growth factors or other factors during treatment that correlate with the later incidence of pneumonitis or fibrosis. The underlying rationale of this approach is to identify and intervene in the early expression of gene products that may participate in the pathogenesis of pneumonitis or fibrosis. The goal would be to define factors that could be monitored regularly and routinely during treatment. The requirement of such a test would be that these factors be easily accessible for multiple sampling.

Transforming growth factor b is a ubiquitous cytokine present in a number of organs undergoing fibrosis.[154,155 and 156] TGF-b also has been implicated in the causation of chronic pulmonary fibrosis in rats and mice exposed to bleomycin and cyclophosphamide[141,157,158,159,160 and 161] and in the development of hepatic fibrosis in irradiated rats.[162] For this reason, it has been suggested that plasma levels of TGF-b may be increased before the onset of fibrosis. Recently, Anscher and colleagues measured the circulating levels of TGF-b in breast cancer patients undergoing bone marrow transplantation[162] and correlated these values with the later incidence of pulmonary fibrosis and hepatic venoocclusive disease, both of which are significant side effects of this treatment. TGF-b was determined initially after induction chemotherapy but before the administration of high-dose chemotherapy and subsequently after high-dose chemotherapy and transplantation. Hepatic venoocclusive disease and lung fibrosis were observed clinically between one to three weeks and 40 to 75 days after transplantation respectively. Analysis of the TGF-b levels after induction chemotherapy with the later incidence of liver and pulmonary fibrosis in individual patients showed that plasma levels of TGF-b had a positive predictive value of more than 90% for the development of fibrosis in either of these organs in a given patient. Although plasma levels of TGF-b were not determined before any treatment, and thus its usefulness in selecting patients more likely to develop lung fibrosis before treatment begins is unknown, these data suggest that routine monitoring of plasma TGF-b in individual patients undergoing radiation or chemotherapy for lung cancer could be useful as a predictor of lung fibrosis. More recently, Anscher and colleagues[163] investigated in a prospective study the usefulness of TGF-b1 as a predictive marker for the development of radiation-induced lung damage. In this study, 73 lung cancer patients were treated with curative intent; all treatment parameters were similar in this patient cohort. TGF-b1 levels were measured before, weekly during treatment, and at each follow-up to six months after the completion of radiotherapy, when the study was ended. The end point was the development of radiation pneumonitis at six months after treatment, which was defined by National Cancer Instititute common toxicity criteria. Only 15 (21%) of these patients developed symptomatic pneumonitis. In this study, a normal plasma TGF-b1 level by the end of radiotherapy was more common in patients who did not develop pneumonitis (Figure 13.10). A return of TGF-b1 plasma levels to normal accurately identified patients who would not develop pneumonitis with a positive predictive

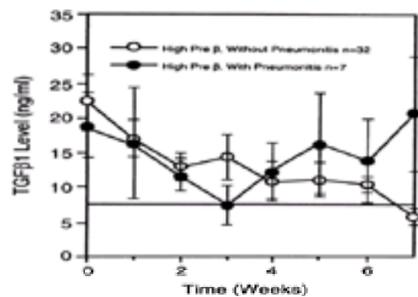
value of 90%, indicating that the level of this cytokine may be useful in identifying patients at low risk for the development of radiation pneumonitis. These patients could then be considered for dose escalation.


FIGURE 13.10. Plasma TGF-b-levels as a function of time for patients with an elevated pretreatment plasma TGF-b level who did not (*open symbols*) or did (*closed symbols*) develop radiation pneumonitis. Although both groups experienced a reduction in TGF-b levels during treatment, in one group this decrease was transient, and the TGF-b levels returned to high levels. This group had a significantly higher risk of developing pneumonitis than those patients whose TGF-b levels remained within control values. (From Anscher MS, Kong F-M, Andrews K, et al. Plasma transforming growth factor b1 as a predictor of radiation pneumonitis. *Int J Radiat Oncol Biol Phys* 1998;41:1032, with permission.)

Such studies provide the impetus to search for other early markers of radiation- and drug-induced lung damage in the hope of preventing these potentially fatal complications.

CHEMOTHERAPY

KENNETH R. HANDE

Combination chemotherapy has been the cornerstone of treatment for patients with small cell lung cancer (SCLC) for nearly three decades. [1] More recently, chemotherapy has also become the standard of care for patients with stage III and IV non–small cell lung cancer (NSCLC). [2,3] Since over two thirds of NSCLC patients present with stages III or IV disease, chemotherapy is now being considered for most of the 170,000 patients diagnosed with lung cancer in the United States. [4] Despite the beneficial effects of drug treatment in producing tumor regressions, improving symptoms, and prolonging life, the use of chemotherapy is not appropriate for every patient. Cancer chemotherapy has a narrow therapeutic window, with the potential for producing life-threatening toxicity. Clinicians recommending chemotherapy for their patients must understand the goals of treatment and the potential for toxicity. This chapter outlines the general principles of cancer chemotherapy, including the pharmacology and toxicity of specific agents used for the treatment of lung cancer.

BIOLOGIC PRINCIPLES

Lung cancers commonly have several characteristics which limit the effectiveness of cancer chemotherapy. These factors include: (a) large tumor volume; (b) the presence of nondividing cells within the tumor; (c) cancer cells with different apoptotic pathways; and (d) the presence of drug-resistant tumor cells. The importance of these factors in treatment will be discussed in the following sections.

Cancer Biology

A 1 cm diameter tumor (rarely are lung cancers detected this early) contains 10^9 cells. A lethal tumor burden is only 3 logs higher (10^{12} cells). Chemotherapy generally kills a specific fraction of malignant cells. [5,6] The fractional cell kill (e.g., 90%, 99%, or 99.99% cell kill) depends on the sensitivity of cells to the antineoplastic drug and upon the dose of drug administered. The model of fractional cell kill leads to two important principles regarding chemotherapy. First, because of the large number of cells present at diagnosis (e.g. 10^{11}), multiple courses of treatment are required for therapy even if a drug or a combination of drugs produces a 99.9% cell kill (i.e., kills 999 of every 1,000 cells present). One treatment with a 99.9% cell kill will reduce a tumor population from 10^{11} to 10^8 cells. At least four treatments are, therefore, necessary to eliminate the final cancer cell, assuming there is no tumor cell growth during the treatment period. In fact, because of toxicity to normal tissues and time needed for normal tissue recovery, cancer chemotherapy is usually given on an intermittent basis. During the period between treatment cycles, tumor regrowth occurs. Thus most curative treatment regimens required multiple courses of chemotherapy, the number depending on the tumor mass at the time of diagnosis and upon the sensitivity of the tumor to the drugs.

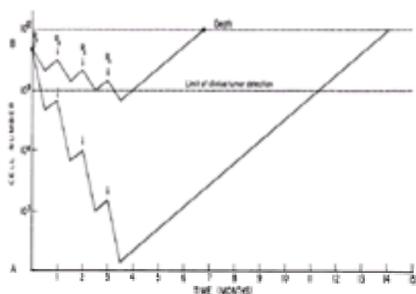
A second concept from this model is that recurrent disease following "complete remission" (disappearance of all detectable disease) can be explained by the inability to detect fewer than 10^6 to 10^8 tumor cells in the body, even by the most sensitive test available. Chemotherapy that kills several logs of tumor cells (e.g., from 10^{11} to 10^4) eliminates all evidence of cancer and prolongs survival, but the cancer will recur at a later time. An example of the fractional kill concept with repeated cycles of chemotherapy is shown in Figure 14.1.


FIGURE 14.1. Schematic representation of clinical course of two patients with small cell lung cancer. Both patients A and B are diagnosed with an average-sized tumor mass (10^{11} cells). Both patients are treated with etoposide and cisplatin every four weeks for four cycles of chemotherapy. One course of therapy for patient A results in a three-log tumor cell kill (99.9%). Patient B's therapy results in only a one-log tumor cell kill (90%). Tumor growth occurs while waiting for normal tissue recovery before initiation of the next treatment. Four months into therapy, patient A has no clinically detectable disease (a CR) while patent B has had only a partial response. Patient A has a long disease-free survival, whereas patient B has a minimal survival advantage.

The cell cycle also plays an important role in designing cancer chemotherapy (see also Chapter 2). Two phases of a cell cycle can be directly observed and monitored: the S-phase and the M-phase. During S-phase (DNA synthesis), DNA replication occurs. During M-phase (mitosis), cellular division into two daughter cells is seen. [6] G_1 (gap-1) is the time from the end of mitosis to the start of the next S-phase. G_2 is the time between the completion of S and the start of M. Cells that have ceased to proliferate for prolonged periods have entered a G_0 phase (or resting phase) of the cell cycle (Figure 14.2). Most lung cancers exhibit a Gompertzian model of cell growth. With Gompertzian kinetics, the growth fraction decreases with time. In a Gompertzian model, large tumor masses have smaller growth fractions with more cells in G_0 phase. Some drugs (alkylating agents or platinum drugs) cause cytotoxicity when exposed to cancer cells in any phase of the cell cycle. Other antineoplastic agents are phase-specific; that is, they are cytotoxic primarily in a selected phase of the cell cycle. Vinorelbine, for example, induces metaphase arrest (M-phase) by blocking formation of the microtubules forming the spindle apparatus. Cells in G_0 are not killed by antineoplastic chemotherapy. Larger masses are, therefore, more resistant to chemotherapy.

FIGURE 14.2. The cell cycle is marked by two observable events, the S- and M-phases. During S-phase, DNA synthesis occurs. In the M-phase (for mitosis) cells divide. G_1 and G_2 (for gap) are times between completion of M and start of S and the completion of S and beginning of M, respectively. During G_1 and G_2, the cell prepares for the S- and M-phases of the cell cycle. Cells may temporarily cease to divide and enter a resting or G_0 phase of the cell cycle. The G_1-S checkpoint is a critical phase in the cell cycle when directions for entering S-phase or committing to apoptosis (programmed cell death) are given. Cells can be damaged by chemotherapeutic drugs or growth factor deprivation. If the damage is sublethal, it may be repaired, and the cell proceeds into the S-phase. If significant DNA damage is present, the process of programmed cell death will be initiated. However, critical factors such as p53 and p21 gene products may be required for the cell to undergo apoptosis.

Antineoplastic Drug Action and Apoptosis

Antineoplastic drugs have a variety of initial targets. However, all antineoplastic agents cause a disruption in some normal cellular process which is so significant as to require the cell either to repair quickly the damage or to initiate the process of apoptosis or programmed cell death. All antineoplastic agents result in cell death through initiation of apoptosis. Apoptosis is the normal physiologic process of cellular suicide which occurs in all living organisms to eliminate unwanted, functionally abnormal, or harmful cells (see also Chapter 2). In apoptosis, in contrast with cellular necrosis, the cell shrinks and condenses, fragmenting into multiple membrane-bound bodies (apoptotic bodies) which are engulfed by surrounding cells without inflammation or damage to the surrounding tissues. Biochemically, apoptosis is characterized by fragmentation of nuclear DNA, as demonstrated by a typical DNA ladder pattern on agarose gel electrophoresis. [7] Several typical events of early cell cycle traverse are associated with apoptosis, for example, upregulation of proto oncogenes, such as c-*myc, ras,* c-*fos,* c-*jun, cdc*-2, and phosphorylation of the protein product of the tumor suppressor retinoblastoma gene. [8] There are different cellular thresholds, or set points, for apoptosis induction and subsequent signaling. Cell types vary in their susceptibility to activating the apoptotic pathway.

There are two general categories of apoptosis: primed apoptosis and unprimed apoptosis. [9] Primed apoptosis is found in most cell types of hematopoietic lineages, where all effector molecules are expressed in the cell. In this situation, the apoptosis program can be executed directly without the requirement of active gene transcription. In unprimed apoptosis, active gene transcription is required, and the process occurs more slowly than primed apoptosis. Cells successfully progress through one round of the cell cycle but die in the subsequent cycle.

The apoptotic process can be divided into four stages. [10] The first involves the interaction between the environment and the cell to provoke a cellular response (e.g., radiation, cytotoxic drugs, growth factor withdrawal, etc.). The second stage involves detection of an apoptotic signal and transduction of that signal to downstream events. The third stage is the effector arm of the apoptotic pathway, which involves a family of cysteine proteases (now called caspases) and endonucleases, as well as other positive and negative regulators of apoptosis. Recent evidence indicates that most signal transduction pathways converge at a common effector. The final stage, corpse disposal, is the phagocytosis and digestion of apoptotic cells by neighboring cells or macrophages.

Apoptosis is closely related to the proliferation status of a cell. Overexpression and activation of genes and proteins related to increased proliferative and cell cycle progression lowers the threshold for apoptosis. While apoptosis can occur during any phase of the cell cycle, sensitivity of proliferating cells to various death stimuli is usually cell cycle–phase specific. [11] Apoptosis induced by various DNA damaging agents can be affected by the presence or absence of the G_1 checkpoint, which is regulated by p53. p53, a tetrameric, sequence-specific DNA-binding phosphoprotein, is the product of a tumor suppressor gene whose mutation represents a genetic lesion found in 50% to 55% of all cancers. [12] With p53 present, the cell cycle is generally halted at the G_1-S checkpoint. At this point, cells determine whether to continue into the S-phase or initiate the process of apoptosis (Figure 14.2).[13] Passage into the S-phase requires activation of a series of enzymes called cyclin-dependent kinases (CDKs) which activate another group of enzymes (the cyclins) required for DNA synthesis. [14] If cellular repair occurs, cyclins are activated. If damage is extensive and/or if repair is unsuccessful, the cell is directed toward the apoptotic pathway. The critical factors needed for apoptosis are currently under investigation, but some important components have been recognized. At times, loss of functional p53 inhibits the induction of apoptosis by anticancer drugs and radiation, and correlates with poor response to chemotherapy. [15] However, p53-independent pathways do exist. Over expression of antiapoptotic genes can render cancer cells resistant to drug effects. *BCL2* and *BCLX*$_1$ have the capacity to block apoptosis induction by a wide spectrum of chemotherapeutic drugs. [16] (See Figure 17.) It is clear that antineoplastic agents provide the initial trigger for initiating the pathway to programmed cell death. However, factors other than the initial interaction between a cytotoxic drug and its effector are important in determining whether tumor cell kill occurs.

Resistance to Anticancer Drugs

In the treatment of lung cancer, an initial tumor response with the subsequent growth of cells resistance to chemotherapy is a common clinical occurrence. Cancer cells can become resistant to an antineoplastic agent in many ways (Figure 14.3). In order for a drug to be active, it must: (a) be taken up into a cancer cell, and (b) be converted into an active metabolite. It must make its way within the cell to its target without being (c) metabolically inactivated, (d) chemically inactivated, or (e) excreted from the cell. Once it interacts with its cellular target, the cell must not be able to (f) alter the target or (g) repair the damage to the target. Finally, (h) mechanisms for apoptosis must be in place, as discussed in the preceding section. Examples of drug resistance caused by all of the mechanisms listed above have been described.

FIGURE 14.3. Potential pathways for antineoplastic drug disposition within tumor cells. In order for a drug to be effective, the drug, or its active metabolite, must reach its target site within the cell. Potential steps in the drug reaching its receptor include: (*1*) uptake into a cell through a particular transport protein; (*2*) enzymatic conversation of the drug to its active metabolite; (*3*) enzymatic conversion of the drug to an inactive metabolite; (*4*) binding of an active metabolite by a cellular protein or thiol, thereby inactivating drug; (*5*) excretion of the drug from the cell via an efflux transport pump; (*6*) alteration in the genetic makeup of the cell, changing the drug receptor site or number; (7) changes in the ability of a cell to repair damage of a drug at its receptor. All steps have been shown to be altered in various drug-resistant tumor cell lines.

Cancer cell, may become simultaneously resistant to several types of chemotherapeutic drugs. Cells expressing the multidrug resistance (MDR) gene produce a glycoprotein of 170 kD weight known as p-glycoprotein or p170.[18] P-glycoprotein is a cell membrane protein that transports several antineoplastic agents across the cell membrane. Most p-glycoprotein transported agents are hydrophobic. These include the vinca alkaloids, epipodophyllotoxins, anthracyclines, actinomycin, and taxanes. Cells in which the MDR gene is activated develop simultaneous resistance to all of these antineoplastic agents. The presence of p-glycoprotein on tumor cells has been correlated with poor prognosis in SCLC.[19] Because of the potential role of MDR in tumor resistance, efforts have been directed at blocking this transporter. A number of agents, including analogs of verapamil and cyclosporine, are inhibitors of MDR. Clinical trials of combinations of these inhibitors with anticancer drugs have been undertaken. Other resistant cell lines have been identified which do not overexpress p-glycoprotein, but display a similar cross-resistance pattern. Some of these lines express a different transport protein called (MRP) multidrug resistance-associated protein.[20] MRP, like p-glycoprotein, is a member of the ATP binding cassette gene superfamily. However, MRP is structurally dissimilar to p-glycoprotein, with different inhibitors. The clinical significance of MRP is under study but, like p-glycoprotein, its presence in tumor cells may be a prognostic factor.

In summary, tumor cells can develop resistance to one or several antineoplastic drugs by numerous mechanisms. Resistance develops as a result of random mutational changes in a population of cancer cells. Mutations to a resistant phenotype are estimated to occur when a mass reaches 10^4 to 10^6 tumor cells, a size smaller than clinically detectable.[20] This suggests that drug-resistant populations will be present in the majority of tumors. It leads to the rationale for: (a) early treatment of cancers to avoid multiple resistant populations, and (b) use of multiple agents with differing mechanisms of action.

Toxicity

Antineoplastic agents have the potential for life-threatening toxicity. The therapeutic window for drugs used to treat lung cancer is narrow. Doses of drug needed to achieve tumor cell kill commonly result in toxicity to normal tissues. Chemotherapeutic agents may cause a variety of toxicities. Myelosuppression and nausea are the most common toxicities seen. Nausea and vomiting, although generally self-limited and not life-threatening, are often considered most distressing by patients. The emetogenic potential of antineoplastic agents varies from drug-to-drug and is dose-dependent.[21] Serotonin receptors, located within the vagal and splanchnic nerves of the gastrointestinal system, are critical in the initiation of nausea by chemotherapeutic agents.[22] The development of specific type 3 serotonin (5-hydroxytryptamine or $5HT_3$) receptor blockers, such as ondansetron and granisetron, has resulted in major improvement in control of acute chemotherapy-induced emesis.[23] The emetogenic potential of chemotherapeutic agents used in lung cancer therapy is indicated in Table 14.1.

Myelosuppression is the most common dose-limiting toxicity encountered with antineoplastic agents. The suppression of specific hematopoietic cell lines is determined by the kinetics of the cell line in the peripheral compartment. Anemia occurs as a late effect because red blood cells have a long half-life (120 days). Thrombocytopenia occurs in an intermediate time frame shortly following granulocyte suppression. The white blood count (WBC) usually drops five to 14 days following drug administration, with recovery in three to ten days.

The range of toxicities associated with antineoplastic agents is great (Table 14.2). Oral,[24] renal,[25] neurologic,[26] hepatic,[27] pulmonary,[28] cardiac,[29] and cutaneous[30] toxicities from anticancer drugs are all seen. Many antineoplastic agents have teratogenic and mutagenic potential. Alkylating agents are the most damaging to testicular and ovarian function. Damage is dependent on drug dose, age of patient (the older being more likely to have toxicity), and sex (males greater than females).[31] Second malignancies (primarily acute leukemia) have been associated with alkylating agents, epipodophyllotoxins, nitrosoureas, and anthracycline.[32,33] Physicians need to be familiar with the toxicities of the drugs they are using and have support facilities adequate to care for patients developing treatment-related toxicity.

TABLE 14.2. TOXICITIES OF ANTINEOPLASTIC AGENTS USED FOR TREATMENT OF LUNG CANCER

GENERAL PRINCIPLES OF LUNG CANCER CHEMOTHERAPY

A physician treating patients with cytotoxic chemotherapy must be certain of the diagnosis (histology is nearly always required). The physician and patient must understand the goals of treatment (cure versus palliation). Optimal therapy requires familiarity with individual to be treated, knowledge of the drugs to be used, and the availability of appropriate laboratory and hospital support services. The physician should discuss with the patient the natural history of the cancer, the goals, and the toxicities of treatment. If cure is the goal, the patient and physician may be willing to tolerate more severe toxicity. The patient must be a partner in such decisions. In many cases, several options may be reasonable, and an informed patient can direct the physician as to whether intensive, potentially toxic therapy should be tried for a relatively small chance of cure.[34,35]

Combination chemotherapy (use of several drugs) is usually employed and multiple cycles of drugs administered to achieve adequate tumor cell kill without life-threatening toxicity or the development of tumor cell resistance. Patient selection factors are important in planning treatment. Age alone is not a reason to exclude patients from chemotherapy.[36,37] However, age-related changes in organ function, including reduced marrow reserve and decreased renal function, are commonly seen and may increase the risk of toxicity. The performance status of a patient usually correlates with response to chemotherapy. The nutritional state of a patient is important. Malnourished patients with hypoalbuminemia have increased toxicity when highly protein-bound drugs are used.[38] Appropriate dosing guidelines for obese patients are not available.[39] Doses based on actual body weight appear appropriate when the goal for therapy is cure,[40] whereas doses based on ideal body weight, with potential escalations later, are reasonable when palliation is the intent. Altered organ function may eliminate the opportunity to use certain drugs (e.g., doxorubicin in patients with heart failure or bleomycin in patients with severe pulmonary compromise). Drug doses should be modified for decreases in blood counts

(Table 14.3) and also for changes in renal and hepatic function (Table 14.4). The patient must be carefully followed for toxicity and response to chemotherapy. It is common to reevaluate patients after two to three cycles of chemotherapy to determine treatment effectiveness. If a response is seen, therapy is usually continued for a set number of courses or two cycles past a complete response. If tumor progression is noted, therapy should be discontinued. For patients with stable disease, an assessment of drug toxicity is important. If therapy is tolerable, a decision to continue treatment is reasonable, with the understanding that disease progression will eventually occur.

	100% Dose	75% Dose	50% Dose	Omit
Granulocyte	<2000	1500-1999	1000-1499	<1000
WBC	>3500	3000-3500	2500-2999	<2500
Platelet	>100,000	75-100,000	50-75,000	<50,000

TABLE 14.4. DRUGS COMMONLY USED IN TREATMENT OF LUNG CANCER WHICH REQUIRE DOSE ALTERATIONS FOR ORGAN TOXICITY

PHARMACOLOGY OF CHEMOTHERAPEUTIC AGENTS USED IN THE TREATMENT OF LUNG CANCER

Many antineoplastic agents have been evaluated for treatment of lung cancer. A comprehensive review of all these drugs is beyond the scope of this chapter. Instead, this section will focus on the agents most commonly used for the therapy of small cell and non–small cell lung cancer. For each class of drugs, the mechanism of drug action, pharmacology, including route of drug elimination, and toxicities will be reviewed.

Alkylating Agents (Cyclophosphamide and Ifosfamide)

Cyclophosphamide and ifosfamide are members of a family of antineoplastic agents whose mechanism of action involves attachment of an alkyl group to DNA. Cyclophosphamide has been used for decades for treatment of both small cell and non–small cell lung cancer. Ifosfamide, an analog of cyclophosphamide, has also demonstrated activity in both diseases.[41,42] Although other alkylating agents are occasionally used for treatment of lung cancers, cyclophosphamide and ifosfamide are the primary agents employed, and their pharmacology will be emphasized.

Mechanism of Action. Alkylating agents covalently bind alkyl groups (one or more saturated carbon atoms) to cellular molecules, including DNA, RNA, and proteins. Alkylating agents form reactive carbonyl groups which attack at electron-rich sites on adenine or guanine in the DNA molecule. [43] The active metabolites of cyclophosphamide and ifosfamide contain two reactive nitrochlorethyl groups, allowing reaction with two strands of DNA, forming cross-linkage (Figure 14.4). Alkylation occurs at the N-7 position of guanine. Alkylating agents are cell cycle nonspecific. Spacing between the nitrochlorethyl groups in cyclophosphamide is slightly different from ifosfamide and may result in different cross-linkage sites.

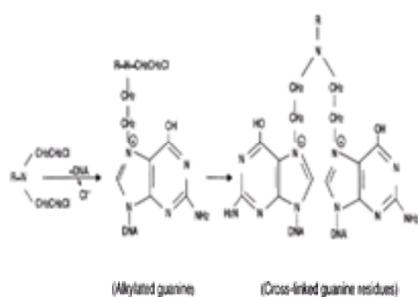
(Alkylated guanine)   (Cross-linked guanine residues)


FIGURE 14.4. Mechanism of action of alkylating agents on DNA. Alkylating agents (in this case those with two nitrochlorethyl groups) form reactive intermediates which bind to two guanine molecules, resulting in cross-linkage of DNA strands.

Thiols are nucleophilic targets within the cell which can bind alkylating agents before they reach their DNA target. Increasing the concentration of thiols decreases antineoplastic drug activity and/or toxicity. Buthione sulfonamide (BSO) decreases synthesis of glutathione (a naturally occurring thiol) and increases drug cytotoxicity.[44] The radioprotective agent amifostine (WR2721) provides an exogenous nucleophilic thiol that can decrease alkylating agent toxicity. [45]

Pharmacology. Cyclophosphamide and ifosfamide require activation via the hepatic cytochrome P450 system to produce 4-hydroxy derivatives which are taken up in tumor tissue and undergo further metabolism to form an active mustard metabolite (Figure 14.5). Drugs inducing or inhibiting the microsomal enzyme system, such as phenobarbital, can alter the plasma kinetics of cyclophosphamide and its metabolites. However, these kinetic changes do not appear to have any effects on the toxicity of this drug.[46] Ifosfamide, a structural analog of cyclophosphamide, has a slightly different metabolite pathway from cyclophosphamide. Less drug is converted to a mustard (activated), so higher drug doses are required. [47] Only a small amount of the dichlorethyl metabolite (Figure 14.5) is formed when cyclophosphamide is administered, but this metabolite is generated to a significant extent following ifosfamide administration. The dichlorethyl metabolite likely accounts for the CNS toxicity seen with ifosfamide.[48] The excretion of reactive acrolein and dichlorethyl metabolites into the bladder following use of either cyclophosphamide or ifosfamide can result in cystitis. Mercaptoethane sulfonate (MESNA) is administered in equivalent doses to all patients receiving ifosfamide and to patients receiving high-dose cyclophosphamide to prevent cystitis by binding these reactive metabolites. [49] In plasma, MESNA circulates in an inactive dimesna form, so that antineoplastic activity

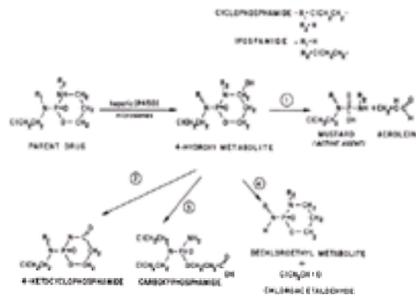
of the alkylating agent is not affected.


FIGURE 14.5. Metabolism of cyclophosphamide and ifosfamide: these drugs can be metabolized to the active agents (mustards) or to inactive metabolites. Because of the minor structural differences, the rate of formation of different metabolites is different between cyclophosphamide and ifosfamide. Less ifosfamide is converted to active metabolite. The dichloro metabolite is formed to a greater extent with ifosfamide.

Toxicity. Marrow suppression occurs in all hematopoietic cells with alkylating agent use. However, a relative platelet and stem cell sparing effect occurs with cyclophosphamide.[50] Nausea and vomiting are frequent with high doses of alkylating agents but decrease with low-dose oral regimens. Pulmonary fibrosis can be seen.[51] Bladder toxicity occurs with ifosfamide and cyclophosphamide. Renal toxicity has been reported with ifosfamide.[52] As previously mentioned, ifosfamide is associated with CNS toxicity (somnolence, confusion), particularly at high doses in patients with low serum albumin (less than 3g per dl) or high serum creatinine (more than 1.5 mg per dl).[53] Cyclophosphamide and ifosfamide, like all alkylating agents, are teratogenic and carcinogenic. Gonadal atrophy and permanent loss of reproductive function can occur.[54]

Platinum Analogs (Cisplatin, Carboplatin)

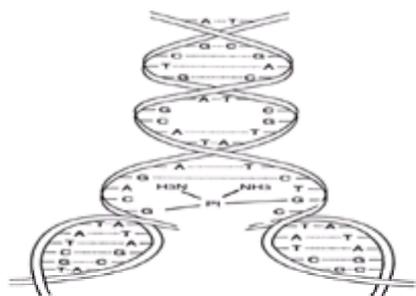
Mechanisms of Action. Cisplatin, carboplatin, and the investigational agent oxalloplatin are heavy-metal complexes that induce tumor cell kill by cross-linking DNA strands in a manner analogous to the alkylating agents. Reactive aquated platinum intermediates are formed within cells that directly and covalently bind to DNA, leading to DNA cross-links[55] (Figure 14.6). Cisplatin is more reactive in water than carboplatin. Chloride-containing solutions are required to stabilize cisplatin. The difference in aqueous stability between the various platinum analogs results in differences in each agent's pharmacokinetics and toxicity.


FIGURE 14.6. A schematic representation of cellular DNA showing covalently bonded cross-links from a cisplatin inhibiting the progress of DNA replication.

Pharmacology. Cisplatin and carboplatin are the only two platinum analogs currently used for treatment of lung cancer. Their pharmacology differs significantly. Cisplatin more rapidly forms reactive intermediates in plasma. Over 90% of cisplatin is protein-bound and inactivated within two to four hours.[56] Thus protein-binding represents the major route of drug elimination. Only the free (unbound) platinum species are cytotoxic.[57] Carboplatin is less reactive, with only 20% to 40% of total platinum protein-bound at two hours following drug administration. Renal excretion is the primary route of carboplatinum elimination (70% of total carboplatin clearance). Carboplatin clearance is highly correlated with creatinine clearance.[58] Carboplatinum doses should be calculated based on an individual patient's creatinine clearance[59] rather than based on body weight or body surface area (BSA).[60]

Toxicity. The toxicity profiles of cisplatin and carboplatin differ.[61] Myelosuppression is rare with cisplatin, although moderate anemia is common. Nausea and vomiting are common cisplatin toxicities, but the frequency of emesis can be reduced with pretreatment use of dexamethasone (Decadron) and serotonin antagonists.[62] Nephrotoxicity, represented by azotemia and electrolyte disturbances (primarily hypokalemenia and hypomagnesemia), is dose-related. Although pre- and posttreatment hydration (with chloride-containing solutions) and diuresis reduce the incidence and severity of cisplatin nephrotoxicity, moderate and permanent reductions in GFR may still occur.[63] Neurotoxicity from cisplatin is cumulatively dose-related and usually begins as a "stocking-glove" type peripheral neuropathy. Hearing loss, cortical blindness, and seizures have also been reported. The toxicity profile of carboplatin is different from that of cisplatin, with dose-limiting myelosuppression (primarily thrombocytopenia) being the major toxicity, following carboplatin administration.[64] The renal, neurologic, and oto-toxicities noted with cisplatin are infrequent occurrences after carboplatin administration.[65] Dose reductions of carboplatin must be made in patients with impaired renal function. Several formulas are available for calculating dose adjustments, based on creatinine clearance and desired nadir platelet count.[59,60]

MICROTUBULAR INHIBITORS (Vincristine, Vinblastine, Vinorelbine, Paclitaxel, Docetaxel)

Several drugs initiate apoptosis through interactions with microtubulin, the protein used to form the mitotic spindle apparatus. The vinca alkaloids block the formation of microtubulin, while the taxanes increase assembly and stability of microtubulin.

Vinca Alkaloids (Vinblastine, Vincristine, and Vinorelbine)

Mechanism of Action. Several vinca alkaloids have been synthesized and evaluated preclinically. Three, vinblastine, vincristine and vinorelbine, are clinically available. All bind to tubulin and inhibit the formation of microtubulin, a protein that is essential for maintenance of cellular shape and for formation of the mitotic spindle.[66] Cells treated with vinca alkaloids are arrested in metaphase. Differences in activity and toxicity of the vinca alkaloids result from variations in their pharmacokinetic properties, differential effects on various tubulin isoforms, and upon differences in tissue penetration and cellular retention.[67] Resistance results from the presence of p-glycoprotein or reduced tubulin-binding within tumor cells.

Pharmacology. All vincas are rapidly taken up into cells. However, the individual agents differ in their cellular retention (vinblastine greater than vincristine). All vincas are extensively bound to tissues and to protein.[68] Their terminal half-lives are long (20 to 60 hours). The vinca alkaloids are metabolized by the liver and excreted into the bile. Doses need to be reduced for hepatic dysfunction but not for renal insufficiency. Specific dose-reduction guidelines for hepatic function impairment are not available.

Toxicity. Vincristine causes little myelosuppression. Neurotoxicity occurs frequently and is dose-limiting.[69] It commonly presents as a symmetric, distal, sensory-motor neuropathy. Loss of deep tendon reflexes in the lower extremities and paresthesias of the fingers and toes are common early findings. Foot-drop or wrist-drop,

neuropathies of cranial nerves, constipation, cramps, and paralytic ileus have been reported. The dose-limiting toxicity of vinblastine is hematopoietic. [70] The onset of myelosuppression occurs earlier with this agent than with other antineoplastics. Severe neurotoxic symptoms are unusual with vinblastine, but use of the drug is associated with myalgias and an autonomic neuropathy manifested by orthostatic hypotension or paralytic ileus. Vinorelbine shows toxicities similar to other vincas. Its dose-limiting toxicity is myelosuppression. Although the incidence of grade 3 to 4 neutropenia is high (60%), only 7% of patients develop neutropenia fever. Nonhematologic toxicity from vinorelbine is generally mild in severity. Constipation (30%), neuropathy (20%, severe in less than 1%) and nausea (grade 3 to 4 in 2%) are seen.[71] Vinca alkaloids are *vesicants* and need to be given with care.

Taxanes (Paclitaxel and Docetaxel)

Mechanism of Action. Paclitaxel and docetaxel bind to a unique site on microtubulin, resulting in increased microtubulin assembly and stabilization. [72] The bundling of microtubules induced by the taxanes blocks cells in metaphase and induces apoptosis. The taxanes have activity against most lung cancers. [73] They are also potent radiation sensitizers. Although both taxanes bind to the same site on the b subunit of tubulin, docetaxel produces microtubules of larger size. Docetaxel is also more avidly taken up by cells and is two to three times more potent than paclitaxel. [74] Paclitaxel and docetaxel are not cross-resistant.

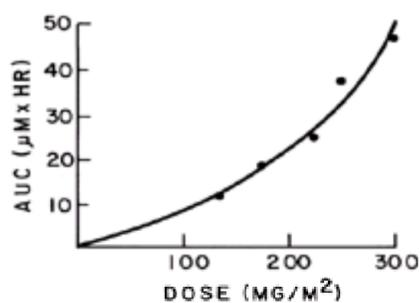
Pharmacology. Paclitaxel is primarily cleared from the body by hepatic metabolism via cytochrome P450 2C8 and 3A4 enzymes. [75] This route of elimination can be saturated so that nonlinear kinetics are noted (Figure 14.7).[76] A 30% increase in drug dose (from 135 to 175 mg per m^2) results in an increased plasma drug concentration of 75%.[77] Docetaxel is also metabolized by the hepatic microsomal enzyme system (predominantly CYP3A4). In contrast to paclitaxel, docetaxel exhibits linear kinetics. It has been postulated that the vehicle in which paclitaxel is dissolved (Cremophor EL) accounts for nonlinear paclitaxel kinetics by inhibiting hepatic drug excretion.[78] Drugs that inhibit CYP3A or CYP2C8 may inhibit the clearance of the taxanes. [79] Several drug interactions have been identified when paclitaxel is used. If cisplatin is given before paclitaxel, delayed paclitaxel clearance is noted, with increased neutropenia. In contrast, the combined use of carboplatin and paclitaxel results in decreased thrombocytopenia. Anticonvulsants and steroids increase paclitaxel clearance. [79] No drug interactions have been clearly demonstrated with docetaxel. Because of their extensive hepatic metabolism, dose reductions of both paclitaxel and docetaxel are needed in patients with hyperbilirubinemia.


FIGURE 14.7. Plot of the area under the concentration time curve (AUC) of paclitaxel plotted against the dose of drug given as a three-hour infusion.

Toxicity. Myelosuppression is the principle toxicity of both paclitaxel and docetaxel. Longer infusion of paclitaxel produces greater neutropenia than shorter infusions.[74] Hypersensitivity reactions (dyspnea, urticaria, and hypotension) were seen in 25% of patients initially treated with paclitaxel. [80] With prophylactic use of decadron and antihistamines, these reactions are uncommon (1%). Paclitaxel induces a peripheral neuropathy. Nausea and vomiting are uncommon but alopecia is seen. Docetaxel induces edema formation and an erythematous maculopapular rash in up to 60% of patients.[81] A syndrome of cumulative fluid retention (pleural effusions, edema) is also an effect unique to docetaxel, occurring in half of patients at cumulative doses of 400 mg per m. ^{2} Fluid retention can be treated with prophylactic steroid therapy. A dose-related syndrome of myalgias and arthralgias is seen 24 to 72 hours after paclitaxel but not with docetaxel. The combined use of paclitaxel and doxorubicin results in an increased rate of congestive heart failure. [82]

Topoisomerase Inhibitors (Etoposide, Doxorubicin, Irinotecan, and Topotecan)

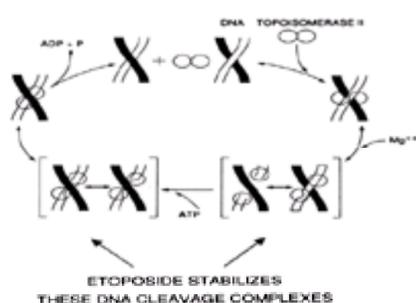
Mechanism of Action. Topoisomerase II (topo II) normally functions within the cell to carry out necessary breakage-reunion reactions of mammalian DNA. [83] Etoposide, an epipodophyllotoxin, and doxorubicin, an anthracycline, bind with topo II and DNA to form a stabilized cleavable complex inhibiting the enzyme's ability to relegate cleaved DNA (Figure 14.8).[84],[85] Irinotecan (CPT-11) and topotecan are anticancer agents that inhibit the activity of topoisomerase I, a separate enzyme also important in maintaining DNA structure. Topoisomerase I functions in a manner similar to topo II to help unwind supercoiled DNA. [86] Unlike topo II, topo I is expressed at relatively constant levels throughout the cell cycle. [87] It is hoped that topoisomerase I inhibitors may therefore be more active in tumors with low growth fractions. Topo I results in single-strand DNA breaks, while topo II can cause double-stranded breaks. The activity of topoisomerase inhibitors appears to be schedule-dependent.[88]


FIGURE 14.8. The catalytic cycle of topoisomerase II. Dimeric topoisomerase II binds to DNA. In the presence of magnesium and ATP, an intact DNA helix can pass through a temporary break in DNA with subsequent relegation. Etoposide and doxorubicin block the cycle at the stage of DNA cleavage.

Pharmacology. While the four topoisomerase agents have similar mechanisms of action, the pharmacology and toxicities of these agents differ significantly.

Etoposide can be given by both intravenous and oral routes. Oral bioavailability ranges from 40% to 70%, with significant interpatient variability. [89] Bioavailability decreases at doses greater than 300 mg. Etoposide is highly protein-bound. One third of drug is excreted intact into the urine, and 40% undergoes hepatic metabolism. Obstructive jaundice does not alter the clearance of etoposide. [90] Etoposide is poorly soluble in water and can precipitate in solution if not adequately diluted. It must be given as a one-hour infusion to avoid hypersensitivity reactions. Etoposide phosphate (Etopophos) is a water-soluble prodrug of etoposide which can be given as a rapid intravenous infusion. [91]

Doxorubicin (Adriamycin) is metabolized in the liver to its alcohol metabolite (doxorubincinol) and excreted into the bile. [92] Dose reductions in patients with hepatic function impairment are recommended. Specific guidelines as to appropriate dosing schedules are lacking. [93] Urinary excretion of doxorubicin is minimal. Use of paclitaxel prior to doxorubicin decreases doxorubicin clearance and increases its toxicity. [94]

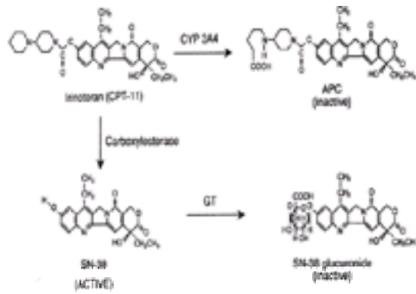
Irinotecan is a prodrug that is rapidly converted through carboxylesterases to the active metabolite SN38 (7-ethyl-10 hydroxycamptothecin) (Figure 14.9). Both irinotecan and SN38 exist in open and closed lactone ring forms in the plasma, with the closed form being active. [95] SN38 is inactivated via glucuronidation. Irinotecan and metabolites are primarily cleared by biliary excretion. Renal excretion accounts for 10% to 35% of drug clearance. Formal recommendations for dosing in patients with renal or hepatic function impairment have not been made, but patients with hyperbilirubinemia appear to at increased risk of myelosuppressive toxicity. [96] Decreased ability to conjugate SN38 may correlate with gastrointestinal toxicity. [97]


FIGURE 14.9. Metabolism of irinotecan. Parent drug is converted to an active metabolite (SN-38) through action of carboxylesterase enzymes. Hepatic metabolism via the hepatic cytochrome system (CYP3A4) or glucuronosyltransferase (GT) converts drug to inactive metabolites.

Topotecan also exists in open and closed lactone ring forms. Elimination of topotecan is primarily through the kidneys (30% to 65% of drug). [98] Dose reductions are recommended for patients with renal insufficiency (creatinine clearance less than 20 ml per min: no treatment; 20 to 40 ml per min: 50% dose reduction). [99] No dosing changes appear needed for patients with liver function impairment, although the number of patient studied is small. [100]

Toxicities. Common etoposide toxicities include bone marrow suppression, mild nausea, and hair loss. [101],[102] Myelosuppression is the dose-limiting toxicity. At doses of 100 mg per m^2 per day for 3 days, 8% of patients develop a WBC nadir below 1000 per mm. [3] An allergic reaction to drug administration, manifested by hypertension, wheezing, fever, and dyspnea, may occur when etoposide is given over periods shorter than one hour. This reaction may be related to the solvents needed to solubilize etoposide. Development of acute nonlymphocytic leukemia (ANNL) in patients treated with either etoposide or teniposide has been reported by several centers.[103],[104] The leukemia is associated with cytogenetic abnormalities involving chromosome 11 (11q23). The six-year risk of developing leukemia in patients receiving high cumulative etoposide doses appears to be roughly 3%. Common *doxorubicin* toxicities include bone marrow suppression, mucositis, alopecia, and cardiac toxicity.[105],[106] Myelosuppression and mucositis follow an acute course, with the maximum toxicity occurring seven to ten days after drug administration. The cardiac toxicity induced by anthracycline antibiotics can be manifested in both acute and chronic forms. [106] The mechanism of myocardial toxicity is thought to be drug-induced oxidative damage caused by free-radical generation. The risk of developing congestive heart failure is greater with increasing cumulative drug dose, increasing age, underlying cardiac disease, high peak plasma concentrations, and previous or concurrent cardiac irradiation. [107] High peak plasma drug concentrations induce greater free-radical formation. Therefore lower, more frequent drug doses result in less potential for development of heart failure. For doxorubicin, the most commonly used total dose limit is 550 mg per m.[2],[108] At this cumulative dose, the risk of clinical cardiac toxicity is 3% to 7%. Heart failure can occur months to years after discontinuing treatment.[109] Dexrazoxane (Zinecard, ICRF-187) is an iron chelator that blocks the generation of free radicals from anthracyclines. It has been shown to prevent cardiac toxicity without altering antitumor activity. [110] Extravasation of the anthracycline antibiotics can lead to severe local tissue damage, which can progress over weeks to months. Administration of doxorubicin can result in recall of radiation-associated tissue damage, such as skin erythema, mucositis, and esophagitis.

Diarrhea and myelosuppression are the primary toxicities associated with *irinotecan* use. Administration of drug on an every three-week schedule produces more myelosuppression, while weekly treatment results in greater diarrhea. [111] Although neutropenia is common with irinotecan, other hematologic toxicities are generally mild, with only a minority of patients developing significant (grade 3 to 4) thrombocytopenia (4%) or anemia (16%). Irinotecan is associated with two forms of diarrhea. The first type occurs during or just after the infusion of irinotecan and has a cholinergic mechanism. The use of atropine at the onset of this diarrhea is effective. The second type of diarrhea begins three to five days after the infusion of irinotecan and may be moderate to severe in 20% of patients. Aggressive treatment with antimotility agents at the onset of the diarrhea (loperamide given at a dose of 4 mg at the time of first loose stool, then 2 mg every two hours until no bowel movements for 12 hours) may obviate the severity of the diarrhea.[112] If the diarrhea is not treated early, it usually runs a 5 to 7-day course. The mechanism for development of diarrhea is unknown but may be secondary to the biliary excretion of the active metabolite SN-38. [97] In addition to dose-limiting myelosuppression and diarrhea, other toxicities reported with irinotecan include alopecia, transaminasemia, and malaise. [95] The dose-limiting toxicities of topotecan are neutropenia and thrombocytopenia, usually short-lived (less than seven days). Heavily pretreated patients have more severe myelosuppression and may need a dose reduction. [113] Nausea is mild. Diarrhea is uncommon except after oral drug use.[114] Other nonhematologic toxicity includes mucositis, alopecia, skin rash, and fever, all mild. [98]

Antimetabolites (Gemcitabine)

Most antimetabolite antineoplastic agents are ineffective in the treatment of lung cancer. The primary exception is gemcitabine [2'-deoxy-2', 2'-difluorocytidine monohydrochloride; dFdC] which has shown significant activity in the treatment of NSCLC.

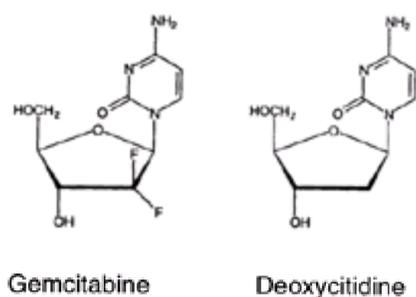
Mechanism of Action. Gemcitabine is an analog of deoxycytidine (Figure 14.10). It is a prodrug which is taken up into the cell and phosphoylated to gemcitabine di- and triphosphates, which are the active metabolites. [115] When gemcitabine triphosphate is incorporated into the DNA chain, DNA polymerase can add only a single additional nucleotide, after which chain elongation is terminated. Importantly, gemcitabine triphosphate in the nonterminal position DNA chain prevents detection and "repair" by proofreading exonucleases.[116] Additional effects of gemcitabine di- and triphosphates include inhibition of ribonucleotide reductase depleting deoxyribonucleotide pools available for DNA repair. [117]


FIGURE 14.10. Chemical structures of gemcitabine and deoxycytidine.

Pharmacology. Plasma concentrations of gemcitabine generally reach a plateau 15 minutes after a 30-minute infusion. There is a linear relationship between the steady-state concentration of gemcitabine and dose up to 1,000 mg per m.[2],[118] Plasma protein-binding is negligible. Gemcitabine is inactivated by several aytidine deaminase in organs (blood, aytidine deaminase in liver, kidneys) so that its half-life is short (32–94 minutes). [119] Almost all administered drug is excreted in the urine

as the inactive metabolite 2 deoxy-2, 2-difluorouridine.[120] No dose adjustments are needed for liver or hepatic insufficiency. Gemcitabine undergoes intracellular metabolism to the mono-, di- and triphosphate moieties; these metabolites are not found in plasma or urine.

Toxicity. The primary toxicity of gemcitabine is myelosuppression. At an average dose of 1000 mg per m^2 given weekly for 3 weeks each month, 4% of patients have grade 4 neutropenia and 2% grade 4 thrombocytopenia.[118,119] Elevation in hepatic transaninases and alkaline phosphatase is frequently seen (10% of patients), but usually is transient and modest. Nausea and vomiting (all grades) are seen in many patients (70%), but are severe in only occasional patients (grade 3: 13%; grade 4: 1%).[120] Other reported toxicities include fever, rash, dyspnea, and hematuria.[121,122] Gemcitabine is not a vesicant.

CHEMOTHERAPY–RADIATION INTERACTION

AFSHIN DOWLATI
RUTH LOUISE EAKIN
TIMOTHY J. KINSELLA

</div>

Combinations of chemotherapy and radiotherapy have been used and investigated in the treatment of human cancers for more than 30 years. During this time, clinical and laboratory investigations have become increasingly complex because the understanding of interactions and mechanisms have improved. Basic clinical observations have been critically important; for example, when local treatment such as radiotherapy was given successfully for apparently localized intrathoracic disease, systemic relapse was still seen to occur in a significant proportion of patients despite the maintenance of local control. Likewise, chemotherapy, which produced good responses in metastatic disease, particularly in the lymphomas, could not prevent relapse in sites of initial bulk disease. The potential advantages of combining modalities were obvious from early days.

The main context in which to consider chemotherapy–radiotherapy interactions in non–small cell lung cancer (NSCLC) is in locally advanced stage III disease, where until the last decade, radiation therapy and surgery have played the major roles. In contrast, chemotherapy has been the cornerstone of treatment for small cell lung cancer (SCLC) with the issues of thoracic radiotherapy and prophylactic cranial irradiation in limited-stage disease becoming increasingly important over the last two decades.

Radiation therapy has developed markedly over the last century, and optimal fractionation schedules continue to be sought, alongside the improvements in its technical and conformal application. Chemotherapy has, over the last 40 years, mushroomed in its complexity of combinations and integration of new compounds. The outlook for patients with SCLC has changed considerably in recent decades because of well-structured clinical trials designed to reveal the optimal combinations of chemoradiation, and is one of the many examples of progress in this field to date. On the other hand, progress in the treatment of NSCLC has made more modest gains. Local control has been hard to improve, and impacts of systemic therapy on survival have only been modest in comparison. Despite this progress treatment results in both major types of lung cancer are still poor overall, although recent developments do allow significant optimism. Progress is being made, and with improved understandings of combined modality therapy at the molecular, cellular, and clinical levels, not only can clinical trial protocols be better designed, but of course, better outcomes, can also be realized for patients with small cell and non–small cell lung carcinomas.

BASIC CONCEPTS

When radiation therapy and chemotherapy are combined, the therapeutic result can be improved over single modality treatment by one or more theoretical means. They can contribute independently of each other (spatial cooperation); they can improve primary tumor response without increasing toxicity beyond tolerance; or they can decrease normal tissue toxicities without changing tumor response, thereby allowing increased doses or the addition of other anticancer agents. Two key considerations in any combination of radiotherapy and chemotherapy are doses and timing, relative to each other. If radiotherapy is given first, tumor bulk is likely to shrink, which would theoretically allow better drug distribution. It is also recognized clinically that chemotherapy is better able to achieve a sustainable response when small bulk of disease is present; however, giving radiotherapy first delays systemic therapy and may allow metastases to grow, making them subsequently less likely to be eliminated by chemotherapy. If chemotherapy is given first, it will theoretically tackle micrometastases at the earliest possible opportunity, thereby giving the best chance of elimination. However, delaying definitive management of the primary tumor can also be detrimental. Whatever way these many possible interactions are viewed, it is vital to be clear about definitions.

Definition of Terms

Having clear definitions is fundamental to the discussion of any complex interaction. [1] Terms that have been used previously in the context of chemoradiation include *synergy,* to describe an additive effect. This term does not clarify whether the synergistic combination resulted in an effect that was equal to the sum of the individual chemotherapy and radiotherapy effects, or whether it was in fact equivalent to slightly more or slightly less than the sum. The term synergy is often used to mean an effect greater than the sum of the individual effects. In addition, it is necessary to try and differentiate the *sensitization* of one modality by the other, from the simple cooperation of geographically remote effects of each modality.

Therapeutic Ratio and Dose Effects

Radiotherapy and chemotherapy *in vivo* unfortunately cannot treat cancer cells exclusively but will inevitably affect normal cells and tissues. During a course of radiotherapy, the target volume and beam arrangements are designed to maximize dose to tumor, while keeping dose to surrounding normal tissues as low as possible. Typically, for lung cancers, the dose-limiting factor is normal tissue tolerances to the adjacent normal lung, esophagus, and less commonly heart. Similarly with chemotherapy, the ability of normal tissues, principally bone marrow, to recover in relation to the rate of tumor regrowth again determines maximum tolerated doses. With certain drugs, such as the platinum analogs, there may be enhanced acute normal tissue toxicities, such as esophageal mucositis, when used concomitantly with thoracic irradiation. The *therapeutic ratio* is therefore defined as the ratio of effect(s) of any given intervention on tumor tissue to its effect(s) on normal tissues. Manipulation of treatment strategies is aimed at improving the therapeutic ratio. It should also be noted that a combination of treatments, in some circumstances, can improve therapeutic outcome without necessarily improving the therapeutic ratio.

In terms of combined modality therapy (CMT), the therapeutic ratio can be calculated using the concept of *dose-effect factor* (DEF).[2] The DEF is the ratio of radiation dose required for a given effect to the radiation dose required with chemotherapy to cause the same effect, and can be applied to effect on both tumor or on normal tissues. Thus the therapeutic ratio can be improved by either an increase in DEF for tumor with no change in DEF for normal tissue, or by no change in DEF for tumor and a decrease in DEF for normal tissue.

Spatial Cooperation

The concept of *spatial cooperation* was first described by Steel and Peckham,[3] and relates to situations where the effects of chemotherapy and radiotherapy are thought to be anatomically independent. Ideally, their combined toxicity is also independent, but in reality this does not always follow. An example of spatial cooperation is seen in SCLC, where prophylactic cranial irradiation is used to treat a common site of spread that chemotherapy does not reach because of the

blood–brain barrier. In this type of beneficial combination, a physical interaction between the two modalities is not required to obtain an overall therapeutic benefit.

Enhancement

Enhancement is a global term for an increased cell-killing effect and should be used when it is not possible to be more precise. If the effect of combined chemoradiation is equal to the sum of the individual effects, then it is considered to be *additive.* If the combined effect is greater than the sum, then it is *supraadditive.* If it is less than the sum, but greater than the more effective single modality, then it is *subadditive.* If one of the two agents does not have an effect on its own, then it causes a *sensitizing* effect. Enhancement is seen to occur with intrathoracic radiotherapy plus combination chemotherapy, again in the CMT of SCLC and to a lesser extent, in the current combined modality treatment of NSCLC.

Diminution

In contrast, *diminution* implies reduction of overall effect. When the combined effect is less than that seen with the more effective single modality, then it constitutes *inhibition.* When it is not as effective as the less active single modality, then it is *antagonism.* When one of the agents is not active against the disease by itself, such as ethylol, then *protection* is used to describe the combined effect as it relates to a reduction of normal tissue toxicity, such as esophagitis.

How to accurately quantify these different combinations of effects remains difficult, although Steel and Peckham have described the important concept of isobologram analysis, in which "envelopes of additivity" are constructed.[3] These, however, only apply when the unimodal dose-response curves are close to linear. There are many known variables, such as the radiation fractionation, the time interval for combined modality therapy, and tumor cell kinetics, which unfortunately make this method not universally applicable.

Mechanisms of Interaction

Cellular damage by radiation is thought to be caused by direct photon "hits" on cellular DNA, and indirectly by free radical formation causing subsequent DNA damage. It is plausible that cytotoxic chemicals could interfere with the radiation reaction at this level by perhaps stabilizing free radicals, by enzyme inhibition, or by physically altering the molecular target for effective cell kill by radiation. The cell survival curves of megavoltage radiation for different cell lines are all remarkably similar, with a shoulder at the low-dose range and a log-linear exponential progression at higher doses. At lower doses, greater potential exists for DNA repair, or sublethal damage repair (SLDR), and the intrinsic repair capacity of the specific cellular DNA irradiated determines the initial slope of the curve. Chemotherapy may, by whatever means, cause inhibition of SLDR, or potentially lethal damage repair (PLDR), and in fact this action is predominantly implicated. These functionally defined repair processes are thought to represent the repair of single- and double-stranded DNA breaks, which occur in the first few hours after irradiation. Radiation could, of course, also inhibit the cellular repair processes activated following chemotherapy-induced damage. A more complete understanding of radiation damage and repair pathways, as currently understood, is reviewed recently (see also Chapter 12, Chapter 13).[4]

Other important radiobiologic components of fractionated radiation therapy include the phenomena of repopulation, redistribution, and reoxygenation. *Repopulation* results from continued cell division, and in some experimental tumor models it has been shown to accelerate after 2 to 3 weeks of treatment. *Redistribution* occurs because of varying sensitivity of cells in relation to the cell cycle, which can lead to recruitment of more cells out of the resting (Go) phase and thus a buildup of cells in any one part of the cell cycle. For example, one of the known actions of hydroxyurea is a G1/S-phase block, which could conceivably cause accumulation of cells by redistribution into a radiosensitive part of the cell cycle, thus enhancing the overall killing effect. By this mechanism, reduction of accelerated proliferation might also be induced, causing an enhanced radiation effect.

The mechanisms of *reoxygenation* are not clearly understood, but are probably caused in part by cell loss and improved vascular supply to acutely or chronically hypoxic cells. Chemotherapy could alter the proportion of oxygenated cells in the radiotherapy portal, thereby altering its effectiveness. Likewise, radiotherapy almost certainly causes improved blood supply and drug delivery to an area, if given prior to chemotherapy.

Whatever way the combination of drug(s) and radiation interact at a molecular or cellular level, clear evidence exists that bulk of tumor tissue plays an important role. This correlation is in part related to reoxygenation but also to improved blood supply, revascularisation, and drug delivery.

These concepts are some of the mechanisms that form the theoretical basis of interaction. Many other factors further complicate and influence these mechanisms to varying degrees, such as the specific chemotherapy drug or combination of drugs, drug doses, drug dose scheduling, radiotherapy fractionation scheme, radiation dose-per-fraction, overall radiation dose, radiation dose rate, and timing of chemoradiotherapy. In addition, the key to benefiting patients lies in the difference between what happens in normal tissues compared to tumor tissues. Dose-responses and timing are discussed in the next two sections.

Dose-Response Relationships

Much work has been done on dose-response for radiation and chemotherapy drugs, both on different tumor types and on different normal tissues. Underlying this work is the definition of cell survival, which is that the cell is able to retain its proliferative capacity for approximately five or six cell divisions; that is, clonogenic survival.

Radiotherapy Dose-Response

Survival curves for radiotherapy are similar in shape for different tissues and tumors. The shoulder, as discussed previously, is in the lower dose range and is thought to represent the ability of the cells to repair sublethal damage. When radiotherapy is fractionated, this phenomenon helps to increase the therapeutic ratio because of the intrinsic difference in SLDR capacity of tumor and normal tissue. Several representative mathematical models have been proposed over the years, the most widely and currently accepted being the linear-quadratic (LQ) model. This model allows for the theory of ionizing radiation either causing a single, lethal, chromosomal double-stranded break (alpha or linear interaction), or causing a sublethal, single-stranded break, in which case more than one is required to produce cell death (beta or quadratic component). On experimentally plotting survival curves for all the different normal tissues, it became apparent that there were basically two quite different types of normal tissue responders—early and late. The early-responding tissues, such as skin, bone marrow, and gastrointestinal mucosa, were noted to be tissues with a rapid cell turnover, and late-responding tissues, such as central nervous system, kidney, or lung, were noted to have a slow normal cell turnover rate. Tumor tissue was seen to act more like acute-responding normal tissues. The effects of increasing dose to tumor and to different types of normal tissue must be appreciated if the potential therapeutic effects of combined modality therapy are to be optimized.

Dose-response to radiotherapy is well documented clinically. One of the interesting questions often asked is in relation to how much more benefit could potentially be achieved by increasing the dose any further than is already achieved at standard dose. The standard dose represents the highest or most effective dose that can currently be given within the context of acceptable normal tissue toxicities. The only ways of further escalating the radiation dose to tumor, relative to normal tissues, would be by using more technical/conformal-based approaches, or by applying *in vivo* modulators (such as radioprotectors/radiosensitizers), both of which have their potential advantages and disadvantages. A recent Radiation Therapy Oncology Group (RTOG) study of hyperfractionated radiotherapy compared dose levels in NSCLC, and was able to indicate a dose above which no additional benefit was achieved.[5] Once a maximum radiation dose-tumor response relationship is established, then alternative approaches must be pursued.

The total radiation dose and radiobiologic dose must also be considered. For example, a total dose of 52.4Gy given over 20 daily fractions (262cGy per fraction) is considered to be radiobiologically equivalent to a total dose of 64Gy given over 32 daily fractions (200cGy per fraction), in terms of tumor cell kill. In this comparison, the higher dose per fraction regimen can cause worse late-normal tissue toxicities, even though the total dose is lower. The current development of altered fractionation schedules is based on radiobiologic data (both laboratory and clinical) suggesting ways of increasing the differential between tumor and normal tissue responses. In a *hyperfractionated* schedule, the total number of fractions is increased without altering overall treatment time, thereby allowing for an increased total dose but necessitating a reduced dose per fraction because of enhanced toxicity. In an *accelerated fractionation* schedule, the overall treatment time is shortened, with total dose, number of fractions, and dose per fraction being unchanged or slightly reduced. These factors are important when considering the addition of chemotherapy.

Chemotherapy Dose-Response

Survival curves for chemotherapy agents vary widely for different tissues. [6] They also vary depending on dose of drug, whether single or combination therapy is used, and whether a single administration or multiple administrations are given. If multiple administrations are given, the interval time and individual drug doses, plus any interaction, all participate in affecting overall response. In addition, the pharmacokinetic properties of individual drugs are extremely important in determining bioavailability, which is often further altered at the tumor site by factors such as heterogeneous tumor blood flow. Sanctuary sites, such as the central nervous system, and drug resistance are other reasons for chemotherapy failure, which simply increasing dose will not overcome.

An abundance of evidence supports the theory that increasing the dose results in increases in tumor response. However, two distinct categories of dose-escalation characteristics have been recognized: A dose-response survival curve, which levels off in the higher range (e.g., vinca alkaloids and methotrexate) and the classical log-linear dose-response curve, which continues indefinitely (e.g., alkylating agents). In recent years, the limiting factor for the latter (i.e., bone marrow toxicity) has been partially breached by the development of peripheral blood stem cell transplantation. It is now the other dose-limiting toxicities, such as gastrointestinal, pulmonary, or neurological toxicities, that continue to produce the barriers to any further dose escalation.

Mechanisms of Cell Death

As can be implicated by the preceding definition of cell survival (i.e., clonogenic or reproductive survival) the converse definition applies to the process of mitotic cell death (i.e., cells that are unable to sustain proliferation beyond one or a few cell divisions). This reaction occurs as a direct result of injury, whether through radiation, cytotoxic chemicals, heat, or other physical insults. DNA degradation occurs late, after cytoplasm and membrane breakdown. In contrast, programmed cell death or apoptosis is a normal physiological two-phase process involving the formation of microscopically recognizable apoptotic bodies, and occurs regularly *in vivo.* Characteristically, DNA degradation occurs first, followed by degeneration of the rest of the cell and subsequent loss of membrane integrity. This process is responsible for such natural events as tissue involution during embryonic development, or as part of the renewal process during regeneration of the gastrointestinal tract lining, and has been identified within tumors as well. Less than 20 years ago, radiation-induced apoptosis was also described, although it is thought to represent only a fraction of all radiation-induced cell death. It has nonetheless become an important line of investigation because the genes and proteins associated with controlling apoptosis become obvious potential targets for therapy. [4]

Timing of Radiation and Chemotherapy

In CMT, clearly the decision about sequencing is a key aspect to achieving optimal therapeutic benefit. Experimentally, the effectiveness can vary dramatically with timing of chemotherapy administration relative to irradiation, as has been illustrated by the varying times of maximum and minimum cell kill in intestinal crypt cells. [2] Hill and colleagues have also demonstrated that initial *in vitro* exposure of mammalian tumor cell lines to fractionated radiotherapy significantly alters their drug-response patterns, but prior exposure to chemotherapy does not generally alter radiation response. [7] The individual variation of different drugs might well prove to be of value, as will be discussed later when considering resistance and strategies.

Sequencing can be considered to fall into three major categories, as follows:

Neoadjuvant (Remote or Sequential)

The term *neoadjuvant* is used to describe upfront chemotherapy, prior to definitive management of the primary site by radiotherapy (or surgery). Advantages of this approach include the earliest possible treatment of micrometastases at a time when metastatic burden is lowest, and causing reduction of primary tumor size with possible elimination of radioresistant subclones. On the other hand, delaying definitive management of the primary site may allow chemotherapy-resistant clones to metastasize, which would otherwise have been dealt with by radiotherapy (or surgery) before becoming able to spread. This method may also increase proliferation of the primary tumor, thereby causing enhancement of its growth during fractionated radiotherapy.

Remote refers to a common practice in the community setting, where a planned break occurs between modalities to allow for normal tissue recovery. In these circumstances, both modalities can be given in full, independent of dose, making the most of the individual dose-response relationships and taking advantage of spatial cooperation. However, any interaction or possible benefit from enhancement at the primary site is minimized. In *sequential* treatments, radiotherapy is started within a few days of completion of chemotherapy. Although this method improves direct interaction at the primary site, it clearly also increases toxicity, which may ultimately prove to be a limiting factor in this neoadjuvant approach.

Concurrent (Including Alternating)

Simultaneous administration of chemotherapy during a course of fractionated radiation therapy has undoubtedly proven itself to be the optimal combination to date in certain situations, most notably in the management of various gastrointestinal cancers, where the important advantage over resection is organ preservation. In other circumstances, maximization of primary tumor response by this method often asks too high a price in terms of toxicity, and is therefore not the current standard of practice. Given the theoretical advantages, alternating protocols are under investigation in an attempt to make the toxicity acceptable. This approach gives chemotherapy (e.g., weekly), and allows gaps in the radiotherapy delivery, perhaps treating one week on, one week off. This type of strategy permits the use of full dose in each modality without undue delay for either, thereby reducing the potential for resistance to either modality.

Adjuvant (Remote or Sequential)

When chemotherapy is given after definitive treatment of the primary site by radiotherapy (or surgery), it is termed *adjuvant.* In this setting, the advantages are that treatment of the primary site is not delayed and that the ability of the local tumor to metastasize is potentially restricted, if not eliminated. The size of the primary tumor mass is reduced, allowing a better chance of complete response to chemotherapy. [8] In remote sequencing, chemotherapy can still tackle micrometastases, but in sequential treatment it does so immediately after radiation therapy. Sequential adjuvant treatment carries the same problems of increasing toxicity as sequential neoadjuvant therapy.

Drug Resistance

When a single chemotherapy drug is administered repeatedly or in a prolonged fashion, such as continuous infusion, a change in cellular response can occur in tumor cells. This change is entirely directed toward resisting the drug and its effects. The likelihood of these drug-resistant cells being present in any particular tumor may be related to the mass of the tumor, implying that smaller tumors are less likely to harbor these drug-resistant cells. Many mechanisms have been identified, and undoubtedly a combination of these mechanisms comes into play in any given situation. The development of drug resistance has clear implications for treatment failure, and consequently for new ways of trying to enhance the efficacy of current combinations. When designing protocols for chemoradiation strategies, overcoming intrinsic and/or acquired resistance is a key consideration.

Mechanisms

These mechanisms are summarized in part, in Table 15.1, and can be considered at a cellular/intrinsic level, or on an anatomic/pharmacokinetic basis. Although resistance can occur because of the latter, the development of intrinsic resistance has provoked much study since it was first recognized. This intrinsic resistance is acquired through self-adaptation of the cell and can be responsible for resistance to other chemotherapy compounds (i.e., cross-resistance). When this happens, it is termed *multidrug resistance* (MDR) and is believed to be responsible for the majority of clinical treatment failures that occur because of drug resistance.

	Mechanism	Enzymes and/or Proteins Involved	Specific Drugs Involved (examples)
Cellular level			
Membrane properties	Decreased uptake; increased drug efflux	P-glycoprotein; Lipidperoxidase; Glutathione	Alkylating agents, Vinca alkaloids, Methotrexate, Anthracyclines, Nitrogen mustard
Altered drug metabolism	Reduced conversion of prodrug to active moiety; enhanced degradation	Kinase	5-FU, Doxorubicin, Cytosine arabinoside, Bleomycin, 6-MP, Cytosine arabinoside
Drug targets	Physical or chemical alteration; increased level of target enzyme	Dihydrofolate reductase; Topoisomerase II	5-FU, methotrexate
DNA	Increased repair capacity	Guanine alkyl transferase; mismatch repair proteins	Cisplatin, Cyclophosphamide, Mitomycin C, Melphalan, Nitrogen mustard, Nitrosourea
Noncellular level			
Sanctuary sites	Unable to cross blood-brain barrier or into testes	—	Most, except Nitrosureas
Macroscopic effects	Poor vascularization; Reduced oxygenation; altered pH; Cell cycle distribution	—	All
In vivo factors	Absorption; Renal excretion	—	All

TABLE 15.1. SOME MECHANISMS AND PATHWAYS OF DRUG RESISTANCE

Multidrug Resistance

MDR refers to the situation when resistance developed because of repeated exposure to one drug and extends to structurally and functionally different classes of drugs. Cross-resistance has been found to be associated, in most cases, with the overexpression of P-glycoprotein, which is an integral part of the cell membrane drug efflux mechanism. The MDR-I gene has been shown to encode for P-glycoprotein. MDR is also associated with inhibition of the spindle cell poisons, including drugs affecting functions of topoisomerase I and topoisomerase II (See also Chapter 14). These mechanisms have been shown to be quite different from P-glycoprotein-mediated MDR. In addition, MDR has been identified with the mechanism of increased activity of the enzymes that metabolize the drugs, such as glutathione. Several different ways of preventing or reversing these actions have been investigated, but none so far has proven to be clinically useful. [9]

Strategies for Chemoradiation

The best way to integrate these two modalities is the subject of increasing study, both in the laboratory and in the clinic. Different types of tumors are known to have different intrinsic levels of radiosensitivity and chemosensitivity. [10] Even within one tumor histology, such as SCLC, a heterogeneous population of cells and tissues often exists. In addition, it is important to remember that even similar groups of patients, with similar types and stages of disease, still have their differences, particularly in how they tolerate aggressive CMT. Nonetheless, it is feasible to construct models, based on factors such as likelihood of resistance and tumor burden, to help in trying to predict the best combination of modalities, doses, and timing that might prove to be superior. These theoretical strategies are important to develop, but they still need to undergo thorough testing in accurately defined conditions. Only by the results of carefully controlled randomized clinical trials will their place in clinical practice be properly defined.

Targeting tumor cells as early as possible in their growth is undoubtedly optimal. The more bulk that exists, the longer it takes to eliminate all the cells, as per the log-cell kill theory. In terms of overcoming drug resistance, it also seems logical to apply different chemotherapy agents as soon as possible so that cells becoming quickly resistant to one type of drug will be targeted by another one to which they have not developed resistance. As has been discussed earlier, good evidence supports the fact that the degree of response and resistance to chemotherapy can be related directly to tumor mass. It, therefore, follows that treating with radiation and combination chemotherapy simultaneously, if toxicity is acceptable, should prove to be superior. However, in order to make it tolerable, dose reductions are often necessary, thereby negating any potential benefit.

One way of trying to deal with this problem is to combine agents and modalities with nonoverlapping toxicities. Several reports have hinted that when compared with neoadjuvant or adjuvant chemotherapy relative to radiotherapy, concurrent treatment has been better in terms of tumor responses, although not reaching statistical significance. [11] In this light, the approach of alternating modalities is under investigation, and Goldie has proposed the use of non–cross-resistant drugs in an alternating rather than sequential fashion as one possible strategy. [12] The additional concept of quantitative symmetry of these drugs is analyzed in detail by Day, which is where the efficacy of individual drugs is taken into account, and delivery in terms of dose and timing is adjusted to compensate. [13] The possible advantages of alternating strategies include being able to maintain the chemotherapy schedule with non–cross-resistant drugs given as early as possible and delivering significant total doses of radiotherapy between drug administration. [14]

Non–Small Cell Lung Cancer

Until this decade, the relative effectiveness of chemotherapy at all, in this disease, was debated. In 1995, a metaanalysis reported a statistically significant survival benefit for chemotherapy, and interest has since grown exponentially (See also Chapter 50.).[15] Several randomized studies have now shown significant improvement with chemoradiotherapy in locally advanced stage III disease (see also Chapter 52), prompting many questions about optimizing the overall combination. [16,17]

In attempting to define the best strategy, it is important to recognize the problems that need to be addressed. The importance of achieving local control in this disease cannot be underestimated.[18] The increasing use of conformal radiation techniques invites not only dose-escalation (overall or radiobiologic) but also improved tolerability of CMT. The optimal fractionation schedule, in itself, is currently a major research topic, and the CHART regimen (Continuous Hyperfractionated Accelerated Radiotherapy) from Mount Vernon reported an improvement in two-year survival from 20% to 30% in locally advanced NSCLC. [19]

Given the persistently high rate of metastatic relapse, neoadjuvant chemotherapy has been a focus for many studies. Although phase II trials consistently showed better responses than in the palliative setting, they failed to be convincing on the matter of any improvement of local or distant control rates. [20,21 and 22] Likewise, studies of adjuvant chemotherapy have been unimpressive to date. However, several phase III randomized trials using CMT have been encouraging, although the radiation techniques and doses were, in retrospect, less than current optimal standards. [16,17,23,24] In Trovo's recent overview, summaries of randomized trials comparing radiotherapy alone to combined chemoradiotherapy are presented. [25] Careful analysis reveals that although some evidence supports superiority of CMT, it is not overwhelming.

The progression to investigation of combination chemotherapy with radiation, including new chemotherapy agents, is reviewed by Vokes. [26] Paclitaxel and carboplatin have been of particular interest[27,28 and 29] but so has the combining of these agents with more advanced radiation techniques. [30,31 and 32] Alternating radiotherapy and chemotherapy in phase II trials has also been reported, from GOTHA (Groupe d'Oncologie Thoracique Alpine), suggesting feasibility and a possible gain in long-term survival,[33] but as yet no mature or substantial phase III data supports these kinds of combinations as optimal. A recently reported cancer and leukemia Group B/Eastern Cooperative Oncology Group (CALGB/ECOG) study did not confirm any significant benefit with concurrent daily carboplatin, given at a dose of 100mg/m^2/week.[34]

The newer drugs, such as the taxanes, navelbine, and gemcitabine, are now being incorporated into protocols, along with biologic response modifiers. [35] Likewise, the pharmacokinetics of combining topoisomerase inhibitors with radiation is under investigation. [36] How to combine these agents effectively with improved radiotherapy fractionation and technology will continue to provide much subject for study well into the next century. The potential for significant improvement in this hitherto relatively unresponsive disease is now very real.

Small Cell Lung Cancer

The benefits of chemotherapy in this essentially systemic disease is not disputed, instead the integration of radiation—how, when, and where—raises most of the questions. Trials incorporating thoracic radiotherapy and predominantly cyclophosphamide-doxorubicin–based chemotherapy, were initiated more than 20 years ago, and the survival benefit attributable to thoracic radiation was confirmed in a subsequent metaanalysis. [37] Since that time, platinum-based regimens and more intensive chemotherapy have become widely used (see also Chapter 53). Nonetheless, the question of radiotherapy timing remains controversial, and until recently was given predominantly as postchemotherapy consolidation. [38] The appropriate target volume (i.e., whether supraclavicular nodal areas should be included) and the correct total dose/dose-fractionation schedule are also unclear. These issues remain to be resolved. Turrisi summarizes some of the randomized trials of chemoradiation in SCLC, dividing them into sequential, alternating, and concurrent. [39] The benefit of thoracic radiotherapy becomes evident, but again, the optimal sequencing, and

other factors, remain uncertain.

In 1996, Johnson et al. from the National Cancer Institute (NCI), reported a phase II trial treating patients with limited-stage SCLC with concurrent etoposide, cisplatin, and hyperfractionated thoracic radiotherapy (1.5Gy twice per day to total 45Gy), followed by cyclophosphamide, doxorubicin, and vincristine. [40] Out of fifty-four patients, nine were alive and disease free at a median time of 4 years (2 to 7 years). Thirty-eight patients had progression of their disease at a median of 1.2 years, and interestingly, one-third of these patients developed and subsequently died of isolated central nervous system (CNS) relapse. Their calculated actuarial survival rates were 43% at 1 year and 19% at 2 years. In contrast, a Southwest Oncology Group phase II study published in 1998 looked at concurrent chemoradiation incorporating prolonged oral etoposide and prophylactic cranial irradiation (PCI), and found this combination to be toxic. [41] Only 50% of patients (28/56) completed chemotherapy as per protocol, with 93% (52/56) completing radiotherapy. Eleven patients (20%) discontinued treatment because of toxicity and two patients died from treatment. Possibly because of poor tolerability, complete response rates were not significantly different from previous studies. The European Organization for Research and Treatment of Cancer evaluated alternating versus sequential treatment modalities in a phase III randomized study but failed to confirm any clinical advantage for either arm.[42] At least two studies have assessed the effects of maintenance chemotherapy after induction with either CMT, or chemotherapy alone, and neither found any advantage. [43,44]

The other main area of controversy is in the use of PCI. Many conflicting studies have been reported, often with heterogeneous patient, tumor, or radiation-dosing factors, making interpretation all the more difficult. Currently, PCI is recommended for good performance status limited-stage patients who achieve a complete response to chemotherapy (see also Chapter 56).[45,46]

Future strategies for SCLC therapy will almost certainly focus also on the growing pool of genetic information, either for patient selection, or as part of treatment in combined therapy protocols.

SPECIFIC CHEMOTHERAPEUTIC AGENTS USED IN CHEMORADIATION

This section concentrates on radiation–chemotherapy interactions of individual agents. More detail on individual drugs can be found in chapter 14, chapter 42, chapter 50, chapter 51 and chapter 52, chapter 53, chapter 54, and chapter 57.

Nucleoside Analogues

Drugs that affect nucleoside and nucleotide metabolism are among the most effective and most widely used agents to sensitize tumor cells to radiation treatment. Some of the older agents include the fluoropyrimidines (5-fluorouracil), thymidine analogues, and hydroxyurea. Newer agents in this category include gemcitabine (difluorodeoxycytidine) and fludarabine.

Hydroxyurea

Mechanisms of Action

Although hydroxyurea is not a nucleoside analogue, its primary mechanism of action is related to its inhibition of ribonuleotide reductase, a key enzyme for the conversion of ribonucleotides to deoxyribonucleotides. [47] Its role in the treatment of hematologic malignancies and myeloproliferative disorders is well established. [48]

Preclinical Data with Radiation

The mechanism of hydroxyurea radiosensitization has been attributed to the inhibition of DNA synthesis resulting from the inhibition of ribonucleotide reductase. [49] Exposure prior to radiation blocks cells at the G1/S phase border, although it is uncertain if this redistribution alone causes increased radiation sensitivity. Another mechanism may be through inhibition of DNA repair, as illustrated by radiosensitization when hydroxyurea is given during or after radiation treatment. [50] There seems to be no differential effect on tumor cells compared to normal cells, although more rapidly dividing cells may be more sensitive to its effect. More recent investigations are focusing on the role of ribonucleotide reductase rather than disruption of cell cycle kinetics. [51] Hydroxyurea may also modulate fluoropyrimidine-mediated radiosensitization of tumor cells. Hydroxyurea depletes intracellular deoxyuridine monophosphate pools, thus increasing the ability of FdUMP to bind with thymidylate synthase. Synergism between these two drugs has been demonstrated in preclinical models.[52] Finally, hydroxyurea may have a role as a biochemical modulator of IdUrd radiosensitization in tumor cells. [53] Exposure to low doses of hydroxyurea with IdUrd prior to radiation has been shown to enhance IdUrd-DNA incorporation and radiosensitization in the human bladder cell line 647V.

Clinical Experience

The use of hydroxyurea as a radiosensitizer has been evaluated in cancer of the head and neck, [54] malignant glioma,[55] and cervical cancer.[56] Its role in cancer of the head and neck as well as gliomas is difficult to appreciate given the fact that hydroxyurea was part of a multidrug regimen in these trials. Positive results have been demonstrated in cervical cancer when hydroxyurea is given with radiation compared to radiation alone. [57] In lung cancer, several studies demonstrated the feasibility of such an approach, but overall it has had little impact on the natural course of this disease. Vokes has used hydroxyurea along with 5-FU and radiation with or without cisplatin in locally advanced NSCLC.[58,59] The role of hydroxyurea is unclear in this setting because cisplatin and 5-FU alone have also been shown to be clinically effective radiosensitizers.

Gemcitabine

Mechanisms of Action

Gemcitabine (2', 2'-difluoro-2'-deoxycytidine) is an analog of deoxycytidine that, unlike cytarabine, has demonstrated effectiveness as a single agent against solid tumors, including pancreatic cancer, lung cancer, and breast cancer. Gemcitabine exhibits cell-cycle specificity by affecting cells undergoing DNA synthesis (S-phase) and by blocking the progression of the cells through the G1/S-phase boundary. [60] Gemcitabine is metabolized intracellularly by deoxycytidine kinase to the active forms of diphosphate and triphosphate nucleosides. Gemcitabine diphosphate inhibits ribonucleotide reductase, which catalyzes reactions and generates deoxynucleoside triphosphates for DNA synthesis. The reduction of intracellular concentration of deoxycytidine triphosphate facilitates the incorporation of gemcitabine triphosphate into DNA. Further chain elongation is terminated after gemcitabine triphosphate and one additional nucleotide are incorporated into the growing DNA strands. Gemcitabine is rapidly metabolized to an inactive uridine derivative by cytidine deaminase. However, in comparison with ara-C, gemcitabine has greater membrane permeability and enzyme affinity, as well as considerably longer intracellular retention.

Preclinical Data with Radiation

Shewach et al. first reported on preclinical investigations of gemcitabine as a radiation sensitizer in human colon carcinoma cells (HT-29). [61] Maximal radiation sensitization was observed when cells were irradiated immediately following gemcitabine exposure instead of before or during drug treatment. Radiation sensitization was found to be dose and time dependent. Exposures of 10 nmol/l for 24 hours or 30 nmol/l for 16 hours both produced a radiation enhancement ratio of approximately 2. Radiosensitization of gemcitabine has also been investigated on pancreatic cell lines. [62] Radiation enhancement ratios of 1.7 to 1.8 have been obtained. Sensitization occurred when gemcitabine depleted the dATP pools below the level of 1 nmol/l. The previous data thus suggest that radiation sensitization is achieved at very low gemcitabine plasma concentrations, which are not by themselves cytotoxic.

Conditions to obtain radiosensitization can be achieved either by a long (24-hour) exposure to a low concentration of gemcitabine (10 nmol/l) or by a brief (2-hour) treatment with higher but clinically relevant concentrations (100 nmol/l to 3 mmol/l). [63] Under the latter conditions, sensitization can be detected 4 hours after treatment and last for up to 2 days. The mechanism by which gemcitabine radiosensitizes tumor cells is unclear. Studies indicate that the observed radiosensitization is not associated with either an increase in the radiation-induced DNA double-strand breaks or with a slowing of DNA double-strand break repair. [64] This finding suggests that radiosensitization by gemcitabine is unlike that produced by the fluoropyrimidines and the thymidine analogs. However, radiosensitization is associated with the depletion of deoxyadenosine triphosphate pools, suggesting that inhibition of ribonucleotide reductase may be relevant. [61,62]

Clinical Experience

A phase I study in head and neck cancer used a starting dose of 300 mg/m^2 week of gemcitabine, along with standard dose radiation (70 Gy in 2-Gy fractions).[65] Gemcitabine was found to be a potent radiation enhancer, leading to marked increase in normal tissue toxicities within the radiation field. In addition, long-term sequelae were noted. Three patients required gastric tubes 5 months after radiation therapy. As a result, doses of gemcitabine in this study were decreased from an initial dose of 300 mg/m2/week to 150 mg/m2/week. However, the observed clinical activity was very encouraging. A phase I trial evaluating the role of gemcitabine as a radiation sensitizer in lung cancer is in progress.[66] The CALGB is conducting a phase II trial evaluating cisplatin and gemcitabine in combination as induction chemotherapy and as radiation enhancers in locally advanced NSCLC.[67]

5-Fluorouracil (5-FU)

Mechanisms of Action

Fluorouracil (5-FU) is a synthetic analog of the naturally occurring pyrimidine, uracil. Several active metabolites of 5-FU have pharmacologic effects on the synthesis and function of cellular DNA and RNA. Inhibition of thymidylate synthase (TS) by 5-fluorodeoxyuridine monophosphate (FdUMP) is believed to be the primary mechanism of anticancer efficacy of 5-FU. Other active metabolites include 5-fluorouridine triphosphate (FUTP) and 5-fluorodeoxyuridine triphosphate (FdUTP). FUTP is misincorporated into RNA and may affect several aspects of RNA stability and function. Similarly, FdUTP can be misincorporated into DNA. Fluorodeoxyuridine nucleotides that have been misincorporated into DNA are recognized and cleaved by a glycosylase, yielding apyrimidinic sites in the DNA double helix and leading to DNA strand breaks.

Preclinical Data with Radiation

Recent laboratory investigations point to biochemical events at the G1/S-phase interface as potentially important determinants of fluoropyrimidine radiosensitization. Our group has shown that the use of minimally cytotoxic doses of fluoropyrimidines prior to irradiation results in an immediate inhibition of TS followed by a later (within several hours) expansion of an early S-phase tumor cell population that correlates temporally with enhanced *in vitro* radiosensitivity.[64] The enhanced radiosensitivity of the early S-phase tumor cell population is not seen using cell synchronization techniques alone. Instead, the period of radiosensitization is best correlated with the time course of an altered dTTP/dATP radio resulting from TS inhibition.[64] It is speculated that an accelerated release of cells from the G1/S checkpoint occurs as a consequence of the nucleoside pool imbalance prior to complete repair of radiation damage. The relationships of the proposed molecular sensors at the G1/S checkpoint (e.g., p53, cyclin-dependent kinases) responsible for ionizing radiation repair and these biochemical perturbations resulting from TS inhibition are currently being studied.

Clinical Experience

Positive trials of combined 5-FU and radiation have been reported for head and neck, esophageal, pancreatic, rectal, and anal cancers. Use of 5-FU in lung cancer has been limited. Multiple trials have been reported; all combined with other chemotherapy agents. Cisplatin, 5-FU, and etoposide have been used as induction neoadjuvant therapy prior to surgery in three different trials.[68] 5-FU has also been combined with hydroxyurea, cisplatin and interferon, and radiation for advanced chest malignancies.[58] In one study, radiation was given with or without a five-day continuous infusion of 5-FU in locally advanced NSCLC. This study demonstrated that the combined therapy arm resulted in a significantly higher response rate but also more toxicity.

Fludarabine

Mechanisms of Action

Fludarabine phosphate (2-fluoro-ara-AMP) is a synthetic analog of the naturally occurring purine nucleotide, deoxyadenosine monophosphate, and is a fluorinated nucleotide analog of the antiviral agent vidarabine. Following intravenous infusion, fludarabine phosphate is rapidly dephosphorylated to 2-fluoro-ara-A; intracellularly, 2-fluoro-ara-A is rephosphorylated to the active triphosphate, 2-fluoro-ara-ATP. This triphosphate metabolite is an inhibitor of several key enzymes in deoxyribonucleotide metabolism and DNA synthesis, including ribonucleotide reductase, DNA polymerase alpha, and DNA primase, resulting in impaired DNA synthesis and repair.[69] Fludarabine has clinical activity against hematologic cancers such as chronic lymphocytic leukemia and follicular non-Hodgkin's lymphoma.

Preclinical Data with Radiation

Kim et al.[70] have demonstrated that treatment with fludarabine and radiation substantially increased the control rate of Meth-A fibrosarcomas in BALB/c mice compared to radiation treatment alone. Investigators at M.D. Anderson Cancer Center have shown that the administration of fludarabine at a dose of 800 mg/kg 1 hour prior to radiation treatment lengthened regrowth delay over a range of conditions, but particularly if irradiation was performed 24 hours after drug treatment.[71,72 and 73] Subsequent studies suggested that this delay in radiosensitization reflected a fludarabine-induced loss of radioresistant S-phase cells (through apoptosis) and partial synchronization of cells into G2/M 24 hours later.

Clinical Experience

No clinical trials of fludarabine and radiation have been reported to date.

Plant Derivatives

Paclitaxel

Mechanisms of Action

The FDA approved the production of semisynthetic paclitaxel in 1995, and this form has replaced the original, which was derived from the bark of *Taxus brevifolia*. Its unique mechanism of action as a promotor of microtubule assembly distinguishes paclitaxel from the vinca alkaloids and other tubulin-interacting drugs. All aspects of tubulin polymerization are enhanced at concentrations as low as 0.05 mmol/l. By stabilizing the microtubule and preventing its disassembly, paclitaxel causes tubulin-microtubule disequilibrium, which eventually leads to cell death.

Preclinical Data with Radiation

In one study, human lung carcinoma cells (SW1573) were given five daily treatments with 3 Gy of x-rays during the continuous presence of 5 nM of taxol.[74] This study demonstrated that taxol, continuously present at low concentration with little cytotoxicity, causes a progressive reduction of the surviving cell population in combination with fractionated radiation, mainly by inhibiting the repopulation of surviving cells between the dose fractions. Other studies have demonstrated that 1 to 10 nmol/L appears to be the optimal paclitaxel concentrations (when given as a continuous infusion) for direct cytotoxicity and radiosensitization *in vitro*.[75] Preclinical data also suggests that low-dose daily infusions of paclitaxel for as long as possible during a course of radiotherapy are more likely to result in radiosensitization and prolonged cytotoxicity than high infusions given once a week.[76] In this study, A375 melanoma and S549 lung carcinoma cell lines were used. The minimum concentration of paclitaxel for measurable radiosensitization was 3nM for both cell lines. A minimum of 18 hours incubation with the drug was necessary for measurable effects, and radiosensitizing effects were soon lost after the removal of paclitaxel. Pharmacokinetic calculations predict that 15 mg/m^2 paclitaxel given as a 1-hour infusion 5 days per week for 3 weeks during radiotherapy should achieve both cytotoxicity and radiosensitization. The presumed mechanism of action of paclitaxel as a radiosensitizer has been that this drug blocks cells at the radiosensitive G2-M interface.[77] This reaction is independent of the p53 mutations in lung cancer. Although p53 mutations have been associated with radioresistance in the case of NSCLC, p53 mutations do not predict response to paclitaxel/radiation in this disease.[78]

Clinical Experience

Of the newer drugs, paclitaxel combined with radiation has been the most studied in lung cancer. A continuous exposure to paclitaxel in the preclinical setting has demonstrated superior radiosensitizing effects, which has been studied in a phase I trial. Rosenthal et al. gave escalating doses of continuous-infusion paclitaxel over 7 weeks concurrently with radiation.[79] Dose-limiting toxicity was not achieved at the time of the report at a dose of 6.5 mg/m^2/day. In a phase I trial of continuous (120 hours) infusions of paclitaxel along with radiation in malignant mesothelioma and NSCLC, the MTD was 105 mg/m^2 repeated every 3 weeks.[80] Twice weekly paclitaxel has also been investigated with radiation.[81] The MTD of paclitaxel was 35 mg/m^2 given twice weekly as a 1-hour infusion for 6 weeks along with the radiation. The MTD of paclitaxel given as a weekly 3-hour infusion along with radiation has been shown to be 55 to 60 mg/m^2 week.[82] Pharmacokinetic data with weekly paclitaxel dosing of 100 to 250 mg/m^2 has been shown to yield plasma concentrations that remain above the putative radiosensitizing threshold of 0.01 mmol/L for 4.5 to 10.7 days.[83] Combinations of paclitaxel along with carboplatin and radiation have also been studied. [84 and 85]

Taxotere

Mechanisms of Action

Docetaxel is a semisynthetic derivative of 10-deacetyl baccatin, a precursor of paclitaxel. It is extracted from the needles of the European yew, *Taxus baccata,* an abundantly available and renewable source. Its mechanism of action is similar to that of paclitaxel, promoting microtubule assembly and stabilization, arresting cells in the M-phase of the cell cycle. In a head-to-head *in vitro* comparison against a variety of human tumors, docetaxel was more cytotoxic than paclitaxel (1.3- to 12-fold). In addition, cross-resistance between these two agents is incomplete.

Preclinical Data with Radiation

Although docetaxel has been shown to have additive effects when combined with radiation, controversy exists as to whether this combination is synergistic. An *in vitro* study by Choy et al.[86] found that both paclitaxel and docetaxel have radiosensitizing effects on the human leukemic cell line (HL-60). When these cells were treated with either drug, up to 70% of the cells were blocked in the G2/M-phase as determined by flow cytometry. The radiosensitizing effects were measured by calculating the dose of radiotherapy required to reduce survival to 25% of baseline, to determine the sensitizer enhancement ratio (SER). The SER was found to be 1.5 to 2.0 when a low concentration of docetaxel (0.3 mM) was used. The synergistic effect was hypothesized to occur because of the drug's ability to block the cells in G2/M. In contrast, a more recent study by Hennequin et al.[87] found no *in vitro* synergism with the combination of docetaxel and radiation using Hela cell lines. In another *in vitro* study, Watanabe et al.[88] also found no synergistic effects with docetaxel and radiation. In this study, lung cancer cell lines, RERF-LCMS (adenocarcinoma) and RERF-LCMA (small cell carcinoma) were exposed to docetaxel for 1 hour. Cells were irradiated for various periods, before and after the 1-hour drug exposure. The combination effects of radiation and drug were analyzed using an isobologram. Results from this study demonstrated that docetaxel with radiation had an additive effect on lung cancer cell lines, but no synergistic effects were noted. Finally, docetaxel has been shown to potentiate the radiation response of the murine mammary carcinoma MCa-4, with the proposed mechanisms being through an increase in radiosensitive mitotic cells (inducing arrest in the G2/M cell-cycle phase) and enhanced apoptosis.[89]

Clinical Experience

A phase I trial of concomitant docetaxel and radiation in locally advanced NSCLC has been conducted. Except for severe dysphagia at docetaxel doses above 30 mg/m^2 given on days 1, 6, 16, and 21 of radiation, this regimen was well tolerated.[90] A phase I/II of accelerated radiotherapy and weekly docetaxel in locally advanced NSCLC has also been conducted. Doses up to 30 mg/m^2 given weekly were well tolerated with an overall response of 73%.[91]

Vinorelbine

Mechanisms of Action

Vinorelbine is a unique semisynthetic vinca alkaloid derived from the leaves of the periwinkle plant. It differs from the natural vinca alkaloids by an eight-as opposed to a nine-member catharanthine ring. This unique structure may be responsible for its greater microtubule specificity and antitumor activity. It is a classic antitubulin in that it causes mitotic arrest of cells by inhibiting tubulin assembly. Vinorelbine causes less neurotoxicity than other vinca alkaloids.

Preclinical Data with Radiation

The activity of this combination *in vitro* was evaluated in the human NSCLC cell line NCI-H460.[92] When cells were exposed to navelbine for 24 hours and then irradiated, the drug potentiated radiation in a dose-dependent manner, with the ratio of fractional survival ranging from 1.7-fold at 1 Gy to 5.5-fold at 6 Gy. When treatment sequence was reversed (i.e., radiation followed by drug exposure), similar survival ratios were obtained at navelbine concentrations that were 10-fold lower. In this cell line, radiation produced a block in the G2/M-phase of the cell cycle with a maximum (60% to 70%) by 10 hours. The best potentiation was seen when irradiated cells were exposed to navelbine after they had plateaued in the G2/M-phase of the cycle. Navelbine given early after radiation, when only 10% to 30% of the cells were in G2/M, produced survival ratios similar to radiation alone. These studies show that navelbine acts as a radiosensitizer, and that the potentiation is cell cycle dependent, with a maximal effect being obtained when the cells have reached the G2/M-phase of the cycle.[92]

Clinical Experience

Patients with advanced chest malignancies that required radiation were enrolled in a phase I study of standard chest radiation and concurrent chemotherapy with cisplatin 100 mg/m^2 every 3 weeks and vinorelbine starting at 20 mg/m^2/week.[93] This regimen was feasible, and the recommended phase II dose was cisplatin 80 mg/m^2 every 3 weeks and vinorelbine 15 mg/m^2 on days 1 and 8 of the 3-week schedule. Esophagitis was the dose-limiting toxicity, and neutropenia occurred at higher doses. The CALGB is currently conducting a phase II trial of this regimen in unresectable stage III NSCLC.

Etoposide

Mechanisms of Action

Etoposide is a derivative of podophyllotoxin, itself extracted from the American mandrake or *Podophyllum peltatum.* The major mechanism of action is through interference with DNA synthesis by interaction with the enzyme topoisomerase II. This enzyme is responsible for "untangling" daughter chromosomes during mitosis. During this process, it causes transient DNA strand breaks. These breaks are then resealed by this same enzyme. The resealing is inhibited by etoposide, leading to permanent DNA strand breakage.

Preclinical Data with Radiation

Etoposide inhibits replication of DNA but does not stimulate repair.[94] *In vitro* studies have indicated an enhanced cell killing with radiation combined with etoposide. Rapidly repairable radiation-induced DNA damage is fixed into lethal lesions by etoposide. Cells arrested in G2-phase by radiation are hypersensitive to etoposide. Apoptosis, a result of the expression of the p53 gene, can be induced by radiation or etoposide in the presence of the gene but not in cells that lack both copies.[95] Giocanti et al.[96] described a decrease in the shoulder of the cell survival curve. Some increase in resistance of cell lines to etoposide has been reported after fractionated radiation. *In vivo* studies using the C3H mammary tumor model suggest that the major enhancement of radiation response is in hypoxic cells.[97]

Clinical Experience

Because etoposide is almost always employed with other chemotherapy agents for lung cancer, it is difficult to discern the effect related to radiosensitization with etoposide. Lau et al. have demonstrated improved survival with concurrent carboplatin/etoposide with radiation in poor-risk patients with locally advanced NSCLC.[98]

However, radiosensitization may be caused by the platinum alone as demonstrated in a randomized trial with platinum and radiation alone.

Vincristine and Vinblastine

Mechanisms of Action

These agents are generally considered to cause mitotic inhibition with arrest at metaphase. This effect is caused by binding of the drug to a pair of sites on each subunit of tubulin, which results in blockage of assembly of microtubules during S-phase. Depolymerized tubulin proteins do not allow assembly of the mitotic spindle, and cell division is thus halted in metaphase.

Preclinical Data with Radiation

Little evidence exists of interaction of these drugs with radiation. In *in vivo* animal experiments, the LAF1 mouse exhibited an MTD of 9 mg/m.[2] There was no effect on the sublethal dose enhancement factor for lung, esophagus, or kidney. In the intestinal crypt cells, vincristine showed a DEF of 1.1 and yielded little cell kill for intestinal crypt cells. There was no effect on repair of ionizing radiation damage.

Clinical Experience

No trials of these agents combined with radiation have been performed in NSCLC. In SCLC, the CAV regimen, containing vincristine, has been used along with radiation.

Topoisomerase I Inhibitors

Mechanisms of Action

Topoisomerases are DNA enzymes that control the topology of the supercoiled DNA double helix during the transcription and replication of cellular genetic material. Topoisomerase I initiates the cleavage of a strand of the DNA molecule, whereas topoisomerase II cleaves both DNA strands. These actions guarantee the subsequent replicative process of the DNA. A partial or complete inhibition of this DNA replicative mechanism results in the accumulation and stability of cleavable complexes and subsequent cell death. Although this process is widely accepted as the main mechanism by which topoisomerase I inhibitors produce their antitumor effect, the mechanism by which this class of drugs achieves any selective toxicity in cancer cells is not fully understood.

Camptothecin and 9-aminocamptothecin

Preclinical Data with Radiation

Studies indicate that the addition of topoisomerase I inhibitors shortly after irradiation causes conversion of single-strand breaks to double-strand breaks, resulting in synergistic lethality to cultured log-phase or quiescent human tumor cells. Dramatic enhancement of the response of a human melanoma cell line (U1-Mel) has been seen with camptothecin.[99] 9-amino-camptothecin also enhanced the cytotoxicity of radiation in a schedule-dependent manner in U1-Me1 tumor cells.[100] This study also indicated that an intact stereospecific interaction between camptothecin derivatives and DNA topoisomerase I is essential in the induction of radiosensitization.

Clinical Experience

There is no experience with the drugs in combination with radiation for lung cancer as yet.

Topotecan

Preclinical Data with Radiation

Preclinical evidence indicates that topotecan may inhibit DNA repair following sublethal doses of ionizing radiation. Enhanced cytotoxicity was noted when topotecan was present during the first 30 minutes after single or multiple doses of irradiation.[101,102 and 103] The effect of topotecan on ionizing radiation-induced cytotoxicity has been studied in NSCLC H460 cell lines (containing high levels of topoisomerase I levels) and in glioblastoma multiforme cell lines (containing low topoisomerase I levels).[104] In this study, topotecan had a superadditive effect to radiation in the glioblastoma multiforme cell lines but not in the H460 cell line, suggesting that a potential clinical interaction exists for topoisomerase I inhibitors in combination with radiation for tumors expressing low topoisomerase I levels. Several studies were conducted to examine the effect of varying doses and time sequences of topotecan administration with respect to the administration of irradiation. Radiation sensitization appeared to depend on the drug concentration, the administration time, and exposure time.[101,102 and 103] Boscia et al.[105] demonstrated that radiation sensitization of topotecan was improved when daily administration of topotecan was followed by daily fractionated radiation as compared to a single dose of the drug with a single dose of irradiation.

Clinical Experience

A dose escalation clinical study with topotecan and concurrent radiation in patients with inoperable NSCLC has been conducted.[106] The MTD of topotecan was 0.5 mg/m^2 when given on days 1 to 5 and days 22 to 26 during a 6-week course (60 Gy) of external beam radiotherapy. Higher doses of topotecan were associated with high hematologic and gastrointestinal toxicity.

Irinotecan

Preclinical Data with Radiation

The ability of CPT-11 to increase tumor radiation-response *in vivo* using human lung tumor xenogratfs has been investigated.[107] Combinations of CPT-11 and radiation resulted in greater tumor regression compared to either modality alone. In flow cytometry studies, the proportion of cells in G2/M-phase, the most radiosensitive phase, increased after 1-hour exposure to the lowest dose of SN-38 (0.5 ng/ml), the active metabolite for CPT-11. The interaction of SN-38 and radiation *in vitro* in monolayer cultures and multicellular spheroids of HT-29 human colon adenocarcinoma cells has been studied.[108] SN-38 at a concentration of 2.5 mg/ml, which by itself was not cytotoxic, greatly increased the lethal effects of radiation in spheroids. Exposure to SN-38 following irradiation inhibited the PLDR. This reaction suggests that the mechanism of the radiosensitization by SN-38 is caused by PLDR repair inhibition.

Clinical Experience

A phase I/II study of concurrent chemoradiotherapy with CPT-11 and cisplatin was conducted to determine the maximum tolerated dose and efficacy of this regimen in patients with advanced NSCLC.[109] This trial had to be discontinued because of severe diarrhea and leukopenia causing chemotherapy delays as well as early termination of radiation. A trial of irinotecan alone with radiation is ongoing.

Platinum Analogs

Mechanisms of Action

The mechanism of cytotoxicity of the platinum analogs is similar to alkylating agents, and these drugs are therefore considered to be nonclassical alkylators. In the relatively high chloride concentrations of plasma, the cisplatin complex is deionized and able to pass through cell membranes. In the presence of low intracellular chloride concentrations, the chloride ligands of the complex are displaced by water and produce the positively charged platinum compound, which is toxic and probably the active form of the drug. The *cis* isomer forms intrastrand and interstrand cross-links between guanine-guanine pairs of DNA and inhibits DNA synthesis.

Cisplatin to a lesser extent binds to protein and RNA, ultimately inhibiting RNA synthesis. Carboplatin is a cytotoxic platinum complex that, similar to cisplatin, reacts with nucleophilic sites on DNA.

Cisplatin

Preclinical Data with Radiation

Cisplatin is one of the drugs that has been most extensively studied for its interaction with radiation. A recent review published by Wheeler and Spencer [110] reported that cisplatin enhances the cytotoxicity of ionizing radiation in several studies using human tumor cell lines in both cell culture and tumor-bearing animals. The drug appears to cause supraadditive effects when given simultaneously with radiation. It also appears to inhibit the repair of sublethal damage. It is a hypoxic cell sensitizer at high doses, although it is unlikely that clinical doses achieve significant hypoxic cell sensitization. Some data suggest that at low doses per fraction, a DEF of 2.3 can be seen.[111] Fractionated radiation *in vitro* can induce cisplatin resistance in surviving cells. [112]

Cisplatin can also enhance radiation effects on normal tissues. The MTD in the LAF mouse is 40 mg/m. [2] At this dose, a DEF of 1.2 is seen in the lung and of 1.7 in the esophagus. With single doses at this level, no enhancement is seen in the kidney. Stewart et al. found a DEF of 1.1 when cisplatin was given 6 hours before but not after radiation.[113] Liliveld et al. demonstrated the highest degree of radiation enhancement of tumor cell kill when cisplatin was administered in a divided daily schedule before radiation.[114] That schedule also resulted in less enhancement of normal tissue toxicities, which is an important observation.

Synergism between cisplatin and 5-FU has been demonstrated in preclinical models *in vitro* and *in vivo.* Scanlon et al. have demonstrated[115] that cisplatin inhibits cellular uptake of methionine and stimulates endogenous synthesis of methionine from homocysteine, consequently increasing conversion of CH3-FH4 to FH4, a precursor of CH2-FH4. The resulting expanded reduced-folate pools enhance the inhibition of thymidylate synthase by FdUMP. Because both cisplatin and 5-FU have radiosensitizing properties, a rationale exists for using these agents in combination with radiotherapy.

Clinical Experience

Significant clinical experience with cisplatin as a radiation sensitizer exists. Trials in head and neck as well as cancer of the esophagus have shown improved outcome with combined chemoradiation when cisplatin and 5-FU are given. The most compelling evidence for the effect of cisplatin alone as a chemosensitizer in locally advanced lung cancer comes from the EORTC,[17] which compared three groups treated with radiation alone, radiation plus weekly cisplatin (30 mg/m2), and radiation plus daily cisplatin (6 mg/m^2). Survival was significantly improved in the combined therapy arms, especially with the use of daily cisplatin (p = 0.0009). The fact that the most benefit was seen in the treatment arm with low-dose daily cisplatin (unlikely to have a direct cytotoxic effect) and that the benefit in survival was only caused by an improvement in local control, is very strong evidence for clinical benefits of radiation enhancement by cisplatin. Numerous studies have combined cisplatin with other drugs along with concomitant radiation, and a complete review is beyond the scope of this chapter. Lau et al. demonstrated excellent one- and two-year survival rates with combined cisplatin and etoposide and concurrent radiation for locally advanced NSCLC. [98] Of interest is that only one randomized trial of sequential chemoradiation versus concomitant chemoradiation has been published in locally advanced NSCLC. This trial demonstrated statistically improved two-year survival rates for the concomitant arm, suggesting a role for radiosensitization and improved survival by improving local control. [116]

Carboplatin

Preclinical Data with Radiation

The interaction between moderate-dose radiation and carboplatin was studied in cisplatin-sensitive (GLC4) and -resistant (GLC4-CDDP) human SCLC cell lines. [117] The radiosensitizing effect of the platinum drugs was expressed as an enhancement ratio calculated directly from survival levels of the initial slope of the curve. Carboplatin showed increased enhancement with prolonged incubation up to 1.21 in GLC4 and was equally effective as cisplatin in GLC4-CDDP. According to the isobologram analysis, prolonged incubation with both platinum drugs showed at least additivity with radiation for both cell lines at clinically achievable doses. The radiosensitizing capacity on both lung cancer cell lines did not depend on their platinum sensitivity. This study showed that the interaction of radiation with the clinically less toxic carboplatin can be improved by prolonged low-dose exposure before irradiation and is as potent as cisplatin in the resistant lung cancer cell line. Evidence for radiosensitization by carboplatin with an enhancement ratio of 1.8 is reported in Chinese hamster lung cells (V79) irradiated in culture under hypoxic conditions.[118] Potentiation of radiotherapy in mice bearing a transplanted mouse mammary tumor (MTG-B) is reported as a supraadditive tumor growth delay when 60 mg/kg carboplatin is administered either 30 minutes before or immediately after 20 Gy of irradiation. Carboplatin is believed to be more effective than cisplatin as a sensitizing agent because higher concentrations of the drug are achieved in free solution. Thus radiation enhancement, which is concentration dependent, might occur more rapidly with carboplatin than with cisplatin.

Clinical Experience

A phase II study of daily carboplatin (25 mg/m^2) given along with accelerated fractionated irradiation to 60 Gy over 4 weeks for locally advanced NSCLC demonstrated a response rate of 84% in 31 patients.[119] Similarly, a phase II study of split-dose radiation along with carboplatin given on day 1 of week 1 and week 6 has been performed with a response rate of 53%.[120] Responders had a significantly higher area under the curve (AUC) of carboplatin than nonresponders in this study. A phase III trial of accelerated radiation therapy with and without carboplatin (350 mg/m^2 day 1, every 28 days) in locally advanced NSCLC is ongoing. [121] Interim analysis showed increased hematologic and esophageal toxicities when carboplatin was added. Trials have also been conducted with the combination of carboplatin and etoposide given along with radiation.

Antimetabolites

Because methotrexate and other antimetabolites are cell-cycle specific, their administration alters the kinetics of surviving cells. Cells in the late S-phase of the cycle are known to be less sensitive to radiation therapy. Certain antimetabolites, however, are active against these cells.

Methotrexate

Mechanisms of Action

Methotrexate (MTX), a synthetic analog of folic acid, is a potent inhibitor of dihydrofolate reductase (DHFR), a key enzyme in folate metabolism. Inhibition of DHFR results in depletion of cellular-reduced folates and interferes with vital cellular enzymes that require reduced folate cofactors (including enzymes of the thymidylate and purine synthesis and amino acid metabolism). Intracellularly, methotrexate is metabolized to active polyglutamate metabolites, which inhibit DHFR and several other cellular enzymes, including enzymes that catalyze formyl transfer reactions in purine biosynthesis.

Preclinical Data with Radiation

Dose-response curves in an experimental mammary tumor indicate that MTX generally kills less than one log of cells using an *in vivo/in vitro* assay and exhibits a mild linear reduction with dose as evidenced by increasing growth delay. Experiments in a rat rhabdomyosarcoma cell line with MTX and radiation showed no evidence of a supraadditive effect.[122] An *in vivo* lung experimental system with MTX has shown a DEF of 1.6 (1.3 to 2).[123] In this experiment, MTX was given at high doses (2.1 gm/m^2) 2 hours before irradiation. No significant effect was seen on esophageal or renal toxicities with these doses. Using a normal intestinal crypt system, MTX yielded a DEF of 1 to 1.8, depending on dose, with the higher value at the higher doses.

Clinical Experience

MTX has been shown to enhance late CNS damage when used in high doses and with whole-brain irradiation. Similar effects can be seen with intrathecal methotrexate when combined with radiation. MTX has also been shown to enhance skin and mucosal toxicity when given with radiation in head and neck cancer patients. The cyclophosphamede methotrexcite and 5–fleurouracil (CMF) regimen containing methotrexate when given with breast radiation in the adjuvant setting increases pulmonary toxicity. Trials of methotrexate with radiation in lung cancer are almost all in the setting of combination chemotherapy, and thus the sole effect of

methotrexate cannot be determined. However, a trial reported in the early 1970s that combined methotrexate with radiation therapy for squamous cell carcinoma of the lung suggested no clinical tumor interaction.

Alkylating Agents

Because alkylating agents have been shown to be ineffective in patients with NSCLC, [15] their clinical use in this setting has largely been abandoned. Additionally, alkylating agents can cause pulmonary toxicity. They are used extensively in other malignancies, so their interactions with radiation are reviewed here.

Mechanisms of Action

Alkylating agents are polyfunctional compounds that have the ability to substitute alkyl groups for hydrogen ions. These compounds react with phosphate, amino, hydroxyl, sulfhydryl, carboxyl, and imidazole groups, which are part of the molecular makeup of the body. In neutral or alkaline solution, these drugs ionize and produce positively charged ions that attach to susceptible nuclear proteins, with the most likely site of alkylation being the N-7 position of guanine. This alkylation reaction can have multiple effects, including abnormal base pairing with cleavage of the imidazole ring of guanine; cross-linking of DNA with interference with DNA replication and transcription of RNA; and the disruption of nucleic acid function. Disruption of DNA adducts represents the predominant mechanism of cytotoxicity. The alkylating agents are not cell cycle–specific agents.

Cyclophosphamide

Preclinical Data with Radiation

Byfield concluded from *in vitro* experiments that cyclophosphamide had no effect on radiation survival curves and that effects were strictly additive. [124] Experiments with *in vivo* spheroids reveal that cyclophosphamide is more effective against the superficial cells but is additive to radiation at all depths. [125] Experimentally in rat hepatoma, Looney et al. showed that alternating chemotherapy with cyclophosphamide and radiation induces a maximal amount of tumor response. [126] Several studies have evaluated cyclophosphamide with radiotherapy and have shown increased injury in the normal tissues, including CNS, lung, bladder, small intestine, esophagus, and skin. The maximum tolerance dose (MTD) in mice is 250 mg/m.[2] At this dose, cyclophosphamide exhibits a DEF of 2.1 for pulmonary lethality but shows little interaction in the normal esophagus. With delayed irradiation, residual cyclophosphamide effect on the DEF was seen at up to 6 months. [127]

Nitrosureas

Preclinical Data with Radiation

In vitro studies indicate increased cell killing, which in some cases is additive, and in others, supraadditive. Decreases in the initial slope and in the final slope of the survival curve are noted. Radiation induces O6 alkyl-transferase, which creates resistance to N,N [1]–bio(2-chlomethyl–)N–nitrosourea (BCNU), greatest at 48 hours after irradiation. The production of radiation-induced single-strand breaks is enhanced in human glioma tumor cell lines. [128] The induction of sister chromatid exchanges by radiation and BCNU appears only to be additive. *In vivc* experimental tumors, including the 9L brain tumor, the KHT sarcoma, and the EMT6 tumor, have shown increased animal survival, decreased metastases, and improved locoregional response with BCNU plus irradiation. In the EMT6 tumor, the greatest effect was seen with drug after irradiation, and the effect was supraadditive. Others [129] suggest that nitrosureas fix radiotherapy-induced DNA damage and that BCNU should be given 6 to 16 hours before or after radiation so that DNA cross-linking products can interact. In the LAF1 mouse, the MTD of BCNU is 75 mg/m. [2] The dose does not appear to enhance radiation injury to the lung, but it does increase the esophageal reaction with a DEF of 1.4. It shows no significant effect in the kidney.

Antitumor Antibiotics

Anthracyclines

Mechanisms of Action

Interference with the action of DNA topoisomerase II in regions of transcriptionally active DNA is the most widely cited and generally accepted mechanism of action of the anthracyclines. This enzyme acts by binding to DNA and nicking one of its strands, thus allowing the supercoiled macromolecule to relax as the opposite strand passes through the break. The enzyme then reanneals the broken ends. Anthracyclines are thought to act by stabilizing the topoisomerase-DNA complex in the cleaved configuration. This event not only maintains the DNA single-strand breaks but also helps to create further DNA double-strand breaks. The ability of these drugs to generate free radicals, which are cytotoxic, has attracted much attention. Anthracyclines are reactive with heavy metal ions. In the cell, adriamycin binds to ferric iron, which then generates highly reactive hydroxyl radical species. This complex binds to cell membranes and causes oxidative cell damage; most tissues possess adequate defenses against this type of event and are able to repair the damage. Cardiac tissue is notably deficient in this respect and is highly vulnerable to oxidative attack.

Preclinical Data with Radiation

In vitro experiments reveal that doxorubicin reduces the cellular capacity to accumulate and repair radiation damage throughout the cell cycle. Double-strand break repair is inhibited. [130] These findings are similar for resistant and sensitive cell lines. [131] Indeed, no evidence exists for an induction of adriamycin resistance by previous irradiation. Experiments in spheroids suggest that drug exposure before irradiation gives maximal enhancement. [132] In the LAFI mouse, the MTD is 24 mg/m.[2] At this dose, the DEF is 1.3 in lung, 1.9 in kidney, and 1.2 for intestinal crypt cells but not significantly elevated in esophagus. Maximal cell kill occurs when doxorubicin is delivered 12 hours after irradiation. Doxorubicin decreases SLDR in intestinal crypt cells by 10%. The greatest degree of reaction occurs with simultaneous administration; however, prolonged residual effects have been noted, as tested by delayed radiation exposure.

Clinical Experience

Clinically, in both NSCLC and SCLC, adriamycin has been used in different combination chemotherapy regimens with and without radiation. No trial of adriamycin alone with radiation in lung cancer has been performed. Enhanced cardiac toxicity with mediastinal radiation and doxorubicin treatment is well established. Furthermore, the radiation recall phenomenon is well established for this agent.

Mitomycin C

Mechanisms of Action

Mitomycin C is a bioreductive alkylating agent requiring *in vivc* activation to the cytotoxic species.

Preclinical Data with Radiation

Mitomycin C has been shown experimentally to interact with radiation through killing of hypoxic cells. This activity is probably not major at doses achievable in the clinic. Various *in vitro* experiments have described additive or supraadditive effects with radiation. [133,134] *In vivc* studies reveal both additive and supraadditive effects. Mitomycin does not change the shape of the radiation survival curve. Acute radiation reactions of skin and soft tissues are enhanced by mitomycin. [135]

Clinical Experience

Mitomycin C has been shown to be an integral component of treatment of squamous cell carcinoma of the anus when given along with 5-FU and radiation. A randomized trial of 5-FU and radiation with or without mitomycin C showed inferior results and increased local relapse in the group not receiving mitomycin C, suggesting that this agent has clinically relevant effects when given with radiation. Furthermore, the only trial in which concomitant chemoradiation was shown to be superior to sequential chemotherapy followed by radiation in locally advanced NSCLC used the MVP regimen, which contains mitomycin C. Multiple other studies

have been performed in which mitomycin was used as part of the combination chemotherapy regimen.

IMMUNOLOGY OF LUNG CANCER

ROBERT K. BRIGHT

Increasing genetic evidence indicates that cancers arise from a series of molecular changes that lead to transformation and unrestrained cellular growth, often resulting in lethal tumor burdens. These changes are frequently manifested as the "aberrant" expression of proteins (mutated, upregulated, or expression of those normally silent) by the tumor cells marking them as potentially foreign, dangerous, or at least "altered" in contrast to the "normal" tissue cells from which the tumor(s) arose. The immune system is endowed with the ability to sort out these changes and distinguish between healthy and diseased, hence "normal" and malignant cells. Thus the proteins encoded by the aberrantly expressed genes of a tumor cell represent targets for the cells of the immune system, serving as tumor rejection or regression antigens. In this light, much effort has turned to the study of the manipulation of the immune response to tumors in the clinical setting. Transfer of immune cells and therapeutic vaccination represent two areas of active research that utilize methods of eliciting lymphocytes with specificity for antigens aberrantly expressed by tumor cells.

It is evident after a review of the literature that hundreds if not thousands of studies have been published on some aspect of tumor immunology or immunotherapy, from animal tumor models to human malignancies. Any attempt to compile all that has been investigated in the field would be a herculean task and beyond the scope or intent of this chapter. Therefore the following text represents an overview of the specific endeavors in immunotherapy alluded to above, namely immune cell transfer and active vaccination. The absence or inclusion of any study or studies was done without prior intent or favoritism, and the author apologizes in advance to those whose excellent and valuable contributions to the field of tumor immunology have been inadvertently missed.

HISTORICAL EVIDENCE FOR THE IMMUNOLOGIC REJECTION OF TUMORS

Early studies that form the foundation on which tumor immunology stands were conducted prior to current understanding of the cellular and molecular mechanisms of immunity. Therefore, it seems appropriate first to review the history of tumor immunity, then to define the cellular players and their roles in the immunologic destruction of cancer.

A prevailing question that puzzled investigators such as Peyton Rous[1] in the early days of tumor immunology (prior to the 1950s) was whether or not the tumor rejection observed in experimental animals was due to rejection of the tissue transplant or the tumor itself (being aware of the fact that a tumor arose from once healthy tissue). In other words, do tumors elicit an immune response that recognizes the tumor as a tumor or simply as a tissue graft that is all too commonly rejected. Due in part to difficulties is distinguishing between tumor immunity and transplant immunity (truly inbred strains of mice were not yet available), the field leaned toward tissue graft rejection (immunogenic differences involving the major histocompatibility antigens) as an explanation, if not *the* mechanism, for tumor rejection, a paradigm that dominated until the early 1950s.

During the late nineteenth century, while tumor transplantation rejection was being studied in animals, a surgeon by the name of William Coley was testing a vaccine preparation known as "Coley's toxin" on lymphoma and sarcoma patients at New York's Memorial Hospital (known today as the Memorial Sloan Kettering Cancer Center). Coley had observed tumor regression and remission in patients who suffered a nosocomial bacterial infection following resection of their tumors. He subsequently isolated the bacterium (later the active component) and demonstrated that this "toxin," when administered to sarcoma and lymphoma patients, could mediate tumor regression in nearly 50% of his cases.[2] The mechanism of action of this toxin-based vaccine is now believed to be mediated by cytokines that are induced following its administration, an observation that likely influenced the current tumor-cell vaccine strategies involving the engineering of tumor cells to express cytokine transgenes. Regardless, Coley recorded perhaps the earliest example of cancer therapy based on the deliberate manipulation of the immune system. However, with the advent of radiation and chemotherapies, along with difficulties in reproducing Coley's results, *immunotherapy* was sidelined for nearly 50 years.

In 1953 the paradigm was challenged when E.J. Foley published his landmark work on the antigenic properties of methylcholanthrene (MCA) induced tumors in mice.[3] Foley eloquently demonstrated that when MCA tumors were ligated to induce necrosis, protection from a subsequent challenge with the same tumor was observed, while tumors grew quite well in unmanipulated animals. Certainly this phenomenon could not be attributed to differences in multiple histocompatibility complex (MHC) molecules (i.e., graft rejection) because the experiments were conducted using syngeneic mice. Excitement grew over the observation that tumors could be rejected by (presumed) immune recognition of antigens *uniquely* expressed on tumor cells. Four years later Prehn and Main confirmed and extended Foley's results by demonstrating that skin grafts were tolerated when mice of the same inbred strain were used. Moreover, ligated and necrosing syngeneic tumors induced protection from subsequent tumor challenge.[4] The conclusive proof of tumor antigenicity came in 1960, when George Klein and co-workers published a series of truly brilliant experiments in which surgical removal of tumors (as opposed to ligation) followed by tumor challenge resulted in protection.[5] More striking was their demonstration that tumor protection was obtained by injection of irradiated (inactivated) tumor cells prior to challenge; this experiment remains today as the standard for assessing tumor cell immunogenicity *in vivo.* Collectively, these experiments established that immune-mediated tumor rejection in inbred strains of mice was not a consequence of histocompatibility differences, but rather a result of tumor antigen recognition.

Numerous studies expounding the complexities of the immunologic rejection of solid tumors were published during the decades of the 1960s and 1970s. The majority of these studies focused on experimental tumor models in mice. As progress was made toward the feasibility of employing the immune system against human cancer, theories concerning the biology and progression of cancer as it relates to incidence and *natural* control of occurrence were also being developed. At the forefront was the *immune surveillance theory.*[6] This theory holds that all tumor cells express antigenic markers capable of eliciting immune responses resulting in tumor destruction, and that this process occurs continuously, preventing the outgrowth of malignant cells in most healthy individuals. As a person ages, the immune system declines, allowing the growth of tumors, hence one explanation for the increased incidence of cancer in people over the age of 50. Conceptually this theory would be difficult to prove *in vivo,* and certainly other mechanisms may participate in controlling cellular transformation and tumor formation in the *healthy* individual (e.g., events at the

molecular and genetic level within the nascent tumor cell). Nonetheless, the power of the immune system lies within its ability to discriminate between self and nonself or, more appropriately, a normal cell from a tumor cell, and thereby selectively and specifically eliminating tumor cells while leaving normal cells intact. The arm of the immune system that is primarily responsible for tumor-specific immunity is classically referred to as the *adaptive* immune response. Adaptive immunity employs a subset of cells of the lymphocyte lineage as the primary effectors responsible for the mechanisms of tumor-specific killing.

T-CELL–MEDIATED IMMUNE RESPONSES

The intent of this review is to focus on the topic of tumor immunology in the context of therapy. However, an overview of the process and components of cellular immunity is essential to the understanding of immune responses to tumor cells as well as the manipulation of tumor immunity through vaccination, for example. In the interest of space, this will be an overview, and some of these concepts are also covered in Chapter 17.

Immunologic rejection of tumors is believed to be executed primarily by lymphocytes, the common position being that T-lymphocyte (cell) mediated immunity is essential for the destruction of most solid tumors. T-cells are typically subdivided into two main groups: (a) those that provide a "helper" function (CD4+ T-cells) for immune responses following recognition of peptide antigens processed and presented, typically from exogenous proteins that have been endocytosed or phagocytosed, in the context of class II major histocompatibility antigens (MHC-II) on professional antigen presenting cells (APCs)—dendritic cells, macrophages and B-lymphocytes, for example; and (b) those that directly mediate tumor destruction (CD8+ cytotoxic T-cells) resulting from recognition of peptide antigens (usually derived from endogenously expressed proteins) in the context of MHC-I molecules expressed on the surface of the tumor cells. MHC-I molecules are normally expressed on all somatic cells in the body, including fibroblasts and epithelial cells, which give rise to sarcomas and carcinomas respectively.

Typically CD4+ T-cells are noncytolytic yet have been shown to play a role in tumor rejection by providing the necessary help for CD8+ cytotoxic T-lymphocyte (CTL) activation and lytic activity. For example, tumor immunity was attributed to the induction of CD4+ T-cells in a murine melanoma model where tumors were engineered to express the human p97 gene,[7] as well as a model for disseminated MHC-II negative lymphoma[8] Topalian and colleagues identified CD4+ T-cells with specificity for tyrosinase, a shared tumor antigen associated with human malignant melanoma.[9] Although there is evidence for the role of CD4+ MHC-II-restricted T-cells in tumor immunity, the vast majority of tumor-reactive T-cells defined for human systems and in animal models are CD8+ MHC-I-restricted CTLs.[10,11]

CTLs recognize peptide fragments (8 to 10) amino acids in length) of intracellular protein antigens in the context of MHC-I molecule heavy chains in association with beta-2 microglobulin. These trimolecular complexes are expressed on the tumor (target) cell surface, giving an extracellular presentation of endogenously expressed and enzymatically processed protein fragments for a CTL to engage using its antigen-specific receptor(s) (T-cell receptor [TCR]).[12] The role of CTLs in tumor destruction has been demonstrated in numerous murine tumor models by inducing tumor-antigen–specific immune responses following immunization with; antigen-coated beads,[13] recombinant viruses,[14] synthetic peptides,[15] or naked plasmid DNA.[16] The presence of tumor-antigen–specific CD8+ CTLs within a developing tumor was first demonstrated for humans by growing the tumor-infiltrating lymphocytes (TIL) from resected melanomas.[17] The *in vitro* growth and adoptive transfer of TILs has become a viable and available therapy for patients with malignant melanoma. These studies (and numerous others) have clearly demonstrated that CTLs can be recruited via immunization or *in vitro* manipulation and deployed against tumors, resulting in complete protection or treatment of tumors in murine models or objective clinical responses for cancer patients. In light of the potential of immunotherapy we are left with the question: Why aren't more tumors immunologically rejected? Unfortunately, much of the skepticism regarding tumor immunology is based on the contention that the immune system has been taught to fight infection (foreign) not cancer (self) and cannot be educated otherwise. Mounting data, however, indicate that the cellular arm of the immune system can be taught to kill cancer and that the tumors themselves are often actively involved in the tactics of immunologic escape and evasion.

MECHANISMS OF TUMOR ESCAPE FROM IMMUNOLOGIC REJECTION

Without question, tumors—both spontaneous and viral induced—express *unique* (foreign or aberrantly expressed) antigenic targets capable of inducing tumor-destructive immune responses. Thus it is reasonable to presume that some form of *immune surveillance* is contributing to the control of tumor formation *in vivo*. However, it is also painfully clear that the incidence of lethal forms of cancer remains high. Perhaps the clinical occurrence of cancer represents those not-so-usual circumstances when the immune system is ineffective. The process of tumor progression in the absence of an apparent immune response is classically referred to as *tumor escape.* Much speculation is given to the mechanism(s) by which tumors escape and evade immune destruction. Although there exists a number of studies describing many possible mechanisms of tumor escape (few however, without accompanying contradictory reports), we will focus on mechanisms most likely to impact the development of immunotherapies, such as vaccines and adoptive cell transfer.

Down-Regulation of MHC-I Expression

As alluded to above, the common belief is that CD8+ CTLs comprise the primary and perhaps the most important arm of immune-mediated defense against solid tumors. The removal or down-regulation of MHC-I molecules from the surface of a tumor cell renders it incapable of presenting MHC-I molecules complexed with antigenic peptides and removes the means by which a CTL recognizes the tumor cell and subsequently destroys it. Indeed, some clinical studies using tumor sections and immunocytochemistry have shown that primary tumors sometimes exhibit detectable decreases in MHC-I expression compared to adjacent normal tissue. Interestingly, metastatic tumors do not seem to be any different from their parent (primary) tumors with respect to the level of MHC-I expression, though they have escaped immune destruction, as evidenced by the metastatic event. Examination of multiple human and experimental tumors has demonstrated that MHC-I expression is often retained on tumors from patient to patient or between tumor histologies; thus it has proven difficult to correlate tumorigenicity, or lack thereof, with MHC-I expression or down-regulation. Nonetheless, animal studies have demonstrated that tumorigenic cells lines capable of forming tumors *in vivo* become less tumorigenic in immunocompetent hosts when MHC-I expression is increased, typically accomplished by cytokine induction or MHC-I gene transfection.[18] The corollary assumption, again supported by data, is that MHC-I expression leaves a tumor cell nontumorigenic (due to increased immunogenicity) in syngeneic, immunocompetent animals. This assumption may not be true in some experimental tumor models. Often tumor models in murine systems include a tumorigenic cell line that expresses MHC-I, as well as an immunogenic tumor antigen capable of eliciting tumor-destructive immunity.[19,20] Although conclusions conflict concerning MHC-I down-regulation and its role as a mechanism of tumor escape, caution directs that it be given careful consideration when developing immunologic therapies for cancer that rely on induction of MHC-I–restricted CTLs.

Absence of Costimulation

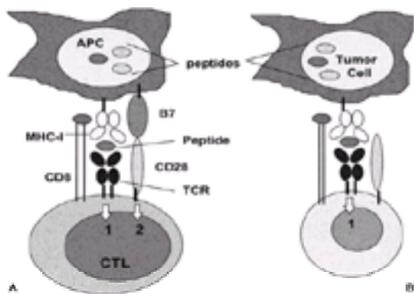
It has become clear in recent years that T-cells require *secondary* signals in addition to those obtained through TCR-MHC-peptide engagement (the primary signal or signal 1) in order to become active effector cells. The B7 family of gene products (which include B7.1 and B7.2) have been identified as key elements that provide the second signal known as *costimulation.* The B7 ligand is found primarily on professional APCs such as dendritic cells and B-cells, and has not been demonstrated on somatic cells such as those giving rise to most solid tumors. The receptor for B7 is the CD28 molecule, which is found on T-cells. When CD28 on a T-cell is engaged by B7, following TCR engagement of an MHC-peptide complex, the necessary 1,2 signals are delivered to the T-cell, resulting in its activation and proliferation (Figure 16.1). Experiments have demonstrated that the first (MHC-peptide) and second (B7-CD28) signals are most efficiently delivered when expressed on the same APC.[21] However, it is possible to deliver the appropriate costimulation *in vitro* by employing the B7 molecule on a third-party cell (author's unpublished observation). When resting or naive T-cells are engaged with a specific MHC-peptide complex through their TCR in the absence of B7 and CD28 engagement the result is *peripheral tolerance* or *anergy.*[22] Since tumors don't express B7 molecules (B-cell malignancies are an exception), tumor-cell antigen presentation to T-cells results in anergy, or functional unresponsiveness, hence the premise for absence of costimulation as a mechanism for tumor escape. Tumor cells that lack B7 expression and fail to stimulate T-cells can be engineered to express B7 and successfully stimulate tumor-specific T-cells.[23] Indeed, tumor cells expressing a B7 transgene are being explored as a "new generation" of whole-tumor-cell vaccines.


FIGURE 16.1. Schematic representation of T-cell recognition of an antigenic peptide in the context of an MHC-I molecule. **A:** Illustration of the events leading up to successful T-cell activation following effective delivery of signal 1 and signal 2 *costimulation* (see text for details). **B:** Illustration of the induction of T-cell anergy following delivery of signal 1 in the absence of signal 2 (see text for details). APC, antigen-presenting cell (e.g., dendritic cells); MHC-I, class I major histocompatibility antigen; CTL, CD8+ cytotoxic T-cell; TCR; T-cell antigen receptor.

Tolerance

As described above, absence of costimulation represents a mechanism of immunologic tolerance to tumor cells. The primary mechanism of establishing peripheral tolerance is neonatal exposure to antigens during ontogeny. This process, involving thymic mechanisms of positive and negative selection, [24] provides the necessary environment for immunologic tolerance of *self*-antigens and the prevention of autoimmune disease. Studies have demonstrated that tumor antigens encountered early enough in fetal development are tolerated by the adult animal and thus are no longer immunogenic. Viral-induced breast tumors in virus-bearing versus virus-free animals represent one instance. [25] Another example is SV40 large tumor antigen (Tag) transgenic mice that develop spontaneous tumors that remain Tag-positive and grow unchecked even though Tag is highly immunogenic in mice. [26] Tumor formation in the SV40 Tag transgenic system is difficult to define as *tolerance* to Tag, since Tag-positive tumors transplanted to syngeneic adult immunocompetent mice grow progressively, resulting in death unless an immune response to Tag is induced prior to transplantation. [19] In addition, when hemagglutinin (HA) of influenza virus was expressed in the pancreas of transgenic mice, driven by a tissue-specific promoter, the viral antigen was well tolerated and no autoimmune disease was evident even when the animals were immunized against HA. Interestingly, when these HA-transgenic mice were immunized with HA, followed by a lethal challenge with HA-expressing tumor cells, the tumors were rejected and HA-specific immunity was demonstrated, yet the pancreas was left healthy and functional. [27] Conversely, when lymphocytic choriomeningitis virus glycoprotein (LCMV), or LCMV-glycoprotein (GP) was expressed in the pancreas of transgenic mice to study the induction of autoimmunity against a defined antigen, tolerance was broken, resulting in autoimmune diabetes following immunization with dendritic cells that express LCMV-GP. [28] The implication here for cancer treatment is that therapeutic immunization against antigens that are not tumor-specific (most of the candidate tumor antigens for human cancer defined thus far are not tumor-specific) could result in autoimmune disease.

Though tolerance is clearly an obstacle in the path of many tumor immunotherapy approaches, complete understanding surrounding the involvement of tolerance in tumor immunity, as well as methods to overcome or manipulate it, require further investigation.

Tumor-Secreted Factors

Cultured tumor cells have been shown to secrete numerous cytokines and various growth factors. Some of these secreted factors are suppressive to the cells of the immune system. An example is transforming growth factor-beta (TGF-b). TGF-b is a family of molecules first identified as supporting transformation as defined by cell growth in soft agar. Many tumor cells secrete TGF-b, which sets up an immunosuppressive microenvironment around the tumor by inhibiting T-cell proliferation and CTL maturation. Tumors may secrete various cytokines as well. Cytokines have been shown to influence or drive T-helper cell function to support either cellular (CTL) or humoral (antibody) immunity. [25] Since CTLs are important for tumor cell killing, a cytokine profile (influenced by cytokines secreted by the tumor) that favors humoral versus cellular immunity could be detrimental to the successful immunologic rejection of the tumor. Therapies employed in such an environment may be aided by administration of anticytokine antibodies, recombinant cytokines (or tumor cells engineered to secrete cytokines), or cytokine analogues that block cytokine receptors on immune cells (e.g., T-cells) that drive a cellular immune response.

ACTIVE MANIPULATION OF THE IMMUNE RESPONSE TO ELIMINATE TUMORS

A realistic goal for the immunologic treatment of cancer is to administer immunotherapy as an adjuvant therapy to surgical resection of the primary tumor, the premise being first to minimize the tumor burden by "de-bulking" the patient's disease. It is clear from animal studies that there is a threshold for effective immunologic rejection of tumors with respect to tumor burden. The larger the existing tumor, the more difficult it is to treat or cure with immunotherapy. Current progress in improving early detection of cancer (with minimal burden and decreased likelihood of metastasis) will provide new opportunities to apply immunotherapy in a setting that should favor remarkable results.

Immunotherapy can be divided into two categories: active and passive strategies. Active approaches comprise both specific and nonspecific strategies, while passive methods involve the transfer of antigen-specific antibodies. Antibodies have been useful clinically as diagnostic tools in the context of enzyme linked immunosorbent assays (ELISAs) or immunocytochemistry on tissue sections. The power of antibodies in this capacity comes by exploiting their ability to recognize surface proteins that are either unique on tumor tissues or overexpressed on tumor cells compared to normal cells. Antibodies have demonstrated potential as immunotherapeutic agents as well, by complexing the antibody with toxins (immunotoxins), [30] radioactive molecules, [31] or as free antibody presumably inducing mechanisms of antibody-dependent cell-mediated cytotoxicity (ADCC). [32] ADCC, for example, is a possible mechanism that is employed during therapy with tiastuzumab (Herceptin), a new passive immunotherapy for breast cancer that targets the HER-2/neu tumor antigen on breast cancer cells with an antigen-specific monoclonal antibody.

Active nonspecific immunotherapy of cancer involves the induction of immune cells that do not rely on tumor antigen recognition and MHC-I restriction. Generally the therapy involves administration of cytokines or immune stimulatory adjuvants such as bacille Calmette-Guérin (BCG) or *Cryptosporidium parvum,* resulting in the subsequent activation of nonspecific effectors such as natural killer (NK) cells or lymphokine-activated killer (LAK) cells. LAK cells have demonstrated limited efficacy as immunotherapeutic agents when activated *in vitro* and adoptively transferred back to the patient.

Countless studies have demonstrated that protective immune responses can be elicited by vaccination with candidate synthetic tumor antigens or peptide fragment(s) (epitopes) from the tumor antigen. [33] In this light, strategies for the development of new therapies for the treatment of human cancer based on the identification and characterization of a target tumor antigen(s) and the MHC-I–binding peptides from the tumor antigen(s) include: (a) *in vitro*–generated antitumor -CD8 + CTLs that may be useful for adoptive cellular transfer immunotherapy, and (b) active immunization with synthetic peptide epitope(s) as subunit therapeutic cancer vaccines.

Adoptive Transfer of Tumor-Specific T-Cells

Adoptive immunotherapy has been defined as the acquisition of immunity in a naive subject as the result of the administration of immunologically activated lymphoid cells. [34] The process of adoptive transfer of tumor-specific lymphocytes involves obtaining T-cells from the patient to be treated, culturing the T-cells *in vitro* to activate and expand them, and finally infusing them back into the patient. As alluded to above, T-cells that infiltrate solid tumor masses (e.g., melanomas and renal cell carcinomas) have proven to be a powerful source of tumor-reactive T-cells for adoptive cellular transfer. These T-cells, designated *tumor-infiltrating lymphocytes* (TILs), have been used successfully to treat patients with malignant melanoma. However, there are reasons why TIL transfer therapy has not seen wider application. For example, not all solid tumors are a source of TILs. In addition, administration of cytokines such as the T-cell growth factor IL-2 with the TILs is often necessary to maintain the T-cells *in vivo,* and it is often difficult to acquire enough autologous tumor cells to use as a source of tumor antigen for *in vitro* activation and expansion. One alternative is to collect lymph-node draining T-cells following immunization with autologous tumor and adjuvant, and to stimulate them *in vitro* with anti-CD3 (the signaling portion of the TCR) antibody. [35],[36] This provides an effective method for generating sufficient numbers of tumor-reactive CTLs for adoptive transfer.

Active Specific Induction of Tumor Immunity

The identification of human tumor antigens and the availability of synthetic peptides representing selected immunogenic/immunodominant peptides from those antigens have made possible the generation of human tumor-specific CTLs. For example, repeated exposure of peripheral blood lymphocytes (PBLs) from melanoma patients to an immunodominant peptide from the shared melanoma antigen MART-1 (methods for antigen identification will be discussed below) resulted in the generation of CTLs that were from 50 to 100 times more potent in specific tumor killing than activated infiltrating lymphocytes harvested from the patients' tumors. [37] A separate study demonstrated the generation of CTL with specificity for the shared human melanoma antigen gp100 by *in vitro* stimulation of patient's PBLs with synthetic peptides representing CTL epitopes on gp100. [38] In addition, a number of studies demonstrated the feasibility of inducing tumor-reactive CTLs *in vitro* by coculturing PBLs from cancer patients with tumor cell lines expressing matched or autologous MHC-I antigens. [39,40,41 and 42] Most striking were the results from a recent clinical trial involving melanoma CTL-MHC-I peptides as a therapeutic vaccine administered to patients with advanced metastatic disease. Therapeutic-peptide vaccination resulted in a higher percentage of clinical responses (including complete responses) in patients than has previously been seen for any other therapy for melanoma. [43]

Indeed, this and other studies underway are clearly demonstrating the power and potential of therapeutic-peptide-based vaccines for the treatment of advanced cancer. In spite of the evidence for the existence of tumor-reactive CTLs in patients with cancer and in murine tumor models, as well as the potential of peptide-based therapeutic vaccines, most efforts to demonstrate an ongoing CTL response against tumor antigens in humans have failed. However, it is of the utmost importance to remember that in most murine tumor models (e.g., the Balb/c SV40 tumor model) the tumor of interest, though it expresses a highly immunogenic tumor-specific antigen (e.g., SV40 Tag) and MHC-I molecules, grows rapidly and aggressively *in vivo,* ultimately killing the immunocompetent host if an antigen-specific immune response is not present prior to or concurrent with tumor transplantation. [19]

IMMUNOTHERAPY OF LUNG CANCER

Of all the malignant diseases that plague humans lung cancer is the number one killer, second only to heart-related illness in overall mortality. Despite newfound optimism for high-dose chemotherapy for certain types of lung cancer (namely, small cell lung cancer), [44] overall treatment options are limited. This seemingly desperate situation demands investigation into new treatments and reevaluation of treatments such as immunotherapy with the application of new advances in technology. Typically, tumor immunotherapies can be divided into nonspecific and specific approaches. Nonspecific therapies primarily involve the administration of bacterium or components of bacterium with the expectation that an ensuing inflammatory immune response will result in accompanying immunity against the tumor. Specific immunotherapy involves either the passive transfer of tumor-reactive immune cells or antibodies that target and destroy the tumor, or active induction of tumor-destroying immunity following injection (vaccination) with inactivated tumor cells or molecular components of tumor cells (antigens).

Nonspecific Immunotherapy

The nonspecific immunotherapy of lung cancer dates back to the 1970s and 1980s, with trials showing little to no benefit. [45] Most efforts focused on the administration of BCG or *C. parvum* with limited success clinically. More recently, O'Brien and colleagues began trials to evaluate the efficacy of treating lung cancer patients with a different species of *Mycobacterium M. vaccae*) devoid of toxicity, in combination with chemotherapy. [46]

Administration of cytokines represents another arm of nonspecific immunotherapy for cancer. Cytokine therapy for lung cancer had its origin with the T-cell growth factor interleukin-2 (IL-2) administered alone or in combination with LAK cells. Interferons (IFN) have also been explored as possible nonspecific immunotherapies against lung cancer. In recent years, recombinant IFN-a has been reevaluated clinically as a maintenance therapy following chemotherapy. Overall, the use of nonspecific approaches of immunotherapy has been disappointing and the hope in such treatments has waned. As the use of nonspecific immunotherapy declines, efforts to target tumors actively and specifically with cytolytic immune responses is on the rise.

Passive Specific Immunotherapy

As alluded to above, passive immunotherapy has traditionally involved either the infusion of tumor-specific antibodies or transfer of tumor-reactive immune cells. For passive antibody therapy, monoclonal antibodies (mAb) have seen the greatest utility. Antibodies have been administered alone—for example, L6 mAh, which recognizes a surface carbohydrate antigen on non–small cell lung cancer (NSCLC) [47]—or complexed to toxic molecules such as *Pseudomonas* exotoxin-A[48] or ricin for (SCLC).[49] Antibodies, for the most part, have not demonstrated much usefulness as therapies for lung cancer but remain valuable as diagnostic and prognostic tools.

The adoptive transfer of tumor-reactive immune cells into patients with advanced cancer was pioneered by Rosenberg and colleagues. [50] The earliest efforts involved the *ex vivo* expansion of lymphocytes in the presence of high-dose IL-2; the resulting effectors were designated lymphokine-activated killer cells or LAK cells. LAK cells behave somewhat like natural killer (NK) cells in that they are not MHC-restricted T-cells but do exhibit an increased propensity to kill tumor cells. In time, LAK cells were replaced by more potent, tumor-specific, MHC-I-restricted CTLs isolated from resected tumor following culture of the tumor in the presence of IL-2. Again pioneered by Rosenberg and colleagues, these CTLs, known as tumor-infiltrating lymphocytes (TILs), have demonstrated objective clinical responses when transfered into patients with malignant melanoma or renal cell carcinoma. [51] Gene therapy using cytokines is described in Chapter 17.

In the past, adoptive transfer trials for lung cancer involved LAK cells alone or with IL-2 or in combination with different chemotherapies. Though most these efforts were disappointing, it was reported by Kimura and colleagues, that LAK cells and IL-2 showed a significant survival benefit over radiotherapy, chemotherapy, or radiochemotherapy when administered to 105 randomized patients under going noncurative resection for lung cancer. [52] Adoptive transfer trials for melanoma have demonstrated that TILs are more potent that LAK cells; however, TILs have been difficult to isolate from malignancies other than melanoma (examples include breast, prostate, and lung cancer). A recent strategy to generate tumor-specific CTLs is to immunize patient with his or her own tumor cells in the presence of an immunostimulant such as the cytokine GM-CSF, then isolate and culture CTLs from the patient's draining lymph nodes or peripheral blood for expansion *in vitro* and subsequent transfer back to the patient. [53] Small-scale studies to evaluate this strategy for the therapy of lung cancer are just beginning; time will reveal their usefulness. Because most of the more common and deadly tumors do not easily (if at all) give rise to TILs, and the generation of CTLs *in vivc* as alluded to above is labor-intensive, taking weeks to accomplish, much effort has turned to active specific immunotherapy involving *tumor vaccines.*

Active Specific Immunotherapy

Early studies demonstrated that immunization of mice with inactivated tumor cells resulted in protection from a subsequent lethal tumor challenge, prompted trials to evaluate *whole-tumor-cell vaccines* in lung cancer patients. This early approach to tumor vaccination usually involved injection of irradiated autologous or allogeneic tumor cells alone or with an adjuvant such as BCG (more recently cytokines such as GM-CSF have been used). Unfortunately, like the nonspecific immunotherapy approaches to treating lung cancer, whole-tumor vaccines have not produced very promising results. [54] One explanation is that there are components of a whole-tumor cell that are at the very least detrimental if not suppressive to concomitant immunity. In this light, much effort has turned to the development of molecularly defined tumor vaccines. For example, Garbrilovitch and colleagues have recently begun evaluation of lung cancer vaccines comprised of either mutated *ras* oncogene products or mutated *p53* tumor suppressor gene products in an attempt to take advantage of the aberrant expression of these proteins in human lung cancers. [55] These and other studies are beginning to reveal the importance of identifying tumor-associated antigens (TAA) toward their development as defined therapeutic tumor vaccines. (See Chapter 17.)

TUMOR-ASSOCIATED ANTIGENS

A hallmark of active immunity that has formed the foundation of the field of *vaccinology* (pioneered for infectious disease such as polio and smallpox) is the ability of the immune system specifically to target and destroy invaders or diseased cells while leaving adjacent healthy cells intact. Specificity arises from immune cell recognition of defined targets, or *antigens,* on diseased cells (as described above, T-cell antigens are comprised of a peptide in the groove of an MHC molecule). As mentioned previously, the first evidence for antigens on tumor cells came from the pioneering work of Foley and Prehn and Main. For decades since, researchers have hunted for evidence of tumor-associated antigens (TAAs) on human tumors with the hope of employing the power and specificity of the immune system specifically to destroy tumor cells. The premise was that if TAAs could be identified that were exclusively expressed on tumor cells, then the immune response could be manipulated against these TAAs much as had been demonstrated for infectious agents, namely viruses. In this light, the hunt for tumor viruses began.

Viral Proteins

Certain cancers are believed to be caused by viral infection, although a direct causal relationship is difficult to define. Some viruses considered to be associated with human malignancies include HBV with hepatocellular carcinoma, HTLV-I with T-cell lymphoma, EBV with Burkitt's lymphoma, and the human (HPV) with cervical papillomavirus carcinoma.[56] Viruses by nature possess the ability to alter host cell function and directly influence the multi-step process that leads to transformation. Viral-induced transformation may occur through the induction of genetic aberrations resulting from physical interaction of viral DNA with the host genome or through viral gene products expressed following infection. Since viral infection (in permissive as well as nonpermissive hosts) often results in the expression of viral-encoded protein antigens, cancers with true viral etiologies or associations represent prime candidates for the development of targeted, specific, immunologic therapies (Table 16.1).

Virus	Candidate TSA	Tumor Association
EBV	EBNA 1–4, LMP	Burkitt's lymphoma
		Naso-pharyngeal carcinoma
HBV	HBsAg	Hepatocellular carcinoma
HHV-8*	(none yet)	Kaposi's sarcoma
HTLV-I	tax, gp46	T-cell lymphoma
HPV-16, 18	E6, E7	Cervical carcinoma
SV40†	Tag	Mesothelioma,
		Osteosarcoma,
		Ependymoma,
		Glioblastoma

* May not be involved in tumorigenesis.
† Involvement and association remains unclear.
EBV, Epstein-Barr virus; HBV, Hepatitis B virus; HHV, human herpes virus; HPV, human papilloma virus; SV40, simian virus 40; EBNA, Epstein-Barr nuclear antigen; LMP, late membrane protein; HBsAg, Hepatitis B virus surface antigen; Tag, large tumor antigen.

TABLE 16.1. VIRUS-ENCODED TUMOR-SPECIFIC ANTIGENS (TSA)

The foremost example of targeting viral antigens for the immunotherapy of human cancer is that of HPV and cervical carcinoma. Clinical studies of malignant lesions indicate that greater than 90% of cervical carcinomas contain HPV genetic sequences. [57] The induction of tumor-killing CTLs by vaccination with MHC-1 peptides from E6 and/or E7 has been demonstrated most notably in murine models for HPV-16–induced cervical carcinoma. [58] Taken together, such information has led to clinical trials involving the vaccination of cervical carcinoma patients with peptides from the E6 or E7 oncoproteins of HPV. A second virus from the papovavirus family, simian virus 40, has recently been implicated in several different human malignancies.

Simian virus 40-like DNA sequences (in particular the SV40 large tumor antigen, *Tag,* gene) have been amplified from human tumors of the bone (osteosarcomas), brain (ependymomas and glioblastomas), and mesothelium, with over 60% percent of ependymomas exhibiting expression of the SV40 Tag protein. [59] Further, reports have demonstrated that 60% of malignant pleural mesotheliomas (MPM) contain SV40 Tag genetic sequences and proteins. [60],[61] The viral genes and gene products, though present in MPM tumors, could not be found in the normal mesothelium of the same patient. Studies involving other papovaviruses such as HPV as targets for immunotherapy of cervical carcinoma, along with data from murine models demonstrating the immunotherapeutic potential of SV40 Tag against Tag-positive tumors, [19] suggest that SV40 Tag represents a shared tumor-specific antigen that may be a target for the immunotherapy of MPM in humans. In spite of the enthusiasm surrounding the immunologic targeting of HPV and SV40 for the therapy of certain human cancers, it has become clear that viruses do not represent candidates for immunotherapy in the majority of human malignancies.

Oncogene and Tumor-Suppressor Gene Products

The tumor immunology specters of tolerance and autoimmunity have historically driven TAA hunting in the direction of antigens that are "non-self," such as viral antigens, or at least tumor-specific, such as mutated cellular proteins. With the dimming light of hope for finding tumor viruses to target in the more common human cancers (e.g., lung, breast, and prostate cancer), the next logical place to turn was to the proteins linked to the process of transformation and oncogenesis. Oncogene products provide the desired tumor-specific and also the potential for being a target that is shared among tumors of multiple histologies. The following are a few of the more common examples of TAAs from expressed oncogenes or tumor-suppressor genes.

The transmembrane tyrosine kinase *HER2/neu* has been demonstrated to be overexpressed in several clinically important human malignancies, including cancers of the breast, ovary, colon, and lung (see also Chapter 4). Although *HER2/neu* is expressed on some "normal" tissues and cells, it exhibits a significant increase in expression in some tumors compared to the corresponding normal tissue. This overexpression or upregulation has been demonstrated to be sufficient to elicit an immune response against *HER2/neu*. CTLs with specificity for *HER2/neu* epitopes have been identified in the peripheral blood of breast cancer patients, [62] and antibodies against an extracellular domain of *HER2/neu* have formed the basis for an antibody-based therapy, (Herceptin), recently approved by the FDA for certain breast cancers.

Oncogenesof the *ras* family are the most frequently expressed oncogenes in human cancers, including lung cancer (details on *ras* function and expression are covered in Chapter 4) *Ras* proteins that are involved in malignant transformation often differ from the normally expressed gene products by a single amino acid substitution. Studies have demonstrated that CTLs can be generated that recognize an epitope (containing a single amino acid substitution) on tumor cells that express mutated-activated *ras,* resulting in tumor protection *in vivo*.[63] Though single amino acid substitutions limit the number of possible peptide epitopes that may drive CTL-mediated killing of corresponding tumors (particularly with respect to the differences in peptide motif specificities demonstrated for the various human HLA molecules), the data suggest that activated *ras* may be a shared TAA target for the immunotherapy of multiple human cancers. Yet another tumor-specific antigen derived from a mutation in the normal protein resulting in a single amino acid substitution is that of b-catenin. [64] This candidate TAA, a cell adhesion protein, was cloned from melanoma cells using TILs generated *in vitro* from a surgically resected melanoma.

Similarly, mutations in the tumor suppressor *p53* have been identified in an increasing number of human cancers making it the leading shared TAA discovered for human malignancies to date.[65] (See also Chapter 6). The single amino acid substitutions that comprise the increased immunogenicity of "mutated" *p53* come with the same caution as that discussed above for mutated *ras* proteins, that is, they provide a limited number of potential targets for immunotherapy. However, a more recent study demonstrated that CTL immunity can be directed against nonmutated or "normal" epitopes in the *p53* protein, suggesting that tolerance can be broken against *p53,* making it a more viable shared candidate TAA.[66] Moreover, immunologic reactivity to normal *p53,* as well as other normal self TAAs to be discussed below, in the absence of apparent autoimmune-related pathology will expand the list of potential TAAs beyond that of foreign or tumor-specific/unique to include normal tissue differentiation antigens.

Antigens Cloned from Melanoma

The vast majority of TAAs discovered thus far for human cancers have been cloned from malignant melanoma. In general the melanoma antigens can be divided into two main categories. One group includes the MAGE, BAGE, and GAGE gene family of TAAs expressed on melanomas and a variety of other tumors, including lung cancers, but not on normal cells (the exception are the testes), [67] and the other group is comprised of normal melanocyte differentiation or lineage antigens (involved in skin pigmentation) which include tyrosinase, MART-1, gp100, and tyrosinase-related proteins-1 (TRP-1). [68] Several tumor antigens from each of the groups are currently being evaluated in clinical trials as therapeutic vaccines for melanoma (expanded on below).

Other Antigens

There are TAAs that have been identified and characterized that are distinct from viral proteins, mutated oncogenes, or the melanoma antigens discussed above (see Table 16.2.) The *mucin* family of genes and carcinoembryonic antigen (CEA) are examples of such TAAs. MUC-1 is a mucin found on malignant as well as normal ductal epithelial cells of the breast, ovary, pancreas, lung, and prostate. [69],[70] Tumors will express a MUC-1 that is aberrantly glycosylated compared to MUC-1 on normal tissues. The altered glycosylation renders MUC-1 immunogenic, as has been demonstrated in animal tumor models. [71] CEA is normally silent in healthy adults

but is expressed on many of the same tumors as MUC-1. This dual association[72] could lead to vaccine trials targeting CEA and MUC-1 in breast cancer patients.

Tumor Antigen	Tumor Association
K-ras	NSCLC
p53	NSCLC, SCLC
HER2/neu	NSCLC
CEA	NSCLC, SCLC
MUC-1	NSCLC, SCLC

CEA, carcinoembryonic antigen; NSCLC, non-small cell lung cancer
(may include histologies such as squamous cell adenocarcinoma);
SCLC, small cell lung cancer.

TABLE 16.2. TUMOR ANTIGENS ASSOCIATED WITH HUMAN LUNG CANCER

In the past 5 to 7 years alone, great strides have been made toward the definition of relevant molecular targets on human tumor cells that may serve as TAAs for immunotherapy. Although the list of candidate TAAs has grown rapidly, it is nowhere near complete or inclusive of all malignancies. Yet, the growing list of TAAs on many human cancers has given investigators the necessary reagents to explore strategies of active immunotherapy against human cancer, namely therapeutic cancer vaccines.

CANCER VACCINES ([TABLE 16.3](#))

Vaccine Source	Vaccine Design
Cell-based	Whole-tumor cells (modified with cytokine genes)
	DC-pulsed with peptide, protein, mRNA or transduced with recombinant retrovirus
Protein-based	HSPs
	recombinant protein in adjuvant
Peptide-based	T-cell epitopes in adjuvant
	B-cell epitopes in adjuvant
Plasmid DNA	naked plasmid DNA
	DNA-coated particles (ballistic*)
Viral vectors	recombinant vaccinia, other pox viruses
	recombinant adenovirus
	recombinant AAV

HSP, Heat Shock Proteins; DC, dendritic cells; AAV, adeno-
associated virus (AAV is a less immunogenic vector).
* Gene gun.

TABLE 16.3. TUMOR VACCINE STRATEGIES

The twofold premise for the development of therapeutic cancer vaccines is that there are differences in tumor and normal cells—differences that are manifested as abnormally expressed genes (TAAs)—and that there exist in patients the immune cells (CTLs) capable of discriminating between the normal and tumor cells though TAA recognition, resulting in CTL-mediated tumor killing. It is reasonable to speculate that these conditions exist for all human tumors and the patients who harbor the disease. With candidate TAAs in hand (for a limited number of cancers) and empirical evidence that antigen-specific tumor-killing CTLs exist in cancer patients, the challenge for investigators is to use the TAAs to elicit therapeutic immune responses in patients. However, in order to expand the study of cancer vaccines beyond tumors such as melanoma, investigators are faced with an additional challenge; to develop methods for identifying TAAs in the more common cancers to include cancers of the lung ([Table 16.3](#)).

Whole-Tumor Cells

As alluded to above for the immunotherapy of lung cancer, trials with inactivated whole-tumor cells administered as vaccines have been at best disappointing. It has been surmised that the reason for the ineffectiveness of whole-tumor cell vaccines in humans is the lack of costimulatory molecules on tumor cells and/or lack of secretion of the cytokines necessary for activating professional APCs (e.g., dendritic cells). To this end, tumor cells have been modified to express costimulatory molecules such as B7.1, cytokines such as GM-CSF, TNF-a, IFN-g, or one of several interleukins.[73] Animal studies have demonstrated that immunization with GM-CSF–secreting inactivated tumor cells resulted in increased antitumor immunity *in vivo*.[74] Data such as these have led to the recent evaluation of GM-CSF-modified tumor cells as vaccines for several human cancers, including renal cell carcinoma.

Proteins or Peptides

Purified protein vaccines against cancer have primarily consisted of artificially engineered tumors with model antigens in murine tumor systems, for example, solid tumors expressing ovalbumin (OVA)[75] or the bacterial enzyme beta-galactosidase (b-gal).[76] Although these TAAs are completely artificial and the tumor models are irrelevant to real-life cancers, the information gained through these studies has and will continue to prove invaluable to the field of cancer vaccine development. Recombinant viral proteins (e.g., SV40 Tag and HPV) have also been tested as protein vaccines in animal tumor models.[77,78] Information gathered form these studies may be directly applied to human cancers with the corresponding viral association (see section on viral tumor antigens).

Synthetic peptide epitopes from cloned tumor antigens would be valuable for clinical trials for the following reasons: (a) peptides can be easily produced with minimal cost in large quantities that are stable and free of contaminating substances; (b) such peptides could be used to stimulate and expand CTLs from patients *ex vivc* for therapeutic transfer back to the same patient; (c) these anticancer CTL-inducing peptides could be developed as vaccines to be delivered parenterally for therapeutic treatment of cancer. A striking example is a recent clinical trial involving melanoma-derived TAA peptides as a therapeutic vaccine administered to patients with advanced metastatic disease. Peptide immunization resulted in a higher percentage of clinical responses (including complete responses) in patients than had previously been seen for any other therapy for melanoma.[43] Investigators are hopeful that peptide-vaccine studies currently underway will demonstrate the power and potential of therapeutic peptide-based vaccines for the treatment of cancer.

Nucleic Acids and Recombinant Viruses

Advances in recombinant DNA technology have ushered in some novel and exciting approaches for anti-cancer vaccine development, namely nucleic acid vaccination.[79] Injection of plasmid DNA-encoding TAAs has been successful in inducing tumor immunity in animal models when administered either ballistically as DNA-coated gold particles[80] or as "naked" DNA in saline.[16]

Viruses have long been known to be potent inducers of CTL-mediated immunity.[81] Efforts to deliver TAAs as vaccines with the greatest potential for CTL induction have employed recombinant viruses. Some examples include recombinant adenoviruses that express murine homologues to human melanoma antigens[82] and recombinant pox viruses including vaccinia, canary pox, or modified vaccinia viruses (MVA). Recombinant vaccinia viruses expressing model tumor antigens have not only been successful inducing protective immunity to tumor challenge, but also in treating established tumors in mice.[83,84]

Heat-Shock Proteins

A series of recent studies has revealed a new and potentially powerful source of TAAs as well as a novel strategy for vaccination against cancer. Srivastava and

colleagues have demonstrated that heat-shock proteins (HSP) chaperone peptides from the cytosol of tumor cells to the endoplasmic reticulum, thereby playing an active role in the process of antigen presentation. More strikingly was their demonstration that purified heat-shock proteins (bearing peptides from intracellularly digested TAAs) effectively serve as vaccines against the tumor from which they were purified.[85] These studies have led to trials involving the extraction of HSPs from tumors resected from patients followed by therapeutic immunization with the purified HSPs.

Dendritic Cells

Dendritic cells (DCs) are arguably the most potent of antigen-presenting cells, expressing both MHC-I and MHC-II molecules, as well as a full complement of costimulatory molecules.[86] Therefore it is not surprising that DCs have been a recent focus of experimental cell-based cancer vaccines. Briefly, DC-based tumor vaccines include: DCs pulsed with recombinant protein TAAs, synthetic peptides [87] or mRNA-encoding TAAs,[88] DCs transduced with retroviruses expressing TAAs,[89] or DCs fused to tumor cells forming a DC-tumor hybrid cell vaccine.[90]

CONCLUSION

The overall rise in cancer incidence, coupled with a high mortality rate for many forms of cancer, necessitates the need for alternative therapies for treatment and prevention. Immunotherapeutic strategies for cancer treatment represent attractive alternatives to standard protocols for the following reasons: (a) The immune system has the ability to recognize changes as small as a single amino acid in a complex protein as well as distinguish "normal self" from "non-self" or "diseased self," thereby eliminating the overwhelming and sometimes fatally toxic side effects associated with most of the available conventional therapies. (b) The immune system is by nature systemic, that is, the cells and products of an immune response possess the ability to reach tissue sites harboring microscopic metastatic deposits of tumor cells not detectable or resectable using standard procedures. In this capacity immunotherapy holds great promise in the near future as a follow-up therapy for surgical resection of primary tumors. (c) Possibly the most powerful hallmark of the immune system is its unique ability to mount an amnestic response. This attribute has made possible, through vaccination, the eradication of deadly viral diseases such as polio and smallpox.

The widespread utilization of treatment modalities designed to induce an active immune response against human cancer has yet to be clinically realized. Progress to this end has been hampered, in part, by difficulties in identifying TAAs. With the exception of melanoma, very few candidate tumor antigens have been defined for human malignancies. Interestingly, the majority of melanoma antigens have been identified by screening cDNA libraries (generated from autologous or allogeneic melanoma cell lines) with CTLs from melanoma patients possessing melanoma-specific reactivities. The two key elements that made these antigen discovery efforts successful were melanoma cell lines and a source of "primed" T-cells from patients (e.g., TILs). Unfortunately, tumor cell lines have been difficult to generate for the more common malignancies (e.g., breast, prostate, and lung cancer), and the generation of TILs has not been convincingly demonstrated for any cancers other than melanoma (an exception might be renal cell carcinoma). Thus new approaches (Table 16-4) are needed to identify candidate TAAs for the more common cancers such as breast, prostate, and lung cancer.

TABLE 16.4. STRATEGIES FOR TUMOR ANTIGEN DISCOVERY

One approach is to screen libraries from tumor cells using tumor-specific antibodies from cancer patients.[91] Another is to use biochemistry and mass spectrometry to examine the peptide profile eluted from the MHC-I molecules expressed on tumor cells.[92] Finally, tumor-specific or upregulated TAAs could be identified by analysis of differentially expressed genes in tumor cells compared to normal cells of the same histology. This could be accomplished by (a) generating normal cell subtracted, tumor cell cDNA libraries (requires large amounts of mRNA, so normal and tumor cell lines are critical); (b) using serial analysis of gene expression (SAGE) techniques,[93] or (c) differential display, RT-PCR[94] (see also Chapter 1). Sequence information from cloned differentially expressed genes would allow investigators to test whether a series of candidate antigens are capable of stimulating PBLs to generate CTLs (via *in vitro* peptide stimulation) that are capable of killing the tumor cells from which the TAAs were originally cloned.

It is evident that a single shared TAA that could be applied against cancer in general does not exist. It is also becoming clear that there may be multiple candidate TAAs for any one type of cancer (as with melanoma). Taken together, this information supports the possibility of multiple TAAs that may be clinically useful for specific tumor immunotherapy. However, it is likely that the number of candidate TAAs is finite and definable for a given type of cancer. Future clinical application may consist of early detection screening, at which time a tissue specimen could be examined for expression (molecular biology techniques, perhaps microchip arrays) of any one or more of the defined TAAs for that type of cancer (see also Chapter 1). The patient could then be treated with a vaccine (made up of TAAs expressed by the tumor) at a time point where tumor burden (minimal, perhaps following resection of primary lesion) and immune status of the patient would not undermine the efficacy of the therapy and subsequent response.

GENE THERAPY

CHOON-TAEK LEE
SAMIR KUBBA
KEITH COFFEE
DAVID P. CARBONE

Lung cancer continues to be a major cause of cancer death all over the world. Despite recent advances in chemotherapy, radiation therapy, surgery, and a host of combinations of these, only relatively small real advances have been achieved in improving the likelihood of surviving lung cancer. Major advances, however, are being made in the field of molecular biology and the understanding of the genetic basis of this disease, and the hope is that this information will ultimately lead to rationally designed treatments that improve the outcomes of lung cancer patients. Gene therapy is an early attempt at utilizing molecular biology in lung cancer therapeutics, and the status of the field and its specific application to this disease will be reviewed in this chapter.

Gene therapy is the treatment of cancer using genetic material as a therapeutic agent. The basic approaches of gene therapy can be broadly classified into one of two groups: (a) modification of the host response to the tumor, for example by inducing immunity or altering angiogenenic responses, or (b) production of a direct antitumor action in which the introduced genetic material directly affects the cancer cell to halt its growth or kill it. These two approaches will be discussed separately.

MODIFICATION OF HOST RESPONSES TO TUMORS

Improving Immunologic Recognition

During the process by which a normal cell becomes a neoplastic cell, a series of genetic lesions occur that result in the loss of normal growth regulation and the acquisition of the ability to avoid immune surveillance. Many of these genetic lesions directly or indirectly result in the expression of potential tumor antigens. Cytotoxic T-cell responses specific for several of these can be detected or artificially induced, but it is very clear that clinically evident tumors have managed to avoid induction of an effective immune response. Gene therapy techniques can be used to deliver biologically active genes intended to alter the tumor's local immunologic microenvironment, increasing the immunogenicity of cancer cells or the responsiveness of T-cells, improving antigen presentation, or providing missing paracrine factors.

MHC Molecules

The chromosomal region containing the MHC was originally identified because of the ability of genes in this region to mediate transplant rejection as well as to control the immune response of mice and guinea pigs to simple antigens (see also Chapter 16). The analogous genetic region in humans was subsequently shown to encode the genes called the human leukocyte antigens, or HLA molecules. The proximate function of the HLA molecules encoded within the MHC is the presentation of antigenic peptides to T-cells. HLA class I and class II molecules are cell surface glycoproteins, anchored to the membrane by hydrophobic transmembrane segments. HLA class I molecules bind to endogenously synthesized peptide fragments and present them on the cell surface for recognition by the T-cell receptor (TCR) on CD8+ T-cells. HLA class II molecules are primarily involved in presenting foreign antigens to CD4+ T-cells during the initiation and propagation of the immune response. HLA class I molecules are distributed widely among most somatic cells of the body, with the exception of red blood cells. Class II molecules have a much more restricted tissue distribution, generally limited to cells of the immune system such as B cells, macrophages, dendritic cells, and some subsets of T-cells. Class II interaction induces the production of cytokines necessary for the expansion of cytotoxic effectors.

Tumor cells have some level of expression of MHC class I molecules on their surface, but in many tumor cells expression of MHC may be low. Allogenic MHC class I genes have been introduced into tumor cells, and this results in the expected induction of allo-MHC-specific cytotoxic T-cells. Importantly, responses against endogenous tumor antigens are also induced. The allo-MHC-specific T-cells presumably assist in the generation of T-cells specific for previously silent tumor-specific antigens by producing cytokines in the tumor microenvironment. In a murine lung cancer system (3LL/3) from C57BL/6 mice (MHC type H-2 ^{b}), transfection of the allogenic MHC molecule H-2L^d caused a reduction in tumorigenicity and protection against unmodified 3LL/3.[1] Plautz and colleagues[2] showed that expression of a murine class I H-2K^s gene in CT26 mouse colon adenocarcinoma (H-2K^d) or MCA 106 fibrosarcoma (H-2K^b) induced a cytotoxic T-cell response to H-2K^s and, more importantly, to other antigens present on unmodified tumor cells which had not been recognized previously. Recently, allogenic MHC transfection has been applied to humans with HLA-B7 gene transfer. Nabel and colleagues[3] reported the reduction of tumor size in a melanoma patient after the direct gene transfer of an HLA-B7 gene in a liposome complex. Clinical protocols of HLA-B7 gene transfer by lipofection in advanced cancer including melanoma, renal cell cancer, and colon cancer have shown immune responses and tumor shrinkage.[4,5,6,7,8,9 and 10] Shrinkage of noninjected tumors was also reported in some of these studies.

Therapeutic transfection of syngeneic MHC class I and II molecules has been attempted in several different tumor model systems. Transfection of syngeneic MHC class II (A) in sarcoma cells induced an immune response against both transfected tumor cells and nontransfected tumor cells.[11] This finding suggests that transfected MHC class II molecules can induce T-helper cells specific to nontransfected tumor cells as well.

Low MHC class I molecule expression in some tumors may lead to decreased presentation of tumor-specific antigens on the cell surface, which could be one mechanism for their escape from immune surveillance. Transfection of syngeneic MHC class I molecules could induce or increase the presentation of endogenous peptide fragments derived from tumor-specific antigens, leading to generation of CD8+ CTLs specific for parental tumor antigens. Once induced, this response can cause recognition and lysis of nongene modified cells with lower levels of MHC expression. Increased MHC class I expression on tumor cells may thus result in enhanced immunogenicity and decreased tumorigenicity of tumor cells. Plaskin and co-workers[12] showed that high expression of a transfected H-2K^b MHC gene in highly metastatic Lewis lung carcinoma cell (3LL) resulted in the conversion of a high metastatic phenotype to a nonmetastatic or low-metastatic phenotype and protection against the metastatic spread of 3LL.

Costimulatory Molecules (B7)

For the induction of T-cell–dependent cellular and humoral immune responses, there is a requirement for two different types of stimuli. The first is antigen-specific engagement of the T-cell receptor (TCR) with the antigen/MHC complex, and the second is the antigen-independent stimulation of another set of receptors called costimulatory molecules. This second signal is transmitted by the antigen-independent binding of costimulatory molecules on antigen-presenting cells (APC) with their

corresponding receptors on T-cells. This signal is required to induce primary T-cell proliferation and other effector functions of the immune response.

The most extensively characterized costimulatory molecules are CD28 and CTLA-4 on T-cells and their ligands, CD80 (B7/BB1, B7-1) and CD86 (B70, B7-2), on professional APC. Ligation of CD28 on T-cells by its counter-receptors, CD80 (B7-1) and CD86 (B7-2), leads to the secretion of cytokines such as IL-2 and induces cytolytic T-cells. One of the reasons that professional antigen-presenting cells such as dendritic cells are such potent inducers of immunity is the high levels they express of both MHC and costimulatory molecules. Tumor cells may have tumor-specific antigens and MHC class I expression but only rarely express B7, and thus are extremely poor direct inducers of immune responses. The rationale of transfection of B7 into tumor cells is to provide or supplement the necessary costimulation for effective immune induction. Townsend and colleagues [13] demonstrated that B7-transfection into MHC class I and II positive melanoma induced the rejection of tumors *in vivo.* This rejection was mediated by CD8+ T-cells and did not require CD4+ T-cells.

Kato and co-workers[14] augmented the antitumor effect against existing tumors by the combination of B7 and interleukin 12 (IL-12) gene transfer, and found that these modified tumor cells could induce the rejection of metastatic tumors in syngeneic mice. They first transfected mouse lung carcinoma 3LL with mouse B7 using a plasmid vector and established transfectants expressing cell surface B7 (B7/3LL). Subsequently, interleukin-12 (IL-12) was transduced into these cells using retroviral vectors encoding two subunits of murine IL-12—p35 and p40 respectively—generating stable transfectants producing IL-12 (IL-12/3LL and IL-12/B7/3LL). Four weeks after 3LL inoculation, lung metastasis was significantly reduced, with a mean metastatic colony number of 55.2 with B7/3LL compared to 23.8 with IL-12/B7/3LL. These results indicate that potent therapeutic antitumor immunity can be induced by combination of costimulatory B7 and IL-12, and that this approach could potentially be useful for cancer gene therapy.

Carcinoembryonic antigen (CEA) is an oncofetal protein expressed by many adenocarcinomas, including those of lung origin. Recently, cotransduction of recombinant vaccinia virus expressing RVB7-1 and one expressing CEA (RV-CEA) resulted in CEA-specific T-cell responses and antitumor immunity against a murine carcinoma expressing human CEA. These findings suggest that B7 increased the immunogenicity of CEA.[15] B7 transduction into murine fibrosarcomas expressing a *p53* mutation resulted in the induction of mutant p53-specific CTL and loss of tumorigenicity as well as protective immunity against challenge by untransduced tumors. [16] Similar induction of immunity was found for the P1A epitope in the P815 (murine plasmacytoma) tumor model. Another study demonstrated that B7 and CD28 interaction provide costimulatory signals not only for T-cells but also for natural killer (NK) cells. [17] Tumor cell resistance to NK cells is associated with high expression of MHC class I molecules; B7:CD28 interaction induced by B7 transfection can overcome the MHC class I–mediated inactivation of NK cells, increasing their tumoricidal activity. All of these studies provide the experimental groundwork for attempts to utilize B7 in cancer gene therapeutic approaches.

Cytokines

Since the 1970s, immunotherapy against lung cancers using cytokine-gene–modified cancer cells has been studied as a novel approach for anticancer immunotherapy in many laboratories. Rosenberg was the first to report that systemic administration of IL-2 with or without *in vitro* expanded autologous lymphokine-activated killer cells (LAK) in advanced cancer patients was associated with significant antitumor responses. [18] However, the toxicities of systemic cytokine administration interfered with the popularization of this approach. To avoid systemic side effects and, more important, to approximate normal physiological conditions, gene therapy has been used to insert cytokine genes into tumor cells and induce local production of cytokines in the vicinity of tumors. These altered immunological microenvironments are then postulated to provide favorable conditions for host immune detection of tumor cells and previously unrecognized tumor-specific antigens. Effective recognition of these antigens and induction of a response can therefore allow detection and killing of nongene-modified tumor cells with the same tumor-specific antigen, even though they may be located far from the site of gene modification.

A number of cytokines have been tested for efficacy in animal models of cytokine gene therapy. IL-2, IL-4, IL-6, IL-7, IL-12, IFN-g, TNF-a, G-CSF, and GM-CSF, among others, have been investigated. Basic experiments revealed that the subcutaneous injection of cancer cells modified by cytokine genes such as IL-2, [19,20,21 and 22] IL-4,[21,23,24] IL-6,[25] IL-7,[26] GM-CSF,[27] IFN-a, b, g,[19,22,28] and TNF[29] induced tumor-specific immunity.

IL-2 in particular has been investigated extensively. Fearon and associates [30] demonstrated that IL-2 cDNA transfected into murine colon carcinoma (CT26) resulted in the loss of tumorigenicity and bypassed deficient T-helper function in the generation of an antitumor response. Ley and colleagues [31] showed that IL-2–transfected murine mastocytoma (P815) cells induced P815-specific CTL which led to regression of established tumors. Using a highly malignant and poorly immunogenic Lewis lung carcinoma, IL-2 production by retrovirally transduced tumor cells induced antitumor CTL and eliminated the generation of lung metastasis. [32] In natural immune responses, IL-2 is produced by CD4+ T-cells activated by the binding of TCR and antigens presented by MHC class II molecules on APC. IL-2 will activate CD8+ T-cell precursors to cytotoxic T-cells. IL-2 secretion by gene-modified tumor cells may activate CD8+ T-cells directly, bypassing T-helper cells. IL-2 can overcome defects in signal transduction of T-cells of tumor-bearing patients caused by the decreased levels of p56 ^{lck}, and p59^{fyn}.[33] Early-phase clinical trials of IL-2 cytokine gene therapy have been performed, and immune responses as well as disease stabilization have been reported. [34,35,36,37,38,39 and 40]

IL-4 also shows antitumor effects in animal tumor models. IL-4 is produced by Th2 subset of helper T-cells and mast cells, and has many functions. It can induce LAK cells, stimulate B-cell proliferation and maturation, and activate endothelial cells to express vascular cell adhesion molecules. [41] Tepper and co-workers[42] demonstrated that IL-4 production from transfected tumor cells had antitumor effects in various tumor cell lines. This effect is blocked by anti–IL-4 antibody related to the level of the production, and is evident in nude mice. Infiltration of the transduced tumor site with macrophages and eosinophils suggested that inflammatory mechanisms were involved.

IL-6 is the pleiotropic cytokine that can stimulate the differentiated functions of B-cells and T-cells and induce the production of mature myeloid cells and megakaryocytes.[43] IL-6 has antitumor effects on murine models of lung cancer. The immunization of inactivated, IL-6–transfected Lewis lung carcinoma cells induced antitumor CTL and reduced the metastatic potential of these cells. [25]

IL-7 is a bone marrow stromal-cell–derived cytokine that stimulates pre–B-cell expansion. IL-7 also functions as a growth factor for thymocytes and CD4+ and CD8+ T-cells. IL-7 can enhance the antigen presentation indirectly by increasing expression of costimulatory cell adhesion molecules such as ICAM-1 and inhibit the production of immunosuppressive cytokines such as TGF-b.[44] The production of IL-7 by retroviral transduction in fibrosarcomas can decrease tumorigenicity and induce protective immunity against unmodified tumor challenge, and IL-7 transduction of immunogenic tumors can cause the regression of established lung metastasis.[26] A clinical trial of cytokine gene therapy with IL-7 is planned in lung cancer, but no preliminary results are available.

Interferon-g produced by activated T-cells can modulate the immune response in a number of ways. IFN-g can induce MHC class I and II molecules which will increase the presentation of antigen on the cell surface, and can induce the activation of macrophages. [45] Low expression of MHC molecules on tumor cells is one postulated mechanism by which tumors escape from host immune surveillance. Increased expression of MHC molecules by IFN-g should increase the presentation of tumor-specific antigens and assist the induction of antigen-specific CTL. Transduction of a weakly immunogenic tumor (CMS-5) by retroviral IFN-g induced the abrogation of tumorigenicity and persistent and specific antitumor immunity against the unmodified CMS-5 challenge. [46] The effect of IFN-g has also been demonstrated in the 3LL mouse lung cancer model. Retroviral IFN-g gene insertion into poorly immunogenic 3LL-D122 showed a significant decrease in tumorigenicity and metastatic potential, and induced tumor-specific CTL when modified tumor cells were injected after irradiation. [28]

Tumor necrosis factor has direct cytolytic effects on tumor cells and attracts and augments the tumoricidal activity of macrophages. [47] Systemic administration of TNF, however, was too toxic to achieve significant *in vivo* antitumor effects. Local production of TNF-a by retroviral transduction into the TNF-insensitive tumor cell line (J558L) drastically suppressed tumorigenicity in a syngeneic animal, even though it did not appreciably affect growth *in vitro.*[48] Administration of an anti–type-3 complement factor receptor to block the migration of inflammatory cells abolished the antitumor effects of TNF-a, which suggested the involvement of an inflammatory mechanism including the activation of macrophages. [48] The antitumor effect of TNF-a was also proven in human lung cancer cell lines, even though most human tumor cells are resistant to TNF-a. Insertion of human TNF-a cDNA into several human lung cancer cells resulted in decreased tumorigenicity in nude mice. [49] Furthermore, injection of a mixture of 50% gene-modified and 50% parental cells also showed decreased tumor formation. These data suggest that local production of TNF-a can induce antitumor effects on human lung cancer cell growth, and every tumor cell need not be gene-modified to produce local antitumor effects.

GM-CSF appears to be one of the most active cytokines in the induction of antitumor immunity. In a comparison of the efficacy of a number of cytokines using retroviral vectors, GM-CSF demonstrated the most potent, specific, and long-lasting antitumor immunity. [27] The antitumor immunity induction after gene therapy with GM-CSF was dependent on both CD4+ and CD8+ T-cells. This activity may be related to its ability to promote the differentiation of hematopoietic precursors to dendritic cells and other professional antigen-presenting cells. [50] Because culture and stable transduction of human tumors are problematic, "paracrine" GM-CSF release from gelatin-chondroitin microspheres mixed with irradiated tumor cells was tested and found to evoke antitumor immunity comparable to a

GM-CSF–transduced tumor vaccine.[51] We have designed and produced an adenovirus-GM-CSF vector that also overcomes many of the limitations of *in vitro* culture of primary human tumors. Transduction of 3LL with this adenovirus-GM-CSF vector eliminated its tumorigenicity and induced tumor-specific CTL and the regression of established 3LL tumors.[52] Furthermore, we showed that this was associated with an increased number of dendritic cells in the tumor vaccine injection site. Simons and co-workers reported the result of a phase I trial of renal cell carcinoma vaccine transduced with GM-CSF. They showed the infiltration of dendritic cells and delayed type hypersensitivity reaction with one partial response. [53]

IL-12 is a new cytokine with dramatic antitumor effects and relatively modest systemic toxicity in animal models. IL-12 has the ability to promote the differentiation of uncommitted T-cells to Th1 cells, thought to be key to the production of effective antitumor immunity. [54] IL-12 also activates the CD8+ T-cells and NK cells and generates LAK cells.[55] Tahara and colleagues[56] demonstrated that IL-12-retroviral transduction of murine sarcomas showed suppression of tumorigenicity, induction of protective antitumor immunity, and suppression of preinjected nontransduced tumors. This group has also completed a phase I trial of IL-12–transduced autologous fibroblasts.[57] The efficacy of IL-12 was confirmed when delivered via recombinant vaccinia virus [58] and adenovirus.[59] In addition, IL-12 transduction of dendritic cells may improve their function in cancer patients.

To improve and facilitate the clinical application of cytokine gene therapy, several modifications of the published animal model tumor systems are being evaluated. Most animal studies and some human trials have used *in vitro* cultured autologous tumor cells as targets for gene transfer. In practice this approach has serious limitations in a clinical setting, in that generating an autologous tumor-cell line from each patient's tumor is difficult, expensive, and time-consuming, and not possible in many circumstances. However, the key to cytokine gene therapy appears to be the production of appropriate cytokines in the vicinity of tumors, and not necessarily from tumor cells themselves. Several types of cells have been used for gene transfer, including fibroblasts, tumor infiltrating lymphocytes (TILs), endothelial cells, [60] and dendritic cells. Transduction of fibroblasts has many advantages over transduction of autologous cancer cells, as they can be obtained from skin biopsies, grow easily in culture for many passages, and can be efficiently transduced with viral vectors *in vitro*. Fakhrai and colleagues[61] showed that immunization with a mixture of irradiated tumor cells and IL-2–transduced fibroblasts induced protective antitumor immunity and remission of established tumors. A similar result was reported for IL-12.[62]

Further improvements in immune effectors to increase cytotoxicity have been explored. Various protocols based on gene transfer into tumor-infiltrating lymphocytes (TILs), tumor cells, or fibroblasts to express cytokine genes have been initiated. TILs are lymphocytes within a tumor mass which have localized to the tumor. Rosenberg and co-workers[63,64] have utilized TNF-gene–transduced autologous TILs in advanced cancer patients and demonstrated enhanced antitumor effects with less toxicity than systemic administration. Transduction with chimeric T-cell receptor and antibody has the potential to improve targeting and killing by these effectors as well.[64]

To augment antitumor effect, a combination of two different immunogenes has been used to obtain a synergistic effect. Kato and co-workers [65] transfected mouse B7 and/or IL-12 into mouse lung carcinoma 3LL. CTL activity induced by the inoculation of IL-12/B7/3LL was increased about tenfold compared to parental 3LL inoculation. Four weeks after 3LL inoculation, lung metastasis was significantly reduced by IL-12/B7/3LL postinoculation, indicating that potent therapeutic antitumor immunity can be induced by combination with costimulators B7 and IL-12. Combination of syngeneic MHC class I transfection and IL-2 transduction in the mouse melanoma cells also showed synergistic effects on the eradication of established lung metastasis by the combined effects of efficient CTL induction and NK/LAK activity compared with single-gene–modified tumor cells. [66,67]

Genetic Immunization

For defined target antigens, induction of epitope-specific immunity has typically been accomplished using synthetic peptides. [68,69] A variety of strategies have been employed to enhance the efficacy of peptide-based vaccines because the use of peptides as immunogens is complicated by their weak inherent immunogenicity and variable chemical and physical properties. [70,71,72 and 73] The chemical and physical problems of protein-or peptide-based vaccines can be avoided by the use of "genetic vaccines," purified plasmid DNA expression vectors encoding the entire cloned open reading frame of proteins introduced into living animals. These DNA vaccine vectors may generate substantial humoral and cellular immunity with little or no toxicity. [74,75,76,77 and 78] We have shown the induction of T-cell epitope-specific (mutant p53) cellular immune responses and antitumor effects after introduction of a "genetic epitope" vaccine consisting of an expression cassette containing only an oligonucleotide coding for the desired epitope. [79] In this study we used a particle gun which traumatically delivers microscopic gold particles coated with the plasmid DNA into the shaved skin of living animals. A plasmid vector containing the adenovirus E3 leader sequence was constructed, which facilitates transport of the mutant p53 epitope into the endoplasmic reticulum, showing that it can be important for optimal CTL induction and tumor-protective immunity. The use of epitope-minigene genetic vaccines may thus have significant potential for the induction of responses against identified T-cell epitopes in tumors. Direct mechanical introduction of genes into the skin is also effective. [80]

When genes are introduced into the skin or tissues to induce immunity, it is very likely that the cell that is responsible for induction is the dendritic cell or its cutaneous counterpart, the Langerhans cell (see also Chapter 16). Dendritic cells (DCs) are the most effective antigen-presenting cells (APCs) and another important target for gene therapy directed at induction of antitumor immunity. Defective antigen-presenting function of DCs in advanced cancer patients has been demonstrated, and vascular endothelial growth factor (VEGF) produced by tumor cells is one of the factors responsible for this defective DC function. [81] DCs also have the ability to produce several cytokines that are critically involved in tumor antigen presentation by APC. DCs can be generated from human peripheral blood cells cultured with GM-CSF and IL-4. Due to their pivotal role in the induction of immunity, DCs are an important target for cancer gene therapy. Unfortunately, transfection into DCs is not easy. Retrovirus, liposome, and calcium phosphate have been used with low transfection rate. Adenovirus has shown the better transduction rate into DCs. [82] Polylysine-modified adenovirus has also been shown to be effective. [83] A variety of antigens have been transduced into dendritic cells, and this results in highly efficient induction of immunity. [84] Transduction of tumor-specific antigen (MART-1) by adenovirus could induce melanoma-specific CTL. [85,86] Minigenes encoding mutant forms of *p53*[87] or wild-type *p53*-expressing adenovirus-transduced DCs[88] have been able to induce specific CTL. Transduction of cytokine genes such as IL-12 could also be a powerful method to induce tumor-specific CTL. [89]

To date, many protocols have been conducted or are underway worldwide designed to augment the immune response against cancers by gene therapy (i.e., by vaccine or direct cytokine or costimulatory molecule gene transduction). It remains to be seen whether the theory developed in animal models can be successfully applied to the therapy of human cancer. It is likely, however, that combinations of approaches along with vaccine therapy will be the most successful, especially those that are aimed at reversing cancer-associated immune defects.

Antiangiogenic Gene Therapy

Of the approximate 200 gene therapy trials currently underway, about half target the cancer cell. These strategies include the introduction of genes that (a) produce a toxic molecule when expressed in tumor cells, (b) attempt to correct or prevent a genetic mutation, (c) attempt to make tumor cells more sensitive to chemotherapeutic drugs, and (d) increase the immunogenicity of tumor cells. Another emerging branch of gene therapy focuses on tumor antiangiogenesis. While most gene therapy protocols directed against cancer must overcome (a) the limitations of access to tumor cells, (b) varying populations of tumor cells, (c) selection of resistant cells, and (d) dependence on cell cycling, antiangiogenic gene therapy is directed against the endothelial cells that are recruited to provide blood supply to the developing tumor. Antiangiogenic gene therapy is attractive because it has potentially less systemic toxicity, does not require that the gene enter the tumor cells, is independent of growth fraction or tumor cell heterogeneity, and does not induce drug resistance. [90]

Strategies for antiangiogenic gene therapy include local versus systemic therapy. In a review of this subject, Kong and Crystal [91] argue that this approach should be used exclusively in a local or regional setting. This argument rests on the possibility that (a) the bystander effect of antiangiogenic gene therapy may be greater than other forms of gene therapy directed only against the cancer cell, and (b) potential side effects of systemically administered antiangiogenic gene therapy may be avoided. Potential systemic side effects include delayed wound healing and effects on endometrial maturation and neonatal growth; however, some data suggest that these side effects are dependent on the specific gene used. [92,93 and 94]

Lin and colleagues report on studies investigating Tie2, an endothelium-specific receptor tyrosine kinase known to play a role in tumor angiogenesis. [95] An adenoviral vector was constructed to deliver a recombinant, soluble Tie2 receptor capable of blocking activation of the Tie2 receptor on endothelial cells. Plasma concentration of the soluble receptor was maintained for about eight days, and growth of two different primary tumors was significantly inhibited following a single injection of the Tie2 adenovirus. Mice that were coinjected with tumor cells and the Tie2 adenovirus developed few grossly apparent metastases compared to numerous large, well-vascularized lung metastases in mice that received a control virus.

Several studies have demonstrated that interference of VEGF-mediated angiogenesis with either anti-VEGF antibodies [96,97 and 98] or antisense[99] is sufficient to inhibit tumor growth and metastasis (see also Chapter 11). Goldman and associates also report on studies in which tumor cells were transfected with cDNA encoding the native soluble FLT-1–truncated VEGF receptor, which can function by sequestering VEGF and by forming inactive heterodimers with membrane-spanning VEGF receptors in a dominant negative fashion. [100] Transient transfection of the truncated FLT-1 receptor significantly inhibited the implantation and growth of human fibrosarcoma cells in nude mice. Survival was also significantly improved in mice injected intracranially with human glioblastoma cells stably transfected with the FLT-1 dominant negative receptor.

As with most forms of gene therapy, limitations exist to these approaches using antiangiogenesis vectors. The adenovirus typically yields only short-term expression that limits its use for antiangiogenic therapy. Newer vectors, including adeno-associated virus and lentivirus, under development should increase expression to weeks or months. If the concerns surrounding systemic therapy are satisfied through further studies, antiangiogenic gene therapy could become an important adjunct therapy, for example following surgery to prevent recurrence or metastases, in combination with conventional chemotherapy, vaccine therapy, immunotherapy, or other types of gene therapy.

Drug Resistance Genes

Various groups are attempting to enhance marrow protection during chemotherapy by transducing the multiple drug resistance gene (MDR1) into normal bone marrow or blood-derived stem cells. The MDR1 gene produces p-glycoprotein, which functions as a cellular efflux pump and may be responsible for the resistance of some tumor cells to various hydrophobic cytotoxic drugs. Insertion of the MDR1 gene into normal marrow stem cells produces a population of cells that can be selected for resistance to a systemically administered chemotherapeutic agent and thus permit higher doses of chemotherapy to be given with less toxicity and more efficacy. Retrovirus-mediated expression of the DNA repair protein O-methylguaonidine-DNA-methyl-transferase protected mouse primary hematopoietic cells from nitrosourea-induced toxicity. Marrow from mice expressing methotrexate-resistant dihydrofolate reductase was protective against methotrexate toxicity in recipient syngeneic mice. Breast and ovarian cancer protocols using MDR1 alteration have been initiated using Pac (Taxol) as the chemotherapeutic agent. This approach does have the disadvantage of higher doses of medications, may not infer higher response, nonhematologic toxicities may be dose-limiting, and the therapy may be complicated by the prior contamination of the marrow with the tumor cells.

DIRECT-ACTING GENE THERAPY

Genetic abnormalities have been found in the cancer cell that functionally contribute to the process of carcinogenesis. Introducing genetic material can directly inhibit tumor growth by replacing a damaged tumor-suppressor gene, decreasing the expression of activated or overexpressed dominant oncogenes, or by introduction of an enzymatic activity that confers sensitivity to an otherwise nontoxic drug.

Tumor-Suppressor Gene Therapy

Recent advances in the cellular and molecular biology of lung cancer have identified many genetic alterations that represent potential new molecular targets for cancer therapy.[101] Cells are chronically faced with decisions to divide, differentiate, or undergo programmed cell death (apoptosis). Two major classes of genes are known to affect this process: dominant oncogenes and recessive oncogenes (tumor-suppressor genes). Protooncogenes (the normal homologues of dominant oncogenes) participate in critical cell functions, which include signal transduction and transcription. Only a single mutant oncogene allele is required to induce malignant transformation. Modifications of the dominant oncogenes that confer gain of transforming function include point mutation, amplification, translocation, and rearrangement. Tumor-suppressor genes that are frequently found to be mutated in lung cancer include *p53,* usually altered by a point mutation combined with loss of the associated wild-type allele, or *RB,* which is usually inactivated by deletions.

Tumor-suppressor gene products appear to play a role in governing proliferation by their regulation of transcription and cell-cycle control (see also Chapter 2). Replacement of inactivated tumor-suppressor genes by gene therapy has been extensively investigated, and several tumor suppressors are potential candidates for this approach. The inactivation of *p53* may be the most common genetic alteration in human tumors and is found in human lung cancer with high frequency.[102,103] The *p53* gene encodes a nuclear phosphoprotein which controls cell proliferation and suppresses neoplastic transformation. The wild-type (wt) p53 protein delays S-phase entry in the case of DNA damage, allowing for DNA repair and preventing the propagation of mutations and chromosomal rearrangements to the next cell generations.[104,105] Normal cells tolerate this cycle arrest, but cancer cells that are driven by activating mutations in dominant oncogenes undergo apoptosis and die. Thus in order for cancer cells to survive, they often mutate *p53* and are thus resistant to this sort of apoptotic cell death. One copy of the chromosomal region 17p13 which contains *p53* is frequently deleted in both small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC), and mutational inactivation of the remaining allele occurs in more than 90% of SCLC and 50% of NSCLC.[102,103 and 104,106] The complexities of the three-dimensional structure of the p53 tumor-suppressor gene product and the radical changes in this structure induced by a single point mutation makes it extremely difficult to restore its function with pharmaceuticals. Thus the basic concept of tumor-suppressor gene thereapy utilizing *p53* is to reintroduce a functionally active copy of the defective genes in the cancer cell by direct gene transfer to directly induce cell death by apoptosis. Reintroducing a wild-type *p53* gene into lung cancer cells, including bronchioloalveolar lung cancer (BAC), dramatically inhibits tumor cell growth and promotes tumor cell death despite the presence of mutations in multiple other genes. [106] Preclinical *in vitro* and *in vivo* murine studies in head and neck cancer and NSCLC demonstrated a significant antitumor effect of Ad- *p53*. Replacement of *p53* via retroviral vectors to human lung cancer cell lines with mutated *p53* resulted in stable expression of p53 protein and apoptosis *in vitro*.[107,108] In an orthotopic lung cancer model produced by intratracheal inoculation of human lung cancer cell lines into immunodeficient mice, direct intratracheal administration of retroviral-wt *p53* expression vectors inhibited tumor growth.[109] The difficulties associated with retroviruses have led most investigators to use a recombinant adenovirus. Initial experiments in which the H358 (a p53-null BAC cell line), H322 (p53 mutant), and H460 (p53- wild-type) human NSCLC cell lines were treated with Ad-p53 resulted in significant inhibition of cell growth in the H358 and H322 lines.[110] Direct peritumoral injection of adenovirus-p53 also inhibits solid tumor growth in nude mice. [111] In these studies, the antitumor effect of *p53* introduction appears to be primarily cell-cycle arrest followed by the induction of apoptosis.

Several human clinical trials are under way using wild-type *p53.* A trial of retrovirus expressing wild-type p53 directly injected into NSCLC endobronchial or intrapulmonary nodules has recently been completed at MD Anderson. [112] The results from the first nine patients on the retroviral p53 protocol have been reported. All nine patients (median age 68 years: range 51 to 73 years) had a history of primary NSCLC carcinoma. Of these nine patients, four had recurrent endobronchial lesion (three squamous cell carcinomas and one adenocarcinoma) and were treated with bronchoscopic injections of the retroviral *p53* expression vector ITRp53A. Another four patients had chest wall lesions (two large cell carcinomas, one squamous cell carcinoma, and one adenocarcinoma) and were treated with percutaneous injection under CT or fluoroscopic guidance. The ninth patient had a left adrenal metastasis from a large cell carcinoma, which was treated with percutaneous injection of the vector under CT guidance. All patients in the study had failed existing treatments and had cancers that were growing progressively. Three of the seven patients evaluable for response showed evidence of tumor regression in the treated lesions. In the remaining four evaluable patients, tumor growth stabilized in three patients for periods ranging from eight to nine weeks. The fourth patient had a chest wall lesion that continued to progress after the first cycle of treatment. Each of these four patients had other sites of disease not treated by gene replacement that continued to progress during treatment with the vector.

Swisher and colleagues have recently completed a protocol in which an adenovirus vector was utilized (personal communication). Fifty-three patients were enrolled in this study and were treated by intratumoral injection at monthly intervals for six cycles. Patients were treated by direct assignment with or without CDDP 80 mg per m^2 intravenously over two hours and given three days before Ad-p53 injection. No significant vector-related toxicity was seen with up to six monthly injections. The severity of CDDP-associated toxicity (grade II or higher) was not increased with coadministration of Ad-p53. At the initial assessment at two months, four patients (8%) had a partial remission, while 33 patients (65%) had stable disease.

Major tumor regression in lung cancer has been documented independently by Nemunitis and associates (PRN Research, Dallas TX), who have entered patients in a current phase I trial. Of the first 35 patients on whom complete data is available, five of 14 (36%) receiving Ad-p53 alone had growth arrest of their tumor for more than four months. Six of 15 (40%) patients receiving Ad-p53 plus CDDP had growth arrest of their tumor for more than four months despite three of the six progressing on CDDP or carboplatin. Thus the above three human trials showed responses by p53 introduction with minimal vector-associated toxicity.

A study has recently being activated by Swisher and colleagues (personal communication) for stage III NSCLC in those patients who cannot tolerate surgery due to cardiac or pulmonary compromise, consisting of docetaxel (Taxotere) 20 mg per m^2 weekly for a total dose of 100 mg per m^2, along with 60 cGy radiation with concomitant Ad-*p53* intratumoral instillation on weeks 1, 3, and 5. End points are local control at three months and will be compared to historical controls currently at only about 20%.

In all of these studies, it has been difficult to deliver recombinant virus into solid tumors so as to transduce a significant fraction of the tumor cells, and the effect is limited to the injected nodule, which may be of limited real clinical benefit. This is because adenovirus has a limited diffusion range in a solid tissue. Thus many investigators are focusing on clinical situations where improved transduction efficacy might be achieved with meaningful clinical results. Examples might include pleural effusions or peritoneal carcinomatosis, where small volume disease is limited to a closed body cavity, or BAC. BACs are chemoresisistant and radioresistant.[113],[114] and [115] In this disease, cancer cells grow initially as a thin monolayer along the pulmonary alveoli and bronchiolar surfaces without destruction of the underlying lung structure. This biology results in progressive shortness of breath and death by suffocation in the majority of these patients, but also makes this tumor uniquely appropriate for delivery of therapeutic agents directly to the tumor cells via the airways. The authors of this chapter have begun a pilot phase 1 trial of an adenovirus p53 gene delivered via bronchoalveolar lavage in patients with locally advanced BAC. Endobronchial delivery of recombinant wtp53 adenovirus via bronchoalveolar lavage may be a highly efficient means of gene transfer and a highly effective local therapeutic in this disease. Effective local palliation could well translate into significant clinical benefit. While BAC is only a subset of all NSCLC, the large numbers of NSCLC deaths each year and the complete lack of good therapeutic options for unresectable or recurrent BAC make the potential clinical impact of this therapy significant.

Systemic gene therapy with liposome-p53 complexes has been reported to cause a significant reduction of greater than 60% in primary tumor volume as compared to a control group.[116] Nude mice inoculated with breast carcinoma cells were injected every 10 to 12 days with liposome p53 via the tail vein. Analyses of the growth pattern revealed that the majority of the p53-treated animals had tumor regression. Induction of p21, marked histological changes, and increased apoptosis were present in the tumors of the p53-treated group. In addition, the p53-treated group had significantly fewer lung metastases. Introduction of p53 via liposomes was effective in the treatment of early endobronchial cancer in mice [117] and was shown to enhance radiation sensitivity in head and neck cancers.[118] The endobronchial use of p53 liposomes may be less toxic than the use of adenovirus vectors in this situation and deserves further clinical exploration.

Other tumor-suppressor genes have also been used therapeutically. These include the retinoblastoma protein (RB), which is mutant in the majority of SCLCs and about 20% of NSCLCs.[119],[120] RE introduction has definite antitumor effects which appear to depend on the extracellular environment of the tumor. [121] A p53-inducible inhibitor of cyclin-dependent kinases, WAF/CIP1, is another candidate gene for the replacement therapy. [122] A large part of the growth regulatory action of p53 appears to be mediated by this protein, which also known as p21. Overexpression of these two genes can arrest the cell cycle in G1 phase. [122] Adenovirus-p21 therapy of p53-deleted mouse prostate cancer cell lines induced growth arrest and resulted in a reduction of CDK2 kinase activity. Intratumoral injection with adenovirus-p21 but not with adenovirus-p53 prolonged the survival of tumor-bearing mice. [123],[124] Inhibitory activity was also found in human NSCLC cell lines. [125]

p16 is another tumor-suppressor gene that can also be a candidate for tumor-suppressor gene therapy. Genetic abnormalities of p16 have been found frequently in NSCLC but rarely in SCLC. Homologous deletion or point mutations have been found in 10% to 40% of NSCLC. Furthermore, hypermethylation in the 5' CpG island of p16 allele without genetic alteration will explain the high prevalence (30% to 70%) of absent p16 protein expression in lung cancer. [126] Introduction of a p16 gene by a recombinant adenoviral vector induced growth arrest and G1 arrest. In lung cancer, adenovirus-mediated p16 gene transfer could inhibit the proliferation of p16-negative lung cancer cell lines and induce dephospholylation of pRb. [127]

Combined tumor-suppressive gene therapy with adenovirus-p53 and adenovirus-p16 could cooperate to induce cancer cell apoptosis and suggests potentials for development of new cancer gene therapy strategy.[128]

p27 is another possible tumor-suppressor gene even though it is rarely mutated in human cancers, including lung cancer, but low levels of p27 are associated with poor prognosis in NSCLC.[129] Catzavelos and colleagues showed that alteration of p27 levels played an important role in lung tumor progression, and low levels of p27 not related with ras mutations may have independent poor prognostic significance in NSCLC. [130] Overexpression of p27 after transduction with an adenoviral vector induced growth arrest and apoptosis in breast cancer cell lines. [131] A comparison study of several adenoviral vectors with cyclin kinase inhibitors showed Ad- p27 induced potent suppressive effect on tumorigenicity. [132] From the above studies, p27 overexpression in NSCLC may be another replacement gene therapy modality.

The major conceptual problem with tumor-suppressor gene replacement therapy is that all clonogenic tumor cells would theoretically need to receive the therapeutic tumor-suppressor gene in order for there to be an observable clinical therapeutic impact. This is readily accomplished in tissue culture but it is obviously very difficult or impossible to achieve in patients, except perhaps in special clinical circumstances such as BAC, as outlined above, or after multiple applications of the gene. It is clear from chemotherapeutic studies that even single-log reduction of tumor bulk (90% cell kill) has only marginal clinical significance, so much work on delivery systems needs to be accomplished before this is more generally applied to clinical problems.

Ionizing Radiation and Gene Therapy

Tumor necrosis factor-a (TNF-a) is a cytokine that activates the cellular immune response and is directly cytotoxic to some tumor cells. Mechanism of direct cell killing by TNF-a involves both apoptosis and necrosis. When combined with radiation in vivo, TNF-a is reported to enhance tumor control through immune modulation. Hallahan and co-workers have reported that TNF-a enhances direct tumor cell killing in vivc and in vitro following exposure to ionizing radiation, and a clinical study that combined systemically (intravenously) administered TNF-a and therapeutic local/regional radiation demonstrated promising results in local tumor control. Systemic toxicity attributed to TNF-a limited the therapeutic efficacy of the treatment regimen. Hallahan and co-workers selected the CArG elements of the Egr-1 promoter (425 bp upstream from the transcription site) to regulate TNF-a because these elements are inducible by radiation in several types of human tumor cell lines.[133] They ligated a region containing the six CarG elements of the promoter enhancer region of the Egr-1 gene upstream to a TNF-a cDNA. A replication-defective adenovirus type 5 (Ad5) was used to deliver the Egr-TNFa genetic construct to tumors. It was observed that production of TNF-a in human tumor xenografts infected with the Ad.Egr-TNFa and treated with radiation enhanced tumor control as compared with radiation alone. A tenfold increase in TNF-a protein was observed after radiation.

Gene activation targeted by ionizing radiation is a new concept for cancer treatment whereby transcription of therapeutic genes is localized and regulated by ionizing radiation. The combination of proteins produced by targeted genes with the cytotoxic effect of ionizing radiation may enhance tumor cures without a significant increase in local or systemic toxicity. Temporally fractionated radiation provides a method for repeated gene induction resulting in prolonged, accentuated gene expression and thus may have wider applications in gene therapy and cancer treatment.

Drug-Sensitizing Gene Therapy

This approach has been used to induce selective transduction of tumor cells with a gene whose product can convert a relatively nontoxic prodrug administered systemically to a toxic metabolite in the cancer cell expressing the transduced gene product. Since Moolten originally suggested the potential utility of herpes simplex virus thymidine kinase (HSV-TK) gene for cancer treatment, drug sensitivity gene therapies have been widely adopted in animal and human therapeutic approaches.[134] Tumor cells that express the activating enzyme are killed, and cells without the transduced gene and enzyme are not affected. Several drug-resistant genes and drug combinations have been tested, including HSV-TK and ganciclovir, cytosine deaminase and 5-fluorouracil, and cytochrome P450 2B1 gene and cyclophosphamide.

The HSV-TK and ganciclovir combination has been the most widely investigated. Good responses have been observed in animal studies. [135] Thymidine kinase is the enzyme responsible for phosphorylation of thymidine and is involved in the salvage pathway for DNA synthesis. In contrast to cellular thymidine kinase, HSV-TK has an ability to phosphorylate not only thymidine but also several nucleoside analogues, including the guanosine analogue ganciclovir. Ganciclovir can be phosphorylated by HSV-TK to the triphosphorylated form. This triphosphorylated GCV enters the DNA synthesis pathway instead of the guanosine triphosphate, blocking DNA synthesis and inducing cell death. In vitro tumor cell line experiments have shown that ganciclovir sensitivity in HSV-TK gene–transduced tumors is at least 1,000 times greater than control, nontransduced tumor cell lines. Furthermore, HSV-TK–transduced tumors showed regression after ganciclovir treatment in animal tumor models. In a study done by Kumagai and colleagues, herpes simplex gene was ligated with four repeats of the Myc-Max response elements (a core nucleotide sequence CACGTG), rendering c-, L-, and N- myc overexpressing SCLC cell lines significantly suppressed by ganciclovir. [136]

It has been observed by this technique that a small fraction of tumor cells may be affected by HSV-TK, but the cytotoxic effect of transduced cells occurs on nontransduced cells too. This is termed the "bystander effect." Thus all tumor cells in a solid tumor need not be transduced in order to get 100% killing. The precise mechanism of this bystander effect has not been fully elucidated, but there are several mechanisms. The transfer of apoptotic vesicles by endocytosis from killed HSV-TK–positive cells to adjacent HSV-TK–negative tumor cells has been identified in some cases. [137] Recently metabolic cooperation between cells via gap junctions has been demonstrated, making the cell-to-cell passage of small molecules, including toxic metabolites of GCV, possible. [138] Another mechanism that may play a role

in some circumstances is the induction of an immune response by the recruitment of macrophages and CD4 and CD8 T-cells to the tumor site.

There are more than 20 protocols using this strategy. More than 100 patients have been entered in these ongoing protocols.[139] Major tumor regression has been reported in eight of 62 patients in various kinds of tumors.

Cytosine deaminase (CD) and 5-fluorocytosine (5-FC) make up another well-studied drug sensitizing gene system. CD-expressing cells can deaminate the relatively nontoxic prodrug 5-FC to highly toxic drug, 5-fluorouracil, resulting in the killing of CD-expressing cells and adjacent cells by the bystander effect. The efficacy of CD and 5-FC has been proven in lung cancer model. Hoganson and associates compared three different toxin genes (HSV-TK, CD, and human deoxycytidine kinase) in human lung adenocarcinoma and reported that CD was the most promising.[140] They also reported that CD gene transfer followed by prolonged 5-FC could inhibit the growth of a lung adenocarcinoma in an animal model.[141]

The combination of drug-sensitizing therapy and cytokine gene therapy has been tried as well. The release of tumor-specific antigen by tumor cell death due to drug-sensitizing genes and the attraction of immune effector cells to tumor cells by cytokine may synergistically enhance the chance of generating tumor-specific CTL. Kwong and co-workers reported that combination of HSV-TK and IL-2 via adenoviral vectors could prevent the metastasis of murine lung cancer and improve animal survival.[142] Combination gene therapy of HSV-TK and GM-CSF plus bone-marrow–derived dendritic cells to improve the antigen presentation ability has been shown to lead to regression of established lung tumors in mice and confers protective immunity against rechallenge of parental tumors.[143]

Antisense cDNA and Oligonucleotide Approaches

Various efforts are under way to develop and apply oligonucleotides for therapy of a number of diseases. The phosphodiester backbone in the oligonucleotide is often modified to methyl-phosphonate or phosphorothioate to reduce degradation by nucleases. There are three principal types of *in vitro* and *in vivc* applications of this methodology: (a) Antisense oligodeoxynucleotide (ODN), which binds specifically to a target mRNA and prevent translation. Treatment with antisense nucleic acids attempts to block expression of the endogenous messenger RNA through the formation of translationally inactive RNA-specific duplexes. Plasmid or viral vectors have been used for transfering an open reading frame fragment of the desired gene oriented backwards (3' to 5') behind a powerful promoter, resulting in the production of an antisense RNA. Antisense RNA transcribed from these constructs forms an RNA duplex with sense mRNA, inhibiting translation.[144] (b) Triplex ODN, which bind specifically to double-stranded DNA and prevent transcription. These modified antisense oligonucleotides can enter tumor cells by endocytosis and form DNA-RNA duplexes with endogenous sense mRNA, inhibiting translation. (c) Antiprotein ODN, or "Aptamers," which bind to proteins and exert a biologic effect.

A variety of genes and cellular pathways have been targeted by this approach, including activated oncogenes such as K- *ras* and c-*myb,* and growth factors such as HER2/neu or insulinlike growth factors (IGF) and the IGF-1 receptor. The specific cell cycle regulatory proteins are also reasonable targets for cancer gene therapy. (See also Chapter 2) The tumor-suppressor genes *p53* and *RB,* discussed earlier, directly down-regulate progression through the cell cycle, but a number of cyclins and growth factors act to promote proliferation and thus are reasonable targets for gene-specific inhibition. Cyclin G1 (CYG1) is one member of the G1 cyclins that is overexpressed in human osteosarcoma. Antisense cyclin G1 (CYG1) delivered via a retroviral vector showed inhibition of growth of human osteogenic sarcoma cells.

Insulinlike growth factors are often essential for the maintenance of the malignant phenotype, and in lung cancer the IGF-1 receptor (IGF-1r) is often expressed at high levels.[145] Stable transfection of antisense plasmids expressing the first 300 bp of the IGF-1r reduces the tumorigenicity of a variety of tumor cell lines and has been reported to induce systemic antitumor effects on established, nongene-modified tumors in animal system models.[146] We have constructed an adenovirus-expressing antisense IGF-1r (Ad-IGF-1r/as), and a single transduction of this into human lung cancer cell line NCI H460 cells decreased the receptor number by about 50% and decreased soft agar clonogenic ability by almost ten fold. The intraperitoneal treatment of nude mice bearing established i.p. NCI H460 cells resulted in prolonged survival compared to that of nude mice treated with a reporter virus.[147] This suggests that Ad-IGF-1r/as has a therapeutic effect on established human lung cancer xenografts and may represent an effective and practical cancer gene therapy. Clearly there is potential for the antisense approach for therapy of lung cancer.

BCL2 is often overexpressed in small cell lung cancer, and antisense oligonucleotides spanning the length of the open reading frame were tested by Stahel and collegues for antitumor activity.[148,149] In these studies, an oligonucleotide from an internal portion of the protein was found to be the most effective and produced highly efficient killing and chemosensitization of a number of SCLC cell lines *in vitro.*

Epidermal growth factor (EGF) and its receptor (EGFR) have an important role in the pathogenesis of NSCLC. Blockade of EGFR by monoclonal antibody has been shown to suppress the growth of NSCLC overexpressing EGFR.[150] In human squamous cell carcinoma of head and neck, direct inoculation of EGFR antisense plasmid inhibited tumor growth and increased apoptosis by suppressing EGFR protein expression.[151]

Ribozymes

Ribozymes can be engineered to cleave selectively to a wide variety of RNA targets, thus modifying gene expression. The hairpin ribozyme is a 50 nt RNA enzyme under current development as a promising agent for sequence-specific RNA inactivation in gene therapy. Ribozymes are essentially antisense oligonucleotides that contain an RNAse active site. A ribozyme possessing this activity allows catalytic gene ablation by sequence-specific cleavage of the target transcript. This ability of ribozymes to confer gene "knock-out" at the mRNA level and inhibit normal gene expression by targeted cleavage of RNA renders them as valuable tools in fundamental studies of gene function both in cells *in vitro* and in transgenic models. Ribozymes have been used in cancer therapeutic approaches to inhibit activated oncogenes (*ras* and *bcr*-abl), oncogenic viruses, and the MDR1 gene as alluded to earlier.[152,153,154 and 155]

Dominant Inhibitory Growth Factor Receptors

For the uncontrolled proliferation of tumor cells, strong growth stimulation through the growth factor pathway is essential. Cancer cells acquire a growth advantage by active secretion of growth factors and overexpression of those receptors. Cancer cells are uniquely dependent on these autocrine or paracrine growth-signaling pathways and thus they can be targets for cancer therapy. Antisense intervention acts by inhibiting translation of the receptor protein, but this does not affect protein that is already present in the cell, even low levels of which may allow cancer cell survival. Mutant forms of these receptors can be introduced into cancer cells that can inactivate signaling through preexisting receptors, and these are called "dominant negative" receptors. An example of this is the design of defective IGF-IR or soluble mutant of IGF-IR that suppresses tumorigenicity and progression of tumors by a dominant negative mechanism.[156,157]

Intracellular Antibody

Overexpressed oncoproteins in cancer cells can be targeted in cancer cells by the delivery of a gene encoding for what is known as an "intracellular antibody."[158] The introduced gene encodes for a single chain Fv which, when expressed and translated intracellularly, recognizes and entraps the oncoprotein, inhibiting its function. This has been successfully applied to *erbB-2* in ovarian cancer.[159,160] Dramatic growth inhibition and prolonged survival of human tumors in xenografted animals was observed after delivery of the gene with a recombinant adenovirus. As this oncoprotein is also expressed in breast and lung cancers, it has therapeutic potential for these tumor sites as well.[161,162 and 163]

Oncolytic Virus

In gene therapy, viruses have been used for the delivery of therapeutic genes to tumor cells. Typical viral vectors in gene therapy have been designed to deliver a therapeutic gene and to be unable to replicate by themselves, even though wild-type forms of the virus can replicate and destroy the infected cells. Many investigators have begun to develop strains of virus that can specifically replicate in and destroy cancer cells directly and then propagate to adjacent cancer cells and kill them as well. Several viruses, such as herpes simplex type 1 virus and Newcastle virus, have been used for that purpose.

Adenovirus has been the best studied for this approach. For the replication of wild-type adenovirus in the host cells, it is essential to inactivate host p53 protein by the adenoviral E1B 55kD protein. Frank McCormick and colleague generated a mutant adenovirus lacking the E1B-55kD gene (ONYX-015), designed to replicate and lyse p53-deficient human tumor cells but not cells with functional p53.[164] More than a half of human tumors but no normal human cells have inactivated p53 function. The potential utility of this virus would be enormous. They also showed that ONYX-015 could cause tumor-specific lysis and also augment the efficacy of standard chemotherapeutic agents.[165] In the preliminary data of phase II trials in patients with head and neck cancer, intra- and peritumoral injection of ONYX-015 showed that

p53-mutant tumors have undergone remarkable destruction (4% to 100% reduction), but no damage to adjacent normal tissue has been found. [166] The similarity of head and neck cancer and lung cancer in the pathogenesis and p53 mutation rate suggests the potential use of this strategy in lung cancer. Possible obstacles of this approach are the heterogenity of p53 status in human tumors and the generation of antiadenoviral humoral immunity that can prevent the replication of ONIX-015. Combination of ONYX-015 and other gene therapies, such as HSV-TK and/or CD, could be an another alternative. [167]

SUMMARY

Cancer arises when mutations occur in genes that control cell growth, DNA repair, and cell death. Novel treatments targeting these genetic lesions include gene therapy. Lung cancer, the leading cancer killer in the United States, is refractory to many types of therapy and is thus in need of such novel approaches. However, its poor immunogenicity and frequent metastases make the problem more difficult.

While gene therapy has received much attention, it has also been met with significant (and sometimes justified) skepticism for many of the reasons outlined above. Early trials of gene therapy have seen some promising results that we feel deserve more rigorous development. The practical contribution of gene therapy to clinical oncology is still minimal, but we believe that judicious application of gene therapy to specific clinical situations may ultimately improve lung cancer patient outcomes.

INITIATION OF CELL CULTURES FROM LUNG TUMOR BIOPSIES

HERBERT K. OIE
ADI F. GAZDAR

COLLECTION AND TRANSPORT OF TUMOR SPECIMENS

Lung cancer is the most common malignancy in the world and the cause of most cancer deaths in the United States.[1] The four major types of lung cancers described by the World Health Organization classification [2] are small cell lung cancer (25% of lung cancers), adenocarcinoma (30%), squamous cell carcinoma (25%), and large cell carcinoma (15%). All four major lung cancers are generally believed to have endodermal origins.

Squamous cell carcinoma, large cell carcinoma, and adenocarcinoma are usually grouped as non-small cell lung cancers (NSCLCs) based on differences in natural history, clinical behavior, and biologic properties but mainly because treatment centers follow different treatment policies for these malignancies. [3] Small cell lung cancer (SCLC) has attracted widespread interest because of its unique biologic and clinical properties. SCLC expresses many neuroendocrine features, most interestingly the secretion of many hormones and neuropeptides. [4,5] Some of the neuropeptides (e.g., gastrin-releasing peptide) [6,7] may function as autocrine growth factors. A detailed understanding of the mechanisms that mediate their mitogenic actions may provide alternate ways of treating these cancers.

Truly representative characterization of a tumor cell type would require large numbers of cell lines. Toward this end, we established and characterized more than 200 lung cancer cell lines (Table 18.1). Much of the available knowledge, especially of SCLC biology and molecular genetics, has come from studies utilizing these cell lines. It is hoped that more extensive studies on larger numbers of each lung cancer cell type will lead to more effective strategies for the treatment of lung malignancies.

Tumor Specimens	Number of Cell Lines
Lung cancers	224
SCLC	126
NSCLC	92
Mesothelioma	6
B-lymphocytes*	50
Colorectal cancers	18
Other cancers	7
Myeloma	2
Estesioneuroblastoma	1
Adrenocortical carcinoma	1
Gastric cancer	1
Breast cancer	2

NSCLC, non-small cell lung cancer; SCLC, small cell lung cancer.
* B-lymphocytes isolated from specimens cultured for tumor cell growth.

TABLE 18.1. CELL LINES ESTABLISHED FROM HUMAN TUMOR SPECIMENS (1976–1990)

In this chapter, we describe in detail the procedures and techniques that have evolved by modifying existing methods and devising new techniques (Table 18.2). Using these methods, we have succeeded in establishing many cell lines, mostly from SCLC and NSCLC specimens but also from a variety of other human cancers (Table 18.1).

Tumor Specimens
Solid tumors
Bone marrow aspirates
Pleural, pericardial, and ascitic effusions
Transport Methods
Solid tumors—in culture medium
Bone marrow aspirates—with heparin
Effusions—with heparin
Processing Methods
Solid tumors—mechanical spillout method
Bone marrow aspirate—Ficoll gradient separation
Effusions—Ficoll gradient separation
Culture Media
SCLC—HITES, HZ, SCLC-2, R10, ACL4(S)
NSCLC—ACL4, ACL4(S), SCCRh, R10, HZ
Mesothelioma—ACL4(S), SCCRh, R10, HZ
B-lymphocytes—R10, ACL4(S), SCCRh, HZ
Isolation Methods
Selective media (HITES, ACL4, SCCRh)
Differential trypsinization
Colony picking
Transfer of floating tumor aggregates
Removal of floating normal cells
Tumor cell overgrowth
Maintenance
Routine culture (split every 7–10 days)
Freeze isolated cells early and at several passages
Characterization

SCLC, small cell lung cancer; NSCLC, non-small cell lung cancer; FBS, fetal bovine serum; HITES, serum-free defined medium for SCLC; R10, RPMI 1640 + 10% FBS; HZ, HITES + 2% FBS; SCLC-2, HITES plus cholera toxin, epidermal growth factor, transferrin, and bovine serum albumin; ACL4, serum-free defined medium for adenocarcinoma; ACL4(S), ACL4 plus 5% FBS; SCCRh, special medium for squamous cell carcinoma.

TABLE 18.2. PROCEDURES FOR THE ESTABLISHMENT OF HUMAN LUNG CANCER CELL LINES

Tumor specimens obtained for *in vitro* cultivation are basically solid tissues (i.e., cancer masses from the lung, lymph node, and extrapulmonary sites) or fluid samples (i.e., pleural and pericardial effusions, ascites, and bone marrow aspirates). The samples may be from primary or metastatic lesions. Generally, the resected specimen was taken to the pathology laboratory where the tissue was divided for distribution; the largest portion was fixed in formalin, and the remainder was apportioned to the various researchers. If the specimen for cultivation was small (i.e., obtained by needle biopsy), it was put between sterile, saline-moistened pieces of gauze to keep it from drying, placed in a sterile container, and transported to the cell culture laboratory.

Larger samples were put into sterile specimen jars containing cell culture medium (e.g., RPMI 1640, Eagle's MEM), with or without antibiotics. Occasionally, serum, albumin, or polyvinylpyrrolidone were used to preserve cell viability.

Because of the extensive handling and occasional lapse in sterility, the interval between surgical removal of the tumor and the distribution of the samples for transport to the cell culture laboratory presents the best opportunity for the introduction of contaminants into the tissue samples. Probably the best scenario for obtaining viable tumor tissue for cultivation is as follows: with the mutual consent of surgeon and pathologist, the investigator desiring a specific tumor specimen for culture attends the operation, accepts the entire resection in a sterile covered tray, takes the specimen to pathology, and designates to the pathologist the area of the resection he or she thinks would most likely yield viable tumor cells for culture. A cross section or a wedge-shaped piece providing as much of the tumor edge as possible is most likely to

yield aggressively growing tumor cells.

Before any specimen is obtained for culture, a detailed explanation of the intended usage of the sample should be presented to the patient and, if necessary, a consent form signed.

Any specimen that cannot be transported to the cell culture laboratory within 1 hour is stored in a refrigerator. In collecting fluid specimens, special care should be taken to prevent clotting. Preservative-free heparin 5 μg/mL is added to pleural, pericardial, and ascitic effusions. Bone marrow aspirates are collected with a heparin-coated syringe and needle, deposited into tubes containing heparin, and transported to the cell culture laboratory.

Tumor specimens submitted to the cell culture laboratory from outside sources are collected as described previously, packed in wet ice, and delivered by overnight express service.

Many solid tumors contain necrotic tissue, which releases enzymes that are detrimental to cell viability. To reduce cell destruction from this source, specimens can be put into media containing polyvinylpyrrollidone or methylcellulose and kept on ice from the time of collection and during transport, until the tissue is processed for culture.

Sodium bicarbonate-buffered tissue culture media require CO_2 to maintain a desired pH. Exposure to the air results in the medium becoming alkaline, a condition not favorable for cell viability. It is preferable to use a bicarbonate-free medium, such as L-15, initially supplemented with serum or a serum-substitute polyvinylpyrrollidone to preserve cell viability.[8]

PROCESSING TUMOR SPECIMENS FOR CULTURE

Specimens should be processed for culture as soon as possible after arrival in the cell culture laboratory. If this is not possible, the samples should be refrigerated.

Solid Tumors

Solid tumors with adequate masses are disaggregated by mechanical procedures, proteolytic enzyme digestion, or a combination of the two methods. After placing the specimen in a Petri dish with a small amount of medium to keep the tissue wet, necrotic tissue, blood clots, fatty tissue, and connective tissue are trimmed from the specimen with scissors. The tissue is then cut into small, 1- to 3-mm squares, either with scissors or by cross-cutting with two scalpels. In many cases, this process of mincing the tissue released tumor aggregates into the medium. Several washes of these tissue pieces usually yield sufficient tumor cell aggregates for culture.

Several different enzyme mixtures have been used to disaggregate tumor tissues. Duchesne and colleagues[9] used a combination of pronase, DNase, and collagenase for lung cancer disaggregation. Rheinwald and Beckett[10] digested squamous cell carcinoma of the tongue, pharynx, and skin with 0.2% trypsin and 0.2% collagenase. Twentyman[3] combined mechanical and enzymatic methods to obtain cell suspensions for culture. Using either the cross-cutting scalpel method or scissors, the tumor tissue was chopped into fragments 1 mm square or smaller and then digested with bacterial neutral protease (1 mg/mL) at room temperature for 1 hour.

Although trypsin or a combination of trypsin and EDTA was widely used by early cell culturists, its harsh mode of action has resulted in its replacement with milder enzymes or enzyme combinations. During early years of attempting to culture SCLC from resected tissues, trypsin and EDTA digestion was found to be unsatisfactory because of poor recovery of viable cells. Additionally, resulting suspensions contained both tumor and normal cells in monodispersion, which produced a culture of tumor and normal cells uniformly distributed over the flask surface. Generally, the normal cells, usually fibroblasts, had the advantage of faster growth and overgrew the slower proliferating tumor cells.

Mechanical methods for disaggregating solid tumors have been used by several groups to establish cancer cell lines. Campling and colleagues[11] disaggregated lung cancer tissue by forcing small pieces through a wire mesh and separating the live cells from debris by Ficoll-Hypaque density gradient centrifugation. Kirkland and Bailey[12] obtained tumor cell clumps from colorectal adenocarcinoma tissue by "gentle teasing." The Dartmouth Medical School group led by Pettengill[13] initiated cultures of SCLC by seeding minced biopsy or autopsy specimens.

We have found that the simplest, fastest, and least traumatic method of processing not only SCLC but also NSCLC and other tumor specimens is by the mechanical spillout method.[8] Tumor tissue is chopped into small pieces using cross-cutting scalpels or scissors. The aggregates of tumor cells released by this mincing process are harvested by several series of choppings and washings. The washings are pooled and centrifuged. If necessary, erythrocytes and debris can be removed by Ficoll density gradient separation. The minced tissue suspension usually contains sufficient tumor cells for culturing without further processing.

The mechanical spillout method allows the harvesting of mostly tumor cell aggregates because normal cells are not easily dislodged from the tissue matrix by simply mincing. Because colonies of tumor cells develop from clumps instead of isolated single cells, the tumor cells are given a better start and are better able to compete with normal fibroblasts for growth.

Bone Marrow Aspirates

Because bone marrow specimens are usually quite bloody, the samples are subjected to Ficoll gradient separation to remove the erythrocytes as well as to concentrate live tumor cells. Usually 1 to 3 mL of aspirate is received. After diluting the specimen at least two to five times with serum-free medium in a 15-mL conical centrifuge tube, 2-mL Ficoll is carefully deposited at the bottom of the tube. The tube is then centrifuged in a refrigerated table-top Beckman GPR centrifuge at 1,500 rpm for 15 minutes at 4°C. Cells at the interface are harvested with a pipet, pelleted by centrifugation, washed twice in 10 mL of medium at 1,000 rpm for 5 minutes, and cultured in 25-cm^2 flasks in 4 mL of media per flask containing penicillin 100 U/mL, streptomycin 100 μg/mL, gentamicin 5μg/mL, and fungizone 5 μg/mL.

Pleural, Pericardial, and Ascitic Effusions

Effusions may be received in volumes as little as a few milliliters or as large as 2 to 3 L. Cells from small volumes are centrifuged and, without further processing, placed into culture flasks. Large volumes are concentrated by centrifugation, and if large amounts of erythrocytes are present, the cell suspensions are subjected to Ficoll gradient separation. The interface layer of cells is harvested, washed twice with medium, and seeded into 25-cm^2 flasks.

The pellets from the gradients usually contain large aggregates, which break through the gradient and pellet with the erythrocytes. The pellets can be resuspended in medium and allowed to stand at room temperature so that the heavier cell aggregates sediment by gravitation. By removing the supernatant fluid, much of the erythrocytes are removed. Repeating this process results in a relatively erythrocyte-free tumor aggregate suspension suitable for cultivation.

CULTIVATION, ISOLATION, AND ESTABLISHMENT OF LUNG CANCER CELL LINES

Small Cell Lung Cancer

HITES is the acronym derived from the five growth factors (hydrocortisone, insulin, transferrin, estradiol, and selenium) added to the defined medium (RPMI 1640) to produce the selective medium for the growth of SCLC cells.[14] Other commercially available defined media such as Ham's F-12, Eagle's MEM, or DMEM can also be used. Duchesne and colleagues[9] used Ham's F-12 plus the HITES ingredients to grow lung cancer cells. Most other investigators used RPMI 1640, the defined medium used to develop the HITES medium.

Our experience has shown that in some cases, the specimen submitted for culture contains a mixture of lung cancer cell types. Hence, when sufficient tissue is available, the specimen is routinely seeded into 25-cm^2 flasks containing the following media: HITES, HITES plus 2.5% fetal bovine serum (FBS), squamous cell carcinoma Rheinwald (SCCRh),[15] RPMI 1640 plus 10% FBS (R10), and adenocarcinoma lung lines (ACL4)[16] plus 5% FBS. Cells from a very small percentage of SCLC specimens do poorly in all of the aforementioned media. These cells may require cholera toxin, bombesin, or epidermal growth factor for *in vitro* proliferation.

Therefore, we include a flask containing the medium SCLC-2,[17] which contains all of these growth factors.

Most early epithelial cell cultures grew attached to the flask surface. Oboshi and colleagues [18] reported the first human SCLC line that grew as a floating culture. Most of the SCLC cell lines we have established in HITES and R10 grow as floating aggregates. In contrast, the cell lines developed in Waymouth's MB 752/1 medium supplemented with 20% FBS by the Dartmouth Medical School group were mainly adherent cultures.[13] Pettengill attributes the high calcium content in Waymouth's medium and the attachment factors present in FBS to the large number of adherent SCLC lines established by the Dartmouth group. [13]

SCLC tumors are rarely resected; therefore, most SCLC cell lines are derived from metastatic sources, including bone marrow aspirates, pleural effusions, and lymph nodes. Usually, SCLC clumps are microscopically observed as tightly packed, floating spheroids in the classic aggregate morphology. Individual cells in the aggregates are difficult to distinguish. Other aggregates are formed of loosely packed cells in the variant morphology. The lack of substrate attachment and strong cell-to-cell adhesion may be the result of the production of neural cell adhesion molecule (NCAM). [19,20]

Most SCLC cells grow as floating aggregates or as loosely attached colonies. In contrast, stromal cells require firm attachment to flask surfaces to proliferate. It is a simple matter to detach the loosely adhering SCLC colonies by gently rapping the flask, harvesting the detached aggregates, and transferring them to new flasks. A series of these transfers usually yields pure SCLC cultures. Although most SCLC cells grow as floating aggregates even in serum-containing medium, a few cell lines usually contain adherent cells. By repeatedly removing the floaters, adherent cell lines can be eventually isolated. Whether attached or floating, the properties characterizing SCLC cells are usually retained.

The development of a serum-free, growth factor-supplemented HITES medium has enhanced the ability to establish SCLC cell lines. The absence of serum significantly reduces the growth of stromal cells, and the additives promote the proliferation of most SCLC cells.

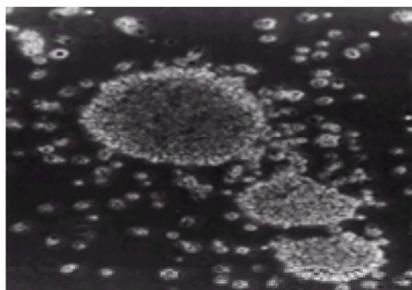
The more difficult cell contaminants to cope with in growing SCLC cells are the proliferating B lymphocytes (BL), which, similar to SCLC cells, grow as floating aggregates (Fig. 18.1). Proliferating BL cells are Epstein-Barr virus-transformed B-lymphoblastoid cells, which are present in some bone marrow aspirates, and lymph node biopsy specimens, the most common specimens obtained from SCLC patients.


FIGURE 18.1. Proliferating B-lymphocytes, present as floating aggregates in culture, occasionally contaminate small cell lung cancer primary tissue cultures (100 × magnification).

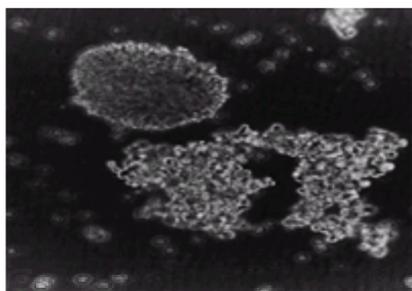
BL aggregates are relatively easy to differentiate from SCLC cell clumps; the BL cells are loosely aggregated and have spikelike structures (uropods) projecting radially from the aggregates. These cells grow rapidly and cause acidification of the medium. Because BL cells require serum for proliferation, isolation of SCLC cells from a mixed culture is achieved by growing the cells in serum-free HITES medium. BL cells can be isolated by growing the mixed culture in the selective medium ACL4, in which BL cells grow well but SCLC cells do poorly (Fig. 18.2). Paired SCLC cell lines and "normal" BL cell lines from the same patients prove to be very useful in studies comparing the changes that occur in tumor cells, such as cytogenetic alterations.


FIGURE 18.2. Proliferating B-lymphocytes (*round aggregate*) in a culture with variant small cell lung cancer (*irregularly shaped cellular aggregate*). These lymphocytes can serve as "normal cells" for molecular genetic studies if they can be isolated and grown free of the tumor cells (100 × magnification).

The addition of serum diminishes the selective property of HITES medium. However, the growth of most SCLC cells is enhanced by the addition of small amounts of serum, suggesting that HITES medium, although supplying the minimum requirements for SCLC growth, lacks certain factors for optimum *in vitro* growth.

Non-Small Cell Lung Cancer

Early lung cancer cell lines can be established from NSCLC specimens because of the availability of large amounts of resected tissue. Most cell lines are grown and established in commercially available defined media (i.e., MEM, DMEM, McCoy's 5A, Ham's F-10, Ham's F-12) supplemented with 10% to 20% FBS, although several NSCLC lines have been developed in HITES medium plus 2.5% FBS.[3,11,21] Among the early NSCLC cell lines still in widespread use are A-549 and A-427 [22] and Calu-1 and SK-MES-1.[23]

The NSCLC group includes three of the four major cell types of lung cancer—adenocarcinoma, squamous cell carcinoma, and large cell undifferentiated carcinoma; SCLC is the fourth major type. The diversity of these cell types presents a more complex problem in cultivation than the growing of SCLC cells. The development of the serum-free medium ACL4[16] for the selective growth of adenocarcinoma and of SCCRh,[15] a medium originally developed for the growth of skin keratinocytes that has proven useful in growing squamous cell carcinoma cells, helps to enhance the culturing of these two cell types. No special medium has been developed for large cell carcinoma.

To ensure that media for all cell types are provided, the NSCLC specimens should be grown [8] in ACL4, ACL4 plus 5% FBS, SCCRh, R10, and HITES plus 2% FBS. The inclusion of serum in SCCRh medium allows normal cells to grow, but this medium is especially useful in initiating cultures from specimens containing a mixture of adenocarcinoma and squamous cell carcinoma. Addition of FBS to ACL4 reduces its selective capabilities, but many adenocarcinoma cells grow better in this medium with serum. Therefore, we have adopted the procedure of initially growing the specimens in serum-free media to suppress normal cell growth while the tumor cell colonies establish themselves. After the tumor colonies are fairly large, serum is added to help enhance tumor cell growth.

Because both NSCLC cells and normal cells grow as adherent colonies, isolation of tumor cells is a major problem. Various methods are used to obtain pure tumor

cell cultures. One method utilizes the relative difference in attachment rates to separate tumor cells from normal cells. In some cases, small aggregates of tumor cells attach to the flask surfaces within four to six hours, while the normal cells are still in suspension. By removing the medium, a reduction in the amount of contaminating stromal cells and erythrocytes is achieved. With pleural effusions, the normal cells (e.g., mesothelial cells, monocytes) usually attached faster, so by removing the floating aggregates of tumor cells and transferring them to new flasks, the number of normal cells is reduced. Erythrocytes can be eliminated by routine media changes. The use of several of these manipulations can result in the isolation of tumor cells.

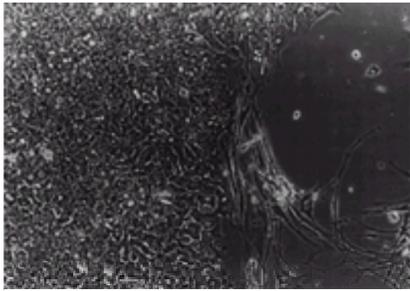
Culturing of tumor cell aggregates obtained by the mechanical spillout method for processing solid tumor specimens produces adherent colonies of tumor and normal cells randomly distributed over the flask surface (Fig. 18.3). Tumor cells can be isolated in several ways under these circumstances. Well-isolated tumor colonies are dislodged by scraping the wall of the flask with the bent tip of a Pasteur pipet, aspirating the colonies into the pipet, and depositing them into the wells of a 24- or 96-well cell culture plate. Tumor cells can also be harvested by taking advantage of the differences in cell susceptibility to the action of trypsin and/or the chelating agent EDTA. By exposing a mixed culture of tumor and normal cell colonies to low concentrations of trypsin, EDTA, or both, cells are selectively detached from the flask surface. If normal cells are detached, the trypsinate is removed and discarded. The attached tumor cells are washed once with medium and refed with growth medium. Trypsinates containing mainly tumor cells are transferred to tubes and centrifuged. The pellets of cells are washed once with medium, centrifuged again, resuspended in growth medium, and seeded into new flasks. The old flask containing attached normal cells is then discarded.


FIGURE 18.3. A culture of adenocarcinoma cells (**left**) contaminated with spindle-shaped fibroblasts. Adjusting serum concentrations and using mechanical methods of cloning can rid the culture of these contaminating normal cells (100 × magnification).

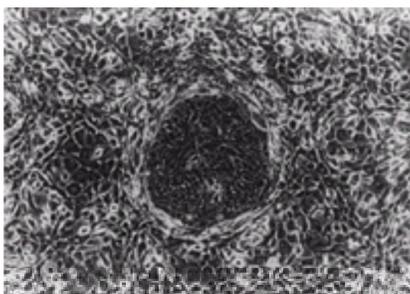
Some adenocarcinoma colonies, when completely surrounded by fibroblasts, produce aggregates of cells loosely attached to the tumor cell colony in response to the impediment of lateral growth by fibroblasts (Fig. 18.4). Gentle rapping of the flask easily dislodges these aggregates, which are harvested and cultured in new flasks.


FIGURE 18.4. Colonies of adenocarcinoma (**center**) are surrounded by normal mesothelial cells (100 × magnification).

Some NSCLC cells, especially large cells and squamous cells, produce densely packed colonies. The peripheral cells continue to grow and migrate laterally, infiltrating the surrounding fibroblast monolayer and eventually, if bacterial or fungal contamination can be avoided, displacing the fibroblast cells. This displacement of fibroblasts after long periods of cultivation can be attributed to the ceasing of fibroblast growth as a result of contact inhibition, which eventually results in the deterioration of fibroblast cells by aging.

MAINTENANCE OF CELL LINES

We arbitrarily designate isolated tumor cell cultures as cell lines only after 25 passages and six months of continuous *in vitro* culture. The cells are maintained in 75-cm^2 tissue culture flasks, usually in the medium of isolation, and passaged every 7 to 10 days at low split ratios (1:2 or 1:3). For passaging, adherent cells are treated with a warm solution of 0.4% trypsin and 0.02% EDTA in Ca^{2+}- and Mg^{2+}-free phosphate-buffered saline (PBS) for one to two minutes at room temperature following a single wash with warm PBS to remove serum and divalent ions (Ca^{2+} and Mg^{2+}). The serum contains trypsin inhibitors, and divalent ions are used by cells for attachment. Fresh serum-containing medium is added to the detached cells to stop the action of trypsin, and the cells are triturated with a pipet to break up cell clumps and sedimented by centrifugation. The cell pellet is resuspended in growth medium and distributed into new flasks.

Feeding adherent cultures is achieved by aspirating the spent medium with a suction apparatus fitted with heat-sterilizable platinum tubing. Platinum is ideal for this purpose because it heats and cools rapidly. Flasks of floating aggregate cultures are placed on a specially designed wooden block with a V-notch cut into it. The bottom corner of a flask is placed in this notch, and the cells are allowed to sediment to this corner by gravitation. Spent medium is aspirated by the suction apparatus and replaced with fresh medium. Alternatively, the cell aggregates are broken into smaller clumps by trituration, transferred to new flasks at lower densities, and refed with fresh medium.

The cultures are fed once during the 7- to 10-day period, usually 3 to 4 days after passaging. Established cultures are fed with antibiotic-free medium so that periodic mycoplasma testing can be done using Gen-Probe.

It is important to freeze isolated cultures early and at several passages to prevent loss of these early cultures to laboratory accidents (e.g., bacterial, fungal, or mycoplasma contamination, wrongly prepared medium). Freezing medium consists of filter-sterilized 40% RPMI 1640, 10% dimethyl sulfoxide, and 50% FBS. Cells are stored at 135°C or lower in nitrogen or a compressor-driven ultra-low-temperature freezer, preferably in several freezers located at different sites to prevent loss of frozen cell stocks to freezer breakdown. A large stock of frozen cells is essential for cell lines that can only be used for limited passages.

CHARACTERISTICS FOR EARLY IDENTIFICATION

Identification of a tumor begins long before a sample of the tumor reaches the cell culture laboratory (Table 18.3). Information on the tumor type submitted with the specimen is invaluable in selecting the processing method and media. This is especially true in choosing a selective medium. If only a small sample is available, the wrong choice of selective medium usually results in loss of the specimen.

TABLE 18.3. CHARACTERISTICS FOR EARLY IDENTIFICATION OF HUMAN LUNG CANCER CELLS

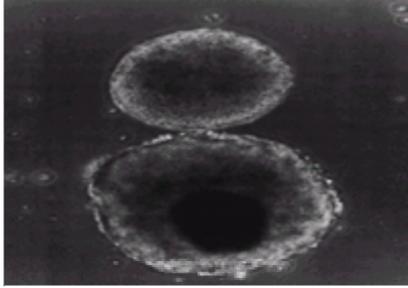
SCLCs grow in the serum-free, defined medium HITES as floating aggregates, which can be tightly packed spheroids in the classic morphology (Fig. 18.5) or more loosely structured aggregates in the variant morphology (Fig. 18.6). The cells are positive for L-dopa decarboxylase (DDC), creatine kinase brain-type isoenzyme, neuron-specific enolase, and bombesinlike immunoreactivity. [24],[25],[26] and [27] Variants usually have barely detectable or no DDC activity but retain the other biochemical markers. Cytospin preparations of SCLC cells show small round cells with scanty cytoplasm and a few inconspicuous nucleoli. Variant cells are slightly larger, with more cytoplasm and more prominent nucleoli.


FIGURE 18.5. Classic cell aggregate morphology of small cell lung cancer in culture is characterized by floating, tightly packed spheroids (100 × magnification).
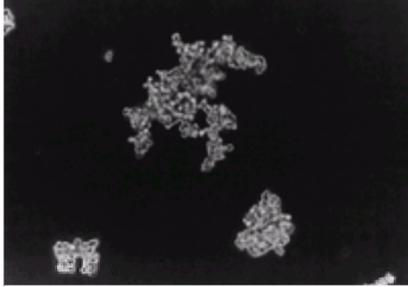

FIGURE 18.6. Cell aggregates of variant small cell lung cancer in culture have more loosely structured appearances compared with the classic morphology (100 × magnification).

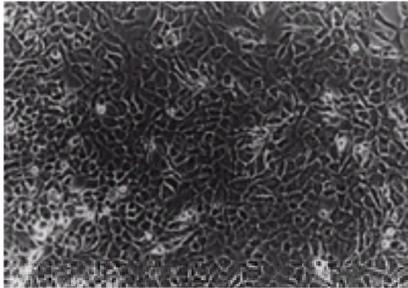
Large cell carcinoma cells grow as attached epithelial cells that are generally uniform in size (Fig. 18.7). These cells show no evidence of squamous cell or adenocarcinoma differentiation.


FIGURE 18.7. Large cell lung cancer in culture. These cell lines appear epithelial and uniform in size (100 × magnification).

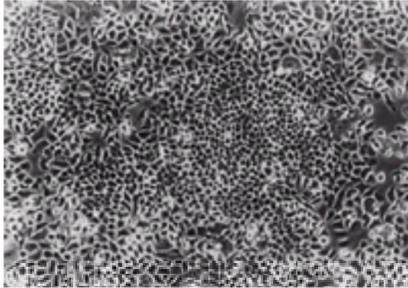
Squamous cell carcinoma cells grow as adherent cultures, forming whorls that resemble keratin pearls (Fig. 18.8). Cornified envelope formation is the most distinguishing characteristic of squamous cells, which are only seen in multilayered cultures. Unfortunately, cornified envelope formation is a terminal event. Only cultures that can be maintained in a delicate balance of dividing undifferentiated cells and nonreplicating differentiated cells survive.


FIGURE 18.8. A monolayer culture of squamous cell lung cancer (100 × magnification).

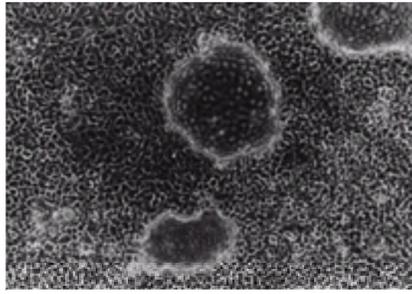
Adenocarcinoma cells grow in the selective medium ACL4 as adherent cultures. The cells are large and vary in size. Mucin production ranges from a few small vacuoles to goblet cell production. A few adherent cultures produce domes, which occur when fluid lifts the cells off the substrate (Fig. 18.9). Some adenocarcinomas grow as floating aggregates and produce glandular structures. Approximately 20% of adenocarcinomas show neuroendocrine phenotype, [3] and these cells usually are DDC-positive.


FIGURE 18.9. Adherent culture of adenocarcinoma of the lung. Dome formation is also seen (100 × magnification).

BLs grow as floating aggregates resembling variant SCLC clumps. They form loose aggregates and characteristically have spikelike protrusions (uropods) radiating outward from the aggregates. Giemsa-stained smears show cells with abundant cytoplasm and large nucleoli. BL cells express Epstein-Barr virus nuclear antigen. These cells require serum for growth, so they could be easily suppressed by growing them in serum-free HITES or ACL4 medium.

CONCLUSIONS

Earlier attempts to establish lung cancer cell lines were greatly impeded by the need to use serum-containing media, which favored fibroblast cell growth. Hence, fibroblasts outgrew and overgrew the slower growing carcinoma cells. The development of the serum-free, growth factor—supplemented media HITES for the selective growth of SCLC cells and ACL4 for the culturing of adenocarcinoma cells eliminates this problem. As a result, large panels of well-characterized SCLC and adenocarcinoma cell lines have been established. The easy availability of large numbers of well-characterized cell lines has generated an intense interest in lung cancers, resulting in a rapid accumulation of knowledge regarding the biology and molecular genetics of lung cancer.

The development of new technologies in cell culture and the determination of nutritional requirements for an ever-increasing number of tumor cell types will make cell lines from most human tumors available.

ANIMAL MODELS FOR STUDYING LUNG CANCER AND EVALUATING NOVEL INTERVENTION STRATEGIES

ALVIN M. MALKINSON
STEVEN A. BELINSKY

"Pulmonary carcinogenesis is studied in animals in order to determine the pathogenesis, prevention, early detection, and treatment of this disease on behalf of man." [1] Lung tumors in domestic animals were periodically observed by veterinarians, but it was not until Livingood's histologic description 100 years ago of a papillary tumor in a mouse[2] that the use of animals as experimental tools began. Genetically homozygous mice were established in the 1920s following generations of inbreeding, and inbred strains could be distinguished by their susceptibility or resistance to spontaneous or chemically induced lung tumor development. Procedures for testing putative carcinogens in rodent bioassays became more standardized, and are used today by regulatory agencies to assess carcinogenic risk. The most commonly used species in experimental respiratory carcinogenesis are mice, rats, hamsters, and dogs.[3] This chapter describes how animal models help in understanding lung cancer: by revealing the biology and molecular events during experimental pulmonary oncogenesis, by delineating genes that regulate tumor development, and by providing a convenient testing ground for innovative chemopreventative and chemotherapeutic strategies.

EXPERIMENTAL ADVANTAGES OF ANIMAL MODELS

Animal models allow discovery of genotoxic compounds which induce tumors and nongenotoxic agents that modulate carcinogenesis. Genes that regulate susceptibility to these agents and the timing of molecular events during tumor progression can be elucidated. Because different species develop different types of tumors, several animal models may prove valuable for delineating the biochemical changes that characterize a particular class of lung tumor.

Defined Exposure to Tobacco or Compounds with Related Mechanisms

People are continuously exposed to potentially harmful mixtures of chemicals and physical agents. The laboratory environment allows controlled administration of these environmental toxicants to animals (Table 19.1). Experimental variables typically include dosage, dosing frequency (e.g., lifetime exposure, a single injection of a rapidly metabolized substance), and host factors at the time of exposure (e.g., age, genetic background, and nutritional and proliferative status). Inbred strain A/J mice given a single intraperitoneal injection of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), a carcinogenically potent tobacco-derived nitrosamine, at any time after birth, develop dozens of benign lung adenomas within a few months.[4] When more time elapses following carcinogen administration, many of these induced tumors progress to adenocarcinomas that are histopathologically indistinguishable from human adenocarcinomas. [5]

Inducing and Promoting Agents	Protective or Regression-Inducing Agents
Cigarette components	Antioxidants (e.g., butylated hydroxytoluene)
Nitrosamines in smoke	Cruciferous vegetables (e.g., cabbage)
Polycyclic aromatic hydrocarbons in tar	
^{210}Po in tobacco	Retinoids
Carbonaceous particles	Anti-inflammatory drugs (e.g., sulindac)
Phenols	
Diesel exhaust	cis-platinum
Heavy metals (e.g., uranium)	Isothiocyanates
Fibers (e.g., asbestos)	Tea polyphenols
Radionuclides (e.g., radon particles)	Glucocorticoids
Carbamates (e.g., urethane)	Farnesyltransferase inhibitors
Butylated hydroxytoluene	Sulindac sulfone

TABLE 19.1. CATEGORIES OF AGENTS THAT STIMULATE OR DISCOURAGE LUNG TUMOR DEVELOPMENT IN ANIMALS

In order for the full complex mixture of cigarette smoke to induce adenomas and adenocarcinomas in A/J mice, chronic exposure (e.g., six hours per day, five days per week for five to six months) followed by a recovery period in air for over four months is necessary. [5]

Modulations of Tumor Formation by Nongenotoxic Chemicals

The antioxidant, butylated hydroxytoluene (BHT), a widely used food additive, inhibits both tumor incidence and multiplicity in adult A/J mice receiving this agent prior to carcinogen administration.[6] Antioxidants inhibit lung tumor formation by interfering with the conversion of an inactive carcinogen to a more chemically reactive metabolite. Conversely, BHT, but not other antioxidants, can be converted through cytochrome P450 metabolism to an oxidative species that causes pneumotoxicity. Interestingly, if repeated doses of BHT are administered after carcinogen exposure, tumor multiplicity is enhanced. [7] One current explanation for this seemingly paradoxical behavior is that growth factors released at the injury site selectively stimulate the division of mutated cells. For example, in BALB/C mice exposed to 3-methylcholanthrene (MCA), a polycyclic aromatic hydrocarbon (PAH) found in cigarette smoke, tumors do not develop in the absence of BHT treatment. [8] This corresponds to a classic initiation/promotion protocol.

The experimental advantage is that the promotion stage is reversible, involving only altered gene expression, and does not include additional irreversible changes to

DNA structure, such as those that cause oncogene activation or tumor-suppressor gene inactivation. The promotion stage is thus amenable to chemoprevention strategies. Among the changes BHT elicits that would encourage the growth of initiated cells are inflammation,[9] altered apoptosis,[10] and diminished cell to cell communication.[11] A role of inflammation in lung tumor development may account for the efficacy of anti-inflammatory drugs and tea polyphenols in inhibiting tumor formation (Table 19.1). Isothiocyanates inhibit lung tumorigenesis at the initiation stage by altering carcinogen metabolism. Cruciferous vegetables accelerate carcinogen clearance from the body. Farnesylation inhibitors prevent the *KRAS* oncogene product activated by an initiating mutation from binding to the plasma membrane to exert its activity.

Dissection of the Complex Ways That Cancer-Related Genes Respond to Environmental Agents

A/J mice develop tumors by the end of their lifetimes even in the absence of any applied carcinogen, but C57BL/6J mice do not. C57BL/6J mice are also resistant to lung carcinogens, even if they are given at a high dose or in multiple doses.[12] Similar or identical genes probably regulate susceptibility to both spontaneous and chemically induced lung tumor development. Susceptibility to a complete carcinogen such as urethane and susceptibility to a promoting, nongenotoxic agent such as BHT are regulated by different genes, however. Tumor multiplicity is affected by BHT in only some of the strains of mice that respond to urethane.[9]

Evaluating the Temporal Sequence of Tumorigenesis

Because tumorigenesis is initiated by the experimenter, each stage of neoplasia (i.e., hyperplasia, benign tumor formation, and the benign-to-tumor transition) can be studied independently. Thus the researcher can distinguish between molecular changes that precede the onset of hyperplastic foci and those that characterize the evolution of malignancy from a benign stage, and thereby identify phenotypes that might be used for preclinical diagnosis.

PRIMARY LUNG TUMORS IN MICE

Mice are the most frequently studied animals in lung tumor research. Mice are less expensive to maintain, even for lifetime studies, than other species. Susceptible strains of mice develop lung tumors within a few months after carcinogen administration. The scientific advantages of mouse lung tumors as an experimental tool are their similarity to human adenocarcinomas[13,14] and the ability to apply genetic analytical techniques. A disadvantage is that mechanisms underlying small cell lung cancer (SCLC) and squamous cell carcinoma cannot be examined, because these classes of tumors do not occur in murine models.

Histogenesis

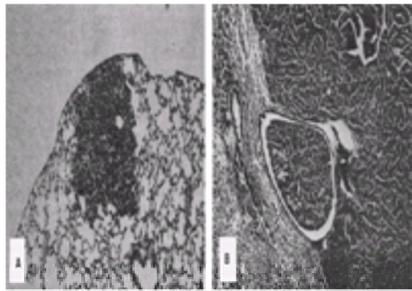
The only type of lung tumor that develops in the mouse is the peripheral adenoma, which often progresses to adenocarcinoma. Adenomas are benign, glandular structures with no evidence of invasion into the surrounding adjacent tissue. These adenomas can be of a solid lepidic pattern and grow along the alveolar septae without compression, or they can adopt a papillary, fingerlike growth pattern (Fig. 19.1). Most mice contain both adenoma types, but the relative proportion of these types within a single mouse depends on the length of time following carcinogen application, the genetic strain used, the age of the mouse at the time of administration, and the nature of the carcinogen. Among inbred strains, adenoma growth patterns vary from all papillary to all solid. In each strain, however, the percentage of papillary adenomas increases as a function of time following carcinogen administration.[15] Papillary adenomas tend to have a longer latency period than solid adenomas, and malignant tumors have been observed to arise within a papillary adenoma.[16] When adult A/J mice are treated with urethane, 80% to 85% of the adenomas present 14 weeks later are solid. Following transplacental carcinogenesis, however, all tumors formed are papillary.[17] Because the proportion of the two histologic tumor types is not related to the tumor multiplicity that is characteristic of a particular strain, a unique set of genes for pulmonary adenoma histologic type (*pahi*),[18] has been hypothesized to regulate lung tumor phenotype.


FIGURE 19.1. A: Solid or lepidic and **(B)** papillary tumors induced by urethane in A/J mouse lung. Hematoxylin and eosin stain; (50 × magnification). (From Thaete LG, Gunning WT, Stoner GD, et al. Cellular derivation of lung tumors in sensitive and resistant strains of mice: results at 28 and 56 weeks after urethane treatment. *J Natl Cancer Inst* 1987;78:743, with permission.)

These observations imply that the differentiation status of the lung at the time of carcinogen application determines adenoma histology. The cells within solid tumors have ultrastructural and biochemical features (i.e., round nuclei and lamellar bodies that synthesize surfactant) that typify alveolar Type II pneumocytes.[19] These are the stem cells of the alveoli; when the fragile Type I cells that compose more than 90% of the alveolar surface are injured and die, the Type II cells divide and differentiate to replace them. Type II cells are one of the few pulmonary cell types that proliferate in an unstimulated lung or following the release of growth factors during injury.

Three hypotheses have been advanced regarding the cellular origins of papillary tumors.[20] First, these tumors may arise by direct neoplastic conversion of nonciliated Clara cells, the putative stem cell of the bronchiole. The cells within these tumors have many features of Clara cells, including ultrastructure, enzyme and isozyme composition, and cytokeratin content. Clara cells metabolize carcinogens and undergo hyperplasia following carcinogen injection.[21] Other species, such as humans[22] and hamsters,[23] develop adenomas from Clara cells. The second hypothesis is that papillary tumors are the more aggressive structures to which some solid tumors progress and, therefore, like the solid adenomas, also arise from type II cells.[24] This hypothesis is based on the longer latency of the papillary tumors, the fact that type II cells can also metabolize carcinogens, a Clara cell-like morphology of some neoplastic type II cells, and the absence of CC10 (Clara cell-derived protein of 10,000 to 16,000 molecular weight, also called CC16); this is a secreted uteroglobin frequently used as a cellular biomarker for Clara cells. The third hypothesis is that developmental precursor cells, either multipotential stem cells that can differentiate into a Type II or Clara cell, or type II-specific precursors whose differentiative fate is altered by a carcinogen-induced activation of a protooncogene, are the papillary cells of origin. The main support for this hypothesis is the predominantly papillary tumor composition following transplacental carcinogenesis,[17] an ontogenetic stage in which a presumably high content of these precursor cells exist. The plasticity of type II and Clara cell structures (i.e., the wide range of structures that these cells can assume), the changes in cell composition that occur upon neoplastic transformation, and the many similarities between these two cell types make it difficult to distinguish among these possibilities.

The *pahi* genes either determine which cell type is more susceptible to neoplastic growth or regulate the progression of a benign solid adenoma to an aggressive papillary adenoma that may become malignant. It is also important to clarify this phenotypic diversity because it has been postulated that a large portion of human adenocarcinomas arise from type II and Clara cells because many adenocarcinomas express genes characteristic of these cell types.[22,25,26 and 27] Over the past few decades, both the absolute incidence and relative incidence of adenocarcinoma among non–small cell lung cancer (NSCLC) patients have increased, whereas the relative frequency of squamous cell carcinoma has decreased. Adenocarcinoma is now the most frequent histologic type of human lung cancer in the United States and Japan. The incidence of lung cancer among nonsmokers has become the eighth most commonly diagnosed human cancer, and adenocarcinoma is the main tumor type in these people. The etiologic cause for this increased incidence of adenocarcinoma is unknown.

Molecular and Biochemical Changes during Mouse Lung Tumor Progression

Figure 19.2 illustrates the timing of some of the molecular and biochemical changes that occur in the course of mouse lung tumor progression; they are described in

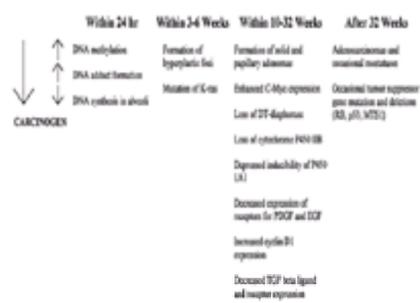
the following sections. Inbred strains vary at several points along this temporal pathway, and these variations can be used to understand the role of each change.


FIGURE 19.2. Time scale of mouse lung tumorigenesis. Sequential molecular changes following carcinogen application. Increased (↑) and decreased (‾) activity are indicated. *RB1, P53,* and *p16* are tumor-suppressor genes.

The biochemical changes detectable in neoplastic lung cells encourage cellular autonomy by increasing their resistance to normal host-mediated control mechanisms and to applied chemotherapeutic agents. The neoplastic mouse lung cell demonstrates the following factors:

1. *Enhanced ability to proliferate.* Mutant *KRAS* p21 allows continuous stimulation of downstream protein kinases, which leads to increased expression of proteins that stimulate cell proliferation. *MYC* expression enhances cell proliferation and is frequently overexpressed in lung tumor cells. *p53* mutation increases the half-life of *MYC,* and *p53* is a proliferative stimulus. *RB1* is a cell-cycle brake; its deletion and inactivation by mutation interfere with cell-cycle control.
2. *Resistance to negative growth factors.* The disturbances in cAMP signal transduction, as well as other pathways that allow cells to respond to environmental change (e.g., glucocorticoids, protein kinase C, gap junctions), may permit these cells to ignore or misperceive signals emanating from outside the cell that instruct the cells to stop dividing.
3. *Resistance to agents that might cause cell death.* These agents include the losses of constitutive and inducible P450 isozymes and NADPH-dependent quinone oxidoreductase (NQO1), all of which modulate the toxicity of foreign compounds.

DNA Structure and Behavior Are Modified Within 24 Hours After Carcinogen Application

The earliest alterations that have been detected are *DNA methylation,* covalent binding of an unmodified or metabolically altered form of the carcinogen to DNA, and diminished cell proliferation. The methylation of cytosines, particularly those associated with CpG islands within the promoter regions of genes, is emerging as a fundamental mechanism for transcriptional repression of tumor-suppressor and regulatory genes in cancer.[28] Changes in the balance of methylation within the cell have been linked in part to increased activity of DNA-methyltransferase (DNA-MTase), the enzyme that catalyzes DNA methylation at CpG sites.[29] Exposure to NNK results in increased DNA-MTase activity and genomic 5-methylcytosine levels, indicative of hypermethylation, in alveolar Type II cells isolated from A/J mice.[30] This change was detected seven days after carcinogen treatment, occurred in Type II cells but not Clara cells, and was specific to sensitive A/J mice; these changes were not seen in cells isolated from resistant C3H mice. In addition, DNA-MTase activity increased incrementally during lung cancer progression in A/J mice and coincided with increased expression of the DNA-MTase gene in hyperplasias, adenomas, and carcinomas. Thus increased DNA-MTase activity and concomittant hypermethylation are strongly associated with neoplastic development and may constitute a key step in carcinogenesis and a biomarker for premalignancy.

The persistence of DNA *adduct formation* has been correlated with lung tumor incidence. For example, NNK forms significantly more O^6-methylguanine adducts (O^{6}MG) in Clara and type II cells than in whole lung.[25] Additionally, the activating mutation in the *KRAS* protooncogene can be correlated with the particular DNA adduct formed by a carcinogen. NNK causes a G®A transition in the second base of codon 12 in *KRAS,* which could result from base mispairing caused by O^{6}MG.[31]

A rough estimate of the carcinogenicity of a compound is its effect on the proliferation of the target cell population.[32] Administration of many tissue-damaging agents to an animal causes a rapid but transient decrease in the ^{3}H-thymidine *labeling index* of the target cell population. This reduced level of ^{3}H-thymidine incorporation into DNA probably reflects the removal of cells that have been fatally damaged by the toxicant. Both lung-tumor–susceptible and –resistant strains exhibit a similar decrease in the labeling index of their Type II cell populations.[33] Strains vary, however, in their proliferative behavior after this initial reduction. Lung-tumor–susceptible strains such as A/J contain more dividing type II cells seven to 14 days after urethane treatment than prior to carcinogen administration.[33,34] Resistant strains, such as C57, merely recover their original proliferative level, and the timing of this recovery occurs later. Strains of mice with intermediate susceptibility (i.e., those that develop fewer tumors than A/J mice) show a smaller "overshoot" than A/J mice. These areas of intense proliferative activity are regionally localized and constitute the hyperplastic foci that will give rise to tumors. The relative basal proliferative rates (i.e., cell division in the absence of carcinogen treatment) of the alveolar type II and bronchiolar Clara cells in these strains correlate with tumor multiplicity.[35] It is easy to imagine how an increased proliferative rate could enhance the actions of carcinogenic inducers. For example, when a cell divides before a DNA adduct can be repaired, this increases the likelihood that the adduct will cause improper base pairing during DNA replication.

Biochemical Alterations Have Occurred by the Time the Benign Tumor Stage Is Reached

When DNA from benign tumors is transfected into NIH 3T3 cells, multilayered cell islands accumulate; growth above a monolayer is a neoplastic characteristic. The gene responsible for this neoplastic transformation is usually *KRAS.*[31] In fact, mutations in *KRAS* can be detected if hyperplastic foci are microdissected from tissue sections (see also Chapter 27), their DNA is extracted and amplified by the polymerase chain reaction (PCR), and the DNA is then sequenced.[25,36] It is probable, therefore, that mutation of *KRAS* is one of the events that initiates the tumorigenic process. The mutations in *KRAS* are in codon 12 or 61, the same sites where activating mutations typically occur in many human adenocarcinomas.[37] Moreover, the mutational spectrum seen in lung tumors from A/J mice relates directly to the specific mutagenic adducts formed as a result of carcinogen activation.[31] Spontaneous lung tumors have *KRAS* mutations at these same codon sites, but in contrast to chemical activation, mutational specificity is not observed. The resulting conformational change in the mutated *KRAS* p21 protein product interferes with GTP hydrolysis and renders the *KRAS* molecular switch in a permanently "on" position. This allows the transcription of genes associated with proliferation without growth factors.[38]

Although most chemically induced tumors in A/J mice contain *KRAS* mutations, activation of this gene is not always observed in lung tumors induced in other mouse strains. Half of the lung tumors induced in the CD-1 mouse by diethylnitrosamine (DEN) do not contain mutant *KRAS.*[39] The AXB and BXA recombinant inbred strains derived from A/J and C57 display a continuous pattern of lung tumor susceptibilities; some strains are as susceptible as A/J, some as resistant as C57, with the others in between. Tumors induced in those strains with the highest tumor multiplicities all had *KRAS* mutations, whereas the mutation incidence in strains with lower susceptibility was less.[40] The identity of the activated oncogene or oncogenes responsible for tumorigenesis when *KRAS* retains its wild-type structure is unknown. When ascertained, this will stimulate a search for a similar oncogene in those human adenocarcinomas that lack *KRAS* mutations and may lead to new prognostic strategies.

No mutation in any other oncogene has been identified, although enhanced expression of *MYC* is frequent. Mutations or deletions in the tumor-suppressor genes have been noted in mouse lung carcinomas. *P53* mutations were found in adenocarcinomas but rarely in adenomas, suggesting that this alteration might drive the benign-to-malignant transition.[36] Loss of heterozygosity involving the p16 gene on chromosome 4 is also frequent in malignant but not in benign mouse lung tumors.[41,42] In addition, cell lines derived from these mouse lung tumors often have homozygous deletion[42,43] of the p16 gene, implying that inactivation of this tumor-suppressor gene is a late event in murine lung carcinogenesis. This contrasts with recent studies in the rat and human where inactivation of p16 appears to be a critical early event.[44]

A characteristic of neoplasms is their *resistance to chemotherapeutic agents.* There are numerous mechanisms for this resistance, including enhanced transcription of the glycoprotein that pumps certain classes of xenobiotics out of cells. Another mechanism is a reduction in the content of enzymes that activate prodrugs. This is

particularly relevant to mouse lung tumors, because Clara and type II cells are the main pulmonary sites of xenobiotic metabolism. The content of various cytochrome P450 isozymes, such as the phenobarbital-inducible IIB isozyme, is reduced in mouse lung adenomas. [21] The PAH-inducible IA1 isozyme is negligibly present in mammalian lungs but is highly inducible. The extent of IA1 induction in adenomas is lower than in control lung; by the carcinoma stage, IA1 induction is not detected. [21] There is thus a gradient of P450-mediated xenobiotic resistance of these tumors from the benign to the malignant stages. A functional consequence of a diminished ability of neoplastic tissue to respond to toxicants is exemplified by the decreased CYP2E1-dependent metabolism of 1,1-dichloroethylene (DCE), a chemical that injures Clara cells in mice. Formation of the glutathione-conjugated product of the DCE epoxide, which occurs at a high rate in Clara cells, was deficient in Clara cell hyperplasias, adenomas, and carcinomas. [45] NQO1 detoxifies quinones by catalyzing a two-electron reduction to form a hydroquinone, thereby preventing oxygen radical formation. For some chemotherapeutic drugs, such as mitomycin C, this could result in bioactivation. NQO1 localizes to type II cells, as determined by histochemical assay. [46] By the adenoma stage, no NQO1 activity is detectable, [46] and cell lines derived from these tumors also lack NQO1 activity. This loss in NQO1 activity is one of few characteristics of mouse lung tumors that are dissimilar from human adenocarcinomas. In fact, there is a marked increase in NQO1 activity and NQO1 mRNA content in many types of human NSCLC relative to normal lung or to SCLC. [47] This tumor-specific increase in NQO1 content has stimulated the design of quinones requiring bioactivation by NQO1 that potently inhibit the growth of NSCLC xenografts [48] and are now in clinical trials. It is noteworthy that practical consequences might ensue from the mouse lung tumor model even in this case, where a feature of the model differed from the human equivalent because the mouse studies led to the pursuit of these human investigations.

In addition to becoming relatively autonomous from environmental stimuli by decreasing the concentration of their xenobiotic-metabolizing enzymes, tumor cells also show derangements in their *signal transduction machinery.* As mouse lung tumors advance toward malignancy, several changes in cAMP-dependent protein kinase (PKA), which mediates the actions of cAMP in cells, have been observed. These changes include altered cAMP binding affinity, an enhanced degree of degradation of the regulatory (R) subunits of PKA by the Ca^{2+}-dependent protease calpain, and altered regulation of R-subunit autophosphorylation. [49] These changes make the tumor cells less responsive to hormone- or growth factor-induced elevations in cAMP content. cAMP derivatives inhibit the growth of the mouse lung epithelial cells. [50] Cell lines have been established from normal mouse lung explants. [51] They are immortalized but have features common to other nontumorigenic cell lines, such as anchorage dependence and contact inhibition. Spontaneous transformants of these nontumorigenic cells have been selected, and additional tumorigenic cell lines have been derived from mouse lung tumors. [52] These neoplastic cell lines grow as tumors when injected into syngeneic or immunocompromised mice, and are anchorage-independent; most of them have mutant *KRAS.* [53] Interestingly, these neoplastic lines with less PKA are less sensitive to cAMP-mediated growth inhibition than their nontumorigenic parental cell lines. [50] When the signal-transducing properties of neoplastic cell lines are compared to the nontumorigenic cells, defects in cAMP synthesis, caused by decreased b-adrenergic receptor function and decreased Gsa (the alpha subunit of the stimulatory GTP-binding trimeric complex that transduces hormonal occupation of a receptor to activate adenylate cyclase) function are observed. [54] Depressed R-subunit protein and mRNA content and altered regulation of R-subunit message stability complete this pattern of unresponsiveness. [55] Additional signaling pathways are compromised in these neoplastic cells, as seen by a decreased content of glucocorticoid hormone receptors, [56] epidermal growth factor receptors (EGFR), [57] platelet-derived growth factor receptors (PDGFR), [58] and protein kinase C. [59] Finally, these lung tumor cell lines have a reduced capacity for the intercellular communication that occurs via passage of small molecules from cell to cell through gap junctions. [60]

Genetic Basis of Susceptibility to Lung Tumor Growth

Inbred Strains

"The close genomic organization and functional relationship between the mouse and human genomes make the mouse an ideal mammal for the study of human disease and the disease process. Homologous genes are linked in both the mouse and human. Mutations in identical genes often produce identical or similar phenotypes in both species." [61] Inbred strains of mice provide populations with genetically identical members. Inbred strains are derived by mating brothers and sisters over several generations, and the strains differ from each other at many loci as the result of random loss or retention of allelic forms of each gene. Inbreeding has eliminated genetic variability as an experimental problem and generated differences among strains which can be used to understand the molecular basis of phenotypes. Identification of the genes underlying a particular pathology leads to their possible use in prevention, diagnosis, or therapy.

The genes responsible for determining whether untreated mice develop lung tumors may also regulate responsiveness to carcinogens, because the same strain distribution describes inheritance of spontaneous and chemically induced tumors. [12] Tumor susceptibility is organ-specific; a strain such as A/J is highly susceptible to lung tumor development but resistant to hepatocarcinogenesis. [62] Analysis of strain differences in lung tumor incidence and multiplicity by conventional Mendelian crosses indicates that this is a polygenic trait. Recombinant inbred (RI) strains are a useful tool for genetic analysis. When two different inbred strains are mated, their alleles are randomly shuffled among the F2 progeny, which are then inbred to establish strains with different allelic assortments. The continuous gradient of tumor multiplicities among the RI strains derived from susceptible A/J and resistant C57 strains confirmed the polygenic character of lung tumors. [63]

KRAS

Polymorphisms have been found among inbred strains in the structure of the *KRAS* protooncogene. DNA digestion with the EcoRI restriction endonuclease resulted in fragments of two different sizes, depending upon the strain. When the susceptibility to lung tumor development was compared to the distribution of this restriction fragment length polymorphism (RFLP) (see also Chapter 1) among inbred and RI strains, a good correlation was seen. [64] This indicates that *KRAS* is one of the genes determining susceptibility, referred to as the pulmonary adenoma susceptibility (*Pas*) genes. The basis of the RFLP is a 37 bp tandem repeat present in the second intron of *KRAS;* resistant strains have two repeats of this segment, whereas susceptible strains have a single copy. [65] Because the several dozen inbred and RI strains examined had either one or two copies of this sequence, but neither had zero nor more than two copies, and because this 37 bp sequence was unique to the *KRAS* intron, this is not a random transposition. Linkage analysis using F2 or backcross mice produced from crosses between sensitive A/J and a resistant strain also suggested that a major susceptibility site mapped near the *KRAS* gene on chromosome 6. [40,66,67,68 and 69] These quantitative trait locus (QTL) mapping studies indicated that the *KRAS* locus, or a gene linked very close to it, accounted for about two thirds of the variation in tumor multiplicity between sensitive and resistant strains. [69]

KRAS is a *pas* gene and is also the site of the probable initiating mutation. The number of copies of this 37 bp sequence often reflects the susceptibility to lung tumor induction. The polymorphism does not change the structure of the *KRAS* protein product because of its location within an intron. Rather, the presence or absence of a second 37 bp copy may regulate transcription. [65,66,70] If a mutant oncogene is not expressed, the mutation will be phenotypically silent. [71] The polymorphic difference within intron 2 has been used to determine which *KRAS* allele contains mutations in NNK-induced lung tumors from the C3A mouse (F1 hybrid cross between the C3H and A/J mice). The A/J allele was mutated and overexpressed in 90% of the lung tumors from carcinogen-treated C3A mice. [65] This predominance of mutations within the A/J allele from hybrid mice could stem from higher rates of transcription of the A/J allele compared with the C3H allele. However, this is not the sole mechanism for selective clonal expansion of the mutated allele from A/J mice. The effects on *KRAS* transcription of reporter gene constructs containing the K- *ras* promoter from either A/J or C3H mice ligated to the intron 2 polymorphic region from each strain were compared through transfection into tumor-derived cell lines from sensitive, intermediate, and resistant mouse strains. No significant differences were found in promoter activity. [72]

Other Gene Candidates for Susceptibility

Congenic strains of mice are selectively bred to be genetically identical except at a single site. Studies of mice congenic for the H-2 locus, which is the mouse equivalent of the human HLA major histocompatibility genes that regulate macrophage-lymphocyte interactions, indicate that H-2 affects lung tumor multiplicity. A/J mice whose H-2 alleles have been replaced by those of the resistant C57 strain get fewer tumors than normal A/J mice. [73] Lung tumors are mildly immunogenic, and this effect of H-2 suggests that some of the factors regulating lung tumor development involve interactions of nascent tumor cells with immune cells. Lymphocytic and macrophage infiltrations into lung tumors have been observed. Genetically or surgically immunocompromised mice acquire more lung tumors, [74] which is consistent with a role of immune factors. The H-2 region, however, also contains genes with functions not confined to the immune system. The structural gene for the glucocorticoid receptor also maps to the H-2 region, and the amount of circulating corticosterone influences tumor multiplicity to the same quantitative extent as does H-2 variation. [75] A urethane-treated, adrenalectomized A/J mouse develops about 30% more lung tumors than a sham-operated mouse, and mice implanted with a pellet that continuously releases excess corticosterone develop 30% fewer tumors. [76] Further, inhalation of budesonide, a synthetic glucocorticoid, nearly abolishes benzo(a)pyrene-induced lung tumor formation. [77] Also, the TNFa gene is located at H-2, and this cytokine regulates growth and differentiation of many cell types. Finally, linkage studies have indicated that susceptibility loci are contained within the H-2 region. [69]

Several chromosomal regions contain genes that confer sensitivity or resistance to lung tumorigenesis (Table 19.2). When the F1 generation resulting from an intercross between a sensitive and a resistant strain is injected with a lung carcinogen, the hybrid mice may contain the arithmetic mean of the tumor multiplicities of their parents. [78] In this case, the sensitive and resistant alleles are contributing equally to the susceptibility phenotype and are designated as *pas* (pulmonary adenoma

susceptibility) alleles, or the resistant allele can display dominant inheritance, and the allele at that gene is described as *pas* (pulmonary adenoma resistance).[78] These chromosomal assignments were made using various mapping strategies that involve linkage analysis, which consists of breeding mice according to various schemes, phenotyping the progeny to see which mice carry the trait (i.e., lung tumor multiplicity), and genotyping them to find where within the genome they map based on their colocalization with previously assigned markers. A class of DNA polymorphisms known as microsatellites has recently been used in human and mouse genetic studies. These consist of simple, tandemly repeated, mononucleotide-to-tetranucleotide sequence motifs flanked by unique sequences, which serve as primers for PCR amplification. Inbred strains frequently vary in the number of repeat units in this motif at many chromosomal sites randomly distributed throughout the genome.[79] The resulting size differences allow visualization on agarose or acrylamide gels.

TABLE 19.2. CANDIDATE GENES FOR THE *PAS* AND *PAR* LOCI AND THEIR HOMOLOGOUS REGIONS ON THE HUMAN CHROMOSOME

Hundreds of genes are contained within each of the chromosomal intervals, identified by linkage analysis, and identifying the single gene within each interval that regulates susceptibility is a daunting task. A further complication is that genes regulating susceptibility can interact with each other (epistasis) and either synergize or antagonize each other's contributions.[80] Many of the genes known to map within the *pas* and *par* loci have functions consistent with a role in susceptibility, such as encoding signaling molecules (i.e., receptors, protein kinases, G proteins, transcription factors, etc.), enzymes that catalyze metabolic activation and detoxification of carcinogens, and cytokines that modulate the immune response and inflammation.[81] Interestingly, many of these sites are deleted in human lung adenocarcinoma, supporting a role for them in neoplastic progression. The reason for expending such effort in identifying these tumor modifier genes is to learn what makes mice resistant to lung cancer, information that will yield new preventive and therapeutic drugs. This has been referred to by Dr. Richard Klausner, Director of the National Cancer Institute, as "the next great revolution in cancer research." The ultimate test of a candidate susceptibility gene, in addition to its polymorphic status between sensitive and resistant strains and its under- or overexpression in the tumors, is using it as a transgene to confer, say, resistant status to a normally sensitive strain. [81]

Transgenes and Targeted Genes with Induced Mutations

Lung tumors can be induced in transgenic mice with a mutated oncogene or tumor-suppressor genes as the transgene. Two relevant transgenic models involve the *HRAS* protooncogene[82] and the SV40 virus large T-antigen.[83] The *HRAS* transgene was attached to a variety of promoter-enhancer elements (e.g., albumin, mouse mammary tumor virus, immunoglobulin). SV40 T-antigen was ligated to promoters that should be preferentially expressed in type II (the surfactant apo-C promoter) or Clara (CC10) cells. The mice generated with either transgene were born with lung tumors or developed lung tumors soon after birth. Because the original genetic backgrounds of the host mice were resistant, these activated oncogenes overcame this inherited resistance. The tumors were adenomas at early stages of growth which later became carcinomas with structural and biochemical features resembling those lung tumors that arise in nontransgenic mice. These mice, genetically engineered to develop lung tumors, have been used to test putative lung carcinogens [84] and for exploring tumor histogenesis. Individual tumors in mice made transgenic with the SV40 T-antigen targeted with an apo-C promoter were heterogeneous with regard to expression of CC10 or SPC. Some cells contained both of these peripheral respiratory epithelial markers, some cells contained one but not the other marker, and some cells expressed neither. [83] This suggests that type II or Clara cells or precursor cells committed to these phenotypes underlie lung tumorigenesis. Other potential uses are to delineate key steps in the cellular dysregulations leading to multi-step carcinogenesis, to examine interactions between known genes with oncogenic potential with each other, and to assess the functioning of these genes in different genetic backgrounds. Investigation into key steps in tumor development have used both transgenic and knock-out mice. Overexpression of prostacyclin synthase raises the levels of prostacyclin, which has anti-inflammatory effects in the lung, and diminishes lung tumor multiplicity in response to carcinogens, implying a role for inflammation in tumor development.[85] Inactivation of O^6-methylguanine-DNA methyltransferase (*Mgmt*), an enzyme that catalyzes adduct removal, gave rise to mice especially sensitive to lung tumorigenesis, [86] emphasizing the critical need for DNA repair in preventing lung cancer.

PRIMARY LUNG TUMORS IN RATS

In the early 1970s, the National Cancer Institute developed a protocol using rodents to evaluate the carcinogenic potential of chronic exposure to environmental agents. This protocol was adopted and refined by the National Toxicology Program and employed the F344 rat and the B6C3F1 hybrid mouse (C57BL/6J × C3H/HeJ). More than 400 chemicals have been tested for carcinogenicity, and these data constitute the primary database available today for the evaluation of mammalian carcinogenesis. The F344 rat appears to be a good model for evaluating the ability of environmental exposures to induce pulmonary neoplasia. In contrast to the A/J mouse, which exhibits a 95% frequency of spontaneous tumors by 20 months of age, the frequency of spontaneous lung tumors in this rodent is only around 2%. [87] In addition, both of the two major histologic forms of human NSCLC, adenocarcinoma and squamous cell carcinoma, can be induced in this animal model by chemical carcinogens.

Histogenesis

Spontaneous neoplasms of the lung in the rat are primarily alveolar-bronchiolar adenomas or carcinomas. The major histologic types induced by carcinogen exposure are alveolar-bronchiolar adenomas or carcinomas and squamous cell carcinomas. The predominant histological type identified from chemical exposure is the adenocarcinoma, whereas squamous cell carcinomas are more prevalent in animals exposed to high doses of radiation. [88] Cells within adenomas and carcinomas grow in a solid, papillary, or mixed solid and papillary pattern. As in mice, adenomas with a solid growth pattern tend to remain benign, whereas the papillary pattern has been associated with differentiation to the malignant state. [89]

Progenitor Cells

Lung neoplasms in the F344 rat originate in the lung periphery from a proliferation of epithelial cells along the alveolar septae. Examination of the ultrastructure of hyperplasias induced following exposure to either NNK [89] or plutonium[90] reveals morphologic features characteristic of type II pneumocytes. These cells typically contain numerous, prominent, cytoplasmic lamellar bodies and large round mitochondria. Ultrastructural examination of several adenomas and adenocarcinomas induced by these exposures also exhibit type II features. The malignant adenocarcinomas identified in the F344 rat lung appear to develop by the progression of alveolar hyperplasia to adenoma and ultimately carcinoma. Adenomas can be detected within hyperplasias, and carcinomas have been observed arising within adenomas.[89]

Determining the origin of the squamous cell carcinoma is complicated by the fact that no squamous epithelium is present in the normal tracheobronchial tree. The tumors exhibit all the ultrastructural characteristics of human squamous cells (i.e., tonofilament bundles, keratin, keratohyaline granules, desmosomes). Development of squamous cell carcinomas is not restricted to a single region of the pulmonary parenchyma; it occurs in both the bronchial and alveolar regions of the lung. However, the squamous cell tumors exhibit ultrastructural characteristics of the type II pneumocyte and do not demonstrate immunoreactivity with Clara cell antigen. These data suggest that the cuboidal epithelial cells that comprise some adenocarcinomas could transdifferentiate to a squamous cell phenotype. [90]

Identification of the type II pneumocyte as the major progenitor cell for lung neoplasia in the F344 rat may prove to be a good model for studying the development of environmentally induced human lung cancers. Adenocarcinoma of the lung is rapidly becoming the most prevalent histologic type of tumor in the world. The reduction of tar and nicotine concentrations in cigarettes has led to a significant increase in puff volume and hence a greater exposure of the alveolar epithelium to the chemical carcinogens present in tobacco. Approximately 50% of human adenocarcinomas are mucin-secreting and consist of tall columnar cells, [26] whereas the remaining

tumors have little or no mucin. Electron microscopy of these non–mucin-secreting tumors shows cells with morphologic features consistent with those of either a Clara cell or a type II cell. The ability to isolate specific lung cell populations from the rat following exposure to environmental carcinogens [86] provides an opportunity to study and identify genetic and epigenetic changes associated with tumor initiation and development.

Environmental Exposures

The contribution of mixtures, rather than of a single component, to the induction of pulmonary neoplasia is an active area of research. The most important mixture contributing to human lung cancer is tobacco, which contains over 4,000 chemicals, gases, and volatiles. Developing an animal model for tobacco-induced cancer has generally relied on carcinogenicity studies of single components such as NNK (described below). However, in recent studies (Nikula et al., unpublished) where F344 rats were exposed to mainstream cigarette smoke equivalent to three to four packs per day, a significant increase in lung tumors was seen. Studying the mechanisms underlying lung tumor development in this cigarette-smoke model may be invaluable for dissecting the process of tobacco-induced cancer in people.

F344 rat lungs are also susceptible to pulmonary neoplasia following inhalation or systemic exposure to specific environmental and occupational chemicals; for example, intraperitoneal injection of rats with NNK-induced tumors at concentrations of NNK ranging from 1.5 to 750 mg. [89] The lowest amount of NNK mimics exposure to this nitrosamine by habitual cigarette smokers (two packs per day). Inhalation of tetranitromethane, a reagent used in industrial nitrosating processes, at concentrations similar to occupational limits induced lung tumors in F344 rats. [91] Thus, the F344 rat lung is a good model in which to study the molecular mechanisms underlying environmentally induced neoplasia.

Gene Dysfunctions

Examination of gene dysfunctions in lung tumors induced in the F344 rat has focused on both genetic and epigenetic mechanisms. Genetic studies have been restricted mostly to evaluating mutation frequency of the *KRAS* and *P53* genes. The prevalence and specificity for activation of *KRAS* vary markedly among environmental carcinogens. Activation of this gene by a GGT-to-GAT transition was observed in 100% of the lung tumors induced by tetranitromethane. [91] *KRAS* was mutated in 40% of plutonium-induced lung tumors, with a GGT-to-AGT transition as the predominant base substitution. [92] In contrast, activation of this gene was observed in only 10% of the lung tumors induced by beryllium metal [93] and none of the lung tumors induced by NNK. [94] Although activated *RAS* genes were not detected in lung tumors induced by NNK, DNA from seven of ten tumors induced subcutaneous tumors in a nude mouse tumorigenicity assay. The presence of an active transforming gene that is not *KRAS* was inferred by the detection of rat repetitive sequences in DNA from these primary nude mouse tumors. Since mutation of *KRAS* occurs in only 30% of human adenocarcinomas, [37] the identification of non-*RAS* transforming genes in pulmonary tumors induced by NNK may aid in defining the process of neoplastic transformation in human lung tumors.

Alterations within the conserved region (exons 5 through 8) of the *P53* gene do not appear to be a common event in rodent pulmonary neoplasia. No adenocarcinomas induced by inhaled beryllium or injected NNK contained a mutation within this conserved region. In contrast, *P53* dysfunction has been detected at variables frequencies (5% to 40%) in squamous cell carcinomas induced by either NNK, x-rays, diesel exhaust, or carbon black. [95] These results are in sharp contrast to the high prevalence of *P53* mutations (50% to 65%) observed in human adenocarcinomas and squamous cell carcinomas. [96] Genes within the *P53* pathway (e.g., *MdmII* or *Waf1*) did not appear to be altered in rodent lung tumors. [95]

The promoters of approximately 60% of human genes are located within areas rich in the CG dinucleotide, referred to as CpG islands. Recent studies [28] have demonstrated an inactivation of critical regulatory genes in cancer cells as a result of promoter methylation. Studies conducted in animal models address several important mechanistic questions concerning whether environmental exposures target genes for methylation, the timing of the corresponding gene inactivations, and the concordance with human studies. Promoter methylation of the estrogen receptor varied in rat lung tumors, being most frequent (80%) in plutonium-exposed animals but inactivated in only 20% of lung tumors induced by NNK. [97] Similar results were observed in lung tumors induced in A/J mice by NNK and human NSCLC associated with tobacco. The mechanisms that inactivate the tumor suppressor gene in human tumors, homozygous deletion and aberrant promoter methylation, also occur in primary rat lung cancers and derived cell lines. Promoter methylation clearly originates in the primary tumor. Inactivation of p16 by aberrant methylation is an early event in rodent carcinogenesis, occurring at a high frequency in alveolar hyperplasias resulting from NNK. [98] Analogously, p16 methylation has been detected at early stages of human squamous cell carcinoma development. [44] Thus inactivating genes by methylation is recapitulated in rodent lung tumors. Future studies of genes such as p16 and estrogen receptor in rodent carcinogenesis models will be invaluable for understanding their roles in neoplastic progression and in defining the mechanisms associated with targeting genes for inactivation by this epigenetic process.

PRIMARY LUNG TUMORS IN HAMSTERS

Hamsters rarely develop spontaneous tumors and display little pulmonary inflammation, so that tumor yield is strictly a function of the experimental treatment. Mixtures of different carcinogens, such as PAHs and nitrosamines, gave an enhanced tumor yield, and combinations of chemicals similar to those found in cigarette smoke can potentially be instilled in these mixtures.

Problems associated with the use of hamsters in carcinogenesis studies include the following: their short tails preclude intravenous injections and make them difficult to handle, they may be aggressive and difficult to maintain, the hibernating status of the animals affects tumorigenesis, and concurrent infections can lead to variable tumor incidences. [99]

Histogenesis

Adenocarcinomas are the main tumor types induced in mice and rats by administration of individual or combinations of chemical carcinogens through any route. Although adenocarcinoma is currently the most common human lung cancer type, in the mid-twentieth century squamous carcinoma was most prevalent. Thus there was great excitement 30 years ago when bronchogenic carcinoma was produced in Syrian golden hamsters after intratracheal instillation of PAHs attached to ferric oxide particles. [100] The metaplastic and dysplastic changes that preceded the formation of frank malignancy resembled those associated with human carcinomas, although whether they are preneoplastic lesions *per se* or markers of chronic injury was not clear. These changes include replacing the goblet cells in the tracheobronchial epithelium with mucous cells, followed by the formation of multiple layers of cuboidal cells on top of a basal cell layer. [101] This change is referred to as "epidermoid metaplasia" because of the keratinization of the surface layer and the presence of a high concentration of desmosomes, as is found in skin. This response to injury is similar to that in humans.

Tumors in hamster trachea and stem bronchi correspond to human bronchial carcinomas, whereas hamster lobar bronchial and bronchiolar carcinomas resemble human peripheral adenocarcinomas. [102] Different tumors are induced by systemic versus topical application of chemicals. For example, subcutaneous or intraperitoneal injection of nitrosamines, such as DEN, induces peripheral tumors with Clara cell cytologic characteristics. These adenocarcinomas frequently contain mutated *KRAS,* but rarely exhibit mutated *p53*. [103] Intratracheal absorption of ^{210}Po, a radioactive soil contaminant present in cigarette smoke, also induces Clara cell adenocarcinomas. [23] DNA adducts can be found in Clara cells after carcinogenesis treatment. [104]

Neuroendocrine Tumors

Neuroendocrine tumors can be induced from a combination of nitrosamines plus continuous hypoxia or hyperoxia. [105] The theory is that the damage caused by aberrant arterial oxygen pressure will stimulate secretion of autocrine growth factors as part of the regenerative response. [106] This proliferation would augment the action of the carcinogen. The hypoxia would mimic the oxygen deficit caused by chronic obstructive pulmonary disease or smoking. Initial reports of hamsters treated in this manner described a 100% incidence of tumors with neuroendocrine features such as the secretion of bombesin, serotonin, calcitonin, and gastrin-releasing peptide. Subsequent studies by other investigators have not reproduced this observation, however, finding instead a marked but transient proliferation of peripheral neuroendocrine cells. [107] Whether this represents division of mature neuroendocrine cells, recruitment from a stem cell along a neuroendocrine route of differentiation, or transdifferentiation from a different cell type, such as Type II cells, is not clear. [108]

Inbred Strains

The number of tumors, the type of tumor induced, and their pulmonary location vary with the carcinogen used and the size of the carrier particles used to absorb the carcinogens in intratracheal instillation studies. Some improved techniques involve deposition of nitrosoureas onto a defined area of the trachea through a catheter to

eliminate the need for particulate carriers, [109] and continuous carcinogen release from endobronchially implanted silastic carriers. [110] Perhaps most critical, however, is the fact that outbred hamsters are used in most research, and genetic variations are seen even when animals are purchased from the same vendor. Different outbred Syrian golden hamsters develop different distributions of spontaneous tumor types at various anatomic sites and vary in their susceptibilities to viral infections. An initial report of the use of inbred Syrian golden hamsters for respiratory carcinogenesis is very encouraging. [111] Tumors histologically analogous to those in humans were observed, and strains varied in their tumor susceptibility.

PRIMARY LUNG TUMORS IN THE BEAGLE

The advent of the nuclear age opened up a new era of research dedicated to assessing the biologic risks from radioactive fallout. Extensive studies using many internally deposited radionuclides were initially conducted in the rat and mouse. Based on data collected from these studies, external exposure limits and internal deposition limits for a large number of radionuclides were established. However, because these data were compiled using small animals with limited life spans, extrapolations to human risk were considered tenuous. The main criticism of the rodent studies was centered around an uncertainty of whether these animal models would exhibit the full array of late-developing effects that were characteristic of low-level radiation exposures in humans. In an attempt to circumvent these problems, life-span studies were initiated in the beagle by the Atomic Energy Commission beginning in the early 1950s. These studies were designed to compare the long-term toxicity of a variety of radionuclides[112] administered in either single or repeated exposures.

Histogenesis

The overall incidence of spontaneous lung tumors in beagles is approximately 0.1% per dog-year up to the age of 12 years, and increases to 0.7% after 13 years of age.[113] Spontaneous canine neoplasms are mainly adenocarcinomas and, to a lesser extent, adenosquamous cell carcinomas. Several different histologic tumor types are induced by radiation. Papillary adenocarcinoma is the most common tumor induced by ^{239}PuO$_2$. These tumors originate in the peripheral lung and are associated with plutonium deposits, fibrosis, and bronchioloalveolar metaplasia. [114] Bronchioloalveolar carcinoma, adenosquamous carcinoma, and epidermoid carcinomas are also induced by plutonium. A similar histologic spectrum of tumors has been observed in dogs chronically inhaling radon daughters and uranium ore dust. [115]

Progenitor Cells and Tumor Morphology

Radiation-induced lung tumors in beagles appear to originate primarily in the lung periphery. Although detailed morphologic analyses have not been conducted, the anatomic location of the neoplasms suggests that the tumors arise from Clara cells, Type II cells, or both. Squamous cell carcinomas may arise by squamous metaplasia of the subpleural lung. Preneoplastic lesions observed in the dog include atypical hyperplasia of the alveoli and bronchial metaplasia of the terminal airways. As in humans, adenomas are rarely detected in the beagle. Most adenocarcinomas exhibit a papillary growth pattern; solid growth patterns are only occasionally present.

Gene Dysfunctions

The analysis of gene dysfunctions in dogs has focused primarily on spontaneous and plutonium-induced tumors. The prevalence for activation of *KRAS* was examined in 21 spontaneous canine tumors.[116] The overall mutation frequency was 25%, and nucleotide substitutions were distributed randomly within codons 12 and 61. Mutation of this gene was not detected in plutonium-induced tumors in dogs. [117] These results contrast with the 40% frequency of *KRAS* mutation in lung tumors induced in the F344 rat by plutonium and in human adenocarcinomas associated with radon exposure. [118]

The expression of *EGFR*[119] and *TGFA*[120] has been examined in spontaneous and plutonium-induced lung tumors; *EGFR* is the receptor for *TGFA*. Overexpression of *EGFR* and *TGFA*[120] was observed in approximately 55% of tumors, irrespective of etiology. A positive association between increased expression of both the ligand and its receptor was not observed within the same tumor. However, 27% of radiation-induced proliferative foci expressed *TGFA,* and one third of these foci also expressed *EGFR.* Increased expression of a growth factor, its receptor, or both in these foci may indicate preneoplastic lesions with a heightened propensity for progressing to neoplasia. The possibility for selective growth advantage of pulmonary lesions via the EGF pathway has also been described in human NSCLC. [121]

Altered expression of *p53* protein has been determined by immunohistochemical analysis. Similar to the rat, the prevalence of *p53* dysfunction was low (less than 15%) in both spontaneous and plutonium-induced tumors and was restricted largely to adenosquamous and squamous histologic types. [117] In contrast, activation of the *p53* gene is detected in 40% to 55% of human lung tumors associated with radon exposure. [122] Species differences in *KRAS* and *p53* mutation frequencies suggest that multiple pathways exist for the development of cancers induced by high-LET (low energy transfer) radiation (plutonium, radon).

PERSPECTIVES FOR THE FUTURE

Chemoprevention and Intervention Using Animal Models

One major challenge in the study of lung cancer is the development of new intervention strategies to prevent and inhibit the spread of this disease in humans. Despite numerous radiation and chemotherapy protocols over the past 20 years, the median survival for nonresectable lung cancers is still only nine months. [123] When the pathways involved in the genesis of this disease are delineated, new therapies can be developed that focus not on cell killing but on modulating enzymes whose deregulation is responsible for cell transformation. New intervention strategies are usually evaluated *in vitro* using epithelial cell lines derived from a variety of human and rodent tumors or using cells injected into athymic nude mice.[124] *In vitro* systems lack endogenous factors (e.g., hormones, cytokines) that could influence therapeutic responsiveness and do not allow for the evaluation of pharmacokinetic variables such as delivery of the therapeutic agent to target cells, a factor that can profoundly influence drug efficacy.

The use of an animal model such as the A/J mouse to evaluate promising new intervention protocols affords an opportunity to study the responsiveness of pulmonary lesions at different stages of progression to chemotherapeutic intervention. The efficacy of this animal model has been evaluated using a classic chemotherapy agent with potential synergistic compounds. [125] Mice containing lung lesions (i.e., hyperplasia, adenoma, carcinoma) induced by NNK were treated for up to eight weeks with *cis*-platinum alone or in combination with indomethacin, metoclopramide, or both, and the effects on tumor growth were assessed. The most dramatic effects were observed in lungs from mice treated for eight weeks. *Cis*-platinum treatment reduced the size of carcinomas by 37%, whereas tumor mass was reduced by 50% to 60% with *cis*-platinum in combination with indomethacin, metoclopramide, or both. As is often observed with a majority of human lung tumors that respond to chemotherapy, tumor mass was reduced in the lungs of A/J mice, but few malignant tumors were completely eliminated. This *in vivo* model is suitable for studying and developing new chemointervention therapies.

13-cis-retinoic acid is used to prevent oral premalignancies and second primary head and neck tumors in humans, [126] and the scientific basis for this application was upper respiratory tract carcinogenesis in hamster models. Squamous metaplasia can largely be prevented in hamsters by simultaneous treatment with retinoids, carotenoids, and selenium along with the carcinogen. [127] Deletion of vitamin A from the hamster diet constitutes a model for squamous metaplasia that is reversed on readdition of this retinoid. Retinoids induce a pathway of mucociliary differentiation (i.e., the production of ciliated and goblet cells from mucous cell precursors), but a retinoid deficiency leads to squamous differentiation and cornification of the tracheobronchial epithelium. [128]

Several dozen compounds have been tested for their abilities to inhibit chemically induced lung tumors in A/J mice, [96,129] but few were potent enough to nearly abolish tumor formation. Budesonide, a synthetic glucocorticoid, reduced benzo(a)pyrene-induced tumor multiplicity by 90% when budesonide was administered through a nose-only nebulizer beginning one week following treatment with the inducer. [77] The convenience of this mode of administration of a chemopreventive agent suggests its practical use for humans at high risk of cancer development, and clinical trials are proceeding. Sulindac sulfone is a metabolite of the NSAID, sulindac, that, unlike its parent compound, fails to inhibit cyclooxygenase activity and the subsequent production of prostaglandins that inhibit neoplastic growth. Nonetheless, this derivative can prevent the formation of different tumor types in various animal models, possibly by stimulating apoptosis through its elevation of cGMP levels. [130] While the sulfone is equal to or less potent than sulindac at inhibiting rat models of mammary and colon tumors, respectively, it was much more effective than sulindac at inhibiting lung tumor formation in mice.[131] Its relative lack of toxic side effects has resulted in the initiation of phase I clinical trials to test the efficacy of sulindac sulfone in humans at high risk.

The next century will see lung cancer incidence in the world reach epidemic proportions due to the escalation of smoking in Asia and the failure of smoking cessation programs for many addicted smokers. In the United States alone, 40% of the population are either current or former smokers; half of the lung cancer patients seen in

the clinic are former smokers. Thus some of the major challenges over the next decade will be dissecting the pathways of lung cancer pathogenesis, identifying biomarkers that detect early lung cancer, developing novel prevention and intervention therapies for high-risk people, and improving the management of disseminated disease. Completion of the human genome and murine genome projects over the next five years will provide a database rich in sequences that await functional studies. Some of the most promising new technologies for gene discovery include serial analysis of gene expression (SAGE), which identifies and quantifies hundreds of thousand of gene transcripts from tumor cells[132] and methylated CpG island amplification for the cloning of differentially methylated genes.[133] In addition, the development of microarrays and silicon-based chips[134,135] will facilitate the analysis of tumors for hundreds of gene alterations. The animal models developed for studying the progression of lung cancer following defined environmental exposures are amenable to this new technology. Novel intervention and prevention approaches need to be developed to reduce the high mortality from lung cancer. Animal models have and will continue to be valuable tools for testing new interventions through oral, intravenous, and inhalation routes.

ETIOLOGY AND EPIDEMIOLOGY OF LUNG CANCER

DAVID SCHOTTENFELD

Lung cancer is the leading cause of cancer mortality in men and women in the United States, accounting for 28 percent of all cancer deaths each year. Whereas lung cancer accounted for only 3 percent of all female cancer deaths in 1950, by 1995 it accounted for an estimated 24 percent of all female cancer deaths. In 1994, the age-adjusted mortality rate per 100,000 was 70.9 for men, and 33.8 for women. In reviewing lung cancer mortality trends between 1990 and 1994, the age-adjusted rate in men decreased by about 1.4 percent per year and in women increased by about 1.7 percent per year. The age-adjusted lung cancer death rates in the United States surpassed those of breast cancer in white women in 1986 and in black women in 1990. Lung cancer is the most common cause of cancer mortality among men in Western industrialized nations.

The incidence patterns, because of persistently poor survival rates, parallel closely the mortality rates; currently, 15 percent of incidence cancers in men and 13 percent in women are attributed to lung cancer. During 1990 to 1994, the average annual age-adjusted lung cancer incidence per 100,000 in United States white men was 76.0, which was exceeded only by prostate cancer (134.7); the average annual lung cancer incidence rate in white women was 41.5, which was second to that of breast cancer (111.8). The United States Surveillance, Epidemiology and End Results (SEER) lung cancer incidence trends from 1973 to 1994 demonstrated, for ages 65 and over, a percentage increase for women (220.5%) that was substantially greater than that for men (18.2%). The age-specific lung cancer incidence rates in men under 65 years of age have declined 16.1 percent since 1973, whereas in women, the rates have increased 58.2 percent. [1]

Lung cancer incidence and mortality patterns follow, after a latency interval of 20 or more years, the temporal patterns of cigarette smoking. In older men in the United States, lung cancer has displaced coronary heart disease as the leading cause of excess mortality among smokers. [2] The risk of dying from lung cancer is associated with age of initiation and duration of cigarette smoking, and with the number and tar concentration of cigarettes smoked each day or as a regular pattern.

Smoking is currently estimated to be the cause of 85 percent of lung cancer deaths. [3] Exposures to other environmental and occupational respiratory carcinogens may be interactive with cigarette smoking, and may also influence trends of lung cancer incidence and mortality.

DESCRIPTIVE EPIDEMIOLOGY

Age and Gender

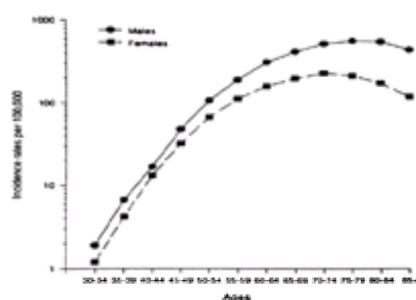
Throughout the world, the age-adjusted incidence rates of lung cancer among men exceed, by twofold or more, that among women. In the United States, the age-adjusted incidence rates in men began to plateau and then declined in the 1980s. The pattern in women differed significantly from that in men. Age-adjusted incidence in women increased on average by 4.1 percent per year between 1973 and 1994, but during 1990 to 1994, the average annual increase was only 0.2 percent. This pattern is attributable to lower prevalences of smoking in cohorts of men born prior to 1910 and of women born prior to 1920. Age-specific rates increase exponentially until the rates plateau and then decline after the age of 80 in men and the age of 70 in women (Figure 20.1). Only 5% to 10% of lung cancer cases are diagnosed under 50 years of age. Epidemiologic studies of lung cancer in young adults emphasize the predominance of adenocarcinomas and the importance of a positive family history. The current smoking pattern and magnitude of relative risk due to smoking in women in the United States are converging on the smoking pattern and risk evident in similarly aged males. [4,5]


FIGURE 20.1. Age-specific lung cancer incidence rates per 100,000 males and females, United States, 1994.

Compared with women, men generally began smoking cigarettes at an earlier age, smoked more cigarettes per day and for a longer duration, inhaled more deeply, and consumed cigarettes with higher tar content. With increasing tobacco smoking in women after World War II, lung cancer mortality increased substantially in North America and Western Europe. Several recent case-control studies have even suggested that female smokers have a higher relative risk of lung cancer than male smokers, after adjusting for age and average daily intensity of smoking exposure. [6,7,8] In a prospective study conducted in Copenhagen, Denmark, although rate ratios for all histologic types of lung cancer increased with number of pack-years of exposure for both men and women, the relative risks did not differ between men and women after adjusting for age and duration and intensity of smoking. [9] The case-control design and the method of estimation of odds ratios in women may have been susceptible to recall bias, underreporting of amount smoked by the cases, and differences in baseline risks of lung cancer between male and female nonsmoking controls (i.e., occupational risk factors, nutritional risk factors, unmeasured exposure to environmental tobacco smoke, etc.). However, the question of gender differences in susceptibility to tobacco smoking merits further investigation. Prospective studies are required to derive unconfounded incidence measures of absolute or attributable risk that may be compared in smoking and nonsmoking men and women.

Race and Ethnicity

The risk of lung cancer in United States black men has been about 50 percent higher than that in white men in the past 10 to 15 years, but the annual rate of decline since 1985 in black men (-3.1%) has been greater than that in white men (-1.2%) (Table 20.1). Among United States black men, lung cancer mortality was the second leading cause of death, ranking below coronary heart disease. The excess mortality from lung cancer among black men, compared with white men, was greatest for the age interval 35 to 64 years. Cohorts of white men born before 1900 had higher (50%) age-specific rates than black men; but this pattern reversed after 1915.

Year of Diagnosis	White		Black	
	Men	Women	Men	Women
1975	75.9	21.8	101.2	20.6
1980	82.2	28.2	131.0	33.8
1985	82.1	35.9	131.3	40.2
1990	80.7	42.5	118.7	47.0
1994	72.6	43.3	110.6	48.0

TABLE 20.1. AGE-ADJUSTED (1970 U.S. STANDARD) LUNG CANCER INCIDENCE PER 100,000, 1975, 1980, 1985, 1990, 1994 IN SEER REGISTRY AREAS, BY RACE AND SEX

During 1975 to 1990, the age-adjusted lung cancer incidence in United States black women was 10% to 20% higher than that in white women (Table 20.1). The increase since 1975 was 120% in black and 89% in white women. Since 1985, the incidence rates have continued to increase at an average annual rate of 2.4% for black and 2.2% for white women.

The SEER program of the National Cancer Institute enables a comparison of risks for the period 1988 to 1992 among various racial and ethnic groups in the United States (Table 20.2). The lowest age-adjusted lung cancer incidence rates in men and women were registered for the Native Americans, Hispanics, and Japanese; the highest rates were reported in blacks, native Hawaiians, and non-Hispanic whites. The ratio of male to female incidence rates reflected elevated risks in men that were 2.5 to 3.5 times the rates in women from the various racial and ethnic groups. Although the ratio of age-adjusted lung cancer incidence rates varied substantially by ethnicity (1.3 to 8.1), the percentage of all cancer deaths attributed to lung cancer in men and women combined was as high in Native Americans (27.7%) as in African Americans (26.1%).

Race/Ethnicity	Males		Females	
	Total	Lung	Total	Lung
African American	560	117.0	326	44.2
Hawaiian	340	89.0	321	43.1
Non-Hispanic White	469	76.0	346	41.5
Chinese	282	52.1	213	25.3
Japanese	322	43.0	241	15.2
Hispanic	319	41.8	243	19.5
Native American (New Mexico)	196	14.4	180	**

* Incidence rate age-adjusted to the 1970 United States standard population.
** Fewer than 25 cases.

TABLE 20.2. TOTAL AND LUNG CANCER INCIDENCE RATES (PER 100,000) BY GENDER, RACE, AND ETHNICITY, UNITED STATES SEER, 1988–1992*

It is generally assumed that the differences in rates of lung cancer can be partially explained by different lifetime patterns of cigarette smoking. Compared with white males, a higher percentage of blacks were current smokers, smoked cigarettes with greater yield of tar and nicotine, and preferred to smoke mentholated cigarettes, which may promote deeper inhalation of cigarette smoke. However, among current smokers, black males smoked fewer cigarettes per day and tended to start smoking at a slightly later age. Reports, which were not confounded by differences in smoking habits, of higher serum cotinine levels, or of 4-aminobiphenyl-hemoglobin adduct levels, in black smokers when compared with white smokers suggested that there may also be differences in susceptibility between blacks and whites as expressed in the metabolism of tobacco smoke.[10]

The age-adjusted lung cancer incidence was 32% lower in Hispanic than in non-Hispanic white men. The percent of current smokers was comparable for Hispanic and non-Hispanic white men, but Hispanic men smoked about half as many cigarettes per day. In a case-control study in New Mexico, where most of the Hispanics were American-born, the estimates of relative risk of smoking and lung cancer were similar for Hispanic and non-Hispanic white males. However, the cigarette smoking patterns in the Hispanic controls indicated that there were substantial ethnic differences in average daily exposure levels. [6,11,12]

Socioeconomic Status

Various studies have reported an inverse association between lung cancer mortality and socioeconomic status. A twofold gradient in mortality was observed between low and high social class, as measured by occupation, income, or education. Smoking patterns accounted for part of the differential risk by social class, with smoking prevalence rates increased among "blue-collar" workers and among those with lower levels of education. [13,14] Socioeconomic status may also serve as a surrogate measure for other risk factors such as occupation, diet, and ambient air pollutants, or may influence the quality, access, and utilization of health care services.

International Patterns

Global lung cancer incidence is increasing at a rate of 0.5% per year, and as a consequence, lung cancer is the leading cause of cancer incidence and mortality in European countries, accounting for about 21% of all cancer cases in men. [15,16] In most parts of the world, rates were higher in urban than in rural areas, and two to six times higher in men than in women. The varying levels of age-adjusted (world standard) lung cancer mortality rates summarized in Table 20.3 were, in general, correlated with cigarette smoking practices that were prevalent at least ten years prior to diagnosis. Worldwide, it has been estimated that 47% to 52% of men and 10% to 12% of women smoke tobacco. In developed countries, 51% of men and 21% of women smoke. The prevalence of smoking men and women, the types of cigarettes and amounts smoked, ages at initiation and duration of smoking exposure, and proportions of heavy smokers in the population, were important determinants of geocultural variations in lung cancer incidence. Recent trends in lung cancer mortality in men exhibited declining rates in all European countries except in France, Greece, Portugal, and Spain. Cigarette smoking in China has followed a pattern similar to that among adults in the United States, although the significant pattern of increase, particularly among men, occurred 40 years later. Of the Chinese deaths attributed to tobacco, 15% are due to lung cancer and 45% to chronic obstructive lung disease. The relatively elevated rates of adenocarcinoma of the lung among Chinese women in China and Singapore have been attributed to exposures to smoking tobacco and to environmental pollutants other than smoking tobacco (e.g., fossil fuel combustion products and cooking oils in the home). [17,18]

TABLE 20.3. AGE-ADJUSTED LUNG CANCER MORTALITY RATES* PER 100,000 POPULATION FOR SELECTED COUNTRIES, IN MALES AND FEMALES, 1992–1995

Histopathology

The distribution of cell types of lung carcinoma based on the SEER program in 1990 were, for male cases: squamous cell (epidermoid) (31.2%), adenocarcinoma (22.7%), small cell (16.6%), large cell (9.3%), bronchioloalveolar (2.5%), and other including adenosquamous and mixed small and large cell (17.7%) (see also Chapter 26). Cumulative exposure to cigarette smoking increases the risks for squamous cell carcinoma, adenocarcinoma, small cell carcinoma and large cell carcinoma, although prior to 1965, the risk tended to increase less steeply in men in relation to intensity and duration of cigarette smoking for adenocarcinoma, when compared with squamous cell and small cell carcinoma. In the early 1970s, data from the SEER program indicated that there were among white males more than twice as many squamous cell carcinomas as adenocarcinomas, whereas among white females, the incidence of adenocarcinoma exceeded that of squamous cell carcinoma by 30% (Table 20.4). By the mid-1980s, because of substantial increases in the incidence of adenocarcinoma in white males, the excess of squamous cell carcinoma decreased to 39%; among white females, the incidence of adenocarcinoma from 1984 to 1986 was 62% higher than that of squamous cell carcinoma. Small cell and non–small cell carcinoma incidence in United States white and African American men peaked around 1984 and then began to decline. Lung cancer incidence in white females, however, increased beyond 1990 for all histologic subtypes. The annual incidence of bronchioloalveolar carcinoma was approximately 1.5 per 100,000, and the epidemiologic features were more characteristic of adenocarcinoma than of squamous cell carcinoma. The increasing age-adjusted incidence rates for lung cancer that were evident during the previous two decades have included increases for the most common histologic types, but were proportionately greater for adenocarcinomas. Similar patterns have been described in Switzerland, Holland, Hong Kong, Korea, Israel, and Japan. The percentage of lung cancer cases classified as adenocarcinoma was higher in Asia than in North American or Europe. Adenocarcinoma is currently the most prominent form of lung cancer in younger persons, women of all ages, lifetime nonsmokers and long-term former smokers.

TABLE 20.4. LUNG CANCER INCIDENCE RATES (PER 100,000) BY HISTOLOGICAL TYPE, RACE, AND SEX IN FIVE UNITED STATES SEER AREAS*

There is no single satisfactory explanation for the changing histologic patterns over the past two decades. The proportionate and absolute increases in incidence trends for adenocarcinoma have occurred in conjunction with declining incidence of the classification "other and unspecified histology." Increasing use of mucin stains and immunocytochemical staining for antibodies to carcinoembryonic antigen has contributed to enhanced recognition of adenocarcinomas. The alterations in histologic patterns have also been interpreted as signaling the effects of changing composition and filtration of cigarette tobacco, with increasing production of volatile nitrosamines and their deposition upon deeper inhalation in terminal bronchioles and alveoli. The tobacco-specific nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone is bloodborne and activated or metabolized in the liver. The deposition of cigarette particulates containing polycyclic aromatic hydrocarbons in proximal lung bronchi is associated with the development of squamous cell carcinoma. [19,20,21 and 22]

LIFESTYLE AND ENVIRONMENTAL RISK FACTORS

Tobacco

The causal relationship between tobacco smoking and lung cancer was established by epidemiologic studies conducted in the 1950s and 1960s. [23,24] The complexity of tobacco smoke, with over 3,000 different chemicals, has made it difficult to identify the contribution of the more than 40 putative carcinogenic agents. The carcinogens in tobacco smoke include the polynuclear aromatic hydrocarbons (PAHs), N-nitrosamines, aromatic amines, other organic (e.g., benzene, acrylonitrile) and inorganic (e.g., arsenic, acetaldehyde) compounds, and polonium 210. The composition of the smoke depends on the ambient conditions of smoking, the blend of tobacco leaf, filtration, additives, paper wrapping, and so on. Tobacco smoke produced by the tobaccos in pipes and cigars is both harsher and more alkaline than that produced by cigarettes. The majority of the compounds in tobacco are produced in an oxygen-deficient, hydrogen-rich environment, arising from pyrolysis and distillation, in the region immediately behind the burning tip of the cigarette. [25]

As mainstream cigarette smoke emerges from the cigarette, it has approximately 10^9 to 10^{10} particles per ml. The aerodynamic diameters of the particles, ranging in size from 0.1 to 1.0 micrometer, determine the sites of deposition in the airways and alveolar regions of the lung. The fraction of smoke retained varies markedly with the pattern of inhalation. The chemical analysis of tobacco smoke is separated into particulate, or "tar," and gaseous phases. Filter tips of cellulose acetate remove volatile nitrosamines and phenols selectively. The neutral fraction of the particulate phase contains potentially important tumor initiators such as the PAHs.

In 1964, the first Surgeon General's report on smoking summarized existing evidence and declared cigarette smoking to be the major cause of lung cancer among American men.[26] In the ensuing 30 years, epidemiologic studies have established that there were increasing risks in women and underscored the relationships with onset, duration, intensity, and cessation of smoking. Three major prospective studies demonstrated a rising trend in lung cancer death rates with increasing average amounts smoked per day in current smokers (Table 20.5).[27,28 and 29] The initial emphasis of epidemiologic studies of lung cancer and smoking was on men who, in almost all countries, began smoking earlier, consumed greater quantities of tobacco, and exhibited higher relative risks than women.

Number of Cigarettes Smoked per Day	American Cancer Society (ACS) Volunteers	United States Veterans	British Physicians
Nonsmokers	1.0	1.0	1.0
Current cigarette smokers*	9.2	12.1	14.0
1–9	4.6	5.5	7.8
10–19	8.6	9.9	17.4
20–39	14.7	17.4	25.1
40+	18.8	23.9	

* Classification of current smokers refers to ACS study. The categories for United States Veterans were 1–9, 10–20, 21+39, and 40+, and for the British Physicians were 1–14, 15–24, and 25+ per day.

TABLE 20.5. RELATIVE RISKS OF DEATH FROM LUNG CANCER AMONG MALE SMOKERS ACCORDING TO NUMBER OF CIGARETTES SMOKED

In the past 20 years, the prevalence of cigarette smoking in many countries, including the United States, has increased significantly among women; concomitantly, changes in smoking practices have been accompanied by increasing relative and attributable risks for lung cancer. [30],[31] In a follow-up study of approximately 600,000 women conducted in the 1980s by the American Cancer Society, the relative risk of dying of lung cancer in current smokers was 12.7; for those who smoked 30 or more cigarettes per day, the relative risk was increased 22.3 times compared with the never smoker. [32] In 1985, cigarette smoking accounted for an estimated 82 percent of lung cancer deaths, or 31,600 deaths. The International Agency for Research on Cancer estimated that the smoking-attributable fraction of lung cancer deaths occurring in the United States and in England and Wales was 92% in men and 78% in women. [25] In 1995, an estimated 47 million U.S. adults and 4.5 million U.S. adolescents were cigarette smokers.

Lower tar content and the use of filters are factors that may result in reduced lung cancer risks in those who smoke. In the earlier American Cancer Society (ACS) Twenty-Five State Study, males who smoked "low-tar" (i.e., less than 22 mg) cigarettes experienced 20% lower risk of dying of lung cancer when compared with males who continued to smoke high-tar cigarettes. The excess lung cancer risk for current smokers was directly proportional to the estimated milligrams of tar consumed daily: standardized mortality ratio (SMR) = 100 + 1.731 × milligrams of tar per day. [33] In the more recent ACS Fifty State Study, Garfinkel and Stellman [34] concluded that doubling the cigarette tar yield would result in a 40% increase in the relative risk of dying of lung cancer, independently of the amount smoked or depth of inhalation. The Federal Trade Commission estimated that the current average sales-weighted tar content of cigarettes manufactured in the United States was about 12 to 13 mg of tar per cigarette, compared with nearly 40 mg in the early 1950s. Lifelong filter cigarette smokers have experienced 20% to 40% lower risk of lung cancer than lifelong nonfilter smokers, after adjusting for differences in the amount smoked. [35],[36]

While these studies suggested that switching to filtered or low-tar cigarettes may modestly reduce the risk of lung cancer, the more significant reduction in risk would be derived from cessation of smoking. Whereas 25% of smoking adults in the United States continue to smoke, an additional 40% to 50% have become former smokers. As shown in Table 20.6, the relative risk of lung cancer among ex-smokers decreased significantly after five years of smoking cessation. In the initial one to four years after quitting smoking, however, the relative risk of lung cancer among ex-smokers may have been higher than among current smokers, presumably because a proportion of individuals may have stopped smoking because of illness or premonitory symptoms of lung cancer.

Cohort	Years after Smoking Cessation					
	0	1–4	5–9	10–14	15–19	20+
British Physicians	15.8	16.0	5.9	5.3	—2.0—	
U.S. Veterans	11.3	18.8	7.5	5.0	5.0	2.1
American Cancer Society*	13.7	12.0	7.2	—1.1—		

All risks relative to lifelong nonsmokers.
* Excludes those who smoked less than one pack of cigarettes per day.

TABLE 20.6. RELATIVE RISKS OF LUNG CANCER AMONG MALES ACCORDING TO YEARS AFTER QUITTING SMOKING

It has been suggested that the risk of lung cancer in former smokers will approximate but never equal that of lifelong nonsmokers. The baseline risk of lung cancer in lifelong nonsmokers increases in relation to age raised to the fourth or fifth power. In the British Physicians Study, Doll showed that the incidence of lung cancer in cigarette smokers increased approximately in proportion to the fourth power of duration of smoking, and was multiplicative with the previously described exponential increase with age among never-smokers. [37] The percentage reduction in risk after quitting depended on the prior duration and average amount smoked each day, being more readily demonstrable among lighter smokers and smokers of lesser duration or those who quit at a younger age. [38] Lung cancer results from a multi-step process in which persistent genetic lesions accumulate at specific chromosomal loci. The vast majority of current or former smokers, in contrast to never-smokers, exhibit loss of heterozygosity at multiple chromosomal sites (e.g., 3p14, 9p21, p16, p53) in both normal and metaplastic or dysplastic bronchial epithelium [39] (see also Chapter 18).

Pipe and cigar smoking were linked to lung cancer, but the estimated relative risks, compared with people who never smoked, were considerably lower than the risks reported among cigarette smokers; the risks among exclusively pipe or cigar smokers in the United States or England varied from no increased risk in some studies, to twofold or higher risks in other studies. In countries such as Sweden, Switzerland, and Holland, where pipe or cigar smoking was nearly as common as cigarette smoking, the relative risks of lung cancer were equally high for all forms of smoked tobacco. [40],[41] Differences in the manner in which pipes and cigars were smoked in different countries, i.e., depth of inhalation or amount smoked, may provide an explanation for differences in the estimated risks. Risks of lung cancer also varied with the type of tobacco used. Dark tobaccos were associated with greater risk of lung cancer than light tobaccos, and with formation of higher levels of 4-aminobiphenyl-hemoglobin adducts. [42]

Environmental Tobacco Smoke

Environmental tobacco smoke (ETS) is comprised of sidestream smoke (about 80%) released from burning tobacco in between puffs and from the exhaled smoke (about 20%) of the smoker. The smoke that the smoker inhales is known as mainstream smoke. Other minor contributors to ETS include the smoke that escapes during puffing from the burning cone, and gaseous components that diffuse through the cigarette paper. These components are diluted by the ambient air and when inhaled, in particular by nonsmokers, are referred to as "passive" or "involuntary" smoking. ETS contains various toxic agents, including mutagens and carcinogens, which, for some chemicals (e.g., nitrosamines, 4-aminobiphenyl, benzo(a)pyrene), have been measured at higher concentrations than in mainstream smoke. Estimates of ETS exposure, based on serum or urinary measurements of cotinine, the metabolite of nicotine, suggest that involuntary smokers absorb about 0.5% to 1% of the nicotine that active smokers absorb, or smoke the equivalent of about one half a cigarette a day. Studies of 4-aminobiphenyl-hemoglobin adduct levels indicate that passive smokers have approximately 14% of the concentration of active smokers. [43]

Table 20.7 lists the relative risks of lung cancer among nonsmoking women based on a review of epidemiologic studies in various countries which have evaluated dose-response trends. [44],[45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60] and [61] The risks increased with amounts smoked by husbands, with about 30% to 150% increases in relative risk experienced in general among those women most heavily exposed. A weighted analysis of 37 published epidemiological studies resulted in the conclusion that there was an elevated risk of 24% (95% confidence interval, 13% to 36%) among nonsmoking wives of *smoking* husbands, when compared with nonsmoking wives of *nonsmoking* husbands. [62] Workplace exposures to ETS are measured with less precision than spousal exposures; however, some studies have suggested that there is a dose-response relationship when combining workplace and spousal sources of ETS. It has been suggested that when using biological markers of nicotine exposure

in studies of ETS and lung cancer, about 5% of female respondents who were in fact smokers may have reported that they were nonsmokers. Correcting for this bias, however, would result in an adjusted relative risk in nonsmoking women who were living with smokers of about 1.15 to 1.20. The report of the National Research Council concluded that about 20% of lung cancers occurring in nonsmoking women and men, or 3,000 cases per year, may be attributable to exposure to ETS; in the context of lung cancer cases diagnosed each year in smokers and nonsmokers, 2% to 3% may be attributable to ETS. [63]

[a] Definitions of heavy smokers varied by study, but typically included those who smoked 20 or more cigarette per day.

TABLE 20.7. RELATIVE RISK OF LUNG CANCER AMONG NONSMOKING WOMEN ACCORDING TO LEVEL OF HUSBAND'S SMOKING

Air Pollution

Pollutants in the urban air other than from tobacco have been investigated as potential causal agents in the epidemic rise of lung cancer in industrialized nations. The products of fossil fuel combustion, principally polycyclic hydrocarbons, have been of particular concern. Other sources of ambient air pollution have been motor vehicle and diesel engine exhausts, power plants, and industrial and residential emissions. The ratio of urban to rural age-adjusted lung cancer mortality rates in many industrialized nations has varied between 1.1 and 2.0. It has been suggested that the net attributable risk effect of protracted exposure to urban air pollutants in men with average smoking habits would be ten cases of lung cancer per 100,000 per year. In most countries, however, a major fraction (i.e., 80% or greater) would be attributable to cigarette smoking, and the independent association with urban residence, or the "urban factor," could not be assessed without controlling for the confounding effect of differences in smoking practices between urban and rural residents. In addition, the "urban factor" has yet to be defined, but is undoubtedly a complex mixture of interacting chemical compounds and elements that vary by geographic area and over time. [64,65] Exposure to combustion-source ambient air pollution has been associated with declining pulmonary function, increased rates of hospitalization for respiratory illnesses, and increased rates of cardiopulmonary diseases mortality. [66]

Evidence in support of the potential association of air pollution with lung cancer may be provided by occupational studies of workers exposed to combustion products from fossil fuels. Workers exposed to emissions from retort coal gas plants manifested smoking-adjusted relative risk of lung cancer that was approximately twice that in unexposed workers. [67] Roofers exposed to coal tar fumes while working outdoors had an approximately 50% increase in lung cancer risk after 20 years of exposure and 150% increase after 40 years. [68]

Benzo(a)pyrene has been used as a surrogate index of ambient urban air exposure produced by fossil fuel combustion and correlated with lung cancer mortality rates. However, putative carcinogenic agents present in ambient urban air may include inorganic particles or fibers (e.g., arsenic, asbestos, chromium, nickel, uranium); radionuclides (e.g., ^{210}Pb, ^{212}Pb, ^{222}Ra); and organic gaseous and particulate combustion products (e.g., dimethylnitrosamine, benzene, benzo(a)pyrene, 1,2-benzanthracene). In the longitudinal study of the American Cancer Society, age-, occupational-, and smoking-standardized rates for lung cancer were computed according to residence. Minimal differences in mortality were observed between urban and rural residential areas, or among cities categorized by indices of pollution. [69] The World Health Organization International Agency for Research on Cancer has declared diesel engine exhaust a *probable carcinogen*. [70] In studies of railroad workers exposed to diesel exhaust, Garshick and colleagues [71] described a 40% increase in the smoking-adjusted relative risk of lung cancer.

In a rural area in Yunan Province in China, an excess risk of lung cancer among men and women was attributed to indoor pollution because of burning soft, smoky coal in poorly ventilated homes. [72] In Shanghai, the elevated risk of lung cancer was hypothesized to be due to prolonged exposure to oil vapors, particularly from rapeseed oil that was used in high-temperature wok cooking. [73] In urban Shenyang in northeastern China, indoor pollution from coal-burning heating devices gave rise to an age-, education-, and tobacco-smoking-adjusted relative risk of 2.3 for lung cancer in the highest exposure group. [74,75]

Indoor Radon

Radon (^{222}Ra), with a half-life of 3.8 days, is an inert, radioactive, colorless, and odorless gas at usual environmental temperatures that can percolate through the earth's crust and accumulate in residential dwellings. At sufficiently high concentrations, radon and its a-particle–emitting decay products, polonium-214 and polonium-218, have been shown to cause lung cancer in cigarette smoking and nonsmoking uranium, tin, and iron-ore miners. These observations have been replicated by conducting experimental studies in rats. [76] Indoor radon exposure accounts for about 50% to 80% of the total radiation received on average in the United States. It has been estimated, based on extrapolations from high-risk miner studies, that indoor radon may cause between 6,000 to 36,000 lung cancer deaths per year in the United States. [77] Joint exposures to tobacco smoke and radon gas have been interpreted to yield risks of lung cancer that were greater than linear and additive and approximated multiplicative or log linear effects.

There have been at least eight epidemiologic case-control studies conducted in five countries of lung cancer risk from exposure to residential radon. [78] Axelson and colleagues [79] noted an increased risk of lung cancer among persons living in stone compared to wood houses in Sweden. In a later study by Pershagen and co-workers, [80] it was concluded that the smoking-adjusted risk of lung cancer increased in relation to the cumulative and time-weighted exposure to radon. The relative risk was 1.3 (95% confidence interval, 1.1–1.6) for average radon concentrations over a period of about 30 years of 3.8 to 10.8 pico Curies (pCi) per liter; for exposure in excess of 10.8 pCi per liter, the relative risk was 1.8 (95% confidence interval, 1.1–2.9). Moreover, there was evidence that the joint effect of radon exposure and tobacco smoking was multiplicative rather than additive. In a study conducted in New Jersey, the risk of lung cancer was increased more than two-fold among women living in homes with radon levels exceeding 4 pCi per liter. [81] However, in a case-control study of women who were recently diagnosed with lung cancer in China, no association was demonstrated between increasing residential radon exposure and lung cancer; 20% of the year-long radon measurements exceeded 4 pCi per liter, the level above which remedial action is recommended in the United States. [82] Conclusions to those from the study in China were recently presented based on a study by Leétourneau and colleagues in Canada. [83] Thus, although radon and its a-particle–emitting decay products are classified as a human lung carcinogen, there is uncertainty about whether residential radon exposure levels contribute to the lung cancer burden to the extent predicted based on extrapolations from studies of underground miners. Epidemiologic studies of indoor radon in the United States must be interpreted with caution because of limitations in estimating lifetime exposures based on current exposure measurements and because average residential exposure levels are generally low, with extrapolated relative risk estimates of less than 1.2, thus potentially confounded by effects of active and environmental tobacco smoke inhalation or of other residential environmental pollutants. Notwithstanding these caveats, recent publications are supportive of risks of lung cancer associated with residential radon exposure that are consistent with extrapolations of risk using underground mining-based models. [78,84]

Occupational Respiratory Carcinogens

Although smoking is the major cause of lung cancer, other respiratory tract carcinogens have been identified, or are suspect, and may enhance the carcinogenic effects of tobacco smoke. Notable among these independent determinants of lung cancer are chemical and physical agents that have been identified in the workplace (Table 20.8). An example of an occupational lung cancer was described in central Europe in the latter part of the nineteenth century in underground metal miners. The likely cause of what was described historically as "mountain disease" has been attributed to the miner's inhalation of radon and a-emitting radon daughters. At that time, lung cancer was a rare disease, and the prevalence of cigarette smoking was low. Other occupational agents classified as Group 1 carcinogens by the International Agency for Research on Cancer include arsenic, asbestos, bis (chloromethyl) ether, chromium (hexavalent), nickel and nickel compounds, polycyclic aromatic compounds (PAHs), and vinyl chloride. Currently, occupational exposures have been estimated to account for 5% to 20% of lung cancers occurring among

men and women of different cultures and nations.[85]

TABLE 20.8. CHEMICALS AND INDUSTRIAL PROCESSES ASSOCIATED WITH HUMAN LUNG CANCER*

Asbestos

The association between asbestos exposure and lung cancer has been established by epidemiological and animal experimental studies. It has been estimated that since the beginning of World War II, up to 8 million persons in the United States have been exposed to asbestos in the workplace. In the United States, more than 90% of the production and consumption of asbestos is represented by the serpentine or curly form of fiber known as chrysotile ("white asbestos"). The bronchopulmonary neoplasms of various cell types induced by asbestos tend to originate peripherally and in the lower lobes, accompanied frequently by the fibrosis of asbestosis.

Asbestos is a general term used to describe a variety of naturally occurring hydrated silicates that produce mineral fibers upon mechanical processing. In addition to the serpentine group described previously, there are the amphiboles, a larger family of straight, needlelike fibers that includes anthophyllite, tremolite and amosite ("brown asbestos"), and crocidolite ("blue asbestos"). The vast majority of mesotheliomas are associated with exposure to crocidolite asbestos. Because of unique physical and chemical properties, such as noncombustibility, withstanding temperatures of over 500°C, resistance to acids, high tensile strength, and use in thermal and acoustic insulation, asbestos has had wide applications in commercial products. Such products include textiles, cement, paper, wicks, ropes, floor and roofing tiles, water pipes, wallboard, fireproof clothing, gaskets, and brake linings.

A variety of morphologic, biochemical, and molecular techniques have been utilized to document events that might be associated with asbestos toxicity at the cellular level. Prolonged exposure to asbestos results in the accumulation of macrophages and inflammatory cells in the alveoli, which is accompanied by the release of oxygen free radicals, the peroxidation of cell membranes, and damage to DNA and other macromolecules. Asbestos fibers that cross the alveolar epithelium may be translocated to the pleura by macrophages. The shape, length, and persistence of fibers may be important in eliciting cellular responses intrinsic to carcinogenesis. Longer, rodlike fibers (i.e., more than 5 to 10 micrometers in length and less than 0.25 microns in diameter) appear to be more cytotoxic than shorter, coarse fibers. Electrostatic charge on the fiber surface may enhance deposition in lung tissue, and the surface biochemistry may also impact the inflammatory response. Experimentally, in tracheobronchial epithelial culture systems, asbestos exhibits the characteristics of a tumor promoter; chronic exposure to asbestos, subsequent to the introduction of subcarcinogenic amounts of dimethyl benzanthracene (DMBA), has resulted in increased DNA synthesis, basal cell hyperplasia, squamous metaplasia, and a low incidence (about 5%) of squamous cell carcinoma. In the induction of mesotheliomas and pleural sarcomas, asbestos is a complete carcinogen.[86,87]

The risk of lung carcinoma in cigarette smokers has been examined in a number of asbestos-exposed populations. In 1968, Selikoff and colleagues [88] reported on the effects of combined exposures to cigarette smoking and asbestos in insulation workers; the relative risk for lung cancer significantly exceeded the level of risk expected if each exposure were to have acted only independently (noninteractively). The synergy resulting from combined exposures to tobacco and asbestos has been demonstrated in asbestos factory workers, Quebec miners and millers, amosite asbestos factory workers, and Finnish anthophyllite miners and millers. [89] Although most studies have concluded that the resulting relative risks were close to multiplicative, as in exposures, to smoking and radon combined, a study among Canadian chrysotile miners and millers concluded that the effect of each agent was independent and additive. [90] Various sources have concluded that asbestos exposure, in the absence of tobacco smoking, increases the risk of both squamous cell carcinoma and adenocarcinoma of the lung. It is assumed that the dose-response relationship is linear and without an apparent threshold.

Mesothelioma has a protracted latency period averaging 35 to 40 years. Unlike carcinoma of the lung, smoking does not contribute to the development of mesothelioma in asbestos workers. Statistics on the incidence and mortality of mesothelioma are not reported routinely, because of problems in histopathologic classification of mesothelial cell hyperplasia and malignant neoplasia and the distinction from metastatic sarcomas or adenocarcinomas. A combination of histochemistry, immunocytochemistry, and electron microscopy may be necessary to achieve a precise and valid diagnosis. In the SEER program, consisting of population-based cancer registries that cover about 10% of the total United States population, the average annual age-adjusted incidence of mesothelioma (per 100,000 population) from 1985 to 1989 was 1.6 among white males and 0.4 among white females. In developed countries, approximately one mesothelioma case occurs concurrently with 100 lung carcinoma cases. The rates in nonwhites were too low to yield reliable estimates during this period of time. As reported in other countries, pleural exceeded peritoneal mesotheliomas by a ratio of 9:1 in males and 3:1 in females. [91] The tumors arise rarely in the pericardium. In the SEER areas over the period from 1973 to 1984, the age-adjusted annual incidence of mesothelioma increased by nearly 12% per year in males and by 1% in females. The incidence rates appeared to have peaked among those born around 1910, and have declined among cohorts born subsequently. Projections for the United States are approximately 2,000 new cases per year in the 1990s.[92]

There are well-documented areas of elevated incidence of mesothelioma, such as the coastal area of Virginia, England and Wales, and Japan, where there were shipbuilding centers; among women in areas where during World War II gas masks with asbestos filters were manufactured; or in South Africa, where excess mesothelioma incidence was concentrated in mining districts. Mesotheliomas may result from neighborhood or environmental (nonoccupational) exposures to asbestos industries and from household contact with asbestos dust, primarily through the laundering of work clothing. [93,94,95,96 and 97]

All types of asbestos have the potential for causing mesothelioma, although the risks in humans are two to four times more significant for amphibole fibers, such as crocidolite and amosite, than for the serpentine fibers of chrysotile. The mechanisms of induction appear related to the physical properties of fiber size and dimension. The amphibole straight rodlike fibers can more readily be transported or penetrate to peripheral segments of the lung. The pathogenesis in mesothelial cells is accompanied by induced protooncogene expression and the formation of oxygen radical species. [98,99]

The association between the physical structure of asbestos fibers and carcinogenicity has raised concerns regarding possible hazards of other fibers, whether natural or synthetic. Inorganic synthetic vitreous substances derived from glass, rock, slag, or clay are used primarily in the manufacture of thermal and acoustic insulation materials. Intrapleural injection of such fibers is associated with mesothelioma or sarcoma of the pleura of laboratory animals. In 1987, the World Health Organization declared that glass wool, rock wool, slag wool, and ceramic fibers were to be classified as 2B agents, namely agents possibly carcinogenic to humans. [100] This category is generally used for agents for which there is limited evidence in humans and where there is the absence of sufficient evidence in experimental animals. Epidemiologic studies of the association of occupational exposures to synthetic vitreous fibers and the risk of lung cancer have not shown a consistent pattern of risk in relation to duration of employment, average intensity and cumulative exposure dose levels, or latency interval. Further, many of the studies have not controlled adequately for confounding by cigarette smoking habits or exposure to other workplace respiratory carcinogens. [101,102]

Nutrition: Antioxidants and Fat

Epidemiologic studies have provided evidence about the nature of dietary deficiencies and excesses that have influenced the risk of lung cancer. The most consistent association, gathered from case-control and cohort studies, was that increased consumption of fresh vegetables, fruits, and carotenoids lowered the risk in men and women, in current or former smokers, and for all histologic types. The higher levels of consumption, as specified by tertile, quartile, or quintile categories, when

compared with the lower levels, tended to be associated with 40% to 50% reduction in the smoking-age-gender–adjusted relative risk of lung cancer of various cell types. Various antioxidants were considered as putative chemopreventive nutrients, but a major focus has been on the carotenoids, particularly b-carotene.[103,104,105,106,107,108,109,110,111,112,113,114] and [115] Some investigators have reported that b-carotene was most protective in current or heavy smokers, whereas others have found that b-carotene or carotenoids were most protective in former smokers or in nonsmokers. In a population-based case-control study of lung cancer in nonsmokers conducted in New York State, Mayne and co-workers[116] concluded that the increased consumption of raw (not cooked) fruits and vegetables was associated with a significantly reduced risk for lung cancer. Dietary b-carotene (odds ratio = 0.70; 95% CI = 0.50 to 0.99), but not dietary retinol (vitamin A), was significantly associated with risk reduction for lung cancer in nonsmoking men and women.

By the mid-1980s, large-scale randomized clinical trials of b-carotene, b-carotene plus retinol, or b-carotene and/or vitamin E were initiated in subjects at increased risk of lung cancer. The a-tocopherol/b-carotene trial (ATBC) in Finland was a primary prevention trial among over 29,000 male smokers of 50 to 69 years of age. [117] The 2 × 2 factorial design evaluated 20 mg b-carotene and/or 50 International Units of a-tocopherol (vitamin E) daily for 6.5 years. These doses represented a fivefold excess over the median intake of a-tocopherol and a tenfold excess over the median intake of b-carotene in the general population. When compared with placebo groups, supplementation with vitamin E did not alter lung cancer incidence; however, participants receiving b-carotene alone or in combination with a-tocopherol had significantly higher lung cancer incidence (relative risk = 1.18; 95% CI, 1.03 to 1.36). The excess lung cancer incidence was demonstrable after the initial 18 months, and the randomized design and analysis controlled for cigarette smoking history.

The b-carotene and retinol efficacy trial (CARET) was a multicenter randomized trial to test whether oral administration of the combination of b-carotene (30 mg per day) and retinyl palmitate (25,000 IU per day) would decrease lung cancer incidence in high-risk populations of women smokers and men smokers and/or exposed asbestos workers. In the treatment group, when compared with the placebo group, the relative risk, after an average follow-up of four years, of death from lung cancer was 1.46 (95% CI, 1.07 to 2.00). The point estimates exceeded 1.1 for the current smokers, asbestos-exposed men, and current women smokers. [118,119]

The Physicians' Health Study was a long-term trial organized to test the effect of aspirin on cardiovascular disease incidence. b-carotene (50 mg) was added in a 2 × 2 design. In this healthy male population with 11% current cigarette smokers, and after an average follow-up of 12.5 years, the investigators concluded that the intervention did not reduce or increase the incidence of lung cancer (relative risk = 0.93). [120,121]

It is disturbing and challenging to reflect about the lack of demonstrable benefit or even an adverse outcome of increased risk of lung cancer in smoking men and women participating in various chemoprevention clinical trials. The results of these clinical trials would appear to contradict the epidemiologic observational studies. b-carotene is only one of many carotenoids ingested in vegetables and fruits and, under conditions of increased oxidative stress as in exposure to cigarette smoke or asbestos, b-carotene can be oxidized to an epoxide or reactive electrophilic derivative that would be mitogenic rather than inhibitory of cell proliferation. [122] Handelman and associates exposed human plasma to the gas phase of cigarette smoke and observed oxidative disruption of carotenoids and a-tocopherol. [123] In addition to carotenoids, fresh fruits and vegetables contain other micronutrients including vitamin C, folic acid, flavones, isoflavonoids (e.g., soy products), protease inhibitors, thiocyanates, and indoles (e.g., indole-3-carbinol in *Brassica* vegetables).[124] Folic acid, methionine, and choline are interrelated in methyl group metabolism. Selective growth and transformation of cells can result from imbalances in DNA hypomethylation and overexpression of protooncogenes, or hypermethylation of promoter regions that may attenuate the expression of tumor suppressor genes.

Various chemopreventive mechanisms of action by micronutrients and nonnutritive phytochemicals in fruits and vegetables have been suggested by *in vitro* and animal feeding experimental studies. The complex interrelated mechanisms by which substances in vegetables and fruits may inhibit carcinogenesis include regulation of cell differentiation; "quenching" or "trapping" of oxygen or hydroxyl free radicals; preventing the formation of electrophilic metabolites from precursor compounds by inhibiting the enzymatic activation pathway (e.g., cytochrome P450) or by inducing the detoxification pathway (e.g., glutathione S-transferase); enhancing DNA methylation; inhibiting the expression of oncogenes; and stimulating immune function [125] (see also Chapter 21, Chapter 25).

Lung cancer mortality is significantly positively correlated in various countries with per capita fat availability and consumption. An excess of lung cancer has been reported in case-control studies among persons with high dietary intake of foods rich in fat and cholesterol, including whole milk and eggs. However, the positive association of dietary cholesterol and lung cancer risk has not been reflected in studies of serum cholesterol levels. Shekelle and colleagues [126] have hypothesized that a low, not elevated, serum cholesterol is predictive of increased risk of lung cancer, particularly in the subgroup of the population with low intake of b-carotene. Studies of the effects of dietary cholesterol and total and saturated fat have attempted to control for the confounding effects of gender, smoking status, and intake of energy, fruits, vegetables, and carotenoids.[127] Despite the positive association with dietary fat, lung cancer risk is not associated with increasing body mass; indeed, several studies have described elevated risks in subgroups in the lowest categories of body mass index. Dietary lipids have been postulated to affect carcinogenesis by promoting mechanisms that affect cell proliferation and gap junction intercellular communication.

Previous Nonneoplastic Lung Disease

Lung cancer risk has been reported to be increased among persons with a history of tuberculosis, pulmonary fibrosis as in silicosis, or chronic bronchitis and emphysema. An increased risk of lung cancer following the diagnosis of tuberculosis has been reported in cohort and case-control studies. For example, in a population-based case-control study of lung cancer that was conducted in Shanghai, Zheng and associates [128] reported that the age-sex-smoking–adjusted odds ratio or relative risk of lung cancer was increased by 50% (95% CI, 1.2 to 1.8) among all survivors of tuberculosis, and by 100% among those diagnosed with tuberculosis within the previous 20 years. Among males, prior infection was reported by 26% of the cases and by 20% of the controls. The relative risk of lung cancer was higher for adenocarcinoma than for squamous or oat-cell carcinoma, and the locations of the granulomatous fibrotic lesions were highly correlated with that of the lung cancers. Based on the estimation of relative risk and the proportion of the population in Shanghai exposed to pulmonary tuberculosis, 9% of lung cancer cases were attributed to prior infection. In a case-control study by Hinds and colleagues, [129] the relative risk of lung cancer in never-smoking women in Hawaii with prior tuberculosis was increased significantly (odds ratio 8.2, 95% CI, 1.3 to 54.4).

The International Agency for Research on Cancer (IARC) has classified silica as a "probable" lung carcinogen (2A). Inhalation of silica causes both lung fibrosis and cancer in rats, but fibrosis in the absence of cancer has been observed in mice. For workers exposed to crystalline silica with clinical indication of pneumoconiosis, as reported in 15 cohort (12) and case-control (3) studies, the combined relative risk of lung cancer was 1.33 (95% CI, 1.12 to 1.45). [130] In a metaanalysis of lung cancer mortality among patients with silicosis, Smith and co-workers[131] reported a pooled estimated relative risk of 2.2 (95% CI, 2.1 to 2.4). Relative risks have been elevated in workers with increased exposure to silica dust that is incurred in mining and quarrying, and in the granite, ceramics and glass, and foundry industries. In underground mining, exposure to silicon dioxide or crystalline silica may be confounded by exposure to radon and its a-particle progeny, diesel fumes, asbestos, and other occupational carcinogens, and/or to tobacco smoke. Increased risk appears to vary with the severity of pulmonary fibrosis, or with clinical signs of obstructive lung diseases that accompany chronic silicosis. [132] The excess risk of lung cancer reported in previous studies has persisted after adjusting for smoking or has not been associated with excess risks for other smoking-related cancers, as in the upper digestive or urinary tract organs.

Cigarette smoking may result in chronic bronchitis and/or emphysema (COPD) and/or lung cancer. In the early 1960s, Passey [133] hypothesized that it was the irritating properties of tobacco smoke, resulting in chronic bronchitis and inflammatory destruction of lung tissue, that was of pathogenic significance in the causal pathway of lung cancer, rather than any direct action by volatile and particulate carcinogens in tobacco smoke. The experiments of Kuschner, [134] however, suggested an alternative explanation; namely, that bronchial and bronchiolar inflammation, accompanied by reactive proliferation, squamous metaplasia, and dysplasia in basal epithelial cells, provided a cocarcinogenic mechanism for neoplastic cell transformation upon exposure to polycyclic aromatic hydrocarbons.

Although cigarette smoking is the predominant cause of COPD, with an estimated attributable risk fraction exceeding 80% in smoking individuals, perhaps only 10% to 15% of current smokers will eventually develop clinically significant sequellae of productive cough, exertional dyspnea, and cardiovascular disease. [135] There are at least ten cohort studies that have reported that chronic obstructive airway disease is an independent predictor of lung cancer risk (Table 20.9).[136,137,138,139,140,141,142,143,144] and [145]

TABLE 20.9. REVIEW OF COHORT STUDIES OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE AND LUNG CANCER

Chronic cigarette smoking retards mucociliary clearance of foreign particulates and respiratory tract secretions, evokes an inflammatory response accompanied by fibrosis and thickening in the membranous and respiratory bronchioles, and causes mucus gland hypertrophy, hyperplasia, and dysplasia in the proximal airways. [146] The manifestations of COPD signal the extent of bronchopulmonary structural and functional damage arising from the interaction of sustained exposure to toxic products of tobacco combustion and host susceptibility. In this context, COPD is a biomarker of both exposure dose level and tissue susceptibility. A more controversial issue would be that of how COPD impacts the development of lung cancer. A conceptual model is proposed that incorporates the potential cocarcinogenic effects of chronic obstructive pulmonary disease in the causal pathway of cigarette smoke and lung cancer (Figure 20.2). The molecular events in the natural history of lung cancer comprise multiple genetic mutations that are determinants of neoplastic transformation and tumor progression, and the elaboration of autocrine growth factors that influence the clonal behavior and morphologic features of neoplastic cells. Chronic inflammation in the proximal and distal bronchial airways is an important cause of obstructive symptoms and provides the dynamic setting for oxidative stress and the formation of free radicals that accompany the reparative proliferative response. Increased proliferation kinetics and the interaction of hydroxyl radicals with DNA augment the likelihood of DNA structural and transcriptional errors.

FIGURE 20.2. Enhancement of the causal pathway of cigarette smoke and lung cancer by the association with chronic obstructive pulmonary disease. (From Islam SS, Schottenfeld D. Declining FEV1 and chronic productive cough in cigarette smokers: a 25-year prospective study of lung cancer incidence in Tecumseh, Michigan. *Cancer Epidemiol Biomarkers Prev* 1994;3:289, with permission.)

GENETIC PREDISPOSITION

In a study of familial aggregation of lung cancer, Tokuhata and Lilienfeld [147] reported a significantly increased risk of lung cancer mortality among nonsmoking relatives of lung cancer cases when compared with nonsmoking relatives of age-race-and-sex—matched controls. Other investigators have reported two-to fourfold increased risks of lung cancer among close relatives of lung cancer patients. In a segregation analysis involving 337 high-risk families with lung cancer, Sellers and colleagues [148] described a pattern of autosomal codominant inheritance, and hypothesized that segregation at this gene locus would account for 69% of the lung cancer cases diagnosed in persons up to age 50 years. Samet and associates [149] concluded that the personal risk of lung cancer was increased more than fivefold if at least one parent had had lung cancer. In a study of families of women with lung cancer, an odds ratio gradient was noted: never-smoker with a positive family history (5.7); smoker with a negative family history (15.1); and smoker with a positive family history (30.0). [150] Familial aggregation of lung cancer may be attributed to shared mainstream and sidestream tobacco smoking or other environmental and/or heritable determinants. On the assumption that a lung cancer susceptibility gene with a frequency of 0.3 to 0.5 would increase the risk of lung cancer in carriers, then an autosomal recessive model of inheritance would predict that siblings of cases would manifest a two-to fourfold increased relative risk of lung cancer. [151]

Multiple inherited and acquired mechanisms of susceptibility to lung cancer have been proposed (a detailed discussion of these mechanisms is reviewed in Chapter 21). Individual susceptibility to tobacco-induced lung cancer may be dependent on competitive gene-enzyme interactions that affect activation or detoxification of procarcinogens and levels of DNA adduct formation, or on the integrity of endogenous mechanisms for repairing lesions in DNA. [152] Nicotine is converted to cotinine in a two-step enzymatic process for which the rate-limiting step is the drug-metabolizing enzyme cytochrome P-450, a genetically polymorphic enzyme. Glucuronyl transferase enzymes conjugate and inactivate carcinogenic compounds, including NNK, a potent procarcinogen in tobacco smoke. In a case-control study by Nakachi and colleagues [153] in which they assessed DNA polymorphisms in the cytochrome P4501A1 gene in relationship to squamous cell lung carcinoma, persons with the susceptible genotype had a relative risk of 7.31 after adjusting for cigarette smoking history. DNA polymorphisms in the cytochrome P450 gene (CYP1A1), or aromatic hydrocarbon hydroxylase, which is responsible for the metabolic activation of benzo(a) pyrene and other polyaromatic hydrocarbons, may represent a locus of a susceptibility gene for lung cancer. Increased activity of CYP1A1 has been demonstrated in lung cancer cells when compared with normal tissue in the same patient, suggesting that dysregulation of the gene may occur in carcinogenesis. However, no association between lung cancer and CYP1A1 polymorphisms was reported in studies in Finland conducted by Hirvonen and co-workers. [154,155]

The genetically controlled ability to metabolize the antihypertensive agent debrisoquine has been linked to the risk of lung cancer. The P450 gene (CYP2D6) that regulates debrisoquine metabolism appears to influence the metabolism of nicotine to cotinine and metabolic activation of 4(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), a tobacco-specific nitrosamine, which is a potent carcinogen in experimental animals. Those who are extensive metabolizers in the hydroxylation of a 10 mg test dose of debrisoquine, a dominant trait affecting up to 90% of the United States white population, have been characterized as being at increased risk of lung cancer. Caporaso and associates [156] had initially estimated the smoking-adjusted relative risk to be increased sixfold, but more recently, studies have suggested more modest increases that are twofold or have failed to demonstrate an association using either the debrisoquine metabolic phenotype or PCR assays for detecting the genotype. [157,158]

Other biomarkers of susceptibility may include glutathione-S-transferase (GST) gene polymorphisms. Isoenzymes of glutathione-S-transferase have been identified, and the presence of the GST-μ isoenzyme is dominantly inherited. [159] Several case-control studies have suggested that subjects with deficiency of the GST-μ isoenzyme or the GSTM1 null genotype, may have a 10% to 60% increase in lung cancer risk. Some studies have also evaluated potential interactions between CYP1A1 and GSTM1 genotypes. [160] Studies in Japan have reported that subjects with the combined GSTM1 null genotype and CYP1A1 polymorphisms were at increased risk. [161]

It is now clear that human tumors result from a complex sequence of mutational events. The bronchial epithelium of sustained smokers progresses from squamous metaplasia, to dysplasia, to invasive carcinoma, which is accompanied by progressive genomic instability. Many of the genetic defects that have been described in somatic cells of lung neoplasms are acquired during adult life, and are related to exposures to environmental carcinogens. Some genetic events, however, are inherited in a Mendelian fashion. Individuals with combinations of alleles that control enzyme systems regulating activation or detoxification pathways may be at

increased risk of lung cancer when exposed to even low dose levels of tobacco smoke or other mutagens. However, the importance of these phenotypic biochemical manifestations in predicting human lung cancer risk is questionable. In a cohort study of monozygotic and dizygotic twin pairs followed in the National Academy of Sciences/National Research Council Twin Registry, it was concluded that inherited predisposition was not demonstrable in relationship to smoking-induced lung cancer diagnosed in men older than 50 years.[162] If one were to assume that 50% of lung cancer deaths before age 50 years were due to genetic predisposition, this would represent only 5% of lung cancer deaths.

GENETIC SUSCEPTIBILITY TO LUNG CANCER

ANN G. SCHWARTZ

Lung cancer has long been considered a disease determined solely by environmental exposures. It is estimated that 80% to 90% of lung cancer incidence can be attributed to cigarette smoking.[1] However, only 10% to 15% of all smokers develop lung cancer[2] and 10% to 15% of all lung cancers occur among nonsmokers. Clearly, individual differences exist in susceptibility to lung carcinogens. This chapter explores whether individual differences in susceptibility to lung cancer are inherited.

EVIDENCE SUPPORTING AN INHERITED COMPONENT TO RISK

The search for evidence supporting an inherited component for disease begins by adressing the following three questions: [3] (a) Does the disease aggregate or cluster in families? (b) Is familial aggregation related to shared environmental exposures, biologically inherited susceptibility, or cultural inheritance of risk factors? (c) What is the pattern of inheritance of genetic susceptibility? If evidence supports an inherited component of disease, then the next set of questions focuses on the localization of disease genes and mechanisms of carcinogenesis.

Familial Aggregation

Familial aggregation or clustering of a disease provides the first piece of evidence supporting the possibility of an inherited component to that disease. More than 30 years ago, Tokuhata and Lilienfeld[4] observed that the number of deaths caused by lung cancer was higher among relatives of lung cancer cases than among relatives of controls. Several other studies since then have demonstrated a familial component to lung cancer risk [5,6,7,8,9,10 and 11] (Table 21.1) (see also Chapter 20) with odds ratios (OR) associated with family history ranging from 1.3 to 7.2. These studies have used traditional case-control designs, in which familial risk is indicated by cases being more likely than controls to report a family history of lung cancer. The consistent demonstration of lung cancer aggregation in families can have several interpretations, including: (a) an inherited component to lung cancer risk; (b) environmental risk factors such as cigarette smoking shared among family members; or (c) family structure (i.e., family size and ages) differs between cases and controls affecting the risk profile of the family. To understand the reasons behind familial aggregation of lung cancer, exposure to cigarette smoke and other risk factors among relatives and the age structure of the family must be known.

TABLE 21.1. CASE-CONTROL STUDIES OF FAMILY HISTORY OF LUNG CANCER

The Causes of Familial Aggregation

Only three studies of familial aggregation of lung cancer have been done using a detailed family study approach, [12] collecting risk factor data for family members. These studies are summarized in Table 21.2. In a study of families of 270 lung cancer cases and a similar number of controls, Tokuhata and Lilienfeld[4] observed that the number of deaths caused by lung cancer was four times that expected among non-cigarette-smoking relatives of lung cancer cases and two times that expected among cigarette-smoking relatives. The effect of smoking on lung cancer risk was greater than the familial effects in males, whereas the reverse was true in females. The effect of family history was stronger among nonsmokers than among smokers. Cigarette smoking and family history interacted, resulting in very high risk of lung cancer among persons with both characteristics.

TABLE 21.2. FAMILY STUDIES OF FAMILIAL RISK OF LUNG CANCER

The second study was conducted among residents of 10 parishes in Louisiana, with families of 336 persons dying from lung cancer in a four-year period. [5] After adjusting for age, sex, smoking history, and occupational exposures for each relative, a 2.4-fold excess of lung cancer was reported among relatives of lung cancer cases as compared to relatives of spouse controls. Parents of cases had a four-fold increased risk of developing lung cancer. Relatives were also at excess risk for cancers of the nasal cavity, mid-ear, and larynx (Relative Risk [RR] = 4.6); trachea, lung, and bronchus (RR = 3.0); skin (RR = 2.8); and uterus, placenta, ovary, and

other female organs (RR = 2.1.)[13]

The third study, the author's Family Health Study in Detroit, was designed to focus on individuals likely to have risk most strongly associated with genetic factors (early-onset cases under age 45) and individuals who demonstrate increased susceptibility to low levels of exposure (nonsmoking and early-onset cases). Population-based, incident lung cancer cases were identified through the Metropolitan Detroit Cancer Surveillance System (MDCSS) of the Karmanos Cancer Institute, a participant in the National Cancer Institute's (NCI's) Surveillance, Epidemiology, and End Results (SEER) program, and population-based controls were selected through random digit dialing.[10]

Excess risk of lung cancer, after adjustment for each relative's age, sex, race, smoking status, occupation, industry, and history of other lung diseases, was limited to first-degree relatives of nonsmoking lung cancer cases 40 to 59 years of age (RR = 6.1; 95% CI 1.1–33.4)[10] and relatives of early-onset cases (RR = 2.1; 95% CI 1.2–3.7) (unpublished preliminary findings). Although not statistically significant, offspring of the nonsmoking cases had seven times the risk of lung cancer,[10] siblings of early-onset cases were at sixfold increased risk, and relatives of younger, female nonsmoking cases with adenocarcinoma of the lung were at the highest risk with a RR of 22.3.[14]

In characterizing lung cancer families in Detroit, other cancers were observed among first-degree relatives. Relatives of nonsmoking cases were 20% more likely to develop any cancer than relatives of controls (RR = 1.19; 95% CI 0.94–1.50).[15] A similar excess risk of cancer was seen for all sites excluding lung cancer (RR = 1.19, 95% CI 0.94–1.51). Risk among first-degree relatives of cases was approximately 1.4-fold or higher than that of relatives of controls for cancers of the digestive system (RR = 1.52; 95% CI 1.02–2.27), breast (RR = 1.72; 95% CI 0.90–2.22), and tobacco-related sites, including respiratory system, oral cavity and pharynx, esophagus, bladder, and kidney (RR = 1.42; 95% CI 0.93–3.18). A positive family history of lung cancer at a very early age (less than 40 years) also increased the risk of any cancer 80% (95% CI 1.2–2.7) and breast cancer 5.1-fold (95% CI 1.7–15.1)[16] after adjusting for age, race, sex, and smoking status of each relative and sex and age of the proband.

The role for inherited susceptibility of lung cancer is suggested by these findings of familial aggregation, exceeding that associated with familial clustering of smoking habits and considering family size and structure. The findings of stronger aggregation when onset of disease is early are indicative of an inherited component to risk. These studies also provide evidence that susceptibility to cancer among relatives of lung cancer cases may not be limited to cancers of the lung. The most prevalent cancers in lung cancer families include tobacco-related cancers and cancers of the digestive tract and breast.

Patterns of Inheritance

These case-control family-based studies add to the evidence supporting an inherited susceptibility to lung cancer but do not explicitly address genetic models, which may underlie familial aggregation. The third question to be addressed, given familial aggregation of lung cancer, is what is the pattern of inheritance of genetic susceptibility? The Louisiana study and the nonsmoking portion of the Detroit study, both described previously, are the only two studies that have addressed this question (Table 21.3). Segregation analysis was used to determine if the pattern of disease occurrence in relatives is consistent with Mendelian dominant, codominant, or recessive inheritance of a major gene, transmission of environmental factors, or is sporadic, after considering the age, sex, and environmental exposures among family members.

Author	Study Population	Mode of Inheritance	Risk Allele Frequency
Louisiana			
Sellers et al., 1990[17]	337 population-based families	Mendelian codominant	q(A) = 0.052
Sellers et al., 1992[18]	106 population-based families of cases < age 60	Mendelian codominant	q(A) = 0.062
	231 population-based families of cases ≥ age 60	Mendelian inheritance, mode of transmission not distinguished	
Metropolitan Detroit			
Yang et al., 1997[20]	257 population-based families of nonsmoking cases	Environmental model	
Yang et al., 1999[21]	47 population-based families of nonsmoking cases age 40-59	Mendelian codominant	q(A) = 0.004
	210 population-based families of nonsmoking cases age 60-84	Environmental model	

TABLE 21.3. SEGREGATION STUDIES OF MODE OF INHERITANCE OF LUNG CANCER IN FAMILIES

In the Louisiana study, the pattern of lung cancer occurrence in families of persons dying from lung cancer was consistent with Mendelian codominant inheritance of a rare autosomal gene with variable age at onset.[17] This putative gene is estimated to be responsible for 69% of the lung cancer at age 50, 47% at age 60, and 22% at age 70. Heterogeneity in inheritance patterns based on age at death of the lung cancer proband was also noted.[18] In the subset of families of probands dying before age 60, the model predicts that virtually all lung cancer occurs among cigarette-smoking gene carriers. Aggregation of smoking-associated cancers (i.e., lung, oral cavity, esophagus, nasopharynx, larynx, cervix, bladder, kidney, and pancreas) in case families was also consistent with Mendelian inheritance.[19]

In the Detroit study of families of nonsmoking lung cancer cases, complex segregation analysis performed for the entire sample of 257 nonsmoking cases and their 2,219 family members, found an environmental model with homogeneous risk across generations best explained the observed data.[20] Both the hypothesis that lung cancer occurrence was sporadic and the hypothesis that a genetic predisposition accounts for the familial aggregation were rejected.

To further investigate heterogeneity by age of the proband, the segregation analysis was repeated, stratified by age of the proband.[21] A Mendelian codominant model, with significant modifying effects of smoking and chronic bronchitis, best explained the observed data in the families of 47 nonsmoking probands 40 to 59 years of age. The estimated risk allele frequency was 0.004. Homozygous individuals with the risk allele are rare in the study population (1.6/100,000), making the attributable risk very low, even considering very high penetrance of early-onset lung cancer (85% in males and 74% in females by age 60). Heterozygous individuals constitute 1% of the study population and have a relatively low risk of lung cancer unless they are smokers with chronic bronchitis. Those homozygous for the low-risk allele were estimated to be at 6% and 2% risk of lung cancer in males and females, respectively, by age 80 if they smoked and had a history of chronic bronchitis. These findings point to a high-risk gene contributing to early-onset lung cancer. The attributable risk associated with the high-risk allele declines with age because the role of tobacco smoking and chronic bronchitis become more important. No evidence suggested a major gene segregating in families of nonsmoking cases age 60 to 84 years.

GENES FOR LUNG CANCER

Consistent evidence suggests that lung cancer aggregates in families, that aggregation is not completely accounted for by clustering of environmental risk factors or family structure, and that the pattern of cancer occurrence in some families is consistent with Mendellan inheritance of a rare major gene, particularly when onset is early. The studies of familial risk described (a) support the existence of a single gene for lung cancer acting in a subset of families, with penetrance modified by environmental exposures, and (b) are consistent with common susceptibility genes acting to moderately increase cancer risk. Single genes and susceptibility genes are distinguished from one another based on several characteristics.[22] Single genes are necessary and sufficient to cause disease, are rare in the population, and are associated with strong familial aggregation and large relative risks, with onset of disease at an early age. Examples of single gene/cancer associations include *RE* and retinoblastoma[23] and *BRCA1* and breast cancer.[24] Susceptibility genes are neither necessary nor sufficient for disease occurrence, are often common (gene frequencies greater than 1%), and are associated with moderate familial aggregation. Common susceptibility genes, at frequencies of greater than 0.20, occur so often in the population that distinct familial aggregation may not be observed.[25]

Single Genes for Lung Cancer

A single gene for lung cancer has not yet been identified. Lung cancer has been shown to occur, on occasion, in Li-Fraumeni families, associated with inherited p53 mutations.[26] Although some lung cancer families may carry a mutated p53 gene, and breast cancer has been seen in conjunction with lung cancer, an excess of

childhood cancers has not been noted, suggesting that inherited p53 mutations do not account for all the observed aggregation.

A genome-wide search for a lung cancer gene can proceed along two paths: linkage studies and relative-pair based studies. [27] Genetic linkage studies aim to localize a disease gene to a chromosomal region by identifying cosegregation of a marker gene and a putative disease gene in families more often than expected. Linkage studies require the accrual of large, multigeneration pedigrees with multiple affected family members and knowledge of the mode of disease transmission. This strategy is powerful when genetic loci are highly penetrant, but power decreases when susceptibility alleles become more common and less penetrant. [26] Relative-pair based methods are also used to detect linkage by demonstrating that affected relatives inherit an identical chromosomal region more often than expected by chance. This approach does not require specification of a mode of inheritance or the collection of large pedigrees, but it may be less powerful than a correctly specified linkage model. The difficulties in pursuing either of these approaches with lung cancer are that lung cancer families are rare, with cases having two or more first-degree relatives affected occurring in only 1% of the population, onset is usually in the mid to late 60s, and because of the high case fatality for lung cancer, affected relatives are typically deceased, requiring the used of fixed tissue for genotyping. Because of the large environmental component to risk, smoking data must be collected on all family members, many of whom may also be deceased.

The Genetic Epidemiology of Lung Cancer Consortium (GELCC) was formed in 1996 and recently funded by the NCI to conduct the first multicenter linkage study to identify a gene for lung cancer. Participating centers include the University of Cincinnati College of Medicine, Karmanos Cancer Institute/Wayne State University School of Medicine, Johns Hopkins University, MD Anderson Cancer Center, University of Texas Southwestern Medical Center, Medical College of Ohio, University of Colorado Health Sciences Center, and the National Human Genetics Research Institute. The GELCC plans to identify high-risk lung cancer families, to genotype informative family members using 400 markers evenly spaced throughout the genome, and to map a gene for lung cancer using genetic linkage analysis.

Susceptibility Genes for Lung Cancer

The existence of common susceptibility genes for lung cancer is also supported by findings of moderate familial aggregation. Candidate susceptibility genes include those associated with carcinogen metabolism, DNA repair, and alpha-1-antitrypsin.

Metabolic Enzyme Polymorphisms

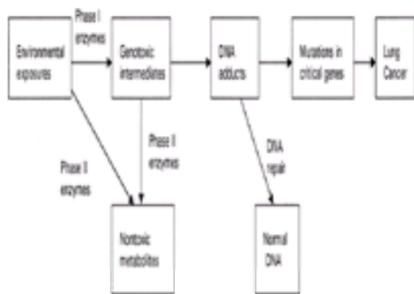
Several genetically determined polymorphisms in the microsomal mixed-function oxidases (cytochrome P450s/phase I) and phase II enzymes have been studied. Phase I enzymes metabolically activate procarcinogens to genotoxic electrophilic intermediates that can bind DNA (Figure 21.1). DNA adducts, if not repaired or removed, can lead to mutations within oncogenes or tumor-suppressor genes initiating the carcinogenic process. Phase II enzymes detoxify genotoxic intermediates by conjugation, forming water-soluble compounds that are excreted by the cell (Figure 21.1). Individual differences in susceptibility to carcinogens are thought to result from the balance between the formation of genotoxic intermediates and detoxification. Individuals who rapidly move through phase I metabolism and are deficient in phase II metabolism, resulting in the accumulation of genotoxic intermediates, are presumed to be at increased risk of lung cancer.


FIGURE 21.1. The role of phase I and phase II enzymes and DNA repair in lung carcinogenesis.

The most widely studied polymorphic loci coding for enzymes involved in the activation and conjugation of tobacco smoke constituents are the cytochrome P450, phase I enzymes CYP1A1, CYP2E1, and the phase II glutathione S-transferases (GSTM1, GSTT1, GSTP1), and N-acetyltransferases (NAT2). Although only limited evidence indicates that CYP2D6 is involved in the metabolism of carcinogens in tobacco smoke, polymorphisms at this locus have also been studies in relation to lung cancer. [29] Several reviews of the associations among these genetic polymorphisms and lung cancer risk have been published, and only a brief overview will be given. [29,30,31 and 32]

Evidence for an association between *CYP1A1* polymorphisms and risk of lung cancer has come primarily from studies in Japanese populations with risks increased more than two-fold [33] and more recently in a population in Hawaii, which included Caucasians, Japanese, and Hawaiians. [34] Risk associated with *CYP1A1* genotype has not been detected in studies of populations in Brazil. [35] Norway,[36] Finland,[37] or the United States.[38] Frequencies of variant alleles differ markedly by ethnicity, with higher frequencies in the Japanese population. Studies in populations with lower frequencies of variant alleles may be underpowered to detect risk differences.

A recent metaanalysis of studies of *CYP2D6* polymorphisms and lung cancer concludes that individuals characterized as poor metabolizers, either by phenotype or genotype, are at reduced risk of lung cancer (odds ratio (OR) = 0.69; 95% CI 0.52–0.90). [39] Expressed in terms of risk associated with extensive metabolism, extensive metabolizers are at 1.4-fold increased risk of developing lung cancer. Two other reviews have estimated that lung cancer risk associated with extensive metabolism is increased 2.3-fold (95% CI 1.6–3.4) [40] or not increased at all (OR = 1.05; 95% CI 0.75–1.47). [41] Bouchardy et al.[42] demonstrated that increased lung cancer risk was only associated with *CYP2D6* phenotype in heavy smokers. Variations by smoking status may explain some of the conflicting findings.

Variants of *CYP2E1* have not been associated with increased risk of lung cancer in Japan, [43] Brazil,[35] or Finland.[37] A recent study in Hawaii reported a 10-fold decrease in risk of lung cancer in individuals homozygous for the variant alleles. [34]

Glutathione S-transferases, examples of phase II enzymes, occur in several classes. *GSTM1* occurs in the null form in approximately 50% of the population. The most recent metaanalysis estimates an overall OR of 1.13 (95% CI 1.04–1.25), suggesting modest increased risk associated with the *GSTM1* null genotype.[44] An earlier review provides a slightly larger OR of 1.41 (95% CI 1.23–1.61), concluding that *GSTM1* deficiency accounts for approximately 17% of all lung cancer cases. [45] Polymorphisms in *GSTT1*[46] and *GSTP1* have not been as well studied. Individuals carrying the null *GSTT1* genotype have not been shown to be at increased risk of lung cancer unless also carrying the *GSTM1* null genotype.[47,48] In two studies, the *GSTP1* low-activity allele has been associated with an approximately twofold increased risk.[49,50]

Only a few studies have been conducted of *NAT2* genotype and lung cancer risk; two studies have had negative findings. [51,52] Cascorbi et al.[53] found a 2.4-fold (95% CI 1.05–5.32) excess risk when *NAT2*4/*4,* was overexpressed yielding fast acetylation. One study found increased risk for slow acetylators among never smokers but an increased risk for rapid acetylators among smokers.[54] The dual role of *NAT2* in both activation and deactivation of arylamines complicate these studies.

The results from several of these studies suggest that the effects of a metabolic enzyme phenotype or genotype may be more evident at low levels of exposure to carcinogens.[35,55,56] At high exposure levels, saturation of enzyme activity may occur among both rapid and slow metabolizers. [57] This activity may not occur among those individuals with lower exposures, so the effects of genotype are more likely to be evident.

The identification of nonsmoking and early-onset lung cancer cases may serve to characterize families with altered metabolism of carcinogens and increased susceptibility. In the author's Detroit study, preliminary analyses of the polymorphisms in *CYP1A1, CYP2E1,* and *CYP1B1* have been conducted. Among nonsmokers, individuals carrying at least one copy of the exon 7 Val allele in *CYP1A1* were at twofold increased risk of developing lung cancer (95% CI 0.6–6.6) after adjusting for age, race, sex, and environmental tobacco smoke exposure.[58] When the analysis was limited to nonsmokers with passive smoke exposure, the OR was somewhat

higher, 2.3 (95% CI 0.7–8.1). Excess risk associated with the *CYP1A1* variant allele was highest among nonsmokers under age 60 (OR = 3.6; 95% CI 0.7–19.7). Although these findings are not statistically significant, they suggest that the *CYP1A1* exon 7 polymorphism may contribute to risk of early-onset lung cancer among nonsmokers. No increased risk of lung cancer was associated with the *CYP2E1* Rsal polymorphism in nonsmokers (OR = 0.69; 95% CI 0.08–6.29). These analyses are continuing, and the larger sample sizes, with the associated increase in power, will allow for a more complete evaluation and exploration of gene-environment and gene-gene interactions.

Cytochrome P4501B1 is a newly identified enzyme that activates polycyclic aromatic hydrocarbons (PAHs) (see also Chapter 3), several aryl amines, and heterocyclic amines to genotoxic metabolites[59,60] and is present in the lung. A polymorphism in the gene coding for this enzyme, a C-to-G transversion in exon 3, results in an amino acid change from Leu-432 to Val.[61,62] In preliminary analysis, nonsmokers in the Detroit study carrying the Val/Val genotype have been shown to be at five times higher risk of lung cancer than nonsmokers carrying either the Leu/Leu or Leu/Val genotype (95% CI 2.4–14.9)(63). Sixty-four percent of these cases reported exposure to environmental tobacco smoke. A statistically insignificant twofold increased risk of early-onset lung cancer was associated with the Val/Val genotype. Eighty percent of the early-onset cases were smokers. This is the only study to date to investigate the relationship between *CYP1B1* and lung cancer risk. These data suggest that when exposure is low, the contribution of low-penetrant susceptibility genes may be revealed.

In general, studies of metabolic enzyme polymorphisms have yielded conflicting results. Conclusions from these studies have been limited by the low frequency of some polymorphisms in the population, variability in allele frequencies by ethnicity, the potential for heterogeneity by histologic type of lung cancer, and variation in risk associated with level of exposure to tobacco smoke. One genotype is unlikely to have a strong effect on risk and interactions between *CYP1A1* and *GSTM1*,[64,65] and *GSTM1* and *GSTT1*[47,48] have been reported. To fully evaluate the role of these polymorphisms in lung cancer risk, alterations at several loci, gene-gene interactions, and gene-environment interactions must be considered, necessitating extremely large, well-designed studies.

Mutagen Sensitivity and DNA Repair Capacity

Individual variability in DNA repair capacity may contribute to inherited susceptibility to lung cancer, with individuals who are unable to repair DNA damage, or do so at a slower rate, accumulating mutations that may modulate risk (Figure 21.1). The mutagen sensitivity assay measures chromatid breaks in cultured lymphocytes after exposure to bleomycin[66] or BPDE (Benzo[a]pyrene Diol Epoxide)[67] as an indirect measure of DNA excision repair effectiveness. The extent of genetic damage in lymphocytes is thought to reflect damage in target tissues.[68] Increased numbers of bleomycin or BPDE-induced breaks have been associated with a 4.3- and 7.3-fold increased risk of lung cancer, respectively.[69] As has been shown for some metabolic enzyme polymorphisms, risk of lung cancer associated with mutagen sensitivity in nonsmokers and light smokers was higher than that seen for smokers and higher in younger as compared to older individuals. These findings suggest that those who are mutagen sensitive may be susceptible at earlier ages and at lower exposures than individuals with fewer mutagen-induced breaks.

Mutagen sensitivity has been shown to correlate with DNA repair capacity.[70] In a pilot study of 51 lung cancer patients and 56 controls, DNA repair capacity was measured using the host-cell reactivation assay.[71] Cases were more likely to have reduced DNA repair capacity (OR = 5.7; 95% CI 2.1–15.7) after adjustment for age, sex, ethnicity, and smoking status. Amino acid substitution variants have been identified in several DNA repair genes (i.e., ERCC1, XPD, XPF, XRCC3, and XRCCI), and studies of these polymorphisms and risk of lung cancer are warranted.[72]

a-1-Antitrypsin

a-1-Antitrypsin is an inhibitor of serine proteinases, protecting the lower respiratory system from damage by neutrophil elastase. A deficiency in this enzyme, associated with the P_i S or Z alleles, increases risk of emphysema.[73] Chronic obstructive pulmonary disease (COPD) and lung cancer share risk factors, can both be familial, and the presence of a history of COPD increases risk of lung cancer (See also Chapter 20, Chapter 22),[74,75 and 76] suggesting that a-1-antitrypsin might also be important in the development of lung cancer, especially in those individuals with low levels of exposure to tobacco smoke. In a recent study, the frequency of a-1-antitrypsin deficiency (a1AD) in a hospital-based series of lung cancer patients was compared to published a1AD frequencies of 7%.[77] Overall, lung cancer patients had a higher a1AD frequency (12.3%). The 34 nonsmoking lung cancer cases in the study had an a1AD rate of 20.6%. This study was unable to adjust for ethnicity, tobacco exposure, or other potential confounders, such as COPD, because it lacked a control group.

In preliminary analyses of the Detroit data for nonsmokers, individuals carrying either the P_i S or Z alleles were at 2.6-fold increased risk of lung cancer (95% CI 0.7–9.1).[78] The carrier frequency was 15.6% in the nonsmoking cases and 5.8% in nonsmoking controls. In nonsmokers under age 60 years, the OR was 13.8 (95% CI 1.4–137), whereas in nonsmokers 60 years of age or older the OR was 1.7 (95% CI 0.3–8.3) after adjustment for age, sex, race, and environmental tobacco smoke exposure. These analyses need to be completed for the entire data set, but the findings suggest that a1AD may be associated with earlier onset lung cancer among nonsmokers.

Results from case-control studies of polymorphic loci and cancer risk must be interpreted with caution. If disease incidence and allele frequencies vary by ethnicity, spurious results might arise.[75] Proper selection of control populations and stratification by ethnicity in the analysis are essential. It should be emphasized that there is likely to be tremendous heterogeneity in lung cancer cause, and the role of lung cancer susceptibility genes should not be underestimated. These genes may be of high frequency and associated with a substantial attributable risk in the population, even when the relative risk of lung cancer is increased only moderately. Large numbers of nonsmoking and early-onset lung cancer patients have not been studied at these candidate loci, and these subgroups may provide the most insight. African Americans and females have also been under-represented, even though, in younger age groups, the incidence of lung cancer among African Americans is higher than in whites, and women have rates comparable to men. The inclusion of multiple polymorphic loci studied within the same population will allow for the study of gene-gene interactions.

SUMMARY

Substantial evidence supports an inherited component to lung cancer. Familial aggregation has been demonstrated, and contributions by a major gene for lung cancer have been suggested. Although a single gene for lung cancer has not yet been identified, several susceptibility genes have been associated with moderately increased risk. Future studies need to consider a wide range of design strategies, including (a) family-based studies with the collection of family history beyond first-degree relatives to further evaluated modes of inheritance and heterogeneity by age at diagnosis; (b) large population-based studies of candidate susceptibility genes and gene-gene and gene-environment interactions; and (c) linkage studies with genome-wide searches for single genes to more fully understand the role of inherited susceptibility in lung cancer. Lung cancer is one of the major cancers, for which only minimal progress has been made in early detection and treatment. Because it is the leading cause of death from cancer, it is exceedingly important to identify high-risk populations. Once high-risk individuals with a genetic predisposition can be identified, they can be targeted for early education, access to developing screening methods, and close medical follow-up.

EARLY DIAGNOSIS AND INTERVENTION IN LUNG CANCER: CLINICAL STUDIES

THOMAS L. PETTY
YORK E. MILLER

Lung cancer is the most common fatal malignancy in both men and women in the United States. In 1999, an estimated 171,600 patients will be diagnosed. Because the diagnosis is most commonly made in later stages, including presentations that manifest as distant metastasis, approximately 158,900 deaths will occur in 1999, if the current survival statistics continue. Today, lung cancer is the third most common cause of death in the world. Worldwide, lung cancer was responsible for more than 900,000 deaths in 1990.[1]

Studies examining the efficacy of screening for lung cancer carried out in the 1970s and 1980s have led to a nihilistic attitude regarding the early diagnosis of lung cancer. Easily obtained clinical indices that can be used to identify individuals at high risk for the development of lung cancer were not appreciated at the time of design of the large screening trials. Unfortunately, these trials were carried out in populations that are not at greatly increased risk for lung cancer and may have yielded falsely discouraging results. The purpose of this chapter is to present an approach to early identification and intervention that could dramatically alter the course and outcome of lung cancer today.

HISTORICAL PERSPECTIVE

The association between chronic lung disease and lung cancer was recognized more than 40 years ago (see also Chapter 20). Advanced emphysema, chronic bronchitis, and chronic tuberculosis antedated the diagnosis of lung cancer in 45 of 86 patients over a 10-year period. More than 90% of these 86 patients had a chronic cough prior to the diagnosis of lung cancer. Ironically, in that era, chest x-rays and sputum cytology screening for lung cancer were advised.[2,3] Later, it was again emphasized that lung cancer commonly accompanied chronic lung diseases such as chronic bronchitis.[4]

On December 4, 1951, the Philadelphia Neoplasm Research Project was initiated to study the natural history of bronchogenic carcinoma in a population of older men by semiannual chest mini photofluorograms and a symptom questionnaire. By December 1965, the project was completed. In all, 6,137 male smokers were enrolled. One hundred fifty-six histologically confirmed lung cancers had been identified; 66 on enrollment and 90 after enrollment.[5] Upon completion of this study, The Philadelphia Neoplasm Research Project concluded that early diagnosis of lung cancer was impractical and did not result in reduced mortality.

In the mid-1970s, the National Cancer Institute (NCI) funded three studies, which were conducted at the Johns Hopkins Medical School,[6] the Memorial Sloan-Kettering Cancer Center,[7] and the Mayo Clinic.[8] These studies enrolled men in a screening program using serial chest x-rays and sputum cytologic studies. At the end of these studies, it was again concluded that screening for lung cancer does not reduce mortality from lung cancer. A study of men at high risk in Czechoslovakia also concluded a lack of benefit from semiannual screening.[9]

With the benefit of hindsight, it is now clear that serious deficiencies existed in the design of these studies. All sought to study high-risk smokers, but the association of airflow obstruction with susceptibility to lung cancer was not widely appreciated at the time of design of these studies and was therefore not exploited to define a high-risk group. The entrance criteria for tobacco use were not high enough to guarantee a high risk for lung cancer (only one pack-year of smoking was required before entry in some cases). Women, who are now believed to be of higher susceptibility than men to lung cancer, were not included.

An important shortcoming was that it was believed to be unethical to have an unscreened control population, so none of the studies carried out in the United States had an unscreened control group. The Memorial Sloan-Kettering and Johns Hopkins studies compared yearly with more intensive screening regimens, and the Mayo study compared screening every three months with a recommendation to have yearly screening. It was hoped that the control group (recommended to have yearly screening), would contain a sizable subgroup that did not comply with this recommendation, but this subgroup was not as large as hoped. It is important to appreciate that at the time these studies were conducted, the yearly chest radiograph was a standard component of health care. In summary, the current practice of not performing any studies on high-risk smokers or ex-smokers with airflow obstruction, sputum production, or additional exposures to carcinogens such as asbestos or radon daughters has not been shown to be equally efficacious as screening; the question has not been studied.

The results of the Mayo Clinic study have now been revisited.[8] Strauss has concluded that, in fact, early identification did result in improved survival in patients found with early stages of disease. Perhaps the Johns Hopkins study is even more revealing because it showed that many cases of lung cancer that were missed might have been diagnosed using more modern techniques applied to libraried sputum cytology specimens.[11]

The NCI studies resulted in a shift of diagnosis to more early stages of disease, and meaningful improvements were made in resectability, survival, and fatality of lung cancer. Although overall mortality was not improved by screening, these studies did demonstrate higher 5-year survival rates than expected. Nonetheless, the current dogma is that screening for lung cancer is not worthwhile, and it is not recommended for even large populations of high-risk smokers.[12]

THE ASSOCIATION BETWEEN CHRONIC AIRFLOW OBSTRUCTION AND LUNG CANCER

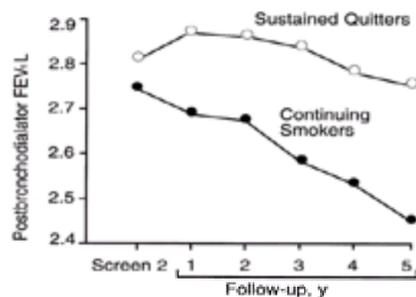
The strong association between the presence of airflow obstruction and lung cancer has been known for more than two decades.[13,14] More recent studies have strengthened this association.[15,16] An interesting observation of the Lung Health Study sheds additional light on this relationship. In a sample of middle-aged men and women, over the age of 35, but not yet 60, with only mild degrees of airflow obstruction and with the requirement of smoking at least a pack a day for 10 years (i.e., 10 pack-years), 5,887 patients were followed for 5 years.[17] The main objective of this study was to learn the impact of intervention via smoking cessation and the use of a bronchodilating anticholinergic aerosol on the rate of decline of ventilatory function. In brief, those patients (approximately 22%) who were sustained quitters throughout the 5-year follow-up had a slight improvement in lung function, followed by only a minor decline (Figure 22.1). At the end of 5 years, ventilatory function as judged by FEV was only slightly below the mean FEV, levels at enrollment. By contrast, those patients who continued to smoke had much more rapid rates of decline. One of the most interesting features of this study was the cause of death, presented in Table 22.1. Fifty-seven, or 1%, had died of lung cancer by the end of 5 years. At this writing, another group of patients have emerged with lung cancer in a late follow-up. Now, more than 100 (i.e., approximately 2%), have either died or developed lung cancer. One would have expected that heart attack or stroke might be the most common cause of mortality, but this was not the case, (n = 37). Thus 20 more lung cancer deaths than heart attack and stroke deaths were reported during the follow-up. Unfortunately, no chest x-rays were done during the Lung Health Study to learn whether or not lung cancer was present at the time of enrollment. One can conclude from all of these studies linking airflow obstruction to lung cancer that the increased risk is approximately four- to six-fold, compared to when no airflow obstruction is present, with all other factors including smoking history, occupational exposures, age, sex, and family history taken into consideration.


FIGURE 22.1. Mean postbronchodilator forced expiratory volume at 1 second (FEV1) for participants in the smoking intervention and placebo group who were sustained quitters (¡) and continuing smokers (l). The two curves diverge sharply after baseline. (From Anthonisen NR, Connett JE, Kiley JP, et al. Effects of smoking intervention and the use of an inhaled anticholinergic bronchodilator on the rate of decline in FEV $_1$. The Lung Health Study. *JAMA* 1994;272:1,497, with permission.)

Cause	Special Intervention	Usual Care	Total
Lung cancer	38	19	57
Cardiovascular disease	25	12	37
Other	35	20	55
Total	98	51	149

* Randomization 2:1 special intervention to usual care.

TABLE 22.1. THE LUNG HEALTH STUDY: DEATHS WITHIN FIVE YEARS*

The new wave of enthusiasm for lung volume reduction surgery has also demonstrated the strong association between advanced emphysema and lung cancer. [18] In resected tissues, 6.4% had cancer, of which several were identified only by pathologic examination. Survival at short-term follow-up was excellent. [18]

RISK FACTORS

By far, the most powerful risk factor in lung cancer is smoking. Approximately 1 in 10 smokers develop bronchogenic carcinoma over a lifetime. [19] Although no safe level of smoking exists, historical tradition has offered the notion that smoking a pack a day for 20 years (i.e., 20 pack-years) or more indicates the populations at highest risk. In general, the year that one starts to smoke and the intensity of smoking over a lifetime magnifies the smoking-related risk. [20] Passive smoking is also an established risk factor for lung cancer. [21]

Certain occupations, such as asbestos mining, those involving asbestos dust exposure, and uranium mining, along with exposure to arsenic, nickel, acrylonitrile, chromium, beryllium, cadmium, chloromethyl ether solvents, and possibly silica, are known occupational risks. [22] Diesel exhaust is considered a risk factor and may explain the increase risk of lung cancer among different types of professional drivers in Denmark. [23] Family history is a definite risk factor, as it is for many organ-associated carcinomas.[24] Consumption of a diet low in fruits and vegetables (possibly because of antioxidant content), may magnify risk. [25] HIV infection may result in lung cancer occurring at a young age, often occurring after a less intense exposure to tobacco than in patients who are not HIV-infected. [26]

IDENTIFICATION OF ROENTGENOGRAPHICALLY OCCULT LUNG CANCER

Chest X-rays

Although the chest x-ray is the time-tested method of identifying lung cancer, a reassessment of the outcome of the screening studies has offered renewed hope that case finding with x-rays or screening in high-risk populations may be beneficial. The course and prognosis of cancer so identified has led to only a modest improvement in overall cancer mortality.[27] This sad reality has called for new approaches to the identification of early lung cancer. [27]

Sputum Cytology

Many years ago, Saccomanno perfected and championed the use of Papanicolaou staining of exfoliated bronchial epithelial cells to identify roentgenographically occult lung cancer. Saccomanno and others studied the evolution and development of progressive stages of dysplasia (mild, moderate, and severe) as a prelude to carcinoma *in situ* and invasive carcinoma.[28,29 and 30] Squamous carcinomas tend to be central and exfoliate early. By contrast, adenocarcinomas, which are peripheral, do not exfoliate quite as readily. Peripheral adenocarcinomas may be more readily identified by newer imaging techniques (see following section). Sputum cytology has been considered the first step in the diagnosis of suspicious pulmonary shadows and nodules, and is less expensive in identifying the presence of malignancy, by far, than fiberoptic bronchoscopy, which is the gold standard for diagnosis today. Bronchoscopic procedures, of course, are appropriate for further confirmation of the histologic type of malignancy and staging. Newer fluorescence-intensified bronchoscopy increases the diagnostic yield in tiny tumors that are difficult to visualize by standard white light bronchoscopy. Sputum cytology is a logical first step in identifying malignancy, which could be further evaluated by invasive techniques.

RESULTS OF SCREENING FOR EARLY LUNG CANCER

Although early-stage lung cancers clearly have a better prognosis than more advanced stage tumors, this outcome may be partly a reflection of innate tumor biology. In other words, the more indolent tumors may spend more time in early-stage disease than do more aggressive tumors. Intensive screening efforts would then be expected to discover biologically more aggressive tumors at an apparently early stage, and stage-specific survival would then decrease. Several reports of outcomes from relatively small series in which an effort to diagnose early-stage lung cancer was made demonstrate excellent survival, which would not be the case if screening were ineffective for this reason.

United States

Pulmonologists working in a modest-sized rural community hospital in western Colorado (St. Mary's in Grand Junction) sought to identify cancer based on clinical clues or other risk factors. In this community, 51 consecutive patients with roentgenographically occult lung cancer were identified. [31] Forty-three men and eight women were identified between the ages of 46 and 81 (mean age 64.2); all but two were smokers. Whether or not environmental tobacco smoke could have played a role in the two nonsmokers is not known. Thirty-nine of these patients were smokers with symptoms of cough, increasing dyspnea, family history, or an x-ray lesion that appeared to be a healed scar. Patients with hemoptysis were not included in this series because hemoptysis is a known sentinel sign and symptom for lung cancer. Twelve cancer patients were screened based on occupational risks, with eleven having had significant uranium mining experience at a time when uranium was mined on the Colorado plateau. One was an asbestos worker.

In this study, sputum cytology revealed either carcinoma *in situ* or invasive carcinoma in some of the patients. Establishing the source of these abnormal cytologic

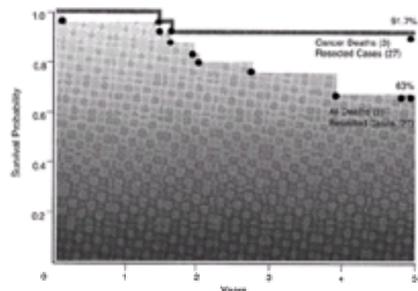
findings by fiberoptic bronchoscopy was the next step. Thirty-one cancers (61%) were found on the first biopsy. Additional biopsies were required for confirmation of cancer, with two bronchoscopies required in eight cases (17%), three in another eight cases (17%), and more than three in three patients. Thus the knowledge of lung cancer, as demonstrated by sputum cytology, urged the physicians in their bronchoscopic approaches to confirmation, preparatory to surgery or other therapies. In this series, 86% were squamous carcinomas, 6% were adenocarcinomas, 4% were large cell carcinoma, and 4% were undifferentiated carcinoma. This histologic destruction reflected the fact that squamous carcinomas are central and tend to exfoliate early. As revealed in the study, sputum cytology does not identify all patients with adenocarcinoma. The cancer stage was *in situ* in 7 (14%), stage I in 38 (74%), and stage II or stage II-A in 2 (4%). Thus only four (8%) patients were at a stage precluding a surgical cure. Twenty-seven of the patients received curative surgical therapy. Their outcome is presented in Figure 22.2. Only three patients had died of cancer at 5 years. Total mortality was only nine patients. Nineteen additional patients were candidates for ablative radiation therapy. Taken together, both surgical and radiation treatments resulted in a much better lung cancer survival rate, with only 9 deaths at 5 years, and total mortality of 21 deaths in 5 years (Figure 22.3). This result is far better than in cancers identified either accidentally or on the basis of symptoms, where the overall cancer mortality rate is approximately 85% at 5 years.


FIGURE 22.2. Survival predictions based on actuarial experience of the 27 patients who received resectional surgery for cure (Kaplan-Meier life table method). Both cancer deaths and deaths from all causes are listed. Circles indicate time of death. Vertical lines indicate survival at the time of original report. (From Bechtel JJ, Kelley WR, Petty TL, et al. Outcome of 51 patients with roentgenographically occult lung cancer detected by sputum cytologic testing: a community hospital program. *Arch Intern Med* 1994;154:975, with permission.)
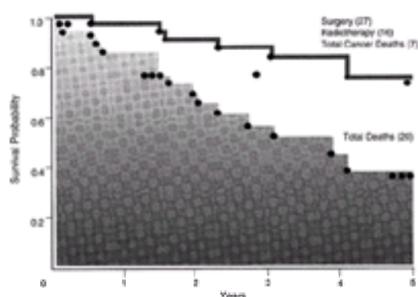

FIGURE 22.3. Actual survival in all 46 patients who received treatment with expectation of cure (27 surgery and 19 by radiation; Kaplan-Meier life table method). Both cancer deaths and deaths from all causes are included. Circles indicate time of death. Vertical lines indicate survival observation at the time of original report. (From Bechtel JJ, Kelley WR, Petty TL, et al. Outcome of 51 patients with roentgenographically occult lung cancer detected by sputum cytologic testing: a community hospital program. *Arch Intern Med* 1994;154:975, with permission.)

Japan

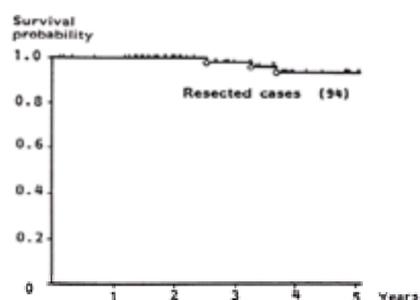
The results of surgical treatment for roentgenographically occult bronchogenic squamous cell carcinomas has also been reported to be excellent. [32] Ninety-four such patients received surgical resection. The survival over 5 years is presented in Figure 22.4 and Figure 22.5. A total of seven patients with a subsequent primary cancer had surgical resection with no recurrence after the second operation. Two deaths from lung cancer occurred. These favorable results included an 80.4% survival rate at 5 years, including deaths from all causes, and a 93.5% survival rate considering only lung cancer deaths. Although subsequent primary cancers remained a challenge, the reliability of sputum cytology to identify the presence of roentgenographically occult lung cancer was exceedingly good. [32]


FIGURE 22.4. Survival probability of patients with resected roentgenographically occult bronchogenic SCC (time of death from lung cancer).

Scandinavia

The long-term survival of patients with lung cancer from a defined geographic area in Sweden, before and after radiologic screening, showed a much better survival with carcinoma identified with semiannual screening, compared to when it was identified following symptoms.[33] Combined survival at 4 years was 41.7%, compared to 10.3% for those discovered by symptoms (P < 0.001). Thus it seems certain that the early identification of lung cancer, either roentgenographically or by sputum cytology, will identify patients with early-stage carcinoma who are suitable for curative therapy, either by surgery or by radiation therapy.

A PRAGMATIC APPROACH TO SCREENING IN HIGH-RISK POPULATIONS

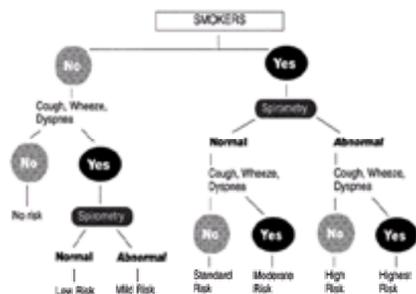
Because heavy smokers (i.e., those with airflow obstruction) and symptomatic patients are most apt to develop lung cancer, a systematic approach to stratified screening has been proposed.[34] This approach has resulted in the development of two simple algorithms, by which it was proposed that a high yield of lung cancer could be obtained in a targeted population (Figure 22.6 and Figure 22.7). That this approach can result in a relatively high yield of occult lung cancer was shown in a study of 613 patients, where sputum cytology was obtained at home, with mall-in specimen containers.[35] Five carcinomas *in situ* and six invasive carcinomas, both squamous and adenocarcinoma, were identified (Table 22.2). Three patients with severe atypia can also be considered to have pre- or early-stage carcinoma. Thus the yield in smokers of 30 pack-years or more with airflow obstruction is well above the yield of other screening tests for lethal malignancies such as breast cancer, where the overall yield is approximately 0.23% in women age 50 to 54 to 0.48% in women 75 to 79 years.[36] Interestingly, four more carcinomas have already been identified in the group with only moderate atypia. At this writing, the entire cohort is being followed to identify the final yield that will occur in the targeted population of heavy smokers with associated airflow obstruction.


FIGURE 22.6. Algorithm to assist in the determination of level of risk of lung cancer of smokers versus non-smokers. Assumes no additional risk; for example, asbestos exposure, uranium mining, chloro methyl ethyl ether exposure, or family history of lung cancer.

FIGURE 22.7. Practical diagnostic approach to lung cancer.

Dysplasia Grade	Number	Percentage
None	72	12.0%
Regular metaplasia	63	11.0%
Mild atypia	309	50.0%
Moderate atypia	155	25.0%
Severe atypia	3	.2%
Carcinoma in situ	5	1.8%
Invasive carcinoma	6	
Total	613

TABLE 22.2. RESULTS OF SPUTUM CYTOLOGY IN HIGH-RISK PATIENTS

Peripheral lung cancers, which are most often adenocarcinomas, can be readily identified by spiral CT scans, which can be completed in 15 seconds with a single breath hold. The dose of irradiation is similar to that associated with mammography. Screening trials for lung cancer utilizing low-dose spiral CT scans are currently underway.[37],[38] Recently, a new mobile CT scanner unit has been used in a population-based study that involved mass screening for lung cancer in Japan.[38] Five thousand, four hundred eighty-three people between 40 and 74 years old volunteered. This program was promoted by public announcements by local governments and by leaflets. For comparison, two control groups, from the annual general health survey (n = 10,966), were matched by sex and age within 2 years, and included the smoking habits for smokers of at least 30 pack-years. Of the 5,483 participants, 3,967 underwent CT scans and photofluorography. This group included 64% men and 36% women. Nineteen patients were diagnosed as having lung cancer (0.48%), which is significantly higher than previous standard mass assessments done in the same area. CT missed one case that was found solely on the basis of sputum cytology. Several clinically significant benign lesions were also identified in the study.

Among the 19 patients in whom the workup showed lung cancer, 18 had surgery and one refused surgery but later developed metastasis. The most frequent cell type was adenocarcinoma. Of the 19 patients, 16 were stage I and three were stage IV. It is a fact that the mini-photofluorography had shown no evidence of cancer in 18 of the 19 patients. It should be pointed out that this trial was done in rural Japan where the rate of lung cancer is reported to be low (i.e., only 30 to 50 cases expected per 100,000 in population). The authors found the CT identified almost 10 times as many cancers as were identified by standard mass screening previously done. This study strongly suggests that CT scanning may replace chest x-rays in early case finding or in screening of high-risk populations.
