2.3 The appropriate treatment volume remains undefined. Data from the LCSG surgical trial comparing wedge or segmental resection to lobectomy in *surgical* stage I NSCLC suggests that local control and probably survival are decreased by the more conservative resection without any gain in preservation of pulmonary function. It is not clear, however, that such a conclusion should be extended to patients with *clinical* stage I disease, or to those in whom poor pulmonary function is a major reason for their avoiding surgical therapy in the first place. Several of the series with the best survival results have used small treatment volumes encompassing only areas of known macroscopic disease, with a margin but without elective irradiation of nodal regions of suspect drainage. There is also a suggestion, although not universal agreement, that such reduction of target volume will reduce the incidence of pulmonary toxicity. It may well be that, for this patient population, such restricted target volumes are most appropriate. The introduction of three-dimensional treatment planning techniques will allow dose escalation and normal tissue sparing to a greater degree as the target volume is kept limited. [65,66] At the present time, it seems quite reasonable to treat these patients to restricted target volumes without routine prophylactic irradiation of hilar or mediastinal lymph nodes.
3. With current treatment techniques, both local and systemic failure are major causes of treatment failure, and both need to be addressed in order to improve treatment outcomes. The advanced age and frequent multiorgan disease in these patients may limit their suitability for treatment with many current chemotherapeutic agents, although recent development of less-toxic drug analogues (e.g., carboplatin versus cisplatin) and improvement in management of treatment toxicities (e.g., ondansetron for management of nausea and vomiting, hematopoetic growth factors such as G-CSF for amelioration of myelosuppression) may make such therapy reasonable for some patients. The frequency of local failure, as well as the possibility of treating limited-target volumes for this patient population, make them good potential candidates for applications of altered radiation fractionation schemes, such as dose escalation with hyperfractionation, accelerated fractionation, or concurrent boost approaches.

These broad conclusions are fairly consistently reached by the authors of most of the recent treatment series as well as reviews. [26,67] Radical radiation therapy has an established position as a potentially curative modality for those patients with stage I and II NSCLC who are medically inoperable and/or refuse surgery, and should be offered to them rather than relegating such patients to observation or treatment without curative potential. As both local and systemic failure are common with radiation therapy techniques, continued clinical research to improve both components of therapy is needed.

ALTERED FRACTIONATION SCHEDULES
FOR LUNG CANCER

MINESH P. MEHTA
PAUL M. HARARI

Of the 170,000 to 180,000 lung cancer cases, approximately 50,000 patients present with locoregionally advanced, nonmetastatic, non-small cell lung cancer (NSCLC). This group generally receives definitive radiation therapy. [1] Unfortunately, with standard radiation therapy alone, the overall cure rate is less than 5%. [2] With a survival advantage demonstrated from recent sequential chemoradiation trials for these patients, the standard therapy for these patients is two cycles of vinblastine-cisplatin chemotherapy followed by 60 Gy external-beam radiation therapy. [3] Despite the small survival gains achieved through this strategy, the overall long-term survival remains poor because of an unacceptably high frequency of local and distant failure. The role of radiotherapy is to improve local control. One change would be to alter the conventional 1 fraction per day, 5 days per week given over 6 weeks to shorten overall time and deliver multiple daily treatment. We address the biologic rationale for such altered fractionation schedules and assess the various manipulations of standard fractionation. Subsequently, we discuss the clinical data supporting the role of altered fractionation in the management of locoregionally advanced nonmetastatic NSCLC.

Standard schedules preclude high local failure rate. [3] Data from the Institut Gustave Roussy in Paris indicated that distant metastasis was achieved with combination therapy, but local control remained only 8% at 5 years. [4] Improving the control of local disease remains a very high priority. Several clinical trials are currently undertaking this mission, either by incorporating surgery into the regimen or by altering the radiotherapeutic strategy by escalating or intensifying the radiation with strategies such as hyperfractionation, acceleration, brachytherapy boost, three-dimensional (3-D) conformal techniques, and the use of radiosensitizers.

FRACTIONATION

Biologic Basis for Fractionation

Manipulation of fractionation, or doses per session, for radiation therapy has received considerable attention in recent years. The original observations regarding the advantages of fractionating radiation into multiple doses over single doses date back to the early 1900s. [5,6] Current understanding of radiobiologic principles focus on tumor division times versus acute and late effects in normal tumors. Indeed, work published in the early 1980s postulated that the more specific modifications of dose/fractionation parameters might improve tumor control rates. [7,8,9] and [10] These reports clarified a differential radiation repair response between early-responding and late-responding tissues. Early-responding tissues, including epithelium of the aerodigestive tract and some tumor types, are not as efficient at repairing damage from small radiation doses compared to late-responding normal tissues. The late-responding tissues, such as kidney and spinal cord, efficiently repair radiation damage between individual small fractions. Fractionation modifications must recognize this differential tissue repair capacity to radiation, and that late-tissue damage is not time-critical but more dependent on size of fractions and interval between fractions. The more common of these altered fractionation strategies are further defined.

Fractionation Factors

The four primary fractionation factors are:

- Dose per fraction
- Total dose
- Overall treatment time (for completing the entire radiation schedule)
- Interfraction treatment interval

Each of the altered fractionation methods exploits manipulations of one or more of these four primary fractionation factors in an attempt to provide a therapeutic advantage. The two most common strategies are referred to as "hyperfractionation" and "acceleration," and the differences between these are illustrated in Table 47.1.

Hyperfractionation
  ↓ fraction size
  ↑ fraction number
  ↑ total dose
  Maintain overall treatment time
Rationale: Allows safe delivery of slightly higher tumor dose
  without increase in late normal tissue toxicity.
Acceleration
  ↓ Overall treatment time
  Maintain or slightly reduce:
    Fraction size
    Fraction number
    Total dose
Rationale: Counteracts tumor cell proliferation in tumors with
  short T_{pot} by decreasing overall treatment time.

TABLE 47.1. COMMON STRATEGIES FOR ALTERED FRACTIONATION

Hyperfractionation

Hyperfractionation requires a reduced fraction size (below 1.4–1.5 Gy per exposure), an increased fraction number, and a modest increase in total dose with minimal

extension of the overall treatment time. The main benefit of hyperfractionation rests in the sparing of late normal tissue complications. By using an increased number of smaller doses (1.0–1.2 Gy) per fraction, late-effect injury is reduced. The increased total dose is safely accomplished by the use of smaller doses per fraction that "spare" the late-reacting normal tissues from increased complication rates. The most important predictor of enhanced late radiation morbidity is an increase in the size of the radiation fraction. An example of hyperfractionation is provided in Table 47.2.

Clinical Examples of Altered Fractionation*		Comments
Hyperfractionation		
60 fx × 1.1 Gy twice daily = 66 Gy (6 wks)		↑ No. of small fractions
[30 fx × 2.0 Gy per day = 60 Gy (6 wks)]		↑ Total dose, same overall time
Acceleration		
25 fx × 2.0 Gy per day = 50 Gy (3.5 wks, Mon–Sat)		↓ Overall time
[25 fx × 2.0 Gy per day = 50 Gy (5 wks, Mon–Fri)]		
Accelerated Hyperfractionation		
55 fx × 1.2 Gy twice daily = 66 Gy (~5 wks)		Combination of features above
[30 fx × 2.0 Gy per day = 60 Gy (6 wks)]		
Dose Escalation		
Large Field	25 fx × 2.0 Gy per day = 50 Gy (5 wks)	↑ Dose per fraction at time of field reduction
Boost Field	5 fx × 2.5 Gy per day = 12.5 Gy (1 wk)	
	Total = 62.5 Gy (6 wks)	
Hypofractionation-Split Course		
Part I	5 fx × 4 Gy = 20 Gy (1 wk)	Simple and effective regimen for palliation
	Two-week break	
Part II	5 fx × 4 Gy = 20 Gy (1 wk)	
	Total = 40 Gy (4 wks)	

* Schedules in italics represent comparable conventional schedules.

TABLE 47.2. FRACTIONATION SCHEMES

Acceleration/Accelerated Fractionation

The primary rationale for accelerated fractionation in radiation therapy is to deliver radiotherapy to a tumor cell population dividing more than once in 24 hours and to reduce the overall treatment time. This approach limits the surviving tumor cells' repopulation during the radiation treatment course. Tumor cell repopulation during treatment increases clonogenic cell number, thereby decreasing tumor control for a given radiation dose. Flow cytometry techniques allow more understanding of human tumor kinetics. Cytometric data support the concept of the tumor potential doubling time (T_{pot}). T_{pot} represents the minimum time it takes for a tumor to double. Because cell loss occurs, cell-doubling and volume-doubling are independent, but *in situ* measurements of T_{pot} from human biopsy estimate (T_{pot}) values of 3 to 6 days. Volume-doubling times (T_{vo}) for human tumors are commonly on the order of several months (cell loss factor includes processes such as necrosis, exfoliation, apoptosis, etc.). Acceleration provides a reduction in the overall treatment time, fraction number, and total dose. An example of treatment acceleration is provided in Table 47.2.

Growth Kinetics of Lung Cancer

The data for volume-doubling time of lung cancer comes from patients with solitary lung nodules followed or observed. Two such follow-up trials conducted in the late 1960s and reported in the early 1970s suggest that radiographic doubling times of asymptomatic solitary nodules range from 30 to 490 days with an approximate median volume-doubling time of 120 days.[11,12] Unfortunately, the identification of such long volume-doubling times led to the clinical belief that lung cancers do not proliferate rapidly. Despite the time measured to double volume, active cell division, cell loss, and opportunities to metastasize occur. Therefore, prolonged courses of radiation therapy theoretically would not be detrimental in the management of these patients. As alluded to previously, recent biologic advances have allowed us to identify the concept of the tumor potential doubling time, which is a more appealing measure of cellular proliferative activity. Recent studies have confirmed that NSCLC proliferates rapidly, with relatively short potential doubling times, with a median of 7 days.[13]

Accelerated Hyperfractionation

This common altered fractionation strategy incorporates components of both hyperfractionation and acceleration as defined previously. This amalgamation of features from the two primary altered fractionation themes (hyperfractionation and acceleration) exploits both the concept of reduced fraction size to minimize normal tissue effects and reduced overall treatment time to diminish the adverse impact of tumor cell repopulation during therapy. Many examples of accelerated hyperfractionation exist in clinical cancer therapy, and a representative example is provided in Table 47.2.

Dose Escalation

Dose escalation can be accomplished by altered fractionation that simply employs an increase in the individual fraction size during a course of radiotherapy. A patient receiving 2.0 Gy fractions in the initial phase of a treatment course might escalate to 2.5 Gy fractions during the reduced volume boost segment of his or her radiotherapy treatment course. An example of this dose escalation concept is provided in Table 47.2. The rationale is to enhance the "dose intensity" during the latter segment of treatment, while exposing only the smallest target volume to these higher doses.

Hypofractionation

Despite the sound radiobiologic rationale and promising clinical results with intensified fractionation schedules that exploit the concepts of hyperfractionation and acceleration, there remains an important clinical role for hypofractionation in radiation therapy. With this method, significantly fewer radiation fractions are employed, with higher doses per fraction, such as 4 Gy times 5 = 20 Gy. Hypofractionation may provide advantages for palliation. For the symptomatic patient with limited overall life expectancy, concern about late normal tissue toxicities many months after radiation therapy may be misplaced. Because the late normal tissue effects of radiation generally require 9 to 24 months to emerge, the use of hypofractionation may facilitate rapid and efficient treatment completion with effective doses with lesser concern over long-term side effects. Daily fractions of between 3 and 8 Gy, depending on the particular setting and anatomic treatment site, may provide rapid, cost-effective palliation of pain, bleeding, obstruction, or tumor progression using a brief delivery schedule, which inconveniences the patient less. In some settings, a single fraction of 8 Gy may control the symptom complaint for the remainder of the patient's life. For larger treatment volumes, schedules employing 3 to 7 Gy fractions over 1- to 3-week schedules may be used to deliver radiation doses with a high biologic effect in light of the large dose per fraction (See example in Table 47.2.)

Split-Course Fractionation

Although split-course radiation fractionation is uncommonly used in the context of curative radiation therapy because of the current understanding of the importance of repopulation and tumor proliferation, this method remains a useful method for palliation. *The main disadvantage of split-course radiation is the treatment break between two components of the treatment schedule. This break enables accelerated tumor repopulation. The original basis for this strategy was to allow adequate repair to be completed in acutely responding normal tissues, reoxygenation of the tumor, and thereby reducing the toxicity of the radiation schedule. Biologically, however, this philosophy is not sound because the therapeutic ratio could actually deteriorate as a consequence of tumor repopulation. The strategy is characterized by splitting the total radiation course into halves with an interdigitated break lasting several days. The clinical rationale allowed for a field reduction in the second portion of the radiation course. It also selected patients who would either progress or deteriorate during the break. These would then not be treated further. The biologic rationale for split-course radiation included the expectation that a several-day break would enhance reoxygenation by allowing neovascularization and angiogenesis, permit an improvement in the therapeutic ratio by allowing greater normal tissue repair in comparison to tumor repair, and cause redistribution of cells from G_0 to more sensitive phases in the cell cycle. This method is particularly valuable for bulky, locoregional solid tumors involving the head and neck or lung, for which palliation is the primary treatment objective. The brief hypofractionated initial course allows delivery of a moderate radiation dose in large fractions to initiate tumor shrinkage. The split-course break is then introduced to prevent brisk acute toxicity and to provide several weeks for tumor shrinkage. The second hypofractionated treatment course can thereby be delivered to a smaller treatment volume to maximize the effectiveness and durability of the palliative regimen. (See example in Table 47.2.)

Advantages and Disadvantages of Altered Fractionation Strategies

Although the potential radiobiologic advantages of altered fractionation strategies have been well formulated and confirmed in a variety of clinical treatment settings, several potential disadvantages are worth considering. The primary advantage for intensified fractionation strategies involves the potential for higher tumor control

rates, particularly for rapidly proliferating tumors in which radiation therapy plays a dominant treatment role. [15,16anc17] The most well-studied histology and anatomic site for such altered fractionation approaches involves squamous cell carcinoma of the head and neck. [18] Randomized trials have revealed a reproducible improvement in locoregional disease control rates with the use of both hyperfractionation and treatment acceleration strategies. However, one clear consequence of these intensified fractionation approaches includes increased acute toxicities that occur with this more rapid accumulation of total dose. Accelerated hyperfractionation schedules provide an increased total dose delivered in smaller fractions over a reduced overall treatment time compared to standard therapy. The enhancement of acute mucosal toxicity can influence not only the patient's tolerance to therapy, but also the degree of medical assistance that must be provided during and after therapy with regard to pain control, nutrition, and subsequent healing processes. For slower growing tumors for which radiation therapy does not play a dominant therapy role, the potential advantages of intensified fractionation schedules may be outweighed by the increase in acute toxicity.

Today, split-course radiation is less used in the context of curative radiation because of the concern that treatment interruption may allow tumor proliferation. Although significant data regarding the negative impact of treatment interruptions are available from a variety of other epithelial neoplasms such as head and neck carcinoma and cancer of the cervix, limited data exist for NSCLC. The best evidence for such a negative outcome results from an analysis of three Radiation Therapy Oncology Group (RTOG) studies (8311, 8321 and 8403), where the impact of treatment delay was evaluated. [19] Whereas only 3% of patients in protocols 8321 and 8403 had any significant treatment interruptions, 11% of patients on RTOG 8311, a protocol that evaluated hyperfractionation, experienced treatment interruptions. The proportion of patients experiencing delay in timely completion increased with total dose. Survival was significantly shortened in those patients whose treatment duration was prolonged compared to those treated per protocol. Estimated two- and five-year survival rates were 24% and 10%, respectively, for patients treated without interruptions, compared to 13% and 3% for those experiencing treatment interruptions. These data, although possibly influenced by other variables, provide a suggestion that prolongation of the treatment schedule may result in accelerated tumor repopulation with subsequent negative impact on survival.

CLINICAL APPLICATION OF ALTERED FRACTIONATION REGIMENS

Split-Course Radiation

Split-course radiotherapy for lung cancer was standard during the 1960s and 1970s. At least five clinical trials tested the split-course concept. [20,21,22,23 and 24] None of these randomized clinical trials proved a survival benefit from split-course radiation therapy. Although Holsti and Mattson [20] concluded that split-course was better tolerated, and Lee and colleagues[21] suggested that this regimen was "more practical," Levitt's study[22] found that more side effects occurred in the group receiving split-course radiation therapy than in the group receiving continuous fractionated radiotherapy. In addition, Perez's study [23] reported that local control was superior in the 60 Gy continuous arm compared to the 40 Gy split-course arm. In that particular study (RTOG 7301), the intrathoracic failure rate with split-course radiation therapy was 44% compared to 33% with the continuous fractionated course. In a more recent trial, Routh and colleagues also could find no survival advantage from the split-course schedule, but like Lee suggested that it was associated with lower morbidity. [24] As a consequence of these trials, split-course therapy cannot be substituted as standard for NSCLC.

Hypofractionation

This method utilizes fewer radiation fractions but a higher dose per fraction. It has the advantage of efficiency and cost-effectiveness by less use of radiation therapy equipment. Additionally, the reduced total number of clinic visits may potentially have a bearing on patient convenience and quality-of-life issues. However, the use of large fraction radiation typically has a higher frequency of late toxicity. This method has been less widely utilized in curative lung cancer treatment. In fact, in a trial by Pritoli and colleagues, [25] 86 patients with NSCLC were randomized to receive weekly fractions of 5.57 or 8.8 Gy to a total dose ranging from 42 to 44 Gy. These patients experienced an unusually high rate of late pulmonary (56%) and connective tissue (40%) toxicity. In two other studies, [26,27] no significant increase in late toxicity was identified. This outcome however, may be influenced by the paucity of patients alive after 2 to 3 years. Despite toxicity, neither of these two latter studies found a survival difference. Slawson and colleagues reported on 120 patients randomized to 60 Gy given by a once-a-week schedule with a single fraction of 5 Gy for 12 weeks.[27] These patients were compared to patients receiving standard fractionated radiation therapy to a total of 60 Gy in 30 fractions over 6 weeks. No statistically significant differences in toxicity, response rates, or two-year survival were reported. Although not widely accepted or used, this study raises some interesting considerations. Particularly in patients who can be selected on the basis of poor prognostic factors and identified as having very short expected survival, it may be reasonable to consider hypofractionated radiation therapy.

Hyperfractionated Radiation Therapy

Hyperfractionation represents a plan that uses multiple daily radiation fractions with smaller than usual radiation doses per fraction within a treatment time of 6 to 7 weeks. The advantages of this strategy include a potential reduction in long-term tissue toxicity and the possibility of improving the therapeutic ratio by reduced injury to late-effect tissues, improving reoxygenation between radiation fractions, and redistributing cells into a more radiosensitive phase (G_2-M-phase).

Pure accelerated fractionation strategies have been extensively tested by the RTOG. Between 1983 and 1987, the RTOG enrolled 848 patients in a phase I/II trial where patients were randomized to receive 60, 64.8, 69.6, 74.4, or 79.2 Gy minimum total dose. [28] Two daily fractions of 1.2 Gy each were utilized with a minimum four-hour interfraction interval. Overall, no significant differences in either acute or late toxicities were identified in the five arms of the study. In order to evaluate possible survival benefit, a subgroup analysis was performed on 350 patients who met the criteria utilized by the Cancer and Leukemia Group B (CALGB) Protocol 8433. These criteria included a Karnofsky score of ³70 and <6% body weight loss. In this subset analysis from a phase I/II study, those receiving 69.6 Gy had significantly improved median (13 months) and two-year survival (29%) (p = 0.02) compared to patients receiving lower total doses. Subsequent to these suggestive data, a three-arm prospective randomized trial included a 69.6 hyperfractionated treatment arm. Patients were randomized to the then "standard" radiotherapy, 60 Gy in 30 fractions of 2 Gy each, or two cycles of vinblastine-cisplatin chemotherapy preceding 60 Gy, or the hyperfractionated 1.2 Gy twice daily to a total of 69.6 Gy in 6 weeks. In the initial analysis of this trial, [29] the combination therapy arm verified the principle that chemotherapy improved survival regardless of the radiotherapy-alone schedule used. Median survival was 11.4 months for 60 Gy, 12.3 months for hyperfractionated radiotherapy 69.6 Gy, and 13.8 months for the combined modality arm. The one-year survival rates for the three arms were 46%, 51%, and 60%. The report by Sause et al. on five-year results shows long-term results poorer than long-term results for CALGB[3]—qualitatively similar but quantitatively different. [29]

Accelerated Radiation Therapy

The distinguishing hallmark of accelerated radiotherapeutic regimens is an overall reduction in treatment time with the expectation that this change will overcome accelerated tumor repopulation. From a practical perspective, this goal can be achieved and has been tested in patients with NSCLC using two different strategies; concomitant boost (field within a field technique) and a combination of multiple daily fractions with increased total daily dose (accelerated hyperfractionation).

Concomitant Boost

The technique of accelerating radiotherapy dose delivery reduces the overall treatment time by 1 to 2 weeks by giving the boost as a second fraction during the normal course of standard radiotherapy. Phase I and II studies have been carried out by the RTOG. In the largest such report, 355 patients received 1.8 Gy fractions to standard large fields, followed 4 to 6 hours later by a 1.8 Gy boost, given two to three times each week. [30] The total dose was escalated from 63 to 70.2 Gy in 5 weeks. Although some increase in acute toxicity occurred in the higher dose arm, late toxicities were not enhanced. Median survival remained at 9 months for the various cohorts, but in the high-dose arm, one- and two-year survival rates were 44 and 22%, respectively, comparable to what is contemporarily achieved with combination therapy. This approach has recently been tested in a randomized fashion by investigators from Taiwan. In a preliminary analysis of their data, they have identified improved response rates in the concomitant boost arm compared to the standard radiotherapy arm. Because of limited follow-up, survival data have not been analyzed thus far (Sun et al. personal communication, 1999).

Accelerated Hyperfractionation

The second major radiotherapeutic altered fractionation technique that permits an overall decrease in total treatment time is referred to as *accelerated hyperfractionation* and has recently been extensively tested clinically. The biologic basis for this technique stems from the recognition that the potential doubling time of lung cancer is relatively short (5 to 7 days). [13] The rapid repopulation from these tumor cells implies loss of effectiveness within a couple weeks of initiation of therapy. In order to overcome this loss it would be necessary to considerably shorten the overall treatment time. From a practical standpoint, the easiest way to accelerate is to use multiple daily fractions, less than 1.8 to 2.0 Gy each, but with a daily cumulative dose greater than 2.8 to 3.0 Gy, a biologically comparable total dose, and a significantly shortened overall treatment duration. This concept, therefore, marries acceleration with hyperfractionation and is known as *hyperfractionated*

accelerated radiation therapy (HART). When weekend breaks are eliminated so that no interruption occurs the word "continuous" is added, resulting in the well-known acronym CHART.

Clinical trials of CHART in NSCLC were first reported from England by Saunders and Dische. Based on their encouraging preliminary data, a large multicenter randomized European trial has been completed.[31] A total dose of 54 Gy was delivered over 12 continuous treatment days at 1.5 Gy twice daily, separated by intervals of 6 hours, resulting in an 18-hour treatment day, weekends included. The initial results of this randomized trial demonstrate a significant 10% survival benefit at 2 years compared to a standard 60 Gy schedule. The odds ratio in favor of the CHART regimen was 0.75, suggesting a 25% decline in the risk of death.

The CHART regimen has not gained popularity in the U.S. because of personnel and logistic constraints demanded by three treatments per day. An alternative, more practical regimen, spaced over 15 days, including two weekend breaks, has been piloted by the Eastern Cooperative Oncology Group (ECOG 4593) with a median and one-year survival of 13.5 months and 57% respectively.[32] Although a direct comparison of these various trials is not valid, a simple comparison of the various combination therapy trials and altered fractionation trials is presented in Table 47.3. These data suggest that the more aggressive treatment, including combination therapy and altered fractionation, yield results superior to conventional, once-daily radiotherapy.

TABLE 47.3. SURVIVAL COMPARISON OF SELECTED RADIOTHERAPY, CHEMORADIOTHERAPY, AND ALTERED FRACTIONATION TRIALS

The ECOG HART experience differs from the European CHART trial in that weekend treatment was omitted from the ECOG regimen, resulting in a small prolongation in overall treatment time. This prolongation in treatment theoretically predicts a modest loss in local control because of accelerated repopulation. Investigators at Wisconsin derived the dose and fractionation regimen for the current trial using the linear-quadratic formula and increased the total dose to compensate for the treatment prolongation resulting from weekend breaks.[33] Table 47.4 compares various characteristics and endpoints between the ECOG HART trial and the European CHART trial. The ECOG HART trial has a higher percentage of patients with more advanced primary tumors and a greater proportion of N3 patients. The survival from both trials warrants further comparative trials. Moreover, the one-year survival in the ECOG trial is comparable to that achieved in several contemporary trials using sequential chemotherapy and once-daily radiation therapy. It is also accomplished in a much shorter time frame without the toxicities associated with chemotherapy.[3,26,34]

TABLE 47.4. COMPARISON BETWEEN ECOG 4593 AND CHART

Chemotherapy Plus Altered Fractionation

Based on the principles and results outlined thus far, the logical next step is to test a combination of chemotherapy and altered fractionation. Several such phase I/II trials have now been reported and are summarized in Table 47.5. Results with these methods were reported in a North Central Cancer Treatment Group (NCCTG) study reported by Shaw et al.[35] These investigators treated 23 patients in a pilot of split-course hyperfractionated radiotherapy using 1.5 Gy bid to a total of 30 Gy, followed by a two-week break and an additional 30 Gy using a similar schedule. Two cycles of etoposide and cisplatin were given, one with commencement of the first radiation session, and the other when the second half of the radiotherapy course was commenced. Although toxicities were considerable, with 26% grade 3 or greater acute pneumonitis, the overall median and one- and two-year survival figures were an impressive 26 months and 74% and 51%.[35]

TABLE 47.5. CHEMORADIOTHERAPY TRIALS WITH ALTERED FRACTIONATION

The RTOG has tested the 1.2 Gy twice-daily regimen to 69.6 Gy with vinblastine (5 mg/m^2 weekly × 5) and cisplatin (75 mg/m^2 on days 1, 29, and 50) in their trial 90–15. Enhanced acute toxicities were substantial, with 45% grade 4 or greater hematologic and 24% grade 3 or greater esophagitis. The median and one- and two-year survival rates were 12.2 months, 54% and 28%. In a subgroup with prognostic features similar to CALGB 8433, these survival figures were 17.5 months and 60% and 30%.[36]

These rather excessive toxicities led the RTOG to substitute etoposide for vinblastine because this regimen had previously been tested and better tolerated in SCLC. Seventy-nine patients received two cycles of oral etoposide 100 mg/d, intravenous cisplatin 50 mg/m^2 on days 1 and 8 and hyperfractionated radiation therapy to 69.6

Gy. The median survival for patients comparable to CALGB 8433 was 21 months, with one- and two-year survival figures of 70% and 42% (these values for CALGB 8433 were 13.7 months and 54% and 26%). Unfortunately, the associated toxicities from this regimen were also substantial, with 57% grade 4 hematologic toxicity, 53% ³ grade 3 esophagitis, and 25% ³ grade 3 pulmonary toxicity. [37]

In a 34-patient phase II trial, the feasibility of combined concurrent hyperfractionated radiotherapy (60 Gy in 48 fractions of 1.25 Gy, twice-daily) and chemotherapy consisting of cisplatin (6 mg/m^2 every day of radiotherapy) and vindesine (2.5 mg/m^2 once weekly) was tested. After a three-week rest period, two full cycles of cisplatin (120 mg/m^2 on weeks 10 and 14) and vindesine (2.5 mg/m^2 on weeks 11, 12, and 13) were given. Treatment evaluation with thoracic computed scan, bronchoscopy, and bronchial biopsies was performed 3 months after completion of radiation therapy. Failure rates were estimated using a competing risk approach. The complete response rate was 50%. Local failure rates at 1 and 3 years were 53% and 56%, respectively. Distant metastases rates at 1 and 3 years were 27% and 29%. Overall survival rates at 1, 2, and 3 years were 53%, 33%, and 12%, respectively. Severe esophagitis was observed in three patients (9%). Lethal toxicity was observed in two patients. This phase II trial confirmed the feasibility of this type of approach and suggested that it may improve local control compared to conventional approaches. [38]

The excess toxicity from combining chemotherapy with altered fractionation has been investigated in a multicenter randomized trial using accelerated radiotherapy with or without concurrent carboplatin. One hundred patients with NSCLC were randomized to receive one of four treatments: (arm 1) radiotherapy 60 Gy (2 Gy daily) in 30 fractions in 6 weeks; (arm 2) accelerated radiotherapy (2 Gy twice-daily) 60 Gy in 30 fractions in 3 weeks; (arm 3) radiotherapy as in arm 1, plus carboplatin 350 mg/m^2 during weeks 1 and 5 of radiotherapy; (arm 4) radiotherapy as in arm 2, plus carboplatin 350 mg/m^2 during week 1. The median survival for all patients was 17.1 months, with 33% survival at 2 years. The major toxicities were hematologic and esophageal. Patients receiving carboplatin had more neutropenia (p < 0.0001) and thrombocytopenia (p = 0.002) than patients receiving radiotherapy alone, and this reaction was most marked in patients on arm 3. Both carboplatin and accelerated radiotherapy caused more severe esophagitis when compared to conventional radiotherapy alone (p = 0.011 and p = 0.0017, respectively). Esophagitis was more prolonged in patients having accelerated radiotherapy (p < 0.0001, median duration 3.2 months compared to 1.4 months for patients receiving conventional fractionation). Six patients (23%) treated on arm 2 required dilatation of esophageal stricture, one dying with a laryngoesophageal fistula. [39]

The first statistically significant survival advantage (median survival 34 versus 77 weeks; p = 0.003) from chemo-hyperfractionated radiotherapy was reported by Jeremic in a three-arm randomized trial in the group receiving 100 mg/d carboplatin on days 1 and 2 with 100 mg etoposide on days 1 to 3 of each week during the course of radiotherapy (64.8 Gy; 1.2 Gy twice-daily) compared to the same radiation alone. [4c] However, both acute and late toxicities were increased with this approach. Grade 4 acute toxicities were seen in 2%, 4%, and 11% of patients receiving radiation alone, radiation with weekly chemotherapy, and radiation with chemotherapy on alternate weeks, respectively; the late toxicity values were 2%, 4%, and 9%.

Jeremic's group then conducted a subsequent phase III follow-up study with a design change. To investigate the efficacy of concurrent hyperfractionated radiation therapy and low-dose daily chemotherapy in stage III NSCLC, 131 patients were randomly treated as follows: group I, 1.2 Gy twice-daily to 69.6 Gy; group II, same radiation with 50 mg of carboplatin and 50 mg of etoposide given on each day of radiotherapy. Group II patients had a significantly longer survival time than group I patients, with a median survival of 22 versus 14 months and four-year survival rates of 23% versus 9% (p = .021). The median time to local recurrence and four-year local recurrence-free survival rate were also significantly higher in group II than in group I (25 versus 20 months and 42% versus 19%, respectively, p = .015). In contrast, the distant metastasis-free survival rate did not significantly differ in the two groups. The two groups showed similar incidence of acute and late high grade toxicity. [40]

Further detailed analysis of response, toxicity, and failure patterns in trials combining chemotherapy with radiation either sequentially or concurrently was recently conducted and published by Byhardt and colleagues. [4c] In this analysis, five completed RTOG trials utilizing either sequential chemotherapy followed by standard radiotherapy or sequential and concurrent chemotherapy with standard radiation, or concurrent chemotherapy and hyperfractionated radiation were evaluated. Both acute and late toxicities were compared. Patients were divided into three groups. All patients had a Karnofsky score of ³70% and a weight loss of < 5%. Group 1 included patients receiving sequential chemotherapy followed by standard radiation therapy to 60 Gy in 6 weeks; group 2 included patients who received both sequential and concurrent chemotherapy followed by a standard 60 Gy radiation therapy; and group 3 included patients who received concurrent chemotherapy and hyperfractionated radiotherapy to a total of 69.6 Gy in 6 weeks. The chemotherapy in all five of the trials utilized cisplatin with either vinblastine or oral etoposide. Overall, life-threatening acute toxicities (grade 4/5) were equivalent among the three groups. However, the severe nonhematologic acute toxicities were significantly different based on the treatment regimen. Specifically, group 3 patients had a significantly greater incidence of severe acute nonhematologic toxicity (55%) compared to group 1 (27%) or group 2 (34%). This result was accounted for in large measure by the severe acute esophagitis rate of 34% in group 3 compared to 1.3% in group 1 and 6% in group 2 (p < 0.0001). Similarly, although the overall incidence of life-threatening (grade 4/5) late toxicities did not differ by treatment group, the incidence of severe late nonhematologic toxicity was higher in both groups 2 (26%) and 3 (28%) compared to group 1 (14%). In large measure, this outcome was accounted for not by severe late esophagitis but by severe late lung toxicity, the incidence for which was 10% for group 1, 21% for group 2, and 20% for group 3 (p = 0.033). These data therefore provide a substantial database, suggesting that concurrent chemotherapy and hyperfractionated radiotherapy carry a significantly higher incidence of not only acute esophageal toxicity but also enhanced late pulmonary toxicity.

Despite the encouraging aspects of the results from Jeremic's trials, further supportive evidence is necessary before combination chemo-altered fractionation radiotherapy can be recommended outside a protocol context. The RTOG has initiated an important three-arm randomized trial (RTOG 94-10) comparing sequential chemoradiotherapy to concurrent chemoradiotherapy in one experimental arm and concurrent chemoradiotherapy with twice-daily radiation in the other arm; results of this trial are eagerly awaited.

CONCLUSIONS

Early therapeutic strategies assumed that local control was of paramount significance in leading to cure of lung cancer. High rates of local control could be achieved with conventional fractionation radiotherapy to 60 Gy. Chemotherapy of the 1970s was minimally active, without impact on micrometastatic disease or survival. However, randomized induction chemoradiotherapy trials demonstrated a small but measurable survival gain, resulting from increased control of metastatic disease and some improvement in locoregional control. Contemporaneously, better assessment of local control by bronchoscopy indicated that radiographic evaluation overestimated local control rates, which really were only 8%. This realization leads to renewed efforts at controlling the disease locally. Altered fractionation, which has effects on local disease and normal tissues within the target volume, demonstrates statistically significant and meaningful survival benefit. Combinations of chemotherapy and altered fractionation therefore represent a "new frontier," and although it is too soon to judge its overall impact, this strategy has certainly resulted both in increased toxicity as well as improved survival in preliminary reports. The formidable toxicity needs to be addressed, perhaps with volume reduction or chemotherapy choices.

Are we reaching a therapeutic ceiling? Table 47.6 provides the acute grade 3 and 4 esophagitis rates from various aggressive combination chemotherapy plus hyperfractionated radiotherapy trials. With conventional sequential chemoradiotherapy strategies, the rate of severe esophagitis is usually below 5%, but with the aggressive strategies, the incidence rises to 24% to 53%. Future progress in this disease must balance toxicities with outcome, measured not just in survival terms, but also as it pertains to quality-of-life. The societal impact, particularly cost-effectiveness, will become a critical question. For example, how justifiable is it to treat the majority of advanced, nonmetastatic lung cancer patients with poor prognostic features with aggressive therapies when they have been excluded from the randomized trials? Even if the hyperfractionation results hold up as being equivalent to survival with combination therapy, it may not be useful if toxicity is too high. The provocative benefits of altered fraction schemes require proof from randomized phase III trials. One such study is the prospective randomized phase III ECOG trial (ECOG E2597), in which patients receive two cycles of carboplatin and taxol followed by a randomization to once-daily radiation therapy to 64 Gy, or thrice-daily radiation therapy to 57.6 Gy as piloted in the ECOG HART regimen. Collective and collaborative clinical trial effort will answer such questions.

TABLE 47.6. ACUTE SEVERE ESOPHAGITIS IN LUNG CANCER TRIALS

A few intensified fractionation regimens, which incorporate a split-course design, are delivered with curative intent. The most well studied is the CC Wang accelerated hyperfractionation split-course schedule for head and neck cancer, which uses a 1.6 Gy twice-daily fractionation and provides a 10 to 14-day mid-course break to allow healing of the intense mucosal reactions. [14]

THREE-DIMENSIONAL RADIATION THERAPY

MARY V. GRAHAM
WILLIAM B. HARMS

Radiation therapy remains a cornerstone of therapy for lung cancer. With the emergence of specialized volumetric three-dimensional radiation therapy planning and treatment systems (3DRTP), the potential benefits for lung cancer were quickly realized. [1] These benefits included (a) better localization of the tumor target(s), (b) improved ability to assess and potentially reduce normal tissue toxicity, and (c) increased tumoricidal doses of radiation to the tumor target(s). This chapter reviews the progress that has been made in the last decade in achieving these goals and the emerging issues in 3D radiation therapy for lung cancer.

BACKGROUND

The "standard of care" for the dose, volume, and beam arrangements for the treatment of non–small cell lung cancer (NSCLC) was established by the Radiation Therapy Oncology Group (RTOG) dose-escalation trial 7301. [2] In this study, 375 patients were randomly assigned to receive either 40 Gy in 4 weeks with a 2-week break (split-course), 40 Gy in 4 weeks, 50 Gy in 5 weeks, or 60 Gy in 6 weeks. The complete and partial response rates (as assessed clinically and radiographically) were 48% in patients treated with 40 Gy, 53% in those treated with 50 Gy, and 56% in those receiving 60 Gy. The incidence of local failure (also evaluated clinically) was lower in patients treated with 60 Gy (33%) than in those receiving 50 Gy (39%) or 40 Gy (44% to 49%). Perez and co-workers [3] reported that irradiation technique clearly affected results. Patients with major deviation from protocol compliance had poorer response rates and decreased survival. In this protocol, large volumes of the chest and regional lymphatics were included in the treatment volume. The electively irradiated areas included both hila, bilateral regions of the mediastinum, bilateral supraclavicular areas, and 5 to 8 cm below the carina of the inferior mediastinum. Despite a modest improvement at 3 years, by 5 years the overall survival was approximately 5%.

In the early 1990s the results of several large randomized trials reported increased survival with the addition of cisplatin-based chemotherapy. [4,5 and 6] Each of these trials utilized conventional radiation therapy and delivered 40 to 50 Gy to the elective nodal regions and 60 to 65 Gy to the gross disease. Despite the modest improvement demonstrated in these trials, there remains much room for improvement. Long-term survival is still only 8% to 14%. [4,6] LeChevalier and co-workers [5] reported a decreased metastatic incidence, but both arms had a local control rate of only 15% to 17% when evaluated by bronchoscopy and biopsy at 3 months and 10% at 2 years after completion of therapy. These results are considerably lower than the local control rates of 40% to 60% reported by soft clinical evaluation. [2,3] Perhaps contributing to poor local control was the uncertainty of target delineation and localization. Dillman and associates reported that a retrospective quality control review identified 23% of cases in which portal films failed to completely encompass the tumor. [4] In addition, lung cancers are usually quite large at presentation. It is the norm to have bulky tumors measuring greater than 2 to 5 cm. From basic principles advocated by Fletcher, it is thought that doses up to 100 Gy may be necessary to sterilize the size of tumors often treated in bronchogenic carcinoma. [7]

Further attempts at dose escalation were carried out in the RTOG prospective hyperfractionation trial 8301. [8] Fractions of 1.2 Gy were administered twice daily, and patients were dose-escalated through 60 Gy, 64.8 Gy, 69.6 Gy, 74.4 Gy, and 79.2 Gy. Among the 519 patients, 248 were considered favorable (absence of weight loss and a Karnofsky performance status of 70 to 100). Although no significant difference in disease-free survival was found in the unfavorable patients among the five arms, among the favorable patients a survival benefit was seen at the 69.6 Gy dose level but not higher. The reasons for this outcome have never been fully elucidated, although a higher incidence of high-grade pneumonitis was seen in the higher dose arms of the study.

This result suggested that indiscriminate dose escalation, without knowledge of dose and volume effects to the surrounding lungs may have a deleterious effect on survival. It is well known that the lungs are exquisitely sensitive to the damaging effects of radiation, resulting in a significant chance for injury, including acute pneumonitis and symptomatic pulmonary fibrosis. [9,10] What is less well understood or quantitated is the impact of radiation lung damage on long-term survival.

From the previous discussion, it is apparent that efficacy and toxicity are significantly impacted by volume of tumors treated. 3DRTP may impact on these issues. Thus the primary goals of 3DRTP have been as follows: (a) evaluation and reduction of pulmonary (and possibly other) sequelae, and (b) improved precision and targeting of tumor with dose escalation to improve local control and subsequently overall survival.

THREE-DIMENSIONAL RADIATION THERAPY PLANNING FOR NSCLC

In order to realize the full potential of 3DRTP, all components of such planning must be utilized. Using specific components (i.e., beam's-eye view or limited cuts of computed tomography [CT] data solely) does not constitute 3D therapy. Tumor and target definition using full 3D volume techniques, virtual simulation, 3D dose calculation, and dose-volume histogram plan evaluation are all critical components to successful 3D therapy for NSCLC.

Defining the Target: Aquisition, Immobilization, Views, and Displays

The initiation of 3D radiotherapy is accomplished with the aquisition of the CT data set. The thoracic data set must include not only the entire volume of the tumor but also the complete lung volume. Many institutions have found it important to also included the entire volumes of the brachial plexi (base of neck), the heart, and the liver. If organs are not included in their entirety, then they are potentially inadvertently treated (when noncoplanar beams are utilized and regions not scanned or contoured are irradiated through the entrance or exit of beams), and/or the volumetric analysis and dose-volume histograms (DVHs) are meaningless because of lack of the full volume information of the organ.

At Washington University, patients are "immobilized" in the supine position using an alpha cradle device with the arms comfortably and securely positioned above the head (Figure 48.1). Multiple laser markings on the anterior and lateral aspect of the patient's thorax, arms, and hips help reproducibly set up the patient on a day-to-day basis and move the patient from scanner to simulator to treatment machine. CT slices of 2 to 5 mm thickness are obtained from the level of the patient's larynx through the entire liver (Figure 48.2). This results, on average, in 70 to 120 CT slices, each of which usually requires approximately 0.5 GByte of storage. Although such thin CT slices through regions not harboring tumor are rarely needed, the quality of the digitally reconstructed images (DRRs) is much enhanced by thinner cut and greater number of CT slices. At Washington University, radio-opaque markers are placed on the patient's skin anteriorly and laterally at the time of CT scanning to establish the coordinate system (initial isocenter), which is also used as a reference for the CT and verification simulation. To facilitate the registration of the CT and verification simulation, as well as in some cases the verification port films, DRRs with bony anatomy enhanced are printed out in the anteropostero and lateral beam orientations at isocenter. All movements of the isocenter during planning are made relative to the original isocenter, which is directly translated to the patient's reference marks.

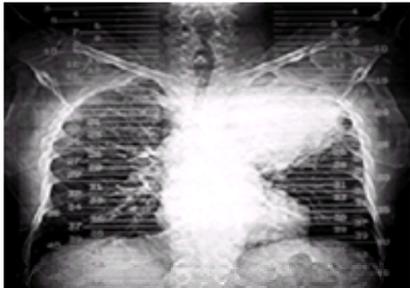
FIGURE 48.1. Lung cancer patient, immobilized using alpha cradle. Note multiple laser setup points to ensure reproducible setup.


FIGURE 48.2. Scout view of lung cancer patient's three-dimensional (3D) computerized tomography (CT) data set.

The next step in treatment planning is to identify targets and normal anatomy on the CT data set. This step, called *image segmentation,* "divides" the CT data set into parts so that anatomic objects of interest and tumor volumes are identified. The skin or external contour is easily identified automatically by threshholding and edge-detection algorithms. Delineation of the skin-air boundary is the 3D analogue of the traditional 2D skin contour measurement and is necessary for dose calculation. Normal anatomy that should be contoured includes the brachial plexi (labeled ipsilateral and contralateral), the total lung volume (the volume of both lungs together), the heart (from its base to the level of the base of the aorta), the esophagus (in its entirety from larynx to gastroesophageal junction), and the liver.

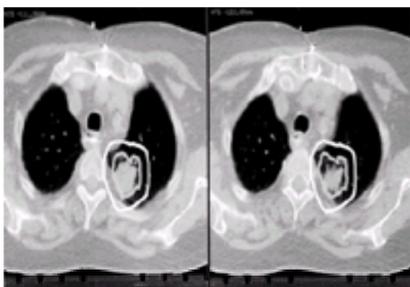
International Commission on Radiation Units (ICRU) 50 defined tumor and treatment targets. [11] The gross tumor volume (GTV) includes all identifiable gross tumor (Figure 48.3). It should include the primary tumor as identified by CT. However, CT data are not perfectly accurate in the identification of lung cancer and staging.[12,13,14 and 15] Other imaging modalities such as magnetic resonance imaging (MRI), endoscopic ultrasound, and/or positron emission tomography (PET) may be important in identifying the GTV. It also includes the grossly identifiable regional lymph nodes, such as those abnormally enlarged on CT (short axis greater than 1 cm),[15] those that are mediastinoscopically positive, and possibly those with abnormal metabolic activity identified on PET scanning. Some institutions have found it useful to designate the primary disease as GTV1 and the nodal disease as GTV2 (or vice versa). We have not found utility in this approach because all GTV is treated to the same dose level at Washington University and on the RTOG dose-escalation trial. However, if in the future different gross disease is treated to different dose levels, then it would be helpful to subdivide these categories at the time of target delineation. The clinical target volume (CTV) is that anatomic region(s) thought to harbor subclinical or microscopic disease (Figure 48.4). Institutions have done this in different ways also. Some define a specific 3D margin around the gross disease and call this CTV2. Elective nodal regions are called CTV1. Both of these could be lumped together. Because of failure to reach consensus of where the CTV is exactly, the RTOG elected not to have a separate CTV and defined the CTV as equal to the GTV.


FIGURE 48.3. Representative gross tumor volume (GTV) on selected CT slices.
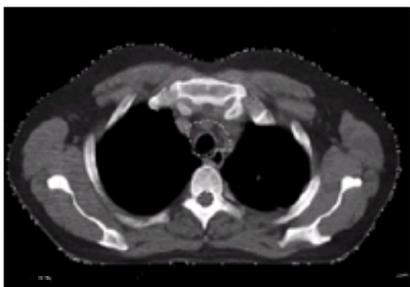

FIGURE 48.4. Representative clinical target volume (CTV) on selected CT slices.

Planning target volumes (PTVs) are 3D growth margins around the GTV and/or CTV to account for daily setup variations and patient motion. Because of physiologic motion in the chest, the volume of the PTV may be significantly larger than the GTV. Recently, Wong and co-workers demonstrated that breath holding can reproducibly "immobilize" targets and lungs between CT scans and presumably treatment sessions. [16] Theoretically, the volume of irradiated lung could be reduced, PTV margins could be reduced, and targets could be better localized during treatment with such a device. Such clinical experience and the measured therapeutic gain from such an approach is expected to be forthcoming.

After the CT data are segmented, a 3D model of the patient is produced and displayed for treatment planning. Organs and targets may be displayed as wire frames,

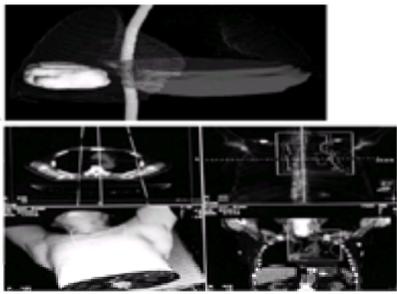
solid surfaces, or with various degrees of opacification (Fig. 48.5A). The 3D images must be reviewed prior to planning or treatment plan acceptance to ensure that organs were contoured correctly, in their entirety, and without image corruption. We have also found it important to ensure at this time that margins for CTV and/or PTV are fully 3D. Figure 48.5B actually shows an example where a 3D margin tool was *not* used, and one can see areas where PTV does not cover the GTV in superior 3D.


FIGURE 48.5. A: Lung cancer tumor target and normal organs displayed in "room view." B: Multiple images of anteropostero (AP) beam for lung cancer treatment. Note in the upper-right image that the green contour CTV does not have an adequate margin around the red GTV contour. This is because a 3D margin tool to generate the CTV was not used, thus only 2D margins were generated. (See Color Figure 48.5.)

Virtual Simulation

Virtual simulation begins after all targets and normal anatomy are contoured and treatment planning begins. [12,13,14,15,16,17,18,19 and 20] In essence, the concept of virtual simulation is that the functions of the physical simulator are emulated by the treatment planning software. The patient in reality goes home, but the planning and "simulation" of the patient model proceed. Quite complex and difficult simulations can be planned without the patient present. This method is ultimately more comfortable for the patient and often more efficient. The objectives of virtual simulation are to design the treatment apertures (portals) and the beam directions (gantry, collimator, and table angles). In most 3D systems, the simulation of the beam arrangement is performed on the 3D model of the patient. At most institutions, one of two approaches is taken. The first is the development of "class solutions" (i.e., a four- or five-field approach with beams AP/PA to spinal cord tolerance and then off cord oblique fields to the desired tumor dose). This approach is often a good starting point and allows the planner to assess target coverage and irradiation to the lungs and other organs to assess the acceptability of this initial plan.

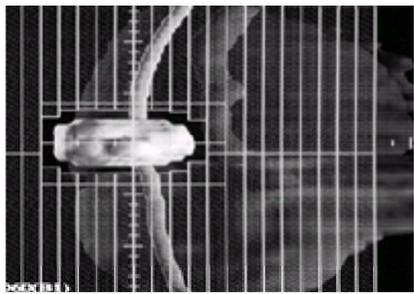
The second approach is for an experienced planner or dosimetrist to utilize the beam's-eye view and develop a unique beam arrangement for any one individual patient by avoiding specific normal organs. For example, noncoplanar, non–AP/PA beams may be particularly desirable for a plan specifically designed to avoid the heart and minimize the treated lung volume. Beam placement is particularly facilitated with the beam's-eye view. [21] Ideally, treatment angles are found that "separate" the tumor from surrounding normal structures (i.e., the beam is angled to treat just the target volume and miss the normal structures). Figure 48.6 shows a beam's-eye view of a field defined with multileaf collimation around a target volume.


FIGURE 48.6. Beam's eye view of tumor with port defined by multileaf colimation. (See Color Figure 48.6.)

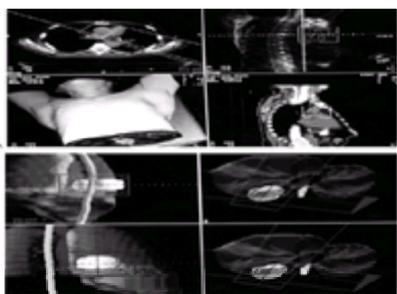
A feature called "autoblocking" is a time-saving tool that allows the planner to choose a specific margin desired around a target and have the block automatically conform to the target and the leaf position numerically and positionally specified. The virtual simulator records and reports all the necessary simulation data, including beam names, energy of beams, table, gantry and collimator positions, isocenter location, and any beam modifiers. The display of such data is often facilitated by multiple images and views of the plan (Figure 48.7). Axial, coronal, and saggital displays, as well as room view display and an opaque view of the patient's skin and the surface appearance of the entrance portal are all often useful in evaluating the virtual simulation process. Most systems also have an icon that displays the position of the gantry and the table to conceptually show their position. Some systems have implemented formal collision prevention components into their software to avoid the development of plans that are not implementable or dangerous to the patient or the equipment.


FIGURE 48.7. A, B: Multiple images used in 3D plan evaluation, including "room view," beam's eye view, axial, and saggital views. (See Color Figure 48.7 A, Color Figure 48.7 B.)

Dose Calculation

Technically, in some systems it may be difficult to separate the process of virtual simulation and dose calculation, so the process of dose calculation and subsequent beam angle and shape readjustment is usually an integral part of the 3D treatment planning. The dose is calculated and displayed on the 3D model. Isodose displays are usually color-coded and can be isodose "nets" or wireframes or color wash displays of dose (Figure 48.8A,Figure 48.8B,Figure 48.8C). Dose may be calculated with a variety of algorithms. It is imperative for the planners and evaluators to understand the strengths and weaknesses of their particular system's dose calculation algorithm. In the near past, the dose calculation methods used in planning systems were based on parameterizing dose distributions measured in water phantoms

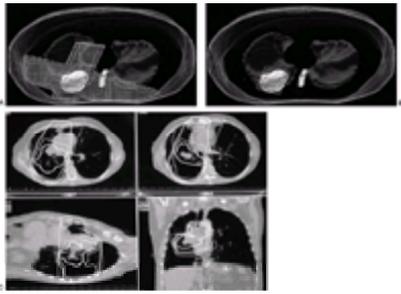
under standard conditions and applying correction factors to the beam representations for the nonuniform surface contour of the patient or the obliquity of the beam, tissue heterogeneities, and beam modifiers such as blocks, wedges, and compensator. However, more advanced models have now been developed that compute the dose more from first principles and that use only a limited set of measurements to obtain a better fit of the model. [22] These 3DRTP methods utilize convolution energy deposition kernels that describe the distribution of dose about a single primary photon interaction site.


FIGURE 48.8. A,B,C: Various images depicting isodose coverage and various dose levels in 3D. (See Color Figure 48.8 A , Color Figure 48.8 B , Color Figure 48.8 C .)

In addition to describing how scattered photons contribute to dose absorbed at some distance away from the interaction site of primary photons, the convolution kernels take into account charged particle transport. This information can be used to compute dose in electronic disequilibrium situations such as in the buildup regions and in the beam penumbra. Therefore, depending on the user's age and development of their treatment planning system, dose may be calculated with simple pencil beam algorithms, with or without heterogeneity, with Clarkson-type irregular field calculations, and/or with scatter effects of blocks and other beam modifiers. A simple example of how this ability may affect planning is that if scatter of penumbra effects are not taken into account in dose calculation algorithm, then the planner must realize that block edges must be wider than the target by approximately 7 to 10 mm or greater. This will not necessarily be appropriately displayed in the target DVHs. There may be significant differences in target coverage and normal organ partial volume irradiation depending on whether heterogeneity corrections are applied or not. The reader is cautioned to be thoroughly acquainted with their own 3D system dose calculation engine.

In the future, Monte Carlo simulations are expected to be the preferred method for 3DRTP dose computation. As the price/performance ratio of computer workstations continues to decrease, this type of dose calculation may be practical in the near future.

Plan Optimization and Evaluation

The optimization of a treatment plan currently involves an expert planner and allows for modification of the beam direction, beam shape, beam weights, and beam modifiers. Rapid calculation and recalculation and display of dose distributions allow the planner to make incremental improvements in plans.

The "optimal" plan must achieve the following goals:

1. The tumor target(s) treated to sufficiently high (prescription) dose. For most 3D institutions this is 70 Gy or greater. Although in the past the uniformity of dose across the tumor was thought to be a desirable goal, this theory has recently been called into question. Theoretical models suggest that even partial target volume irradiation may result in improved outcome. [23] Prior to 3D treatment systems and accurate dose calculation algorithms, there was little way to test this hypothesis. Graham and co-workers presented preliminary clinical data for NSCLC patients suggesting that maximum tumor target doses of greater than 79 Gy resulted in improved survival for patients with low-volume tumors (GTV less than 113 cc). [24]
2. The volume of irradiated lung must be kept sufficiently low. Experience with what constituted acceptable levels of lung irradiation is presented later in this chapter.
3. Radiation dose to other nearby organs, such as esophagus, heart, and brachial plexi, must also be kept minimal. There are few clinical data on what the partial volume tolerance doses for these organs are using 3D data.

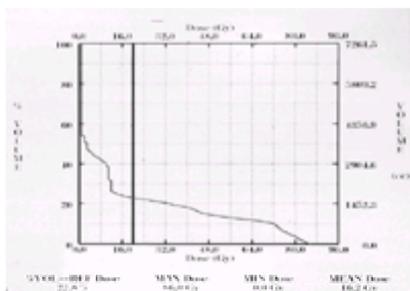
The development of dose volume histograms (DVHs) has greatly facilitated the objective plan evaluation and the consolidation of vast amounts of data depicted in the isodose displays. [25] At present, nothing has replaced the isodose display and "room view" displays for the spatial dose information regarding, but DVHs allow a planner to rapidly assess the adequacy, uniformity, and target dose coverage as well as the potential tolerability of nonuniform normal organ radiation treatment. Each contoured target and organ have a separate DVH. Many systems automatically report specific dose statistics from the DVH, such as minimum, mean, and maximum doses with the structure and the percent of the organ exceeding various threshold dose levels. Typical DVHs depict dose on the x-axis and volume (in absolute or percentage) on the y-axis (Figure 48.9). Traditionally, DVHs of normal organs and targets are depicted in a cumulative fashion. See Figure 48.9, or a DVH showing the 22% of the total lung volume received in excess of 20 Gy.


FIGURE 48.9. Dose volume histogram (DVH) of total lung volume. In this case, 22% of the total lung volume exceeded 20 Gy. Thus the V20 was 22%.

It is anticipated that in the future, optimization of plans will be more automated. This goal will require a greater amount of clinical outcomes to be related to DVH data. But as this data becomes more available, specific parameters upon which to optimize a plan are utilized. Computerized optimization utilizing normal tissue complication probabilities (NTCPs), tumor control probabilities (TCPs), and DVHs and "inverse" planning is used in intensity modulated radiation therapy (IMRT). At the time of this writing, little information on IMRT for lung cancer has been published. This lack is probably because of two reasons: (a) concern about the respiratory movement during treatment and resultant intensity modulated calculations not reproducibly produced during treatment, and (b) heterogeneity factors (most important in the lungs) not reproducibly accounted for in some intensity modulated systems. Pilot planning studies have been reported by Derycke and co-workers. [26] The authors reported that certain class solutions utilizing specific TCP and NTCP parameters could be used to optimize lung plans using IMRT for stage III NSCLC patients.

Other approaches to optimization of treatment planning include (a) a database of previously designed successful (or acceptable) treatment plans could be used to establish a rule-based computer system and used as a template to match the current needs of a given plan. This type of artificial intelligence has not been used very much thus far; [27] (b) utilization of radiation beams that avoid specific normal structures; [28] or (c) various algebraic methods or objective functions for treatment plan optimization. [29,30,31,32,33,34,35] and [36]

A common mathematic design for an objective function is to minimize the sum of the squares of the errors between the dose desired in each volume element (voxel) of the target and normal structures from the dose that would be delivered by a treatment plan condition. The "cost" of not meeting the goal would rise slowly as the solution varied from the goal and would then have a more rapid increase in cost as the deviation increased. In this approach the best solution has the minimum "cost." In fact, this quadratic formulation is common in the literature and was utilized in the first release of the NOMOS planning system for IMRT. However, the only restriction on objective functions is that they can be characterized mathematically, which means that one is not limited to dose as the only parameterization of outcome. Systems using biologic models that incorporate knowledge of dose-volume effects and dose-fractionation effects have been described. [37],[38],[39],[40] and [41] Specific attempts to relate such to lung clinical outcomes are discussed later in this chapter.

Unfortunately, each of these approaches suffers from serious drawbacks. There is a significant lack of correlation of 3D dose-volume data to clinical outcomes. Even if good dose-volume data become available, it is unclear how to combine all the DVH data from the various targets and normal organs into a single "goodness" of plan. Jain and co-workers attempted to develop a figure of merit (FOM) approach to the evaluation of plans. [42],[43] and [44] Unfortunately, neither the FOM approach nor the inverse calculation techniques can consider such factors as patient preferences, patient desire to minimize complications or maintain quality of life, institutional standards or practices, or specific physician beliefs and opinions regarding goals and desired outcomes of a given patient.

CLINICAL EXPERIENCE WITH 3DRTP FOR NSCLC

Treatment Planning Studies

Early studies with 3DRTP were computer-simulated studies comparing 3D with conventional 2D treatment plans for lung cancer. [28],[45],[46] and [47] In each of these studies, the authors demonstrated the improvement in treatment planning by either dose escalation, reduction in dose to surrounding organs, or both. The authors concluded that 3D planning potentially improved tumor target delineation and target volume coverage. [26],[47] It appeared that traditional beam arrangements were inadequate or potentially harmful (in terms of normal lung irradiation effects) in the delivery of target doses of greater than 70 Gy. [46],[47]

Assessment of Normal Tissue Toxicity

The development of acute pneumonitis is an undesirable and potentially very debilitating or even fatal complication after radiation therapy to the chest (Chapter 13). The doses of radiation that cause either acute radiation pneumonitis or chronic radiation fibrosis have only been partially characterized.

Emami and co-workers gathered data of available literature and published initial estimates of partial volume lung tolerance. [45] The data published normal tissue tolerance doses for a 5% (TD5/5) and 50% (TD50/5) chance of a complication occurring by 5 years of uniform irradiation of one-third, two-thirds, and whole lung. The TD50/5 for whole lung was 17.5 Gy, for two-thirds of the lung was 30 Gy, and for one-third of the lung was 45 Gy.

Martel and co-workers retrospectively reviewed the 3D DVHs for the lungs of 21 patients with Hodgkin's disease and 42 lung cancer patients with the development of acute pneumonitis. [48] The authors reported a reasonable prediction for low versus high risk for the development of pneumonitis by dividing the patients into risk groups based on the calculation of the effective volume (Veff) of the total lung volume (both lungs together). There were differences in the mean lung dose between patients with complications versus no complications for both groups of patients. Patients without the development of acute pneumonitis had mean lung doses of 18 to 21 Gy (average doses) versus 24 to 26.1 Gy (average doses) for patients with acute pneumonitis.

A study by Oetzel and coworkers showed good correlation for the pneumonitis risk estimations with observed complication rates for ipsilateral lung DVHs but not paired lungs (or total lung volume). [49] Mean lung dose differed somewhat for patients with and without complications (23.8 Gy versus 20.1 Gy). Marks and co-workers found that the total lung NTCP was the single best predictor for pulmonary symptoms after irradiation. [50] The V30 (volume receiving ³ 30 Gy) was also a strong predictor. Graham et al. reported that the single best predictor of acute pneumonitis was the V20 (volume of total lung receiving ³ 20 Gy), although on univariate analysis both Veff and total lung mean dose were also correlated with acute pneumonitis. [51] Kwa et al. pooled the data from five institutions (University of Michigan, University of Heidelberg, Washington University, Duke University, and Netherlands Cancer Institute) for a total of 540 patients. [52] Mean lung dose was the only dosimetric parameter collected. Increasing mean lung dose correlated well with the increasing pneumonitis rate.

Others have attempted to evaluate local radiation damage and dose-response relationship to the overall volumetric function of the lung. [53],[56] Changes in perfusion and ventilation pre- and postirradiation was examined, and a dose-effect for local changes were determined. Boersma reported that "overall response parameter" as a mean reduction in perfusion over the total lung correlated to the incidence of pneumonitis. [55] Marks investigated whether functional DVHs (fDVHs) resulted in better predictions of pneumonitis. [46] These fDVHs were based on pretreatment SPECT perfusion data, and were used to consider local lung function in the design of the optimal treatment plan. Unfortunately, there appeared to be too many confounding factors, such as patients with very severe PFTs improving after radiation therapy, and the functional DVHs did not result in an improved ability to predict pneumonitis. Further studies at Duke University with biochemical markers such as TGF-b showed elevated levels related to increased pulmonary symptoms, although this could not be related to dose or volume dependence, nor when compared with NTCPs or V30 was it a strong predictive factor for the development of pneumonitis. [46],[56] Another factor not accounted for in the models is the indication that the lower lobes of the lungs, or dependent lung bases, are more radiosensitive than the upper lobes. [51],[52] However, these may simply be a volume effect, and that irradiation of lower lobe tumors results in greater volume of lung irradiation. [51]

Graham and co-workers reported the correlation between the V20 and actuarial incidence of £ grade 2 pneumonitis to be very strong (p = 0.001). [61] When the V20 was less than 22%, the incidence of pneumonitis was 0. When the V20 was 22% to 31%, 32% to 40%, and more than 40% the actuarial incidence of pneumonitis was 7%, 13%, and 36%, respectively. Graham reported the severity of pneumonitis to also be related to the V20. [61]

V20(%)	Grade 2(%)	Grade 3–5(%)
<22	0	0
22–31	8	0
32–40	13	5 (1 fatal)
>40	19	23 (3 fatal)

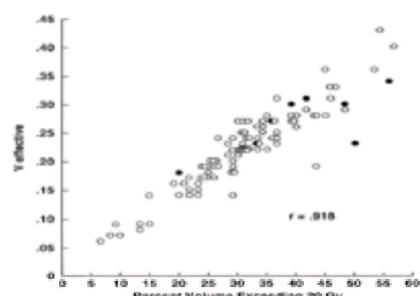
Graham also reported the very close relationship between the V20, Veff, and mean lung dose (Figure 48.10). She reported that from the Washington University data, upon multivariate analysis the V20 was the single best predictor of acute pneumonitis. [51]


FIGURE 48.10. Close relationship between the V20, Veff, and mean lung dose.

Results of Clinical Trials

The results of single-institution 3D clinical trials for NSCLC are shown in Table 48.1. Because these early trials were before significant dose escalation, the doses treated ranged from 60 to 74 Gy. These reports thus represent the results of more standard doses but with the technical support such as BEV and 3D dose calculation. One can see that the results appear somewhat better than those from the large chemoradiation trials of the early 1990s. Of course one must be cautious about any significant conclusions because these are single-institution trials.

Institution	Number of Patients	Dose	Survival Median	1 yr (%)	2 yr (%)	3 yr (%)
University of Michigan	8	≥80 Gy	15 mo	–	3	5
University of Chicago	37	60–70 Gy	19.5 mo	75	37	–
Memorial Sloan Kettering	6	64–72 Gy	16 mo	–	32	–
Washington University	15	60–74 Gy	21.5 mo	57	40	23

Dose-Escalation Trials

The University of Michigan began its dose-escalation trial in 1992. The trial was designed to dose-escalated different patient populations based on their calculated risk of pneumonitis. The Veff parameter was chosen to stratify the patients for their risk of pneumonitis. The risk groups were as follows: (a) the lowest risk group had a Veff of less than 0.20 Gy; (b) the intermediate risk groups had Veffs of 0.20 to 0.25 Gy, 0.25 to 0.31 Gy, and 0.31 to 0.40 Gy; (c) the highest risk group had a Veff of more than 0.40 Gy. As of August 1995, 48 patients had been accrued to the study.[62] Since that time the addition of chemotherapy has been allowed prior to entering the study, and in the lowest risk group the administered doses have been as high as 100.8 Gy. To date no acute radiation pneumonitis has been observed in any volume or dose group. Other encountered toxicity has been the development of two patients with [3] grade 3 esophagitis. Two patients developed exsanguinating hemorrhages (both patients had tumors surrounding the main pulmonary artery). Biopsy-proven radiographic local failures were documented in two patients having received 84 Gy tumor dose. Of the 10 patients treated to [3]84 Gy, biopsy-proven residual disease or locally recurrent disease occurred in three patients, and three patients had complete histologic response on follow-up bronchoscopy.[62]

The Memorial Sloan Kettering Cancer Center reported using dose-volume histogram analysis, grade 3 or higher toxicity occurred in 38% of patients receiving greater than 30% of their lung volume [3]25 Gy versus 4% of patients with less that or equal to 30% of their lung volume [3]25 Gy. Pneumonitis was also correlated with the NTCP. Their dose-escalation protocol proceeds based on a single-dose escalation schema but limits who may enter the protocol to an NTCP of £20%.[60]

The RTOG dose-escalation trial for NSCLC patients stratifies the patients for risk of pneumonitis based on the pretreatment plan V20. The risk groups are less than 25%, 25% to 37%, and more than 37%.[63] Patients have been successfully dose escalated to 83.8 Gy without the development of high-grade acute pneumonitis.

Each of the aforementioned trials has eliminated elective nodal irradiation in an attempt to reduce pulmonary toxicity. This decision was based on the recognition that most failures in lung cancer are at the site of gross disease. It is hoped that in this era of combined modality therapy, chemotherapy will reduce the recurrence of microscopic disease in the regional lymphatics. It is also recognized that even though the mediastinum is not targeted for the presciption dose, it receives some dose. Clearly, portions of the mediastinum and ipsilateral hilum receive varying doses of the entry or exit or scatter dose, depending on their proximity to the gross tumor. However, it has been very difficult to quantitate this dose. The issue of elective nodal irradiation is extremely controversial, and the results of the ongoing trials are imperative to establish the practice as a standard of care or not. In addition, after the maximum tolerated dose or doses for NSCLC are established, further trials comparing 3D therapy to conventional doses and volumes may be necessary to establish a therapeutic advantage. Only in this way will the true value and efficacy of 3D therapy for lung cancer be confirmed.

SUMMARY

3D radiotherapy for lung cancer has emerged as an important component of therapy for lung cancer. Results of single institutions have given us parameters on which to evaluate the risk of acute pneumonitis and thereby stratify patients for dose-escalation studies. Individual planners using 3D planning for NSCLC can use these parameters to assess and reduce (by interactive planning) the lung complication rates in patients. Further clinical data correlated for esophagus, heart, soft tissue, and late pulmonary sequelae are needed. The value of dose-escalation with combined modality therapy remains to be established. It is anticipated that more sophisticated, user-friendly computer-assisted or optimized treatment radiation treatment plans will be used for the treatment of lung cancer in the future.

ENDOBRONCHIAL AND INTERSTITIAL BRACHYTHERAPY

BURTON L. SPEISER
JOHN J. KRESL

BRACHYTHERAPY FOR LUNG CANCER

The treatment of lung cancer by radiation has consisted primarily of the use of external-beam radiation. The use of brachytherapy in the form of manually arranged, low-dose-rate afterloaded sources emerged in the early to mid-1980s. It was not until the mid- and late 1980s that high-dose-rate, remote afterloading brachytherapy began to be utilized in increasing numbers. At the present time it is the most prevalent means of treating endobronchial disease with brachytherapy in the world. Endobronchial brachytherapy, however, has been used primarily for palliation, for new or recurrent disease. The use for curative intent treatment, while performed occasionally, is not as prevalent. Even less common is the use of radiation for occult carcinomas of the lung.

Brachytherapy for carcinoma of the lung, for ease of discussion, is categorized into endobronchial/intralumenal (within a lumen) and interstitial (in tissue) techniques. Endobronchial/intralumenal treatment is divided into low-, intermediate-, and high-dose-rate applications and refers to the temporary placement of the isotope into the tracheobronchial tree. Generally, interstitial implantation most commonly applies to the use of Iodine-125 implanted permanently at the time of surgical resection.

Brachytherapy was probably first used at the close of the nineteenth century when the Curies gave a small radium tube to Danlos for insertion into a malignancy. During the next 20 years, Kernan,[1] using a rigid bronchoscope, reported the implantation of Radon-222 seeds into carcinomas of the tracheas and bronchus. He reported 10 cases treated with Radon-222 seed implantation and diathermy treatment. He commented that, "It was possible to destroy the tumors with diathermy and Radon implantation, and there have been no local recurrences as yet, although one case has been followed for 5 years." During this time, and for the next 10 years, work was being performed on standardization of dose calculation and prescription for brachytherapy. The publication of the Manchester System of Patterson, Parker, and Meredith (1934) set the foundation for brachytherapy dosimetry. This system was expanded by the manual, *Radium Dosage*.[2] Pool[3] reported on Radon-222 used at Memorial Hospital in 42 patients implanted between 1936–1960. The implanted seeds were sealed gold capillary tubes filled with Radon-222 gas. The technique reported by Pool "proved to benefit patients with primary tracheal tumors, and patients with bronchial stump recurrences following pulmonary resection." Radon-222 seed implantation was also used during thoracotomy with the first reported case by Graham and Singer. [4]

To decrease the radiation safety problems (potential leakage) with Radon-222, radioactive isotopes of shorter half-life and lower decay energies were sought. Afterloading techniques, reducing medical personnel's and patient's exposures, inserted catheters or tubes later filled with live, radiation-emitting sources. Henschke[5] introduced standardized afterloading techniques with Gold-198 and, subsequently, Iridium-192. With the shorter half-life of Iridium-192 and afterloading techniques, interstitial implantation became commonplace in medical use. However, despite this general rapid increase, there were few changes and limited use of brachytherapy for carcinoma of the lung. Early transbronchial implantation techniques initially utilizing Radon-222 and then Iodine-125 through the rigid bronchoscope were difficult and associated with a considerable expenditure of physician time and effort. By their nature, these were less commonly afterloaded situations, so this fostered lack of development and acceptance. With the advent of the flexible bronchoscope, a new flexible applicator system was designed and reported on by Martinez and colleagues.[6] In addition, Farber and colleagues in an unpublished study in 1986 described a system using Gold-198 with a flexible bronchoscope system.

The use of intraluminal brachytherapy, the placement of an afterloading flexible applicator bronchoscopically, was first reported in the American literature by Mendiondo.[7] About 1984 the neodymium-YAG laser was introduced into clinical use for treatment of tracheal and endobronchial obstructions for both primary and metastatic lung malignancies. This caused a renaissance of interest in intraluminal brachytherapy, now utilizing the afterloading techniques after YAG laser photoresection.

Most patients with lung malignancies present with locally advanced or metastatic disease. Unresectable patients, whether or not they undergo an attempted resection, have a high risk of subsequent local recurrence. Despite treatment with external beam radiation therapy, doses have been inadequate due to normal tissue limitation, so local recurrence remains a problem. In addition, with improved overall survival and local control for inoperable patients treated with combined radiochemotherapy, local tumor recurrence remains a problem. This component of local recurrence spurred many clinicians to employ brachytherapy to deliver additional ionizing radiation therapy, which concentrates dose to tumor regions and limits dose to sensitive adjacent normal tissue structures.

Brachytherapy provides direct application of radioactive sources to an anatomic site, such as a surgical tumor bed or within a tumor mass. Brachytherapy can be performed by implantation of radioactive sources, such as seeds within the tumor mass (interstitial brachytherapy), or by insertion of the radioactive source within the lumen of a catheter placed within the surgical bed or tumor mass (intraluminal or endobronchial brachytherapy). Brachytherapy offers the potential advantage of providing a high-dose gradient of ionizing radiation that delivers a high dose to the seeded tumor-bearing area and a rapid decrement in dose to the surrounding normal structures. This occurs because of the inverse square law of ionizing radiation, which states that the dose of radiation decreases by one divided by the square of the distance $[R_2 = R_1/D_2]$.

Brachytherapy for lung malignancies may be placed most commonly as a permanent interstitial or temporary endobronchial radiation source, with remote or manual afterloading. Permanent implants are typically low-dose-rate sources of radiation delivered over an infinite period of time (for 1–125 the dose is calculated for 90 days) and for placement of individual radioactive sources/seeds within the target (surgical bed) or tumor (mass) volume. Step one is placement of afterloaded catheters at the target (surgical bed) or within the tumor site. Temporary or afterloaded implants are placed within the lumen of these catheters. Afterloaded implants can deliver either low-intermediate-, or high-dose-rate ionizing radiation at less than 2 Gy per hour (low-dose-rate LDR), 2-12 Gy per hour (intermediate dose rate IDR), or greater 2 Gy per minute (high dose rate HDR). A typical afterloading system utilizes hollow catheters and Iridium-192 seeds embedded in nylon ribbon for low dose rate, or Iridium-192 sources (10 curie) to be placed within the lumen of the treatment catheters.

TECHNICAL ASPECTS OF REMOTE AFTERLOADING UNITS

Most remote afterloading units utilize high-activity radioactive sources of a small physical size, usually Iridium-192, whose initial activity is 10 curie (Fig. 49.1). The radioactive source is securely attached to the end of a wire cable. This is mechanically driven by a high-precision mechanism that allows for positioning of the radioactive source at specific stations within the catheter for specific dwell periods. The translocation of the source between these preassigned stops and times, as well as removal of the source out of the catheter into the shielded unit's compartment is rapid to minimize transit time exposure. The treatment sequence for each

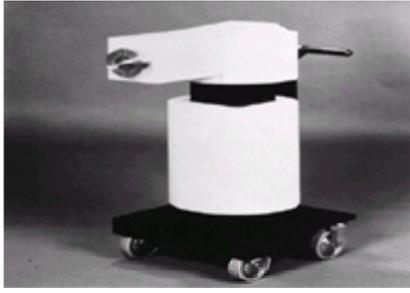
cable/catheter, which defines the various dwell times and dwell positions, is calculated by treatment-planning computers. The plan is executed under the control of an external computer, which drives the remote afterloading unit.


FIGURE 49.1. Micro-Selectron-HDR unit. (Courtesy of Nucletron Corporation, Columbia, MD.)

TREATMENT-PLANNING COMPUTER

The basics of dose-calculation techniques require orthogonal radiographs taken after catheter placement with dummy seeds in place to determine catheter position. On the simulator radiographs, the seed positions are digitized from the first dwell position at the end of the catheter to the most proximal dwell position in the catheter along the dummy source seed line. Next, the treatment target volume is defined by the treating physician. A treatment plan is then formulated, optimizing treatment points (dwell positions) and treatment time (dwell times position). This treatment plan is evaluated in the four cardinal directions utilizing isodose lines as well as evaluation of the patient's individual anatomy to calculate the final prescription dose and point. New techniques use CAT scans for a better three-dimensional picture.

ENDOBRONCHIAL CATHETERS

A variety of commercial catheters are available for use. Basically, physical characteristics of each catheter must allow for easy placement and removal from the endobronchial tree and immobilization within place. The catheters must fit through the biopsy channel of the endoscope and the source-compatible (most commonly used 5 or 6 French with a 1.7 or 2 mm internal diameter, respectively) and must be navigable through the scope. Finally, the catheter has a closed end to prevent loss of dummy seeds or the active sources.

The patient must be able to satisfactorily tolerate an endobronchial procedure. Then, with a pulmonologist, the catheter can be placed in an endoscopy suite. The procedure requires vital sign monitoring, topical anesthesia, and intravenous sedation. By bronchoscopy, the malignant lesion is identified by the pulmonologist and radiation oncologist. Photographic documentation and anatomical characteristics of the malignancy are noted, including distance from anatomical landmarks, such as bronchial segment branch points and carinae. The extent of the malignant lesion can be further localized utilizing radioopaque markers placed externally on the patient's thorax corresponding to the most distal and proximal extent of the malignancy as identified by the bronchoscope and correlated under fluoroscopy. After this visual inspection and fluoroscopic confirmation, a guidewire in a catheter is placed through the biopsy channel. Its placement is confirmed visually and fluoroscopically. The bronchoscope is removed and, when the catheter is positioned so that the tip is several centimeters distal to the most distal point of the malignancy, the proximal end of the catheter is then secured to the nose (Figure 49.2). The guidewire is removed and replaced by a set of dummy seed sources to identify source location for treatment planning and orthogonal simulation films (Figure 49.3).

TREATMENT FOR DOSE PRESCRIPTION

The prescription depth is measured for the three-dimensional volume by multiple points perpendicular to the axis of the catheter or source train to which the minimum target dose is prescribed. The prescriptions that are suggested in the literature range from 0.5–2 cm. To ensure treatment of the entire tumor volume, accommodating possible source or tumor movement due to cardiorespiratory, swallowing, and patient movement, the maximal distance from source center to the edge of the malignancy or target must be considered as part of three-dimensional brachytherapy planning. A longitudinal margin of approximately 2 cm proximal and distal to the malignant margins is commonly used. This margin allows for an effective dose distribution that encompasses the tumor volume without overdosing the tolerance dose to bronchial mucosa. The prescription point should be documented for comparative purposes.

Strategies for Treatment of Occult Carcinomas of the Endobronchus

Occult carcinomas of the lung are defined as carcinomas diagnosed by sputum cytology and bronchoscopy using brushings, washings, and/or biopsy. Frequently, fewer patients undergo bronchoscopy for cough and/or hemoptysis. These cannot be detected by conventional radiographic means before or immediately after the

initial diagnosis.

In 1974, Sanderson et al.[8] published "Bronchoscopic Localization of Radiographically Occult Lung Cancer." In 1980, Cortese et al.[9] published their study, "Roentgenographically Occult Lung Cancer." In the same year, Martini and Melamed[10] published "Occult Carcinoma of the Lung." Initially, the treatment of choice was surgery, either lobectomy or pneumonectomy; however, as photodynamic therapy (PDT) and then endobronchial brachytherapy (EBBT) increased, the "menu" of treatment modalities increased.

This subpopulation of roentgenographically occult carcinomas of the lung is associated with interesting attributes. First, the time interval from the initial abnormal sputum cytology to bronchoscopic confirmation, as reported by the Mayo Lung Project,[9] ranged from 1 to 1,014 days (median, 70 days; 75[10] percentile, 169 days). Second, the disease is most often Tis, T1, and N0 (Saito et al[11] found that of 94 patients, 17% were Tis and 77% were T1.) Third, most cases are squamous cell carcinomas; in a significant number dysplasia initially had been the only finding.[9] Fourth, no findings are apparent on plain radiography or, when available, on computerized axial tomography. Fifth, no adverse prognostic factors (i.e., weight loss) that predict lower cure or survival rates exist, and rarely are symptoms present.[2,3,4,5,6,7,8,9,10,11,12,13,14 and 15] Finally, synchronicity and metachronicity are significant. In a surgical series, Nagamoto et al.[6] reported a rate of 1.09 lesions per patient; Kato et al.[17] found 1.21 lesions per patient; and Saito et al.[11] found 1.2 lesions per patient. In the Mayo Lung Project Study,[9] a metachronous rate of 5% per year was reported, and in a study by Saito et al.[18] a rate of 0.022 lesions per patient-year was documented. In the latter study, the rate was 0.041 lesions per patient-year when synchronous and metachronous tumors were combined.

In this study of Saito et al.[18] if a patient had a second lesion, there was a 47% probability that within 5 years, a third lesion would be identified, at a rate of 0.11 lesions per patient-year. The five-year survival rate for patients with a single lesion and no evidence of synchronous or metachronous lesions was 90%. If, however, there was more than one other metachronous or synchronous lesion, the five-year survival rate was 59%. Survival is inversely related to probability of multiple lesions.

Other factors associated with successful outcomes include the size of the lesion. Many studies have found that lesions (10 mm in size are associated with the most favorable outcomes). In a surgical study of 127 patients,[19] 55 patients had lesions of this size, and no metastatic lymph nodes were identified. Of 46 patients with lesions more than 10 mm but less than 20 mm, 4 patients (9%) had nodal metastasis. Of 26 patients with lesions that were more than 20 mm but less than 55 mm, four patients (15%) had metastatic disease. In summary, there was no documentation of nodal metastasis with lesions less than 10 mm. For lesions more than 10 mm, however, the frequency was 11%. Thus lesion size may determine which patients have probability of nodule metastasis.

In an earlier study by Saito,[11] deep bronchial invasion was documented by pathologic analysis in 16 (17%) of 94 patients. Five (31%) of these 16 patients had nodule disease. Only 1 (1%) of 78 patients had nodal disease without evidence of extrabronchial invasion. No recurrences were identified in 75 patients who had intrabronchial disease, had no lymphatic spread, and who underwent a complete resection. Overall, the cause-specific five-year survival rate was 93.5% and 80.4% for all causes combined.

In 108 patients who underwent surgical resection for occult carcinoma. Nagamato et al.[6] identified 10 patients (9.2%) who had additional squamous cell carcinomas less than 1 mm in size. In turn, these lesions were associated with either dysplasia or marked atypia.

Kato et al.[17] treated 45 lesions fulfilling the criteria for occult carcinomas in 40 patients (1.13 lesions per patient). PDT was the only treatment used for 30 lesions in 20 patients, and the complete response rate was 100%. Three patients (15%) had recurrences, one (5%) of whom later died of the disease. An additional nine patients (45%) died of unrelated causes.

Considerably fewer patients with occult carcinomas were treated with endobronchial brachytherapy (EBBT) than with photodynamic therapy (PDT) or surgery (see also Chapter 24). Sutedja et al.[20] reported two patients with T1 squamous cell carcinoma who were treated with high-dose-rate EBBT. Three fractions of 10 Gy were delivered at a 1 cm depth. Both patients were alive without disease at follow-up examinations, at 54 and 25 months, respectively.

Tredaniel et al.[21] treated 29 patients with a variety of lesions, whose common denominator was that their carcinomas were limited to the bronchus, and were therefore radiographically occult. Consequently, the disease could be encompassed by intraluminal brachytherapy. In contrast to all other reported series, however, these patients had undergone prior treatment, which included surgery, external radiation, and/or chemotherapy. The patients were treated with high-dose-rate EBBT using a dose of 7 Gy calculated at a 1 cm depth for 6 fractions (42 Gy). The median actuarial survival of these patients had not been reached after 23 months of follow-up.

Saito et al.[11] treated 49 occult carcinomas in 41 patients (1.2 lesions per patient) with external-beam radiation using 40 Gy in 20 fractions, and with EBBT of 25 Gy in 5 fractions. Doses were customized, and the prescription point varied between 3 to 9 mm depth, based principally on the average diameter of the airway being treated. With a median follow-up of 24.5 months, only two patients (5%) had experienced recurrences.

A prospective study reported by Perol and coworkers,[22] had the following selection criteria in the treatment of occult lung cancer with EBBT: All cases were proximal non–small cell lung carcinomas from an area not previously irradiated, with a size of less than 1 cm. All lesions were roentgenographically occult, and the patients all had severe chronic respiratory failure or had already had surgery or external radiation for previous lung carcinoma to other sites. An escalating dose protocol was used, and all doses were prescribed at 1 cm.

The first two patients received three fractions of 7 Gy each, the next four patients received four fractions of 7 Gy each, and the last 13 patients received five fractions of 7 Gy each. Two months after the completion of treatment, 15 (83%) of the 18 evaluable patients' cases were locally controlled with negative biopsies. At one year, 12 (75%) of 16 evaluable patients revealed no evidence of disease. Actuarial one- and two-year survival rates were 78% and 58%, respectively, with a median survival of 28 months. Of 13 patients who received five fractions of 7 Gy, two developed necrosis of the bronchial wall. These patients died of hemoptysis, one with no evidence of carcinoma.

This group of patients was selected for minimal disease but also for their common co-morbid conditions: a history of prior lung cancer and moderate to severe medical problems precluding surgery. Ten patients had undergone surgical treatment for a previous lung carcinoma. Six patients had pneumonectomy, and five of these had mediastinal irradiation. Two were treated for previous carcinoma of the lung by radiation therapy alone. One patient was in cardiac failure at the time of treatment, and another patient had HIV infection with severe immunodepression. Of four patients with previous carcinoma of the lung, two were treated before the EBBT, one with cryotherapy and the other with chemotherapy, but without affecting the endobronchial lesion. Thus this group of patients, with their adverse medical history of either prior lung carcinoma (treated by surgery and/or radiation) or severe medical problems, had respectable one- and two-year actuarial survival rates.

The substantial synchronous and metachronous rate and the findings of additional small carcinomas with dysplasia and marked atypia all lead to the concept of a "field defect" (see also Chapter 23). Thus it is likely that the entire bronchial mucosa is at risk with a high probability of more than one lesion developing, either as a synchronous or metachronous lesion, in this select group of patients. If this is the case, then the strategy of treatment must include this as a basic assumption. Although lobectomy and/or pneumonectomy cure a certain percentage of patients, the remaining lung will continue to be at risk.

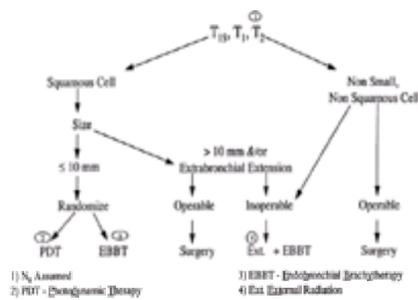
Therefore, selected lesions, that is, those less than 10 mm, with no evidence of extrabronchial extension, and squamous cell histology can be considered for therapies designed to preserve pulmonary function (PDT or EBBT). Lesions more than 10 mm or with evidence or suggestion of extrabronchial extension or nonsquamous histologies are less optimal candidates because they have higher risks of morbid disease. A suggested strategy is outlined in Fig. 49.4. We propose to randomize lesions less than 10 mm with squamous cell histology to the two therapeutic modalities most conserving of pulmonary function.


FIGURE 49.4. Algorithm for the management of an occult lung carcinoma.

We have treated more than 600 patients on protocols using EBBT. Of these patients, only 19% were treated for curative intent, and of these, only five (4%) met the criteria to be classified as radiographically occult carcinomas and are summarized in Table 49.1. The symptom index score used to classify each patient is listed in Table 49.2. This is a semiquantitative symptom index described later in the chapter, which allows for description and scoring of the symptoms of the patients during their medical course. Five patients are included, with a total of six lesions treated, for a rate of 1.2 lesions per patient. The rate of death from intercurrent disease was high, with two of five patients (40%) dying from intercurrent disease. One patient died of recurrence at 676 days. At the time of analysis, two of the patients were alive and with no evidence of disease (NED) at 1,228 and 650 days, respectively. In contrast to other reported studies, these patients were treated with a more conventional approach utilizing the current curative intent protocol described later in detail, which allowed for the delivery of 60 or 64 Gy, with external radiation therapy given concurrently with their EBBT. In this group of five patients treated with the combination of external beam radiation and EBBT, no complications occurred.

TABLE 49.1. BRACHYTHERAPY FOR RADIOGRAPHICALLY OCCULT CARCINOMA

TABLE 49.2. SYMPTOM INDEX SCORING SYSTEM

A frequently asked question is "what percentage of patients with lung cancer will benefit from intraluminal brachytherapy?" To attempt to answer this question, the total number of patients diagnosed with lung cancer within the referral area was approximated. For the greater Phoenix/Maricopa county area, the cases of lung cancer for 1986 through 1996 were estimated to be 9,000 cases. Of these, only 19% received radiation, and 16% of that group, or 3% of all patients, were treated on protocol, whereas an additional 11% of patients receiving radiation, or 2% of all patients, were treated with brachytherapy off protocol. Thus 27% of all patients receiving radiation, or 5% of all diagnosed patients, received brachytherapy. For patients on the curative protocol, these figures were 3% and 0.5%, respectively.

Results of Endobronchial Brachytherapy for Stages I, II, and IIIA or Recurrent Lung Cancer

Bronchogenic carcinoma often leads to symptoms indicating airway involvement, including obstructive pneumonia, atelectasis, hemorrhage, cough, and interference with airflow. YAG laser photo resection has immediate results but is restricted to central airways and to use by highly experienced operators. Unfortunately, conservative photo resection of the tumor without other interventions usually results in a fairly rapid reobstruction of the airway. The principle of endobronchial brachytherapy is that a high dose of radiation is delivered in a short period to the tumor and much less to normal tissues, in contradistinction to external radiation which, because of its inability to avoid considerable amounts of normal tissue, must be given in much lower doses per day to prevent undue complications.

Historically, it is always of interest to note that as early as 1922, Yankauer[23] placed radium capsules into the region of bronchogenic carcinoma for two patients with airway obstruction. In 1933, Kernan[1] used radon seed implantation. With the advent of fiberoptic bronchoscopy, new techniques became possible. The first reported use for transbronchial implantation was by Moylan[24] in 1983, using Gold-198 seeds. Also in 1983, Mendiondo[2] used an afterloading tube placed with the aid of the fiberoptic bronchoscope and then placed an Iridium-192 source into the tube. A total of 3,000 cGy delivered at a 5 mm depth was prescribed, with an average treatment time of 10 hours. From this it was noted that all patients had "significant improvement" in bronchial obstruction. Schray et al.[6,25] reported on afterloading with Iridium-192 in 1985 and again in 1988. A single catheter was used in 65 patients. Fifty-nine of his patients had either prior or concurrent external radiation, and forty of the patients underwent YAG laser photo resection. Roughly 60% of the patients showed a response, 20% were stable, and 20% had progression at follow-up bronchoscopy. In his second report in 1988, 11 patients had developed either fistulas or massive hemorrhage, 7 of which he felt were secondary to treatment. He also noted that six of the seven patients had undergone YAG photoresection and that this may have contributed to the complications.

High-dose-rate (HDR) remote afterloading was first reported in the American literature by Seagren et al.[26] in 1985. All patients in this reported series had endobronchial carcinoma and had previously received a minimum external-beam radiation therapy dose equivalent to 5,000 cGy prior to brachytherapy. Each patient had bronchoscopically documented disease with local symptoms and a Karnofsky performance status of 50 or greater. The HDR remote afterloading unit was a Brachyton using a 3 mm diameter Cobalt-60 source with an average strength of 0.7 Ci. The unit had the ability to oscillate the source up to a maximum of 16 cm. A single catheter was used, and a dose of 1,000 cGy in a single fraction was delivered at a prescription depth of 10 mm. The total time for treatment ranged between 12 and 27 minutes. They reported on a total of 20 patients treated between 1982 and 1983. Four patients had first received YAG laser photoresection prior to the brachytherapy procedure. Complete palliation of symptoms was seen in 25% of the patients, and a partial or complete palliation of symptoms was seen in 94% of the patients. In six of these patients, palliation was long-lasting with no recurrence of symptoms. In 12 patients, these symptoms recurred or progressed, with a mean time

to recurrence of 4.3 months.

Joyner and colleagues (1985)[27] first reported on the use of Iridium-192 solid wire afterloading for endobronchial treatment. They treated 14 patients with stage III non–small cell lung cancer with a combination of neodymium-YAG laser photoresection followed by endobronchial radiation and external-beam radiation therapy treatments. Brachytherapy treatment times were approximately 8–20 hours to deliver 3,000 cGy at a prescription depth of 5 mm. Rooney and colleagues (1984)[28] presented their information on the use of HDR endobronchial treatment utilizing a Gamma Med unit with an Iridium-192 source. This technique allowed for the stepping sequence of the source in up to 12 dwell positions spaced at either 0.5 or 1.0 cm. The patients were treated on a weekly basis receiving 600 cGy per week at a prescription depth of 1 cm with a maximum of five treatments.

Macha et al.[29] published a report in 1987 in which they utilized HDR afterloading with an Iridium-192 source in which the treatment was fractionated into three treatments through a single catheter. The dose was 1,500 cGy at a 5 mm prescription depth. Patients had laser, external radiation, and/or chemotherapy and had a high complication rate.

In all of the studies cited, the procedure consisted of using a single catheter for intraluminal brachytherapy. This is one of the few circumstances in the use of brachytherapy that a single-line linear source is the preferred method of treatment delivery. Volume implants from a dosimetric perspective are almost always preferred over a single-line source. Thus the ability to use more than one catheter allows for better dosimetry as well as better coverage of the disease process, which is rarely limited to a single tubular structure. An ideal system would allow more than one catheter to be used simultaneously. In addition, based on radiobiologic principles, fractionation becomes an important factor when variables of total dose and dose rate are considered. However, the ideal number of fractions for HDR quickly reaches a point that it is not feasible clinically and, thus, compromises must be made. Other physics factors have to be taken into account, including the choice of radioactive isotope, the dose at the prescription depth relative to the radius and inverse square law, as well as correction factors for the attenuation in water equivalent tissue versus air. Iridium-192 has the ability to be fabricated in small physical sizes of high activity, allowing passage through catheters with an internal diameter of 1.5 mm or less. In addition, Iridium-192 has virtually no significant correction for attenuation in water versus air up to a distance of 5 cm from the source. This makes Iridium-192 the preferred radioactive isotope to be used within tissues with a mixed air/water density interfaces such as intraluminal brachytherapy. The major drawback of Iridium-192 is its short half-life of 74 days, such that over a period of months, the activity and, thus, the dose rate changes considerably and the source needs replacement frequently. However, this disadvantage can be moderated by the frequent replacement of the sources and keeping the source strength well within the high-dose-rate range.

Table 49.3 is a compilation of most, but not all, of the studies published on high-dose-rate remote afterloading endobronchial brachytherapy. It covers the years 1985 to 1997 for a total of 2,842 patients. As the reader can see in the tabulation, there are different doses used per fraction, number of fractions, as well as the dose prescriptions point. Although the variation for fatal hemoptysis is extremely large, ranging from 0% to 50% of patients, the mean is 10.3%. Fatal hemoptysis depends on multiple factors, including total number of patients studied, extensiveness of follow-up, and level of aggressiveness of treatment. For a small series, such as that of Khanavkar,[30] where they reported 12 patients in their series and at 50% incidence of fatal hemoptysis, it is felt that this is not representative of what one may anticipate for the level of fatal hemoptysis. Likewise, there are reports of no fatal hemoptysis, such as that of Burt [31] reporting on 50 patients; however, when the same medical group updated their series and reported on a total of 406 patients, [32] their rate of fatal hemoptysis was 8%. Lastly is the question of level of aggressiveness. Some authors have attributed fatal hemoptysis to treatment, such as Bedwinel, [33] who reported a 32% rate of hemoptysis, whereas Macha[34] and Speiser[35] reporting on 365 and 485 patients, respectively, in 1995 reported rates of 21% and 8%, respectively, and had adequate information to indicate that many, if not all, of the cases were secondary to carcinoma, and thus, it can be construed that the treatment was not aggressive enough.

TABLE 49.3. COMPILATION OF ENDOBRONCHIAL HDR STUDIES

In 1986, Speiser and Spratling developed a series of scoring systems (see Table 49.2, Table 49.4, Table 49.5 and Table 49.6) for selecting patients for treatment as well as for outcome analysis. Their initial report [36] was based on experience with an intermediate-dose-rate unit, which was a modification of a low-dose-rate unit, to allow a much higher specific activity of Iridium-192 for rapid delivery of dose. In some of the low-dose experiences, delivery of radiation took as long as 60 hours. The increase of Iridium-192 activity allowed the treatment time to be decreased to 1.5 to 4 hours. The range is based on (a) shorter times when the sources were new, (b) longer times as the sources decayed, and (c) the use for the first time of multiple catheters to deliver treatment. All treatments were performed in an outpatient setting and followed a protocol, which is outlined in the next section. As mentioned earlier, entry into the protocol and analysis of outcome utilized semiquantitative measures, which will be discussed within the protocol area.

ECOG (Zubrod) (Host) (WHO)	Karnofsky	Definitions
0	100	Asymptomatic
1	80–90	Symptomatic: fully ambulatory
2	60–70	Symptomatic: in bed less than 50% of the day
3	40–50	Symptomatic: in bed more than 50% of the day but not bedridden
4	20–30	Bedridden

TABLE 49.4. INFLUENCE OF PERFORMANCE STATUS ON PATIENTS WITH INOPERABLE LUNG CANCER

Weight Loss Score (WLS)	Weight Loss (% of body weight)
0	0
1	1–4.9
2	5–9.9
3	10–19.9
4	>20.0

Location	Percent Obstruction		
	>50	10–50	<10
Trachea	10	5	2
Main stem	6	3	1
Lobar bronchi	2	1	

Atelectasis/pneumonia received additional 2 points per lobe

TABLE 49.6. OBSTRUCTION SCORE

PROTOCOL

Our protocol was initiated in 1986 when EBBT was transformed from low-dose-rate manual afterloading to medium-dose-rate remote afterloading procedures. This was a transitory step of short duration, lasting for 9 months. The high-dose-rate remote afterloader was, in fact, a Nucletron Selectron low-dose-rate remote afterloader that was modified to accept a longer source train and a much higher level of radioactivity. The activity was usually maintained at greater than 20 mc per cm. Dose rates initially were calculated at a 5 mm depth perpendicular to the source train, and were in the range of 5 to 10 cGy per minute.

Eligibility

Eligibility for the protocol includes the following: (a) Disease must involve the trachea, mainstem, or lobar bronchi. (Involvement of the segmental bronchi without involvement more proximal was not considered to be sufficient for entry into the protocol.) (b) The central airway disease must be intraluminal, visualized, and biopsied via bronchoscopy. (Patients requiring transbronchial biopsy were ineligible for the protocol.) (c) Patients must have significant symptomatology within the four symptom groups consisting of cough, dyspnea, signs and symptoms of obstructive pneumonia, and hemoptysis.

Evaluation of the patients meeting eligibility criteria to be placed on the EBBT protocol schedule were reviewed within the context of all patients diagnosed with lung cancer within the referral area from 1986 through 1996. This involved the greater Phoenix/Maricopa county area and utilized a reconstruction of the Tumor Registry to calculate an incidence rate of approximately 9,000 cases of lung cancer during the ten-year period. Of these, only 19% received radiation, and 16% of that group, or 3% of all patients, were treated on protocol, while an additional 11% of patients receiving radiation, or 2% of all patients, were treated with brachytherapy off protocol. Thus 27% of all patients receiving radiation, or 5% of all diagnosed lung cancer patients, received brachytherapy. For patients on the curative protocol, these figures were 3% and 0.5%, respectively.

Indications

Indications for treatment are given in Table 49.7. The first three are those used in the protocol presented later in this chapter. The fourth is presently being used, and the fifth is an indication used occasionally.

TABLE 49.7. INDICATIONS FOR TREATMENT WITH ENDOBRONCHIAL BRACHYTHERAPY

Protocol 1.0 Curative Intent

To be eligible for this protocol, patients must not have had prior radiation within the thoracic area, which would preclude the adequate delivery of a full dose of external radiation. Patients must be inoperable and have a primary lung carcinoma with a non–small cell histology. Stages accepted were $T_{1,2,3} N_{1,2} M_3$. These stages correspond to stage groupings I, II, and IIIa. Performance status using the four-tiered weight loss system, likewise, must be 0, 1, or 2 and correspond to weight losses of 0, less than 5%, or less than 10%, respectively, of the patients weight in the 6 months prior to diagnosis. The rationale for selection of this level of weight loss is described in *Oncologic Assessment Using the Four Tiered Scoring System.*[37] Patients were treated within the group characterized by dose as described in Table 49.8.

Group	Year	External cGy		Internal cGy				Unit
		Dose	FXS	Dose	Depth	FXS		
Curative Protocol								
1	1986–1988	6,000	30	1,000	5 mm	3		MDR
2	1988–1990	6,000	30	1,000	10 mm	3		HDR
3	1990–1992	6,000	30	750	10 mm	3		HDR
4	1992–1994	6,400	32	500	10 mm	3		HDR
Palliative Protocol								
1	1986–1988	3,750	15	1,000	5 mm	3		MDR
				1,000	5 mm	3		MDR
2	1988–1990	3,750	15	1,000	10 mm	3		HDR
				1,000	10 mm	3		HDR
3	1990–1992	3,750	15	750	10 mm	3		HDR
				750	10 mm	3		HDR
4	1992–1994	3,750	15	500	10 mm	3		HDR
				500	10 mm	4		HDR
				750	10 mm	3		HDR
Recurrent Protocol								
1	1986–1988			1,000	5 mm	3		MDR
2	1988–1990			1,000	10 mm	3		HDR
3	1990–1992			750	10 mm	3		HDR
4	1992–1994			500	10 mm	4		HDR

TABLE 49.8. MODIFICATION OF DOSES BY YEAR FOR THE CURATIVE, PALLIATIVE, AND RECURRENT PROTOCOLS

Protocol 2.0 Palliative Intent

Protocol 2.1

Eligibility for these patients includes primary lung cancer with non–small cell histology, and stage T_1N_3 and/or M_1 disease. These stages correspond to stage groupings IIIb and IV. In addition, the patients ineligible for protocol 1.0 because of performance scores of 3 or 4 or a weight loss of 3 or 4 (>10%) were reallocated to this protocol. Patients were treated within the group characterized by dose as described in Table 49.8.

Protocol 2.2

Primary lung cancer consisting of small cell histology, both limited and extensive, primary lung cancer with contralateral metastatic disease involving the endobronchial mucosa, and nonlung primaries with metastases primarily to the mucosa were treated within this category. Patients were treated within the group characterized by dose as described in Table 49.8.

Protocol 3.0 Recurrent Patients

All patients who had received prior radiation for a curative intent for carcinoma of the lung were included within this category. Patients were treated within the group characterized by dose as described in Table 49.8. Group I patients were treated with medium dose rate. In the palliative protocol, brachytherapy was constant and the use of external radiation was optional at the discretion of the treating oncologist. Its use was restricted to patients with extrinsic disease that caused a significant contribution to the level of obstruction and/or symptomatology.

Results

The following results incorporate 600 patients treated in the curative, palliative, and recurrent protocols outlined previously. In each of the successive periods of the operation of the protocol, the eligibility factors for the curative, palliative, and recurrent protocols have remained constant.

All patients treated in curative protocols with external radiation received 2 Gy per fraction, and in palliative protocols, 2.5 Gy per fraction. If patients received concurrent brachytherapy and external radiation, both treatments were not given on the same day. For the curative protocol, brachytherapy was delivered during weeks 1, 3, and 5. For palliative and recurrent protocols, brachytherapy was delivered weekly for three or four fractions, depending on the protocol.

The distribution of patients into the protocol groups was as follows: curative 19%, palliative 48%, and recurrent 33%. The age distribution of the patients had a median of 68 years and a mean of 67.1 years. Most of the patients fell within the range of 60–80 years old. The gender distribution was 62% male and 38% female. The percentage of female patients increased from 28% in group 1 to 41% in group 3 and 4. The breakdown for male/female patients was similar to that of all patients presenting with carcinoma of the lung within the geographic treatment area.

Squamous cell carcinoma is by far the most common cell type, overall, in the study (49%), and even to a greater extent for those treated in the curative protocol (70%). This percentage is considerably higher than is currently being seen in newly diagnosed outpatients with lung cancer (27%). This finding corresponds to long-held observations that squamous cell carcinomas tend to be more central and adenocarcinomas more peripheral.

The use of laser photoresection predated the wide use of high-dose-rate brachytherapy for airway carcinoma. In this study there was a gradual decrease in its use from an initial 32% to 16% in the latter part of the study. It is currently estimated that less than 5% of patients with central airway disease will require laser photoresection in the future.

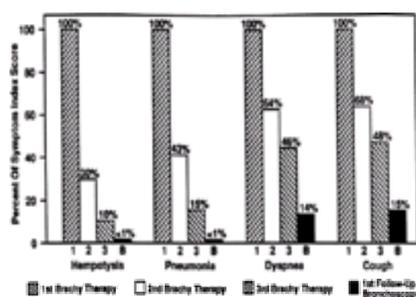
The protocol required that patients must have one or more of the four primary symptom complexes in order to be included in this study. The incidence of the symptoms in the study were cough greater than 99%, dyspnea 97%, hemoptysis 64%, and the signs and symptoms of obstructive pneumonia 49%. Using the four-tiered symptom index as outlined in Table 49.2, the severity of the symptoms were weighted and the total weighted scores were subsequently normalized to 100%. Response for each symptom score is related to each brachytherapy procedure and the first follow-up bronchoscopy (Figure 49.5).


FIGURE 49.5. Percent of symptom index score.

Hemoptysis had the most dramatic and rapid of the responses with improvements of 70%, 90% and more than 99% at each intervention point. Pneumonia improvement was only slightly less dramatic with responses of 57%, 85%, and more than 99%. Improvement in dyspnea occurred in 36%, 54%, and 86%, respectively. Lastly was cough, with improvements of 32%, 52%, and 85%, respectively. The improvements in hemoptysis and pneumonia were commonly seen within the first 24 hours following the first brachytherapy procedure. Thus patients who were admitted to the hospital with obstructive pneumonia and/or sepsis, or with severe bleeding requiring transfusion, have a prompt response allowing them to be moved from an area of intensive care to one of normal care or to be discharged from the hospital.

In the palliative protocol, the use of concurrent external radiation with brachytherapy was optional. When the weighted responses were measured for brachytherapy only, versus brachytherapy and external radiation, the results in terms of improvement at follow-up were as follows: hemoptysis 94% and 97%, pneumonia 86% and 82%, dyspnea 54% and 48%, and cough 51% and 57%, respectively. There was no statistical difference in response for each symptom group for each of these two therapies. The use of brachytherapy only was sufficient in itself to provide palliation without the need to add supplemental external radiation.

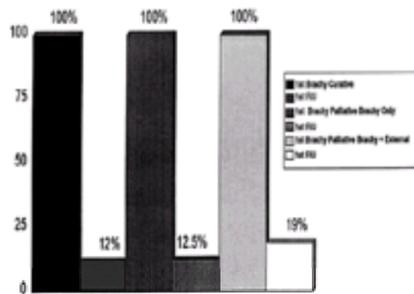
The obstruction scores, as seen in Figure 49.6, were analyzed in a different fashion. All of the scores were converted into median scores, which were normalized to 100%. These were obtained for each brachytherapy procedure and at the first follow-up bronchoscopy. The median score was normalized to 100%, and the residual level of obstruction is expressed as a percentage. (Any tissue including inflammatory tissue was included as part of the obstruction score.) The curative patients and the palliative groups fared better than the recurrent group, with scores of 12%, 12.5%, and 19%, respectively (Figure 49.6). This outcome is not unexpected considering that patients with recurrent carcinoma have had previous external radiation, which may select for a slightly more radioresistant, slower growing carcinoma and thus would be anticipated to be less sensitive to radiation. It is interesting that neither the use of concurrent external radiation or of laser photoresection led to improved clearing of obstruction. Thus, as in the symptom index results, the addition of external radiation or laser resection did not add to clearing endobronchial disease.


FIGURE 49.6. Obstruction score response. Obstruction score (mean) normalized to 100% (score obtained at bronchoscopy at first brachytherapy treatment) and compared to residual obstruction score at first follow-up bronchoscopy. Palliative Group combined result 17%.

The survival of patients by protocol group was 10% for the curative patients and 5% for the palliative-recurrent patients years. The palliative-recurrent patients had disease that was most often recurrent, advanced, and/or metastatic at or shortly after presentation, leading to low survival rates. The cause of death shows a significant failure rate for local disease in all categories. These rates were 31% and 30%, respectively, for the curative and palliative-recurrent protocols. As has been seen in numerous other studies, despite gradual increasing doses of radiation over the last several decades, local disease continues to be a significant problem.

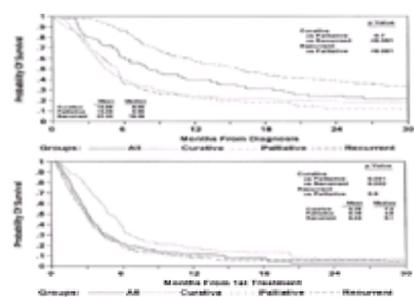
Survival curves for the curative versus the palliative-recurrent patient illustrated in   Figure 49.7 and are calculated from the date of diagnosis and date of the first brachytherapy procedure. There was no statistically different result between these two groups when analyzed from the date of diagnosis (p = 0.1); however, from the date of the first brachytherapy treatment, the p-value was less than 0.0001 comparing the curative versus the palliative-recurrent patients. (The recurrent patients are self-selected by the fact that they lived long enough to develop a symptomatic recurrence. This bias was eliminated when analyzing survival by date of treatment.)


FIGURE 49.7. Survival for curative, palliative, and recurrent groups from initial diagnosis   **(A)** and from first day of treatment **(B)**.

COMPLICATIONS

The complication most often mentioned when discussing endobronchial carcinoma and its treatment is that of fatal hemoptysis. This complication is defined as bleeding that is most often caused by erosion into the right or left pulmonary artery with subsequent exsanguination within the tracheal bronchial tree. This is a known complication of progression of untreated or inadequately treated carcinoma involving the tracheal bronchial tree, most often in the region of the upper lobe bronchi, due to their proximity to the pulmonary arteries. With the advent of intraluminal treatment, it must be considered as a possible complication of this modality.

In this study, the overall rate is 6% with the median time from diagnosis until death of 14 months; however, when measured from the date of the first brachytherapy until death, the median for the entire group is 5 months. Recurrent patients, as would be anticipated, have the highest rate of fatal hemoptysis at 9%, whereas the curative and palliative patients have rates of 5%. Of interest is that, in the different dose groups, there was an increase in fatal hemoptysis as the dose was increased from group 1 to 2; however, there was a slight further increase in the rate of hemoptysis as the dose was reduced and then a decrease in the rate of fatal hemoptysis (2%) with further dose reduction. Thus no dose-response relationship could be identified. In addition, the curative patients who had the greatest radiobiologic effect, in that all treatment was within a short period that is, external and internal radiation, had a rate of 5% versus the recurrent patients who had their treatment over a prolonged period, with a rate of 9%, and the palliative group of patients, who had the lowest doses delivered, had a rate of 5%. Fatal hemoptysis was measured in the palliative protocol patients where 41% of the patients were treated with brachytherapy only, and 59% with brachytherapy and external radiation. The rate of fatal hemoptysis was 5.5% in the brachytherapy-only group, and the combined group receiving higher doses of radiation had a rate of 4%. Once again, there was no evidence of a dose response.

The most common side effect seen that is definitively related to the intraluminal treatment was radiation bronchitis and stenosis. This was not an entity previously described until the initial description by Speiser and Spratling. [36] Table 49.9 is a definition of the grades of radiation bronchitis and stenosis utilized. The incidence of radiation bronchitis and stenosis by group are 9%, 12%, 14%, and 14%, respectively. By protocol, they were 23%, 12%, and 8%, respectively, for the curative, palliative, and recurrent protocols. The rate is clearly highest in the curative patients. When this rate was further analyzed, it was noted that the only significant factor predicting for this response was length of follow-up. Although the true incidence of this complication is not known for patients receiving external radiation only, it is still felt that this complication results primarily from intraluminal brachytherapy with its very high mucosal doses.

Grade	Definition
1	Fibrinoid membrane without significant luminal obstruction: no symptoms
2	Increase of exudation and fibrous membrane with mild obstructive symptoms requiring therapeutic intervention, such as simple debridement or medical treatment
3	Characterized by severe inflammatory response with marked membranous exudate including fibrosis requiring multiple debridements
4	A greater degree of fibrosis resulting in stenosis with decreased luminal diameter requiring laser photo resection, balloon or bougie dilation, and/or stent placement

TABLE 49.9. GRADES OF RADIATION BRONCHITIS AND STENOSIS (RBS)

For palliative patients, this complication was studied in those patients receiving brachytherapy only versus those receiving brachytherapy along with concurrent external radiation, and the incidence was 17% and 10%, respectively. Although the incidence was slightly higher in the brachytherapy-only group, the median time to occurrence was slightly longer in this group at 3.6 months versus 2.5 months for the patients receiving combined treatment.

MANAGEMENT OF COMPLICATIONS

The treatment of brachytherapy-related hemoptysis is the same as hemoptysis from other causes. This includes bed rest, codeine, transfusion for hemodynamic stability, avoidance or reversal of anticoagulants, vascular embolization, electrocautery, or lasocautery to reduce bleeding volume.

One of the largest reported series of patients treated with palliative brachytherapy alone is from the Christy Hospital in Manchester, England. [38] Three hundred twenty-two patients with inoperable non–small cell lung cancers were treated with a single fraction of HDR with a total dose of 15–20 Gy delivered intraluminally with the dose prescription 1 cm from the central axis of the catheter. Patients were evaluated 6 weeks after completing the HDR treatment with regard to their symptoms, including stridor, hemoptysis, cough, dyspnea, pain, and pulmonary collapse. In addition, at various times following the brachytherapy procedure, 83 bronchoscopies were conducted on 55 patients. Massive hemoptysis leading to death occurred in 32 patients (8%). Cox multivariate analysis revealed that treatment-related factors associated with subsequent massive hemoptysis were brachytherapy dose more than 15 Gy, prior laser therapy, second brachytherapy treatment, and concurrent external-beam radiation therapy. Twenty of the 25 assessable deaths related to hemoptysis had recurrent and/or residual tumor suspected at the hemoptysis site. The chronology of the massive hemoptysis leading to death occurred between 9 and 12 months after completion of the HDR procedure. This was in stark contrast to deaths from all other causes, which usually occurred 3 to 6 months after completion of the HDR procedures. [39]

Brachytherapy-related bronchitis and stenosis are managed based on the level of severity of the reaction and/or stenosis. This can include observation for mild treatment-related bronchitis for the least symptomatic presentation, and can be actively treated in a more debilitating form with oral and/or aerosol administration of steroids, aerosol-administrated bronchodilators, codeine- or narcotic-based cough suppressants, and antifungal or antibiotic therapies for symptomatic management, as well as correction of the underlying cause. More aggressive interventional management for debilitating and/or life-threatening levels of bronchitis and/or stenosis may be managed with balloon and/or bougie dilation, laser photoresection, bronchoscopic debridement, and/or placement of intraluminal stents.

Although lung brachytherapy has been advocated by radiation oncologists for the past 20 years, recent technologic developments in the area of high-dose-rate brachytherapy, such as the design of high-activity, physically small Iridium-192 sources and remote afterloading machines have prompted renewed interest in lung endobronchial high-dose-rate brachytherapy. The specific role of lung EBBT is not clearly defined at this time to be instituted within the standard and/or uniform community practice. There is an ongoing evolution for the tumor selection criteria to identify those patients most likely to benefit from EBBT with regard to local control, which may translate ultimately to improved survival. The American Brachytherapy Society (ABS) HDR Consensus Guidelines [40] currently state that, although endobronchial brachytherapy has demonstrated efficacy for symptomatic relief of bronchial obstructions and hemoptysis, either alone or in combination with external-beam radiation therapy, the curative benefit of brachytherapy in additional to conventional external-beam radiation therapy and/or chemotherapy has not been proven. The ABS recommends that brachytherapy for the definitive treatment of lung cancer be done within the context of a controlled clinical trial, if possible. Outside of clinical trials, the ABS suggests that brachytherapy be reserved for palliative treatments alone. Although the guidelines do not clearly state the indications for additional external beam radiation in newly diagnosed lung cancer patients, EBBT alone is recommended for recurrences after full-dose external-beam radiation therapy treatments have been administered. No single-dose fractionation scheme has been identified that provides for superior therapeutic ratio. Dose specifications have been recommended to be prescribed to a depth of 1 cm from the source center for uniform prescription dosimetry comparisons.

A study by the Radiation Therapy Oncology Group (RTOG) evaluated the palliation provided by external beam radiation to patients with newly diagnosed nonmetastatic, non–small cell lung cancers. [41] This study by Simpson et al. demonstrated that a short course of external-beam radiation therapy delivering 30 Gy in 10 fractions provided relief of hemoptysis in 74% of patients, cough in 55% of patients, and dyspnia in 43% of patients. Median survival was in the range of 6 months. Compared to this RTOG study, brachytherapy alone appears to provide equivalent palliation as external-beam radiation, with a similar survival outcome. Given this fact, brachytherapy may give more prompt symptomatic relief of obstructive symptoms in a more cost-effective manner.

In a small group of 19 patients treated with HDR to a total dose of 15 Gy, [42] in which a detailed assessment with rigorous testing was performed before and after administration of the HDR brachytherapy, and chest x-rays, CT scan of the thorax, direct bronchoscopic evaluation, objective obstruction index scoring, five-minute walking stress tests, isotope ventilation and profusion lung scanning, and formal pulmonary function tests with maximum inspiratory and expiratory full-volume measurements were conducted. Symptomatic relief was reported in 17 of the 19 patients. Atelectasis of a collapsed lobe or lung reported in 13 patients was demonstrated to have reinstituted ventilation in nine cases by radiographic imaging. Bronchoscopic evaluation of luminal patency had demonstrated improvement in 18 of the 19 patients. Isotope lung scans showed significant increase in the percentage of total lung ventilation and profusion in the abnormal lung. This rigorous study demonstrated the high correlation between objective and subjective improvement of the presenting symptomatology in these patients. In addition, it confirmed the palliative benefit of brachytherapy, which has been described in larger groups of patients. A prospective randomized study of brachytherapy and external-beam radiation therapy are clearly needed to directly compare treatment efficacy and toxicity, as well as a cost-benefit analysis and quality-of-life analysis in this setting.

CONCLUSIONS

Endobronchial brachytherapy is an excellent means of treatment for palliation of symptoms for patients with lung cancer, with a low probability of cure; that is, the palliative protocol group and patients with lung cancer previously irradiated. This treatment does not require concurrent treatments for most of these patients as long as the disease process involves central airway disease secondary to intrinsic involvement.

For curative intent patients, it provides rapid relief of obstruction and the signs and symptoms of obstruction. In the survey of literature, as well as this study, survival advantage is not shown. This group of patients must, in the future, be randomized to external-beam radiation therapy versus external-beam plus intraluminal radiation to evaluate a possible survival benefit prospectively.

For the future, further studies will be necessary to determine the most optimal dose and number of fractions that will provide the greatest patient benefit, the lowest morbidity, and the lowest cost of treatment. In addition to randomized protocols of external-beam versus external plus internal radiation, it will be necessary to test the hypothesis that chemotherapy adds to the benefit obtained by radiation as the sole therapy. All proposed protocols for lung cancer should include the comorbid features and/or biologic markers that have been shown to be strong predictors for the probability of survival for lung cancer.

INTERSTITIAL

Interstitial brachytherapy began with Radon-222, and later Gold-198 and Iridium-192. Radon and gold in the form of seeds had been used because of their short half-life and rapid deposition of energy within the target area. Iridium-192 was most often used as individual seed sources sealed within polyethylene ribbons or strands, later to be placed in hollow nylon afterloaded tubes. However, it was not until the introduction of Iodine-125 with its low-energy gamma-ray emission primarily in the 30 KeV range (27–32 KeV) and a long half-life of 60 days (59.4) that the sources could be kept within the hospital and available in a standby mode. The newest isotope in use is Palladium-103, seeds that are, like the Iodine seeds, a low-energy gamma emitter (23 KeV), but with a shorter half-life (17 days). This isotope provides an increased dose rate, which is preferred for more rapidly growing tumors. The permanent seed implant with Iodine-125 or Palladium-103 is best used in those patients undergoing surgical resection when the margins are close or positive; the implant provides a high dose to a small volume aiming at improved local control.

The three primary methods of placement of seeds are (a) the use of loose seeds that are placed through a hollow stainless steel needle. The needles are placed within the target volume in an array usually with 1 cm spacings to accomplish a good dose distribution in two planes. The third plane is then set by deposition of seeds at either 5 or 10 mm increments along the needle length. The needles are placed at the maximum depth of interest, and then an applicator is attached to the needles such that the operator has the ability of depositing seeds at intervals of 5 mm or greater. Thus the three-dimensional array is first accomplished by placing the needles in a two-plane or more array and completing the third dimension by depositing the seeds along the needle track, slowly withdrawing the needle, and depositing the seeds. Placing hollow stainless steel needles into vital structures, bones, nerves, and vessels is not possible. (b) The needles or sources can also be placed within gelfoam or dacron sheets, the seeds deposited, and then the implanted material placed sheetlike over an area where implantation might not otherwise be possible. To stabilize the friable gelfoam, a Vicryl mesh or mobilization of tissue is needed to cover the implant to ensure that the gelfoam and seeds do not migrate. (c) A current technique uses Iodine seeds embedded within Vicryl suture. Standard Vicryl suture is modified by placing and spacing the seeds at 1 cm within the mesh suture. The Vicryl suture is supplied attached to a large-caliber needle to allow the operator to sew the strand. The size of the needle precludes its use in most clinical situations but allows the operator to remove the needle and to drape the suture using a needle of more appropriate size. The suture is sewn through an area, allowing excellent placement for spacing and fixation of the seeds. However, more often than not, the tissues in question (such as the major vascular structures and bronchial margins) will not allow this procedure to be performed in this manner, in which case, the needle is removed and the operator can then "implant the suture" by applying it to the critical structure by using vascular clips. The vascular clip should not crimp a seed but should be placed on the suture between the Iodine seeds. The doses judged

sufficient to eradicate macroscopic disease are 160 Gy for Iodine-125 and 125 Gy for Palladium-103 (prior to TG-43).

RESULTS

Because of the varying shapes of the sites in the thoracic cavity, which attempted to be implanted, a reasonable way to assess the benefit of implantation is to look at local control rates as an end point. Clinical groups may have different outcomes. These are seen in Table 49.10: Stage I or higher stage disease as locally advanced, unresectable with negative nodes, unresectable with positive nodes, superior Sulcus tumors and T$_3$N$_0$ chest wall disease. Table 49.10 shows the results for these subgroupings in terms of technique used (including if external radiation was used), and whether local control and survival were influenced. Overall local control is 71%, which, in conjunction with (a) good surgical resection and (b) adjuvant radiation and/or chemotherapy, can lead to an improved five-year survival.

TABLE 49.10. RESULTS OF INTERSTITIAL BRACHYTHERAPY IN NON–SMALL CELL LUNG CARCINOMA

What will not be found in the literature is that this technique requires extensive individual experience and expertise to obtain results similar to those reported by Hilaris[43,44,45, and 46] and Burt[31,32] without having an excessive complication rate. A good example would be the last intraoperative consultation I performed on a patient who underwent a left upper lobectomy with tumor peeled off the left pulmonary artery. The consultation was to determine if I would "implant" the pulmonary artery. Surgery involved stripping the carcinoma off the pulmonary artery. The recommendation was that implantation was not advisable due to an extremely high risk of pulmonary artery rupture. One week postop, the patient's left pulmonary artery ruptured and carcinoma was found in the artery wall at autopsy.

DISCUSSION

Interstitial lung brachytherapy is used infrequently in the United States. This may be due to the difficulty in gaining expertise with interstitial implant procedures, as compared to external-beam treatment planning or even endobronchial brachytherapy procedures. The recent introduction of Iodine-125 with its 60-day half-life and low-energy ionizing photon emissions have made interstitial brachytherapy more practical for consideration and implementation in the clinical practice. However, at this time, there is no proven role for interstitial brachytherapy alone or in combination with other treatment modalities, such as surgery, chemotherapy, or external-beam radiation therapy. The decision to use interstitial brachytherapy modality in concert with other treatment modalities must consider not only possible local control and survival benefits, but also its ability to improve the final outcome of the patient's medical care by symptomatic relief duration and rapidity, treatment costs for acute and chronic toxicity, and the ability to preserve a pulmonary cardiac musculoskeletal and neurological function.

CHEMOTHERAPY FOR ADVANCED NON–SMALL CELL LUNG CANCER

JOAN H. SCHILLER

Lung cancer is a common and lethal disease, killing more than 160,000 Americans in 1997—more people than breast cancer, prostate cancer, and colon cancer combined.[1] Despite recent advances in locoregional therapy, approximately one-third of patients will present with disseminated disease at the time of diagnosis, and thousands more will ultimately die of disease that is amenable to neither surgery or radiation therapy. Clearly, strategies aimed at systemic control are crucial.

Despite the widespread use of chemotherapy for other neoplasms, there has been pessimism on the part of many physicians to prescribe chemotherapy for advanced non–small cell lung cancer (NSCLC). This reluctance arises in part from early studies in which chemotherapy had limited success, and no clear survival benefit could be shown for its use. Over the past 5 years, however, several newer agents have been developed that have resulted in modest improvements in survival. Furthermore, additional studies have demonstrated that chemotherapy can improve the quality of life and control symptoms in many patients with advanced NSCLC. The purpose of this chapter is to review some of the newer chemotherapeutic agents in the treatment of advanced NSCLC.

CHEMOTHERAPY IN THE 1980s

The natural history of metastatic NSCLC is poor at best. The median survival is approximately 5 to 6 months, and only 10% of patients can be expected to be alive at one year.[2,3] Several randomized studies have compared different chemotherapy regimens to best supportive care with mixed results.[3,4,5,6,7,8,9 and 10] The differences in magnitude of benefit caused by chemotherapy may be explained by differences in study size, patient population, and chemotherapeutic regimens, with some of the regimens being alkaloid, rather than cisplatin, based. Recently, metaanalyses have demonstrated a significant benefit in survival with older chemotherapy regimens compared to best supportive care, although this benefit was modest at best. The mean potential gain in survival was only approximately 6 weeks, or 10% improvement in one-year survival.[2,11,12 and 13]

Until recently, no clear advantage to one chemotherapeutic regimen had been demonstrated. Randomized studies showed no significant benefit of cyclophosphamide, doxorubicin, methotrexate, and procarbazine (CAMP) vs. mitomycin, vinblastine, and cisplatin (MVP), etoposide and cisplatin (EP), or vindesine and cisplatin.[14] Indeed, in one randomized trial, first-line MVP resulted in a significantly higher response rate but poorer overall survival compared to single-agent carboplatin, which was associated with an overall response rate of 9% but a significantly longer median survival of 32 weeks.[15]

In one metaanalysis, the only chemotherapy drug that was associated with an improved survival compared to best supportive care was cisplatin.[2] Older trials using alkylating agents actually tend to show a detrimental effect with chemotherapy.[2] Furthermore, an analysis of survival determinants in more than 2,500 patients with advanced NSCLC by the Southwest Oncology Group (SWOG) found that the use of cisplatin was an independent predictor of improved outcome.[16] Hence, most of the newer agents have tended to be utilized in platin combinations.

Four randomized trials have compared single-agent cisplatin to combination therapy with "newer" agents (Table 50.1), which will be discussed in more detail following. All of the trials showed an improved response rate with the combination regimen, and three of the four showed an improvement in survival. Based on the results of the metaanalyses demonstrating an improved survival with chemotherapy over supportive care, and the randomized studies demonstrating an improvement in combination chemotherapy over single-agent cisplatin, the American Society of Clinical Oncology's clinical guidelines recognize that chemotherapy can prolong the survival of advanced NSCLC patients.[17]

	Cisplatin Median Survival (One-Year Survival)	Chemotherapy Combined with Cisplatin	Combination Chemotherapy Median Survival (One-Year Survival)	P
Wozniak[22]	6 mos (20%)	+Vinorelbine	8 mos (36%)	0.010
Sandler[31]	32 wks (26%)	+Gemcitabine	39 wks (39%)	0.003
Gatzemeier[?]	26 wks	+Paclitaxel	37 wks	.15
Von Pawel[39]	28 wks (22%)	+Tirapazamine	35 wks (38%)	0.003

TABLE 50.1. RANDOMIZED TRIALS OF SINGLE AGENT CISPLATIN VERSUS COMBINATION THERAPY

Although cisplatin is the only agent that has been associated with improved survival, it has not been associated with a dose-response relationship. The European Organization for Research on Treatment of Cancer (EORTC) performed a randomized study comparing a high dose of cisplatin (120 mg/m^2) to a standard dose (60 mg/m^2) in combination with etoposide in advanced NSCLC.[18] No difference in response rate or survival was noted between the two arms. The SWOG also randomized patients between standard-dose cisplatin (50 mg/m^2 days 1 and 8 on a 28-day cycle), high-dose cisplatin (100 mg/m^2 days 1 and 8 for four cycles), and high-dose cisplatin plus mitomycin (8 mg/m^2 day 1). No significant difference in response rates or median survival existed among the arms, and the high-dose arms were associated with an increased incidence of ototoxicity, emesis, and myelosuppression.[19]

Since the metaanalyses have been conducted, several new agents have become available which have continued to have a small but significant impact on advanced NSCLC. These agents are discussed in the following sections.

VINORELBINE

Vinorelbine is a newly developed semisynthetic vinca alkaloid that has been shown to have antitumor activity against advanced NSCLC in phase II studies. Recent randomized studies have compared vinorelbine with best supportive care, or with single-agent chemotherapy with fluorouracil plus leucovorin.[20 and 21] In a study comparing vinorelbine to best supportive care in elderly patients ($\geq$70 years old) with advanced NSCLC, a median survival of 27 weeks and a 6-month survival of 54% was observed with vinorelbine compared to 21 weeks and 39% for best supportive care.[20] The one-year survival of 27% for vinorelbine was superior to the 5% one-year survival observed with best supportive care (p = 0.04), resulting in early closure of the trial. In a randomized phase III study comparing single-agent vinorelbine with fluorouracil plus leucovorin in patients with metastatic NSCLC, vinorelbine was associated with a higher response rate, median survival, and one-year

survival (12%, 30 weeks, and 25%, respectively) compared to fluorouracil plus leucovorin (3%, 22 weeks, and 16%, respectively) (Table 50.2).[21]

TABLE 50.2. RANDOMIZED PHASE III TRIALS OF VINORELBINE IN ADVANCED NON–SMALL CELL LUNG CANCER

Subsequent phase III trials comparing vinorelbine plus cisplatin to other combination regimens have also confirmed increased activity and prolonged survival with the vinorelbine-containing regimens. A French study involving 612 patients compared single-agent vinorelbine to vinorelbine plus cisplatin versus the control arm of vindesine plus cisplatin. The one-year survival of 35% in the vinorelbine/cisplatin arm was superior to the one-year survival of 30% in the vinorelbine-alone arm, and the 27% one-year survival in the control arm.[22] Finally, the SWOG confirmed the benefit of vinorelbine by comparing single-agent cisplatin with vinorelbine plus cisplatin in patients with stage IIIB and IV disease.[23,24] Not only was the response rate and median survival higher in the vinorelbine/cisplatin arm, but the trial also confirmed the long-term survival advantage for the combination compared to cisplatin alone. Thirty-six percent of patients treated with vinorelbine/cisplatin were alive at one year compared to 20% of patients treated with cisplatin alone; moreover, the two-year survival doubled on the vinorelbine/cisplatin arm.

One French study failed to observe a survival benefit with the combination of vinorelbine and cisplatin over cisplatin alone.[25] Two hundred thirty-one stage III or IV patients were randomized to receive either 30 mg/m^2 per week of vinorelbine or vinorelbine plus cisplatin (80 mg/m^2 every 3 weeks). Although a significant improvement in response rates and time to progression was observed, the median survival between the two groups was nearly identical (32 weeks versus 33 weeks). Furthermore, the addition of cisplatin resulted in a significant increase in toxicity, so that 21% of patients on the combined modality arm discontinued therapy early, compared to 8% of the patients on the vinorelbine arm.

PACLITAXEL

The taxanes, paclitaxel (Taxol) and docetaxel (Taxotere), have generated considerable enthusiasm because of their broad-spectrum activity against a variety of tumor types both preclinically and clinically. Derived from the western yew tree, *Taxus brevifolia,* and the European yew tree, *Taxus baccata,* respectively, these agents enhance tubulin assembly into microtubuoles and inhibit depolymerization of microtubuoles. Their activity as first- and second-line agents in ovarian and breast cancer is well established, prompting evaluation in other tumor types.

Based on phase I studies that suggested activity in advanced NSCLC, the Eastern Cooperative Oncology Group (ECOG) conducted a randomized phase II study of paclitaxel, merbarone, and pirozantrone in advanced NSCLC.[26] Twenty-four patients were randomized to receive 250 mg/m^2 of taxol as a 24-hour infusion; although the overall response rate was only 21%, the one-year survival was 40%, among the highest ECOG has observed in a multi-institutional trial in this disease. Although the trial design was such that a formal comparison of survival rates was not statistically possible, the one-year survival on the other two arms was 23% and 22%, respectively. These encouraging results with paclitaxel were confirmed by a group at MD Anderson, who also reported a 24% response rate and 38.5% one-year survival rate.[27]

Based on these results, ECOG compared standard therapy with cisplatin and etoposide versus cisplatin plus 135 mg/m^2 of paclitaxel, versus cisplatin plus 250 mg/m^2 of paclitaxel plus granulocyte colony-stimulating-factor (G-CSF) in E5592.[28] See Table 50.3 Five hundred ninety-nine patients were entered on the trial; 194 eligible patients on the control arm, and 190 eligible patients and 187 eligible patients on the low-dose paclitaxel/cisplatin and high-dose paclitaxel/cisplatin/G-CSF arms, respectively. The response rates for the high-dose paclitaxel/cisplatin/G-CSF, low-dose paclitaxel/cisplatin and etoposide/cisplatin arms were 31%, 26%, and 12%, respectively (p < 0.05). Median survival was 10 months, 9.5 months, and 7.6 months, respectively. The one-year survival was slightly higher in the high-dose paclitaxel and low-dose paclitaxel arms compared to the cisplatin/etoposide arm (40% and 37% versus 31%) (p < 0.05 for combined paclitaxel arms compared to cisplatin/etoposide). Neuropathy and myalgias were dose-dependent in the paclitaxel arms. There was increased granulocytopenia on the taxol arms, particularly the non–G-CSF-containing arm (55% on the cisplatin/etoposide, 65% for paclitaxel/cisplatin/G-CSF, and 74% for low-dose paclitaxel/cisplatin). However, the incidence of infections and deaths caused by infections was relatively low and was similar across all three arms. No significant differences in cardiac toxicities were observed. Because no significant differences in survival were observed between the two paclitaxel arms, ECOG has chosen the 135 mg/m^2 dose without G-CSF as the control arm for the next randomized phase III study (Table 50.4).

TABLE 50.3. RANDOMIZED PHASE III STUDIES OF PACLITAXEL/PLATIN IN ADVANCED NSCLC

TABLE 50.4. ONGOING OR RECENTLY COMPLETED COOPERATIVE GROUP RANDOMIZED STUDIES IN ADVANCED NSCLC

Two European trials, however, failed to confirm a survival advantage of paclitaxel plus cisplatin compared to cisplatin alone, or cisplatin combined with teniposide. [29,30] One trial compared 175 mg/m^2 of taxol over 3 hours plus 80 mg/m^2 of cisplatin with 100 mg/m^2 of cisplatin alone. Although the response rate was higher in the combination arm (26% versus 17%; p = 0.028), the median survival was not different (8.1 months for paclitaxel/cisplatin versus 8.6 months for high-dose cisplatin; p = 0.86). In a second study, patients were randomized to 80 mg/m^2 of cisplatin with either 175 mg/m^2 of paclitaxel over 3 hours, or with 100 mg/m^2 of teniposide.[30] Although responses were again higher on the paclitaxel/cisplatin arm, the median survivals were not different (9.9 months versus 9.7 months). With the exception of increased myalgias and neuropathies on the paclitaxel arms, the treatments on both studies were well tolerated. Despite the lack of survival difference, patients on the paclitaxel/cisplatin arms of both studies reported a better quality of life.

These data suggest that the combination of paclitaxel and cisplatin is active in metastatic NSCLC. It is unclear, however, why a survival benefit has not been consistently observed, raising several questions regarding the optimal use of paclitaxel, including: What is the optimal duration of infusion? Would the substitution of other drugs result in enhanced efficacy?

Carboplatin is a platin analogue with a different toxicity profile than cisplatin. Unlike cisplatin, the primary toxicity is myelosuppression, with considerably less ototoxicity, renal toxicity, and neurotoxicity. Although the response rate to single-agent carboplatin is relatively low, it produced the best median survival time (31.4 weeks versus 25.8 weeks or less) in a randomized, five-arm ECOG trial.[15] Because of the single-agent activity of carboplatin and the neurotoxicity of the cisplatin/paclitaxel combination, several phase II trials have been conducted of carboplatin and paclitaxel with encouraging results.

With several exceptions, [31,32] these trials have been phase I/II trials or have been reported only in abstract form. The starting doses of paclitaxel range from 135 mg/m^2 to 175 mg/m^2, and the duration of infusion from 3 hours to 24 hours. [31,32,33,34,35 and 36] Various doses of carboplatin have been utilized, including area under the curve (AUC) between 6 and 11[31,34,37] or doses calculated on body size (300 mg/m^2–400 mg/m^2).[32,33,35,36] Despite these differences in study design, preliminary results have been encouraging. Reported response rates range from 20% to 62%. Median survival on the two phase II trials were 38 weeks and 54 weeks, with one-year survivals of 32% and 54%.[31,32] Because of the tolerability of the regimen and ease of outpatient administration, as well as these early reports of efficacy, carboplatin/paclitaxel has become one of the most widely used regimens in the United States.

Preliminary results from a recent randomized study, however, failed to confirm the superiority of paclitaxel/carboplatin [38] (Table 50.3). Three hundred sixty-nine patients were randomized to receive carboplatin at an AUC of 6 and paclitaxel (225 mg/m^2 over a three-hour infusion), versus 75 mg/m^2 of cisplatin and etoposide (100 mg/m^2 days 1–3).[38] Although the response rate was higher for carboplatin/paclitaxel (14% versus 22%, respectively), the one-year and median survival were not significantly different between the two (37% and 9.1 months for cisplatin/etoposide and 32% and 7.7 months for carbo/paclitaxel, respectively) (results presented at ASCO, 1998). However, carboplatin paclitaxel was reported to be more tolerable than cisplatin/etoposide, with significantly less febrile neutropenia and vomiting.

A second randomized multicenter trial comparing paclitaxel/carboplatin to paclitaxel/cisplatin in advanced NSCLC is currently ongoing. Patients are randomized to receive paclitaxel (200 mg/m^2 over 3 hours) plus carboplatin (AUC of 6 by the Calvert formula) or 80 mg/m^2 of cisplatin every 3 weeks.[39] Six hundred eighteen patients from 16 different countries have been randomized. A planned interim analysis on the first 289 patients showed no unexpected toxicity or any large response difference, and the trial is continuing.

The encouraging phase II data have resulted in carboplatin and paclitaxel being incorporated as one of the study arms in three different cooperative group trials (Table 50.4). ECOG is comparing carboplatin/paclitaxel to the control arm of cisplatin and paclitaxel, as well as cisplatin and gemcitabine, and cisplatin plus docetaxel. The SWOG recently completed a trial comparing carboplatin and paclitaxel to the "standard" of cisplatin and vinorelbine. The Cancer and Leukemia Group B (CALGB) is comparing single agent paclitaxel to carboplatin/paclitaxel.

DOCETAXEL

Docetaxel has been explored as a single agent in phase II trials in patients with advanced NSCLC. Phase II trials have used 60 mg/m^2, 75 mg/m^2, and 100 mg/m^2 of docetaxel as a one-hour infusion every 3 weeks (Table 50.5).[40,41,42,43,44 and 45] Responses in previously untreated patients range from 18% to 38%, with median survivals of 6 to 11 months. Interestingly, a 20% response rate as a second-line agent has been reported in phase II trials. [46,47 and 48]

	Dose (mg/m^2)	N	Overall Response Rate	Median Survival	1 Year Survival
Single Agent					
Cerny[40]	100	35	23%	11 mos	
Francis[41]	100	29	38%	6.3 mos	
Fossella[42]	100	39	33%	11 mos	
Burris[43]	100	14	21%		
Miller[44]	75	20	25%		
Watanabe[45]	60	68	18%		
With Cisplatin					
Cole[50]	75	26	46%		
Cisplatin 75–100 mg/m^2					
Le Chevalier[51]	75	24	25%		
Cisplatin 100 mg/m^2					
Zalsberg[52]	75	36	39%	9.6 mos	33%
Cisplatin 75 mg/m^2					

TABLE 50.5. PHASE II TRIALS OF DOCETAXEL IN NONSMALL CELL LUNG CANCER

In a phase I study when combined with 75 mg/m^2 of cisplatin, 75 mg/m^2 of docetaxel induced responses in 7 of 14 patients.[49] This combination of 75 mg/m^2 of docetaxel and 75–100 mg/m^2 of cisplatin has been evaluated in several phase II studies. [50,51 and 52] Febrile neutropenia was the dose-limiting toxicity in all three studies. Other grade 3 or worse toxicities include hypersensitivity reaction, diarrhea, nausea/vomiting, cardiac abnormalities, fluid retention, and infection. Response rates varied from 25% to 53%.

GEMCITABINE

Gemcitabine is a nucleoside analogue that has several potent actions on cancer cells at both the DNA and RNA levels. The relatively mild toxicity profile and activity in metastatic pancreatic cancer have prompted investigation in advanced NSCLC. Following a series of phase II studies that showed activity of gemcitabine in NSCLC, two randomized phase II studies were conducted in Europe and Taiwan comparing single-agent gemcitabine with cisplatin and etoposide patients. [53,54] Both studies involved randomization between weekly gemcitabine (days 1, 8, and 15 on a 28-day schedule), versus cisplatin administered on day 1 and etoposide administered days 1, 2, and 3 on a 28-day schedule. Although the doses of the drugs were slightly different between the two studies (the European study used 1,000 mg/m^2 of gemcitabine, whereas the Taiwanese study used 800 mg/m^2 and the European study utilized 100 mg/m^2 of both cisplatin and etoposide compared to 80 mg/m^2 of both cisplatin and etoposide in the Taiwanese study), both studies confirmed that single-agent gemcitabine was probably as efficacious as etoposide/cisplatin (Table 50.6). It should be noted, however, that these were randomized phase II trials, and thus not powered to detect small differences between the arms.

TABLE 50.6. RANDOMIZED PHASE II/III STUDIES OF GEMCITABINE IN ADVANCED NSCLC

Three randomized phase III studies have been conducted with cisplatin and gemcitabine (Table 50.6). A multicenter randomized study involving previously untreated patients with advanced NSCLC compared cisplatin (100 mg/m^2 day 1) with and without gemcitabine (1,000 mg/m^2 days 1, 8, and 15 of a 28-day cycle). An interim analysis of the results reported a 31% response rate on the gemcitabine/cisplatin arm compared to a 9% response rate on the cisplatin alone arm (p = 0.0001). [55] Updated results presented at the American Society of Clinical Oncology (ASCO) meeting in 1998 confirmed an improvement in median and one-year survival with cisplatin and gemcitabine (9.0 months and 39%, respectively) compared to cisplatin alone (7.6 months and 28%, respectively). [56]

A phase III European study randomized patients with advanced NSCLC to either gemcitabine/cisplatin (1000 mg/m^2 of gemcitabine on days 1, 8, and 15 of a 28-day cycle plus 100 mg/m^2 of cisplatin on day 2) or to mitomycin (6 mg/m^2 day 1), ifosfamide (3 gm/m^2 day 1), and cisplatin (MIC) (100 mg/m^2 on day 2 of a 28-day cycle). [57] A significant improvement in overall response rate was observed (40% for the gemcitabine/cisplatin arm compared to 28% in the MIC arm; p = 0.03). Median survival was not different between the two arms (35 weeks in the gemcitabine/cisplatin arm and 38 weeks in the MIC arm).

A randomized study comparing gemcitabine/cisplatin to etoposide/cisplatin was conducted by the Spanish Lung Cancer Group. [58,59] Results demonstrate a significantly higher overall response rate in the gemcitabine/cisplatin arm (40.6%) compared to the cisplatin/etoposide arm (21.9%). [60] Overall survival was 8.7 months for the gemcitabine/cisplatin arm compared to 7.0 months in the cisplatin/etoposide arm (p = 0.18) One year survival was 32% from gem/CIS versus 26% from CIS/etop.

TIRAPAZAMINE

Tirapazamine is a novel bioreductive agent with selective cytotoxicity against hypoxic cells in preclinical models. The drug is converted to the biologically active, free-oxidizing radical in a reversible reaction driven by low oxygen concentration and catalyzed by cytochrome P450. The oxidizing radical abstracts hydrogen from DNA, resulting in single- and double-strand breaks. In in vitro and in vivo models, tirapazamine synergizes with cisplatin.

A randomized trial involving 446 patients with stage IIIB disease with pleural effusion or stage IV disease randomized patients to receive tirapazamine plus 75 mg/m^2 of cisplatin versus cisplatin alone. [61] The combination resulted in a 27% response compared to a 14% response rate observed with cisplatin alone (p < 0.001) and a superior median survival of 35 weeks versus 28 weeks, respectively (p = 0.0078). The one-year survival with tirapazamine/cisplatin was 33% compared to 21% with cisplatin alone (p = 0.042).

STANDARD OF CARE IN 2000?

These data regarding the different new possible combinations should be interpreted with caution. First, significant differences in patient populations (performance status and stage) can be found among different trials. For example, although administration of cisplatin on days 2 or 15 has been reported to be more efficacious than administration on day 1 in phase II studies with gemcitabine, [62] the day 2 and 15 studies tended to have more patients with stage IIIA and IIIB disease. Secondly, stage IIIB patients tend to be a heterogeneous group, with some trials allowing any clinical stage IIIB patients, whereas other trials restrict patients to stage IIIB with plueral effusion or pathologically confirmed stage IIIB. Differences in performance status are also critically important. Finally, retreatment of patients on clinical trials with second-line therapy (or in many cases, the crossover drugs) has complicated interpretation of these studies. Thus no definitive statement can be made as to which of these many combinations is "best." Because not all studies are positive, the need for confirmatory, controlled studies is crucial. [25,36] Randomized cooperative group studies comparing these different combinations are ongoing or planned (Table 50.6).

SYMPTOM CONTROL

Numerous studies have shown that chemotherapy improves symptom control. [63] For example, in a Canadian study, bleomycin, etoposide, and cisplatin controlled cough, hemoptysis, and pain in two-thirds of advanced NSCLC patients; one-half of the patients experienced an improvement in fatigue, and more than 40% of patients experienced a reversal of weight loss. [64] A Spanish study reported that 17 of 19 patients with stage III and IV NSCLC (89%) treated with combination chemotherapy with high-dose cisplatin gained weight; 10 of 20 patients (50%) who presented with anorexia improved; 7 of 15 patients (47%) had an improvement in pain; hemoptysis disappeared in 10 of 11 patients (91%); 7 of 9 patients had an improvement in dyspnea (78%); and asthenia was attenuated in 8 of 16 patients (50%). [65] Similarly, a trial conducted by Memorial Sloan Kettering, in which 85 patients with stage III or IV were treated with EDAM, mitomycin, and vinblastine, also reported a significant improvement in symptoms. Sixty-two percent gained weight with treatment, and performance status improved in 44% of patients. [66] In a European study involving 161 patients with stage IIIB or IV NSCLC treated with gemcitabine, improvements in performance status, weight, analgesic requirement, pain, and other disease-related symptoms such as cough, dyspnea, hemoptysis, anorexia, and somnolence were also noted. [67] A second European study evaluated vinorelbine in elderly patients (>70 years old) with advanced NSCLC; performance status improved in 26% of patients, cough and pain improved in more than 49% of patients symptomatic at entry, dyspnea improved in 28%, and approximately one-half of the patients had stabilization of their symptoms. [68]

Fewer studies have carried out formal quality-of-life (QOL) analysis in NSCLC. The ECOG analyzed (QOL) in patients on E1594, a randomized study comparing cisplatin/etoposide to cisplatin/high-dose taxol/G-CSF to cisplatin and low-dose paclitaxel. [69] QOL was measured using the Functional Assessment of Cancer Therapy-Lung (FACT-L) at baseline, 6 weeks, 12 weeks, and 6 months. No difference existed between treatment arms on QOL scores, suggesting that QOL was not adversely affected by myalgias and neurotoxicities. A trial outcome index (TOI) was calculated, which combined the physical, functional, and lung cancer scores. TOI correlated with survival, but change from baseline to assessment had an even higher correlation, suggesting that baseline QOL may be used to stratify patients entering clinical trials, and that QOL change may be a predictor of survival.

An EORTC randomized study comparing paclitaxel/cisplatin to teniposide/cisplatin evaluated QOL with the EORTC QLQ-C30 and LC-13 instruments at baseline and every 6 weeks thereafter. [30] Patients receiving paclitaxel/cisplatin achieved a better score at week 6 for emotional, cognitive, and social function, global health status, fatigue, and appetite loss, although this improvement was lost at 12 weeks. Peripheral neuropathy was higher in the paclitaxel arm. Similarly, a second European study comparing high-dose cisplatin to paclitaxel and cisplatin found that patients in the paclitaxel/cisplatin arm reported a better QOL using the EORTC QLQ-C30 and LC-13 scale. [26] Despite more neutropenia, peripheral neuropathy, and arthralgia/myalgia, patients receiving paclitaxel/cisplatin reported better physical functioning and significantly less nausea and vomiting, anorexia, and constipation than patients receiving high-dose cisplatin.

Two randomized studies from the United Kingdom evaluated mitomycin, cisplatin, and ifosfamide with thoracic radiotherapy in stage III NSCLC, and with best supportive care in stage IV disease. In both stages combination chemotherapy improved QOL and survival. [70]

POOR PERFORMANCE STATUS PATIENTS

Patients with poor performance status (PS $\geq$ 2) have traditionally done poorly on cooperative group clinical trials. ECOG retrospectively analyzed data from 1,960 evaluable patients with advanced NSCLC treated on five ECOG protocols between 1981 and 1994. [71] Performance status was a significant prognostic factor in

predicting survival with patients with a PS of 0 having a median survival of 9.4 months compared to 3.3 months with a PS of 2. SWOG analyzed more than 2,500 patients with advanced NSCLC entered on clinical trials from 1974 to 1988. [16] Performance status was an independent prognostic predictor; patients with a PS of 0 or 1 had a median survival of 6.4 months and a 20% one-year survival, compared to a 3.4 months median survival and 9% one-year survival for patients with a performance status of more than 2.

Patients with a PS of 2 or greater not only are less likely to respond to chemotherapy and have an improvement in survival, but they are also more likely to experience toxicity. The four-arm ECOG trial by Ruckdeschel et al. discussed earlier, reported that PS 2 patients did significantly worse, with a 10% rate of treatment-related deaths. [14] Although their response rate did not differ significantly (PS0 = 26%, PS1 = 25%, PS2 = 20%), the median survival of PS 2 patients was significantly worse (median survival PS0 = 36 weeks; PS1 = 26 weeks, and PS2 = 10 weeks; p = 0.001). The current ECOG study, E1592, originally allowed patients with a PS of 0–2 to be entered. However, based on preliminary data suggesting a higher number of grade 3–5 adverse reactions in patients with performance status of 2, ECOG subsequently revised the study to limit it to patients with a PS of 0 or 1. Thus treatment of poor performance status patients cannot be recommended as because these patients tend to experience increased toxicity and decreased survival, and are unlikely to derive any clinical benefit.

SECOND-LINE THERAPY

Given the activity of some of the new compounds as first-line treatment for advanced NSCLC, it is reasonable to consider whether these drugs have activity as second-line agents.

Somewhat surprisingly, however, relatively few trials have rigorously examined the activity of second-line chemotherapy in NSCLC. Furthermore, these trials in general have not been well controlled for performance status, time to recurrence, and initial sensitivity or refractoriness to first-line chemotherapy. The greatest experience with second-line chemotherapy is with docetaxel. Two identical studies were conducted at the MD Anderson Cancer Center and the University of Texas at San Antonio, in which patients with locally advanced or metastatic disease whose disease was refractory to at least one prior cisplatin-containing regimen received 100 mg/m^2 of docetaxel every 3 weeks. [47] Patients were defined as platinum-resistant if they showed an initial response or stable disease to a platinum-containing regimen but then subsequently progressed, and platinum-refractory if they progressed during a platinum-containing regimen. Seventy-six of eighty-eight patients had a performance status of 0 or 1; 16% had stage III disease and 84% had stage IV. Fifty-eight percent were platinum-resistant and 42% were platinum-refractory. Fourteen of seventy-one evaluable patients (19.7%) achieved a partial response to treatment; the median survival was 9 months and one-year survival rate was 40%. Outcome results were not broken down by whether patients were platinum-resistant or platinum-refractory.

The authors subsequently retrospectively compared their data to a cohort of 36 NSCLC patients who would have met the entry criteria of advanced disease failing one platinum-based regimen and other similar patient criteria. [72] Both groups were balanced in stage, age, gender, histology, amount of prior chemotherapy, and response to first-line therapy, although more patients in the historical control arm (7/36) had a performance status of 2 compared to the docetaxel arm (2/44). Median survival was 42 weeks for the docetaxel-treated patients compared to 16 weeks in the historical control group, with one-year survivals of 39% and 16%, respectively (p = 0.003). An analysis of performance status of 0 or 1 only patients also showed a higher median survival and one-year survival in the docetaxel arm (42 weeks and 42%; n = 42) compared to the historical control patients (16 weeks and 16%; n = 29); (p = 0.018).

A multicenter phase II trial of docetaxel was recently conducted in platinum-treated NSCLC. [48] The results of this trial are somewhat lower than the MD Anderson and San Antonio trials; 12 of 80 patients responded (15%), with a median survival of 7 months and one-year survival of 25%. Confirmation of the activity of docetaxel as second-line treatment for NSCLC awaits the results of two phase III trials comparing docetaxel to best supportive care or a "control arm" of vinorelbine or ifosfamide.

The second-line activity of the related taxane, paclitaxel, has also been evaluated as a single agent. In a phase II study of 40 patients with metastatic NSCLC who had failed one prior platinum-containing regimen, only one partial response was observed out of 35 patients. [73] Median time from last treatment was 2 months; 68% of patients had a performance status of 0 or 1 and 32% had a performance status of 2. A second trial observed two responses out of 14 patients (14%) and a median survival of 120 days, although 5 patients were alive at 202 to 320 days. [74] A phase I dose-seeking study of paclitaxel reported that 6 of 16 patients who had received prior chemotherapy responded to 200 mg/m^2 of paclitaxel given over a one-hour infusion, whereas 0 of 10 patients responded to 135 mg/m^2. [75]

Despite the reported phase II activity of paclitaxel and carboplatin as a first-line treatment for advanced NSCLC, [31,32] no responses were observed in 17 previously treated patients who received paclitaxel (200 mg/m^2 administered over 1 to 3 hours) and carboplatin at an AUC of 6. [76] However, 7 of 18 partial responses were observed in previously treated patients receiving ifosfamide and 250–300 mg/m^2 of paclitaxel. [77] Twelve responses were observed in 17 previously treated patients treated on a phase I/II trial of mitomycin-C, 150 mg/m^2 of paclitaxel, and metronidazole. [74,78]

Vinorelbine has been shown to have modest activity as a single agent for the first-line treatment of advanced NSCLC. [21,22] However, no responses were observed in two phase II trials involving 15 and 18 pretreated patients. [79,80] When combined with 175 mg/m^2 of paclitaxel, three partial responses were observed in 17 patients with refractory disease, with a median survival of 179 days. [81] A randomized trial comparing vinorelbine to docetaxel has recently been completed.

Gemcitabine has also been evaluated in several phase II trials in previously pretreated patients with relapsed or recurrent NSCLC. A phase II study of single-agent gemcitabine (1,000 mg/m^2 weekly for 3 weeks out of 4) in 86 patients with advanced NSCLC previously treated with a platinum-containing regimen was recently reported. [82] Sixty-seven patients had received one prior chemotherapy; 13 patients had received two or three prior regimens, and two had received prior adjuvant therapy. Twenty-four of the eighty-three patients had initially responded to cisplatin-based chemotherapy. Sixteen partial responses (19%) were noted. Median duration of response was 29 weeks, median survival was 34 weeks, and one-year survival was 45%.

1,000 mg/m^2–1,250 mg/m^2 of gemcitabine was administered to 28 patients with a PS of 0–2 and advanced NSCLC who had progressed after prior carboplatin/paclitaxel, including 22 patients with refractory disease (had not responded to prior carboplatin/paclitaxel), six who had progressed within 3 months of treatment (resistant), and 6 who had progressed more than 3 months of prior response to carboplatin paclitaxel (sensitive). [83] Five of twenty-four evaluable patients (21%) responded, including two patients who were refractory to prior carboplatin/paclitaxel. Median time to progression was 86 days, and median survival had not been reached at more than 4 months.

The Greek Lung Cancer Cooperative Group conducted a phase II trial of gemcitabine (900 mg/m^2 on days 1 and 8) and paclitaxel (175 mg/m^2 on day 8 over 3 hours) with G-CSF. [84] Forty-nine patients with a PS of 0–2 who had failed prior cisplatin-based therapy were treated; 27 had also received docetaxel. Two patients (4%) achieved a complete response and eight patients (14%) achieved a partial response for an overall response rate of 18%. The median survival was 11 months.

In conclusion, the results of these studies suggest that single-agent docetaxel or gemcitabine may have activity as second-line agents in this disease, as might higher doses of paclitaxel in combination with vinorelbine, ifosfamide, or mitomycin C. These results, however, should be interpreted with caution until they can be confirmed in larger, multi-institutional, randomized studies. The patient populations that are included in most of these trials generally include good performance status patients. Furthermore, response to prior therapy and time to relapse has clearly been shown to be a significant prognostic factor in second-line therapy of small cell lung cancer (SCLC) [85]; this has not been rigorously reported or controlled for in many of these trials.

FUTURE DIRECTIONS

Several different chemotherapy regimens are currently being explored for metastatic NSCLC. These include the evaluation of non–cisplatin-based therapies involving combinations of gemcitabine, one of the taxanes, or vinorelbine. Another approach that is being considered includes combining three drugs (triplets), and some of these combinations have been reported to be well tolerated with somewhat attenuated doses of the drugs. [86] An alternative approach under investigation includes the utilization of "alternating doublets," in which cycles of a two-drug combination are alternated with a different, non–cross-resistant two-drug combination. Yet another approach involves sequential therapy, such as four cycles of one combination followed by two to four cycles of another regimen.

As these trials near completion, it is appropriate to consider additional prospects that may be available for the treatment of this disease. Many of these new approaches involve exploration of new treatments with a biologic basis. Although many of these treatments are in the earliest stage of development, some examples are worth mentioning to demonstrate the future potential of these approaches.

One of the most exciting areas currently being explored is in the area of antiangiogenesis and inhibition of the metastatic process. Continued growth and spread of

tumors involves several different cellular processes regulating extracellular matrix (ECM) remodeling, tumor cell invasion and migration, and tumor neovascularization. Tumor neovascularization is a complex process that includes the activation, proliferation, and migration of endothelial cells, disruption of vascular basement membranes, and development of vascular tubes and linkage to preexisting vascular networks.[87]

All these tightly regulated processes involve the interaction of a variety of molecules, including adhesion molecules such as integrins, which modulate cell/extracellular matrix interactions. By regulating binding with such ECM components as collagen, fibronectin, and laminin, these proteins may play a role in cell adhesion, migration, blood vessel morphogenesis, and structural integrity.[88] Matrix metalloproteinases (MMPs) are a family of at least 11 proteolytic enzymes that degrade components of the ECM, including collagen and proteoglycan. Two MMPs in particular (MMP-2, or gelatinase A; and MMP-9, or gelatinase B) have been found to be expressed in human NSCLC cells, and their expression is correlated with pathologic invasiveness, suggesting an important role for these enzymes in tumor cell and endothelial cell invasion.[89,90 and 91] Angiogenesis itself is regulated by such positive growth factors as vascular endothelial growth factor (VEGF) and basic fibroblastic growth factor (bFGF); it can be inhibited by endogenous growth factors such as angiostatin or transforming growth factor beta (TGF-b).

All of these processes, therefore, would appear to play critical roles in the growth and spread of cancer cells, and are being investigated as targets for anticancer therapy. Thus anti-integrins, MMP inhibitors, and angiogenesis inhibitors and antibodies are currently in phase I, phase II, and in some cases, phase III trials. For example, an antiangiogenic humanized monoclonal antibody to the vascular integrin a *vb3* is undergoing clinical study in a phase I trial; one partial response has been reported.[93] Several MMP inhibitors are completing phase I and II studies, and are either in, or about to begin, phase III testing in SCLC or NSCLC. These compounds include products by Bayer (Bayer 12-9566),[94] Agaroun (AG3340),[95] and British Biotech.[96] A phase I trial of recombinant humanized monoclonal antivascular endothelial growth factor (anti-VEGF) was recently completed, in which anti-VEGF was reported to be well tolerated.[97] Direct endothelial inhibitors under investigation include TNP-470, a synthetic analog of fumagillin[98]; squalamine, an aminosterol derived from the soft tissues of sharks[99]; and thalidomide.[100] Thalidomide is an oral agent that was originally introduced as a sedative and antimetic but was quickly taken off the market when it was found to induce catastrophic fetal abnormalities. It has since been postulated that limb defects seen with the drug were secondary to an inhibition of blood vessel growth in the developing fetal limb bud, and its antiangiogenesis properties have been demonstrated in a rabbit cornea micropocket assay.[101] Clinical trials are underway in hormone-refractory prostate cancer, metastatic breast cancer, Kaposi's sarcoma, glioma, melanoma, renal cell, and ovarian cancer.[100,102] Thus many of these compounds are about to enter phase III testing in combination with standard cytotoxic drugs in the cooperative group setting for locally advanced or metastatic SCLC or NSCLC.

Another major area of research in the biologic treatment of NSCLC involves manipulation of the molecular biology of the disease. The *p53* tumor-suppressor gene is the most commonly mutated gene in human cancers, and is mutated in approximately 50% of NSCLCs. A retroviral vector and adenoviral vector containing the wild-type *p53* gene have been directly injected into human NSCLC and head and neck squamous cell carcinomas.[103,104] (see also Chapter 6). No clinically significant vector-related toxicities have been observed, and vector-p53 expression and increased apoptosis has been detected in posttreatment tumor biopsies. These approaches are about to be tested in bronchoalveolar carcinomas and in combination with radiation therapy within the ECOG.

The HER-2*neu* gene encodes for a growth factor receptor that signals the cell to enhance growth and has been associated with a poor outcome in metastatic breast cancer. A humanized anti-HER2*neu* antibody increases anticancer activity to first-line chemotherapy in women with HER2 *neu* overexpressing breast cancer.[105] Approximately one-fourth of lung cancers also overexpress the HER2 *neu* protein, although probably not to the same intensity as breast cancer; studies are being planned to determine the prognostic significance of HER2 *neu* overexpression in NSCLC and the possible therapeutic benefit of the anti-HER2 *neu* antibody (see also Chapter 4).

Thus the new treatments that are likely to be employed at the turn of the century will probably include agents other than traditional cytotoxic agents that attack normal and tumor cells alike. Instead, agents that specifically target abnormal cancer cells will continue to be developed, hopefully with increased specificity and decreased toxicity. A challenge will be how to incorporate these newer biologic agents with standard chemotherapeutic agents. The optimal clinical setting for their use will need to be identified—for example, immediately following surgery in patients with micrometastatic disease? In the setting of locally advanced, inoperable disease? To prevent the progression of metastatic disease? Following primary therapy, or in conjunction with chemoradiation therapy? Appropriate end points for clinical trials will need to be rethought: survival, time to progression, or response rates? The classic pathway of drug development from phase I to phase II to phase II trials will also need to be examined if survival is the primary end point, but the difficulties associated with conducting numerous large, randomized phase III trials with limited resources will need to be addressed. These challenges and others will provide continued interest in the development of new approaches to the treatment of advanced NSCLC, and hopefully ultimately result in better therapies for patients.

SECOND-LINE CHEMOTHERAPY FOR NON-SMALL CELL LUNG CANCER

FRANK V. FOSSELLA

In order to gain an appropriate perspective regarding second-line chemotherapy for relapsed non–small cell lung cancer (NSCLC), one must first consider the relative benefits of chemotherapy in the first-line setting. A metaanalysis of the eight randomized studies comparing cisplatin-based combination chemotherapy to best supportive care for advanced NSCLC has shown a modest, although statistically significant, impact on survival; median survival improved from 17 weeks to 27 weeks, and one-year survival increased from 5% to 15% in patients who received chemotherapy. [1,2] In one of those studies, the cost of the outpatient chemotherapy arm was actually less than best supportive care. [3,4 and 5] Experience with some of the newer agents such as paclitaxel, docetaxel, gemcitabine, vinorelbine, and CPT-11 has been encouraging, with more favorable median survivals in the range of 40 weeks. Although this success may be due, in part, to the effects of stage migration and better supportive care measures, certainly improvements in survival also reflect more active agents for NSCLC.

Despite the marginal benefit of chemotherapy for this disease, it has become customary to at least offer a trial of front-line systemic chemotherapy, usually with a platinum-based combination regimen, to patients with advanced NSCLC who have an acceptable performance status (i.e., 0 or 1, and possibly 2), and who are otherwise in good health. This practice is reasonable provided that the patient is fully aware of the risks of treatment and understands that the positive impact of therapy on quality of life and/or survival may be marginal.

Because the benefits of first-line platinum-based chemotherapy for advanced NSCLC are modest, the indications for second-line treatment of the patient who has failed initial chemotherapy are equally debatable. Nonetheless, many such patients do request of their medical oncologist a trial of second-line therapy, and we need to develop rational and cost-effective guidelines to follow in this setting.

DOCETAXEL

Docetaxel (Taxotere) is a taxane that, as a first-line agent for good performance status patients with advanced NSCLC, has shown consistent activity for NSCLC. Response rates have ranged from 24% to 34% at a dose of 100 mg/m^2 over 1 hour every 3 weeks.[6,7,8,9,10,11,12,13,14 AND 15] Average median survival in chemotherapy-naive patients is 39 weeks and one-year survival is 34%.

Docetaxel has also been systematically evaluated in the second-line setting for patients with NSCLC whose disease has progressed or failed to respond to first-line platinum-based chemotherapy. Four phase II studies that were designed specifically to evaluate the efficacy of docetaxel in the second-line setting have consistently demonstrated its activity as a second-line treatment (Table 51.1). Eligibility requirements for these trials included unresectable or stage IV disease and a performance status of 0–2. Patients must have received and failed at least one prior platinum-containing chemotherapy regimen (cisplatin and/or carboplatin). Docetaxel was administered at 100 mg/m^2 as a one-hour infusion every 21 days.

Trial	Docetaxel Dose (mg/m²)	Number of Patients	Response Rate	Median Survival	One-Year Survival
Fossella[16]	100	37	22%	42 wks	44%
Burris[17]	100	35	17%	42 wks	NR
Gandara[18]	100	77	16%	30 wks	25%
Robinet[19]	100	18	22%	NR	NR

NR, not reported.

TABLE 51.1. AN OVERVIEW OF PHASE II TRIALS OF SINGLE-AGENT DOCETAXEL IN PREVIOUSLY TREATED NSCLC[16,17,18 and 19]

A total of 166 patients were treated in these four phase II studies. Most patients had a very good performance status (0 or 1) despite their advanced disease and extensive prior therapy. Most patients had stage IV disease, and the predominant histology was adenocarcinoma. Response rates were consistent and ranged from 15% to 22%. Median survival ranged from 5.8 to 11 months, and estimated one-year survival ranged from 25% to 40%.

The survival outcome of these trials compares favorably to that of historical controls as determined in a retrospective review done at M.D. Anderson Cancer Center (MDACC).[20] For that analysis we identified a cohort of 36 patients with advanced NSCLC who were enrolled in a variety of phase I studies at M. D. Anderson after having failed standard front-line combination chemotherapy. Both the docetaxel group (N = 44) and the historical controls (N = 36) were well balanced with regard to age, gender, stage, histology, number of prior chemotherapy cycles, and response to front-line combination chemotherapy. Median survival (all patients) was 42 weeks for the docetaxel patients versus 16 weeks for the historical control group, and one-year survival was 41% (docetaxel) versus 16% (controls); this difference was statistically significant (p = 0.003). Because the control group had more patients of performance status 2 (which might have skewed the survival in favor of the docetaxel arm), we calculated survival for the good performance status (i.e., 0 or 1) patients only. That analysis also showed a statistically significant improvement in survival for the docetaxel patients: median and one-year survivals were 43 weeks and 42% (N = 42) versus 16 weeks and 16% for the 29 historical controls (p = 0.018).

The most compelling evidence to support the activity of docetaxel in the second-line setting comes from two recently completed large, randomized phase III trials that compared docetaxel to either a comparator regimen of chemotherapy[21] or to best supportive care.[22] (Table 51.2).

TABLE 51.2. PHASE III TRIALS OF DOCETAXEL IN THE SECOND-LINE TREATMENT OF NON–SMALL CELL LUNG CANCER[21,22]

The first of these phase III trials [21] was a multicenter U.S. trial. Eligible patients had locally advanced or metastatic NSCLC, which had progressed on or after at least one prior platinum-based chemotherapy regimen. There was no restriction on the number of prior cycles or regimens of chemotherapy, and, in particular, patients treated with prior paclitaxel were eligible for the study. Prior XRT was allowed. Patients must have had a performance status of 0–2. Patients with treated brain metastases were included.

Patients were stratified by their best response to prior platinum-based chemotherapy and performance status, and then randomized to either docetaxel 100 mg/m^2 every 3 weeks, docetaxel 75 mg/m^2 every 3 weeks, or a comparator arm of either vinorelbine 30 mg/m^2 per week or ifosfamide 2 gm/m^2 for 3 days every 3 weeks. Responses were assessed every two cycles. A total of 373 patients were enrolled, and their key patient characteristics are summarized in Table 51.2. Note that, despite being heavily pretreated, less than 20% of patients had performance status 2, and this was equally distributed across the three arms. The predominant histology was adenocarcinoma. Approximately 90% of patients across the three groups had stage IV disease. Approximately 30% of patients had received two or more prior chemotherapy regimens, and prior treatment included paclitaxel in 30% to 40% of patients.

Results of the trial are summarized in Table 51.2. Partial response rate was 11.9% with docetaxel 100 mg and 7.5% with docetaxel 75 mg, both significantly greater than the 1% response noted in the control group. Median response duration was over 7 months. Interestingly, prior exposure to paclitaxel had no bearing on the likelihood of response to docetaxel.

Overall time-to-progression analysis (TTP) for the intent-to-treat (ITT) population favored treatment with docetaxel 100, and 26-week progression-free survival favored treatment with either docetaxel arm. The 26-week progression-free survivals were 19% with docetaxel 100 mg and 17% with docetaxel 75 mg, each being significantly greater than the 8% 26-week progression-free survival seen in the control group.

Survival analysis (ITT) showed no difference in overall survival by log-rank analysis, with median survival of approximately 5.6 months in the three groups. However, the one-year survival favored treatment with docetaxel 75 mg/m^2. The one-year survival was 32% for the docetaxel 75 mg group compared to 21% with docetaxel 100 mg and 19% in the control group. The difference in survival favoring docetaxel 75 mg was statistically significant. More than one-third of patients in each group received subsequent chemotherapy upon removal from this trial (including taxane therapy in 21% of patients in the control group). Because of the potential impact on survival such subsequent therapy may have had, we therefore generated an ITT survival curve in which survival observations were censored at the point at which patients received subsequent chemotherapy treatment. We observed in this ITT analysis that one-year survival significantly favored treatment with either docetaxel arm. The one-year survival was 32% with either docetaxel 100 mg or docetaxel 75 mg, compared to 10% one-year survival in the comparator group; these differences were highly statistically significant.

Quality-of-life analysis, which was evaluated prospectively using the LCSS, showed a trend favoring docetaxel 100 mg over the control treatment in all parameters considered, and favoring docetaxel 75 mg in all but two parameters. Several of these parameters reached statistical significance.

Grade 4 neutropenia and febrile neutropenia occurred with greater frequency in both docetaxel arms compared to the control group; documented infection and grade 4 thrombocytopenia, however, were equivalent across all three arms. G-CSF use was greatest with docetaxel 100 mg, at 28% of cycles, but was comparable between docetaxel 75 mg and the control group. Severe nonhematologic side effects, including treatment-related death, were equivalent across the three groups.

The second of these phase III trials was reported by Shepherd. [22] In this multicenter international trial, patients with advanced NSCLC, which had progressed on or after at least one prior platinum-containing chemotherapy regimen, were randomly assigned to receive either docetaxel or best supportive care. The initial dose of docetaxel was 100 mg/m^2, but this dose was changed midway into the trial because of toxicity to 75 mg/m^2.

A total of 204 patients were enrolled in this trial: 49 received docetaxel 100 mg/m^2, 55 received docetaxel 75 mg/m^2, and 100 received best supportive care. Patient characteristics are summarized in Table 51.2. Twenty-four percent of patients had a performance status of 2, and approximately 80% had stage IV disease. One-quarter of patients had received two or more prior chemotherapy regimens. The median number of cycles of treatment received was two and four for patients receiving 100 mg/m^2 and 75 mg/m^2, respectively.

Results are shown in Table 51.2. Partial response was observed in 6% of patients treated with docetaxel, and median response duration was 26 weeks. Overall survival favored treatment with docetaxel 75 mg/m^2. Median survival was 9.0 versus 4.6 months (p = 0.016), and one-year survival was 40% versus 16% (p = 0.016). The incidence of grade 3 or 4 neutropenia and febrile neutropenia were highest with docetaxel 100 mg/m^2. With docetaxel 75 mg/m^2, grade 3 or 4 neutropenia was higher than with best supportive care (43% versus 0%); however, no other significant differences in side effects were seen between the docetaxel 75 mg/m^2 arm compared to best supportive care. Quality-of-life analysis also showed statistically significant improvement in disease-related symptoms as compared to best supportive care.

In conclusion, two large randomized phase III trials of second-line chemotherapy for NSCLC have shown significant differences favoring docetaxel for response rate, TTP and one-year survival as compared to either a comparator chemotherapy regimen or best supportive care. Quality-of-life analysis also showed a strong trend favoring docetaxel. Interestingly, prior exposure to paclitaxel did not decrease the likelihood of response to docetaxel (in the one trial where this was looked at), suggesting a lack of complete cross-resistance between these two taxanes. Docetaxel appears to offer clinically meaningful benefit in this setting, with manageable toxicity. Based on the observed response rates, survival, impact on quality of life, and toxicity profile, the optimal dose of docetaxel in this heavily pre-treated population is 75 mg/m^2 every 3 weeks.

PACLITAXEL

The related taxane, paclitaxel (Taxol), has a single-agent response rate of 10% to 36% in good performance status chemotherapy-naïve patients with advanced NSCLC when given at doses of 200 to 250 mg/m^2 over 24 hours[23,24] or at 135 to 225 mg/m^2 over 1 to 3 hours.[25,26,27 and 28] Median and one-year survivals in the front-line setting average approximately 29 weeks and 40%.

The seven studies that report on paclitaxel's activity as second-line therapy for NSCLC show conflicting results: four are negative, two equivocal, and one positive.[25,29,30,31,32,33 and 34] However, interpretation of these data is somewhat hampered by the fact that the trials used varying doses and schedules of paclitaxel, patient numbers are small, some of the trials include both chemotherapy-naïve as well as pretreated patients so that the data regarding second-line activity must be teased out, and most are reported in abstract form only with limited details.

In a study done at MDACC through the Community Clinical Oncology Program (CCOP).[29] 40 NSCLC patients who had failed one prior platinum-containing chemotherapy regimen were treated with paclitaxel 175 mg/m^2 over 24 hours every 3 weeks. One-third of patients had a performance status of 2. Only 1 of 37 evaluable patients (3%) had a partial response (as compared to a response rate of 24% in a chemotherapy-naïve population reported by the same group). Median survival was 17.5 weeks and one-year survival was 16%.

In a trial reported by Socinski,[30] 13 patients with NSCLC, which had recurred after prior platinum-based chemotherapy, were treated with paclitaxel 140 mg/m^2 as a 96-hour infusion every 3 weeks. No objective responses were noted, although eight patients had stabilization of disease. Overall survival data were not reported.

Roa[31] reported on 18 NSCLC patients who received as second-line treatment paclitaxel 200 mg/m^2[32] over 1 to 3 hours plus carboplatin at area under the curve (AUC) 5 every 21 days (a regimen with which this group reported a 50% response rate in chemotherapy-naïve patients). All but two patients had received prior platinum-containing combination therapy (the other two had received a phase II drug). This abstract provided no details regarding performance status and survival. None of the 18 patients had response to the regimen in this second-line setting.

In Stewart's abstract.[32] 26 patients whose NSCLC had failed prior platinum-containing chemotherapy received paclitaxel at a starting dose of 135 mg/m^2 over 1 hour, which was escalated in approximately one-third of courses to 175 to 200 mg/m^2 over 1 hour; paclitaxel was given with hydroxyurea 500 mg orally three times per week. Nineteen percent of patients were of performance status 2. None of the first 20 evaluable patients showed response to this regimen. Survival was not reported.

Two studies have reported a possible marginal response to paclitaxel given as second-line therapy for advanced NSCLC. Tan[13] reported 38 patients who received first- or second-line paclitaxel at either 175 mg/m^2 over 3 hours (five patients) or 135 to 400 mg/m^2 over 24 hours (33 patients). Eleven patients received this treatment as second-line therapy after having failed front-line platinum-based chemotherapy (10 patients) or mitomycin/VP-16 (1 patient). Performance status and survival data are not reported, nor does this abstract provide sufficient detail about which patients received which dose of paclitaxel. Nonetheless, one of the eleven second-line patients (9%) responded to therapy. Ruckdeschel[24] treated 14 patients who had failed prior chemotherapy (the details of which are not reported in this abstract) with paclitaxel at 200 or 250 mg/m^2 (depending on whether the subject had received prior radiotherapy) over 24 hours. Forty-three percent of these patients had a performance status of 2. Two of fourteen patients (14%) achieved a partial response; median survival was 17 weeks.

These five negative or equivocal studies are countered by Hainsworth's trial[25] of 30 NSCLC patients receiving treatment in a second-line setting, having failed one or two prior chemotherapy regimens (26 with platinum-based chemotherapy, and 4 with other regimens of known front-line activity). Patients were randomly assigned to either paclitaxel 135 mg/m^2 over 1 hour (10 patients) or 200 mg/m^2 over 1 hour (20 patients); the calculated dose was given either on 1 day or divided over 3 consecutive days. Neither performance status nor survival data is reported. None of the 10 patients treated at the 135 mg/m^2 dose level had response, but 6 of 16 evaluable patients at the 200 mg/m^2 dose (38%; 30% of ITT population) had a partial response to the second-line paclitaxel.

Given these conflicting data and varying study designs, it is difficult to draw definite conclusions regarding the role of paclitaxel in the second-line treatment of NSCLC. Larger trials using a consistent and effective dose and schedule of paclitaxel in a well-defined patient population are needed to clarify this issue. These studies ideally should randomize patients between paclitaxel versus either best supportive care or some other meaningful control arm to document not only response rate but also the drug's impact on survival and quality of life in these heavily poor prognosis patients.

VINORELBINE

Vinorelbine (Navelbine) is a novel vinca alkaloid. In chemotherapy-naïve patients with advanced NSCLC, the response rate to vinorelbine is in the range of 12% to 30%; median survival is about 30 weeks and one-year survival is 25% to 30%.[35]

Three European studies have been reported evaluating vinorelbine's activity against NSCLC in the second-line setting. Pronzato[36] studied 15 NSCLC patients who failed previous treatment with platinum-based (13 patients) or mitomycin-based (2 patients) combination chemotherapy. Performance status was not reported. None of the 14 evaluable patients responded to second-line treatment with vinorelbine at 25 mg/m^2 per week. Median survival for the group was 13 weeks.

Rinaldi[37] studied 18 NSCLC patients who had progressed while receiving platinum-based combination chemotherapy. These patients received second-line vinorelbine at 20 mg/m^2 per week. None of the 18 patients had a response to treatment (as compared to 2 of 9 chemotherapy-naïve patients enrolled in the same study). Neither performance status nor survival data were reported in this abstract.

Finally, in a small study reported by Santoro[38] 2 of 10 NSCLC patients, all with a performance status of 1, had a partial response to vinorelbine 30 mg/m^2 per week given as second-line treatment after prior chemotherapy. The relevance of this finding is difficult to ascertain, however, because this abstract provides no details about the prior chemotherapy the patients received.

GEMCITABINE

The nucleoside analog, gemcitabine (Gemzar), is an active drug for NSCLC. Several phase II trials show single-agent activity for advanced disease consistently in the range of 20% to 25% when used as a first-line treatment.[39] The experience with gemcitabine in the second-line setting has been mixed.

Crino[40] reported a trial of 32 patients previously treated with platinum-containing chemotherapy who were subsequently treated with gemcitabine 1,000 mg/m^2 per week for 3 weeks every 4 weeks (see also Chapter 50). Most patients had a performance status of 0–1, and 56% had stage IIIb disease. The drug was noted to have activity, with a 25% partial response rate (survival data were not reported). Similarly, Rosvold[41] reported on 24 evaluable patients with NSCLC whose disease progressed after initial therapy with carboplatin/paclitaxel, and who were subsequently treated with gemcitabine 1,000–1,250 mg/m^2 per week for 3 weeks every 4 weeks. Partial responses were noted in 21% of patients (survival data pending).

Three other phase II trials show a significantly lower response rate of gemcitabine in the second-line setting. In a small study reported by Guerra,[42] 11 evaluable patients with NSCLC previously treated with cisplatin-based chemotherapy were treated with gemcitabine 1,250 mg/m^2 per week for 3 weeks every 4 weeks. Only 1 of 11 patients (9%) showed partial response, and overall median survival was only 17 weeks. Garfield[43] reported a trial in which 36 patients received second-line gemcitabine at one of two dose levels: 1,000 mg/m^2 per week for 3 weeks every 4 weeks or 3,500 mg/m^2 every other week. Only 1 of 36 patients (3%) had a partial response (survival not reported). Finally, Fukuoka[44] conducted a phase II trial of gemcitabine 800–1,000 mg/m^2 per week for 3 weeks every 4 weeks for patients with advanced NSCLC who were both chemotherapy-naïve (42 evaluable patients) and previously treated (17 patients). This group reported no responses in the 17 patients treated in the second-line setting, whereas a response rate of 17% was noted in the 42 chemotherapy-naïve patients (survival was not reported).

CAMPTOTHECINS

Approximately one-third of chemotherapy-naïve patients with advanced NSCLC respond to single-agent CPT-11 (irinotecan).[45] Although CPT-11 also shows good second-line activity against small cell lung cancer (SCLC), two Japanese studies evaluating its second-line efficacy for NSCLC are conflicting.

Negoro[46] treated 26 "previously treated" (details of which are not reported) NSCLC patients with CPT-11 100 mg/m^2 per week, and observed no responses (versus a 34% response rate in chemotherapy-naïve patients in the same study). In contrast, Nakai[47,48] has reported that 3 of 22 (14%) "previously treated" (again, the details are not available) NSCLC patients responded to second-line therapy with CPT-11 at 200 mg/m^2 every 3 to 4 weeks (with first-line response in the same study of 31%). The data on second-line activity of the related camptothecin, topotecan (Hycamtin), is limited to a single anecdotal report of a patient with NSCLC progressive on cisplatin/VP-16 who had a complete response to second-line topotecan.[49]

CONCLUSIONS

In conclusion, phase II experience has shown consistent activity of docetaxel for NSCLC that has progressed after first-line platinum-based chemotherapy; this activity has been confirmed in two follow-up randomized phase III trials. These large multicenter phase III trials of almost 600 patients suggest that docetaxel does offer clinically meaningful benefit in good performance status patients. A statistically significant benefit of docetaxel over the control (vinorelbine or ifosfamide in one trial, and best supportive care in the other) was noted with respect to response rate, TTP, survival, and quality of life. Based on the observed activity and toxicity profile, the recommended dose of docetaxel in this heavily treated group of patients is 75 mg/m^2 every 3 weeks.

The related taxane, paclitaxel, has not been as systematically studied in the second-line setting, and available data are conflicting. Although one trial suggests that paclitaxel at 200 mg/m^2 over 1 hour produces a respectable response rate in platinum-resistant patients, the cohort of patients studied was small and survival data are unavailable. In contrast, six other small studies have reported no or minimal second-line activity with paclitaxel (although a greater proportion of performance status 2 patients were enrolled in these trials as compared to the docetaxel studies discussed, which may have affected the results).

Similarly, results of gemcitabine in the second-line setting have been conflicting. Two phase II trials have documented response rates as high as 25% in patients with advanced NSCLC whose cancer had progressed after first-line therapy. However, three other trials would suggest that activity of gemcitabine in the second-line setting may be minimal (at least as measured by objective response rate). The available data for second-line activity of vinorelbine and CPT-11 has been similarly

disappointing (Table 51.3).

Agent (Phase II Studies)	N	Overall Response Rate	Median Survival
Docetaxel (100 mg/m²)[6-11]	166	15%–22%	6–11 mos
Paclitaxel (140–250 mg/m² 24–59h)[25,29,34]	78	0%–14%	4 mos
Vinorelbine (20–35 mg/m²)[35-39]	43	0%–20%	NR
Gemcitabine (800–1,500 mg/m²)[40-44]	124	0%–25%	17 mks (1 trial)
CPT-11[45-49]	48	0%–14%	NR

NR, not reported.

TABLE 51.3. PHASE II TRIALS OF SECOND-LINE CHEMOTHERAPY FOR STAGE IIIB/IV NSCLC: SINGLE-AGENT ACTIVITY[16,17,18 and 19,25,29,30,31,32,33 and 34,36,37 and 38,40,41,42,43 and 44,46,47,48 and 49]

Given these data, a reasonable practice at this time would be to offer a trial of second-line chemotherapy with docetaxel 75 mg/m^2 every 3 weeks to patients with NSCLC who have failed first-line chemotherapy. However, because most of the subjects enrolled in the positive trials were in very good condition, the use of second-line therapy should probably be limited as well to good performance status patients (i.e., 0 or 1).

COMBINED MODALITY TREATMENT FOR LOCALLY ADVANCED, UNRESECTABLE NON–SMALL CELL LUNG CANCER

DAVID H. JOHNSON
ANDREW T. TURRISI

Locally advanced, unresectable non–small cell lung cancer (NSCLC) represents approximately 35% to 40% of all newly diagnosed cases of NSCLC. [1] During the past two decades, the management of these patients has undergone considerable change. Whereas radiotherapy as a sole treatment modality was the norm prior to 1980, current management commonly entails the combination of radiotherapy with chemotherapy in selected patients with good performance status. [2] On rare occasion, surgical resection also is appropriate. Candidates for surgery and this approach are discussed in more detail in Chapter 44. Progress in the management of locally advanced NSCLC came about in part because of the recognition that cisplatin-based chemotherapy imparts a modest but real survival benefit even in patients with far advanced disease[3,4] (reviewed in Chapter 50). With newer combination chemotherapy regimens containing vinorelbine, gemcitabine, or paclitaxel, additional albeit modest survival gains have been realized in recent years. [5,6,7,8 and 9] Thus the survival of individuals with locally advanced, unresectable NSCLC has improved in part because of more active chemotherapy regimens. However, improving local tumor control also is a key factor in optimizing survival. [10] The concepts and controversies surrounding the current management of locally advanced, unresectable NSCLC are reviewed in this chapter.

RADIOTHERAPY IN LOCALLY ADVANCED, UNRESECTABLE NSCLC

Historically, patients with locally advanced, unresectable NSCLC were treated with thoracic irradiation alone with a resultant five-year survival rate of 5% to 7%. [11] This narrow approach was based principally on the assumption that a small percentage of patients with localized tumor can be "cured" with thoracic radiotherapy (TRT). While radiotherapy can sterilize NSCLC within the irradiated field, and numerous retrospective single institutional studies indicate "curative" radiotherapy is associated with a five-year survival rate of 5% or more, it remains unclear if radiotherapy actually cures localized NSCLC. Indeed, it is entirely possible that the biology of certain tumors is such that a five-year survival is possible without any treatment, calling into question the curative potential of radiotherapy. [1,12]

In support of a curative role for radiotherapy are the results of a randomized trial conducted by the Veterans Administration Study Group in the 1960s. [13] These investigators administered TRT (40–50 Gy in 4–6 weeks) or a placebo (lactose tablets) to NSCLC patients with unresectable, locally advanced tumors. Of note, patients with a Karnofsky performance status of less than 50% were included, as were some patients with small cell lung carcinomas (SCLCs). However, only 15% of participants had SCLC, and they were evenly distributed between the two arms. Patients with palpable supraclavicular lymph nodes were excluded. All patients received supportive care consisting of blood transfusions and antibiotics. A statistically significant survival advantage was demonstrated in the irradiated group, although the actual differences in median (142 days and 112 days) and one-year (18.2% and 13.9%) survivals were small and of questionable clinical relevance. This modest survival advantage prompted some experts to question the need for routine irradiation in asymptomatic patients. [14]

Because the Veterans Administration study was carried out in an era prior to the widespread availability of megavoltage equipment and at a time when treatment planning was considerably less sophisticated, the results have been justifiably criticized as not being reflective of present-day radiotherapeutic capabilities. [15] In an effort to address some of these shortcomings, the Southeastern Cancer Study Group (SECSG) undertook a prospective trial employing megavoltage equipment. [12] The study was planned and executed in the early 1980s. Patients were randomized to receive standard radiotherapy (60 Gy in 6 weeks) or no irradiation. The radiotherapy dose was based on the results of a landmark Radiation Therapy Oncology Group trial (RTOG 73-01) in which superior local control was achieved with high-dose irradiation administered without interruption over 5 to 6 weeks. [16] Given the strong prejudicial feelings regarding the curative potential of irradiation that existed at that time, it proved impossible to employ a placebo arm in the SECSG trial. Instead, patients randomized to the no radiotherapy arm received single-agent vindesine, which was believed to be one of the most active single chemotherapy drugs available at the time the study was undertaken. A third treatment arm consisted of standard TRT plus vindesine. Approximately 25% of the patients entered had stage I or II disease and were inoperable because of medical reasons or refusal to undergo thoracotomy. Patients were required to have a Karnofsky PS ³50%, and those with supraclavicular node involvement were included but represented less than 5% of all cases entered. Patients who progressed on the vindesine arm were permitted to cross over to radiotherapy, and those who progressed after radiotherapy were allowed to receive vindesine. However, only one-third of the patients treated with vindesine actually crossed over to radiotherapy. There were no differences in the median survivals of the three treatment arms (TRT alone = 8.6 months, vindesine alone = 10.1 months; TRT + vindesine = 9.4 months), nor were long-term survival differences noted; five-year survivals = 3%, 1%, and 3%, respectively. [12] Other investigators have reported similar results. [17]

Although the SECSG trial results came under sharp criticism from some experts,[18,19] the results nevertheless indicate that modern TRT, when used alone, is rarely curative in patients with locally advanced and unresectable NSCLC. Undoubtedly, some would counter that present day radiotherapy with its improved technology and better treatment planning is likely to improve survival. However, one only has to review the results of several recent randomized trials employing a TRT-alone arm to dispel these beliefs. Even in highly selected patient subsets, median survival remains in the 9- to 11-month range, and long-term survival rarely exceeds 5% to 6%.[20,21] Thus it appears the use of *conventional fractionation and scheduling* of TRT is unlikely to yield substantial further improvements in survival without some additional therapeutic measures or technologic advances.

Analysis of treatment failure patterns provides clues as to how one might overcome the shortcomings of a treatment program and permit the development of new therapeutic strategies and protocols. Based on older literature, the principal cause of treatment failure in locally advanced NSCLC is typically presumed to be extrathoracic metastases. In RTOG 73-01, for example, between 40% and 65% of patients had recurrent disease identified first in extrathoracic sites. [22] Common sites of failure include the skeleton, liver, and central nervous system. Furthermore, as control of the intrathoracic tumor improves, the incidence of recurrence in extrathoracic sites increases.[22,23 and 24] However, local relapse remains a significant problem even when modern planning technology is employed. For example, French investigators found that more than 85% of patients had persistent local tumor when examined by bronchoscopy following a radiotherapy dose of 65 Gy. [25,26 and 27] Others have identified similar high rates of local failure. [22,28]

RTOG investigators have recently reviewed their patterns of treatment failure data derived from radiotherapy trials largely conducted during the 1980s [24] (Table 52.1). With radiotherapy alone, intrathoracic failure was documented as the initial site of failure in up to 60% of cases depending on the original histology of the primary tumor. Distant metastases as the initial failure site occurred in 40% to 70% of patients. Squamous carcinomas were found to have a higher incidence of local recurrence compared to adenocarcinomas and large cell carcinomas, whereas adenocarcinoma and large cell carcinomas were more likely to progress in the brain. [24]

	Squamous Carcinoma		Adenocarcinoma		Large Cell Carcinoma	
	RT Alone (n = 178)	CT + TRT (n = 168)	RT Alone (n = 356)	CT + TRT (n = 103)	RT Alone (n = 243)	CT + TRT (n = 41)
Primary	26%	27%	29%	34%	23%	41%
Thorax	36%	29%	22%	24%	28%	22%
Brain	11%	20%	18%	1%	16%	16%
Distant	13%	48%	42%	14%	24%	16%
Dead NP	13%	22%	24%	26%	15%	14%

NP, progression. From Cox JD, Scott CB, Byhardt RW, et al. Addition of chemotherapy to radiation therapy alters failure patterns by cell type within non-small cell carcinoma of lung (NSCCL): analysis of radiation therapy oncology group (RTOG) trials. Int J Radiat Oncol Biol Phys 1999;43:505, with permission.

TABLE 52.1. INITIAL SITES OF RECURRENCE FOLLOWING TRT OR TRT PLUS CHEMOTHERAPY

Based on the aforementioned data, one might predict that chemotherapy would have a greater survival impact on nonsquamous histologies, whereas strategies designed to increase local control might have a greater impact on squamous carcinomas. Regardless, given these failure patterns, it is apparent that improved systemic and local therapies are required to improve survival in locally advanced NSCLC. [29,30]

CHEMOTHERAPY IN LOCALLY ADVANCED, UNRESECTABLE NSCLC

Only a few antineoplastic agents have recognized activity against NSCLC. [9] In fact, much of what is known about the activity of chemotherapy in NSCLC has been derived from studies involving patients with metastatic disease (i.e., stage IV). In this setting, single agents seldom effect objective response rates greater than 15% to 20%, and complete responses are exceedingly rare. Although combining multiple active agents improves overall response rates (20% to 40%), the impact of the higher response rates on survival in patients with stage IV NSCLC is at best modest and controversial. [31]

Despite the relatively modest benefits seen in advanced NSCLC, good rationale for administering chemotherapy in less advanced disease still exists. [2,32,33,34 and 35] Tumor volume is a well-recognized prognostic factor in most chemosensitive tumors. Less bulky tumors demonstrate higher objective response rates and improved survival presumably because they possess fewer drug-resistant cells and have a higher growth fraction, and possibly a better blood supply, all of which contribute to a greater sensitivity to chemotherapy agents. [32] This phenomenon appears to hold true for NSCLC as well. Indeed, agents with only modest activity in advanced tumors are observed to effect much higher objective response rates in patients with stage III lesions. [2,33] Likewise, combination chemotherapy regimens appear to be more effective in locoregional NSCLC. [2,35,36 and 37] This relationship is perhaps best illustrated using data from an older study conducted by the European Oncology Radiation Therapy Council (EORTC). [38] In the latter trial, 94 NSCLC patients received cisplatin (60 mg/m^2) and etoposide (120 mg/m^2 per day for 3 days) and achieved an overall objective response rate of 38%. However, among the 40 eligible patients with previously untreated locoregional disease, the objective response rate was nearly twice that observed in patients with stage IV lesions (56% versus 32%, p = 0.038). Similar trends have been documented with newer chemotherapy regimens such as cisplatin and paclitaxel or cisplatin plus gemcitabine. [39,40]

Although the higher objective response rates in locally advanced NSCLC cannot be assumed *a priori* to result in a survival benefit, [41] good circumstantial evidence suggests that the higher objective response rates observed in stage III disease are beneficial. To illustrate, Elliott and colleagues treated a group of patients with unresectable NSCLC with either vindesine alone or cisplatin plus vindesine. [42] Nearly 70% of the patients entered into the trial had locally advanced lesions; these patients were evenly divided between the two treatment arms. Patients given the combination chemotherapy regimen experienced a higher objective response rate and marked improvement in median survival compared to individuals given vindesine alone. The survival benefit was most apparent in patients with locoregional disease. Similar observations were made by ECOG investigators using paclitaxel-based therapy in patients with stage IIIB disease. [39] Although the numbers of patients with locally advanced disease entered in the ECOG trial were relatively modest, a clear trend evolved toward improved response rates and survival with paclitaxel-cisplatin compared to etoposide-cisplatin therapy. Similarly, Woods and colleagues compared cisplatin plus vindesine to best supportive care in a large group of patients with unresectable NSCLC. [43] Included among the study population were patients with locoregional lesions. Similar to the aforementioned ECOG trial, too, few patients with locoregional disease were available to make a valid statistical comparison. However, in a subset analysis, an apparent survival benefit was observed for the chemotherapy-treated group (44 weeks versus 22 weeks). Collectively, these data strongly suggest that chemotherapy may be more effective in the setting of localized NSCLC.

COMBINED MODALITY TREATMENT IN LOCALLY ADVANCED, UNRESECTABLE NSCLC

The combined use of TRT and chemotherapy in locally advanced NSCLC is theoretically appealing because it addresses the need to control the primary lesion while attempting to eradicate occult distant micrometastases. [33,35] The possible advantages for combining chemotherapy and radiotherapy have been summarized by Fu and include: (a) changes in the slope of the radiotherapy dose-response curve; (b) decreased accumulation of inhibition of repair or sublethal repair; (c) decreased recovery from potentially lethal damage; (d) perturbation in cell kinetics, with an increase in proportion of cells in a sensitive phase of the cell cycle and proliferative state; (e) decreased tumor bulk and improved blood supply, leading to reoxygenation and recruitment, and increased sensitivity to irradiation and chemotherapy; and (f) increased drug delivery and uptake. [44]

Neoadjuvant Chemotherapy plus Radiotherapy

Pilot studies employing primary or neoadjuvant chemotherapy plus radiotherapy have yielded median survivals ranging from 9.6 months to more than 16 months and two-year survival rates between 20% and 40%. [45,46,47,48,49,50 and 51] These results appear better than those achieved with radiotherapy alone. [10] To validate the results of these pilot studies, randomized trials have been performed, the results of which are summarized in Table 52.2. [26,52,53,54,55,56 and 57] The studies yielded both negative [52,54,55] and positive results. [26,53,56,57]

TABLE 52.2. RANDOMIZED TRIALS OF RADIOTHERAPY VERSUS RADIOTHERAPY PLUS CHEMOTHERAPY

The first cooperative group randomized trial to demonstrate a clear survival benefit with combined modality therapy was performed by the Cancer and Leukemia Group B (CALGB), [53] (Table 52.3). These investigators compared standard TRT (60 Gy in 6 weeks) to the same radiotherapy preceded by two cycles of cisplatin (100 mg/m^2 on days 1 and 29) plus weekly vinblastine (5 mg/m^2 per week for 5 weeks). Because of marked differences in survival detected during a planned interim analysis, the trial was closed early. Median (13.7 months and 9.6 months) and long-term survival rates were significantly improved in the combined modality arm. An

update of this trial demonstrated a continued survival benefit with combined modality therapy even out to 7 years (13% and 6%). [20]

Survival	CT + TRT	TRT Alone
Median	13.7 mo	9.6 mo
2-year	26%	13%
5-year	17%	6%
7-year	13%	6%

TABLE 52.3. CHEMOTHERAPY PLUS TRT VERSUS RADIOTHERAPY ALONE

The CALGB trial differed from the negative studies listed in Table 52.2 in several ways. First, eligibility was limited to patients with a relatively favorable prognosis defined as low-bulk disease (i.e., supraclavicular nodal involvement excluded), good performance status (0 or 1), and minimal weight loss (5% or less of body weight). These selection criteria are fairly restrictive and exclude many stage III patients seen in daily practice. Second, the CALGB trial used cisplatin-based chemotherapy, which is not the case for most of the negative trials. Although no specific regimen can be recommended for all patients, the composition of chemotherapy is likely to be important.[3] Third, the sequence of chemotherapy and radiotherapy administration may have played a role in the positive outcome of this trial not so much because there is a biological rationale for its use but rather, simply because maximum dosages of both modalities were possible with the schedule used. It is a basic maxim of cancer therapy that delivery of maximum intended therapy is theoretically important to achieve optimal outcome.[58,59 and 60] It also should be noted that patients were not stratified according to subcategory of stage III (i.e., IIIA versus IIIB). Accordingly, one cannot easily discern the true relevance of clinical substaging in the CALGB study even though a retrospective analysis was performed to assess this issue.[61] Given these factors, the results of this trial are not clearly applicable to all stage III patients, nor can one assume that ad hoc modifications of the treatment regimen will effect similar results.[62]

The provocative but uncertain nature of the CALGB data, coupled with the statistical concerns raised by some experts,[63] prompted the RTOG and the Eastern Cooperative Oncology Group (ECOG) to undertake a confirmatory trial.[56] Using selection criteria that were essentially identical to that employed by the CALGB, 485 stage III NSCLC patients were randomized to receive standard TRT (60 Gy in 6 weeks), TRT preceded by cisplatin and vinblastine, or hyperfractionated radiotherapy (69.6 Gy given as 120 cGy fractions twice daily). In a small pilot study, RTOG investigators had shown that hyperfractionated irradiation could produce excellent survival in patients meeting the aforementioned selection criteria established by the CALGB.[64] Both median and long-term survivals were superior in the group receiving combined modality treatment, confirming the results of the CALGB study (Table 52.2). A metaanalysis of the available data also affirms the survival advantage of combined modality therapy over radiotherapy alone in this patient population.[65] Lastly, when subset analyses are conducted on the data from some of the negative trials using the same restrictive entry criteria employed by CALGB, a small survival advantage emerges for combined modality therapy.

The observation that chemotherapy plus radiotherapy is superior to radiotherapy alone has led some to speculate that improved local control might be possible with chemotherapy alone and that radiotherapy might be unnecessary. This argument is reminiscent of the polemics that plagued development of combined modality treatment in SCLC almost two decades ago.[66,67] Japanese investigators attempted to address this issue in a prospective trial in which patients with locally advanced disease were randomized to chemotherapy with or without radiotherapy.[68] Median survival was similar in the two cohorts of patients, but long-term survival was clearly superior in the patients who received both chemotherapy and radiotherapy (Table 52.4). Local relapse was greater in the patients given chemotherapy alone. Although the design of this trial was not ideal, the results strongly indicate the need for both chemotherapy and radiotherapy to achieve optimal outcome in localized NSCLC—*chemotherapy alone results in excess local failures; radiotherapy alone results in excess systemic failures.*

Survival	CT + TRT	CT Alone
Median	15.2 mos	14.7 mos

TABLE 52.4. CHEMOTHERAPY PLUS TRT VERSUS CHEMOTHERAPY ALONE

Sequence of Chemotherapy and Radiotherapy

Most of the aforementioned combined modality studies administered chemotherapy and radiotherapy in a sequential manner (i.e., chemotherapy followed by radiotherapy) rather than concurrently. This approach was used to avoid anticipated greater toxicity with the concurrent treatment. However, in SCLC, concurrent administration of chemotherapy and radiotherapy is the norm and is generally well tolerated.[69,70 and 71] Furthermore, concomitant administration of these modalities appears to be superior to their sequential administration.[72,73] Presumably, a similar relationship might apply in locally advanced NSCLC. To test this hypothesis, Japanese investigators compared concurrent and sequential chemotherapy and radiotherapy in a prospective trial.[74,75] The chemotherapy employed consisted of mitomycin (8 mg/m^2 on days 1 and 8), vindesin (3 mg/m^2 on days 1, 8, 29, and 36), and cisplatin (80 mg/m^2 on days 1 and 29) (MVP). In the concurrent TRT arm, radiotherapy was initiated starting on day 2 of MVP at 2 Gy fractions to a total dose of 56 Gy. However, TRT was administered as a split course with a ten-day rest period interposed between the first 28 Gy and the remaining TRT dose. In the sequential TRT arm, radiotherapy was initiated upon completion of the MVP, with the 56 Gy being administered in a conventional manner. Eligibility criteria included unresectable stage III NSCLC with supraclavicular lymph node involvement, age £75 years, and ECOG PS of 0–2. T3N0M0 patients and those with pleural effusions were excluded. A total of 320 patients were enrolled, of whom 314 were eligible. The two groups were well balanced for standard prognostic factors. Overall response rate was higher in the group given concurrent chemotherapy and TRT (84% versus 66.4%). With a median follow-up of 5 years, there is also a survival advantage for the group given concurrent treatment (median survival = 16.5 months versus 13.3 months and five-year survival = 15.8% versus 8.9%) (Table 52.5). Of note, median survival for the sequential arm is similar to that reported from the CALGB and RTOG/ECOG trials employing sequential chemotherapy and radiotherapy.[20,56] These data suggest that concurrent chemotherapy and radiotherapy is superior to their sequential administration; however, additional ongoing trials are assessing this issue. Furthermore, the added toxicities of concurrent chemoradiotherapy are such that caution is appropriate, especially when altered fractionation schemas are also used.[76,77] Not all patients are necessarily candidates for concurrent treatment. Some patients may fare better with and prefer a sequential approach, even though the survival may be slightly less than that achieved with a more aggressive treatment.[78]

Survival	Concurrent CT + TRT	Sequential CT + TRT
Median	16.5 mos	13.3 mos
1-yr	64.1%	54.8%

TABLE 52.5. CONCURRENT VERSUS SEQUENTIAL CHEMOTHERAPY AND RADIOTHERAPY IN LOCALLY ADVANCED NSCLC

New Strategies to Address Local Tumor Control

Although an obvious need exists for improved systemic therapy in locally advanced NSCLC, there also is a need for better local control of the tumor. Based erroneously on results from studies conducted more than 20 years ago, it is often assumed that standard daily fractionated radiotherapy alone can control intrathoracic disease in up to 50% of cases when 60 Gy or higher radiotherapy is employed.[22,79] These studies typically accepted stabilized tumor masses as evidence of local control. Based on more recent data, we know this is a gross overestimate of radiotherapy's ability to control bulk disease. Using more stringent means of assessing local control (e.g., bronchoscopy), fewer than 10% of patients are found to have good tumor control at 5 years posttreatment.[27] Patients who relapse with symptomatic distant metastases or die of intercurrent illness may never develop *clinical* evidence of local recurrence simply because they die before manifesting evidence of local recurrence. In addition, physicians do not usually document the exact pattern of disease recurrence upon recognition of relapse in part because formal restaging is not standard practice even in study settings. Furthermore, there is not an agreed-upon standard approach for restaging studies, and very few patients undergo an invasive procedure to confirm the recurrence histologically. Even if extensive radiographic restaging of the thorax is performed at the time of suspected relapse, the results may be misleading because changes in tumor size as determined radiographically only loosely correlate with actual pathologic findings and long-term survival.[80]

In the rare circumstance where a more extensive reevaluation has been performed, the frequency of local control is surprisingly low. For example, using bronchoscopy to visualize the local tumor site, LeChevalier and colleagues found that local tumor control was present in fewer than 20% of patients given thoracic radiotherapy to a dose of 65 Gy.[25] Thus efforts to improve local tumor control are apparently worthwhile because enhanced local control can translate into improved survival even in the absence of improved control of extrathoracic metastases.[28,81,82 and 83] For example, despite limitations in assessing local control in older trials such as the RTOG 73-01 study, it is noteworthy that patients who achieved a complete response locally enjoyed a longer survival even though no systemic therapy was administered.[28]

Strategies designed to improve local control include (a) the use of radiation-sensitizing drugs,[84] (b) escalated radiotherapy doses,[10] perhaps with three-dimensional (3-D) treatment planning,[85,86] and (c) through the use of altered fractionations of irradiation.[87] Surgical resection may be the ultimate in local tumor control and is discussed in greater detail in Chapter 37,Chapter 38,Chapter 39,Chapter 40 and Chapter 41. To date, however, no study has yet demonstrated that surgery is superior to radiotherapy in maintaining local control in patients with *clinically unresectable* or so-called *"marginally" resectable* disease.[35] An ongoing United States intergroup trial is prospectively comparing these two modalities.

Radiation-Sensitizing Drugs

Several common antineoplastic agents such as cisplatin, etoposide, paclitaxel, and gemcitabine among others have the potential to act as radiation-sensitizing agents.[84,88,89 and 90] These preclinical observations have prompted several investigators to undertake studies combining radiation-sensitizing drugs and radiotherapy. European investigators performed a well-designed randomized trial in which split-course radiotherapy alone was prospectively compared to radiotherapy plus concomitant cisplatin given daily or weekly.[91] The combined administration of cisplatin and irradiation resulted in improved local tumor control and improved survival (Table 52.6). The improved survival was clearly attributable to improvement in the local failure rate because the rate of distant failure was not affected with the addition of the relatively low doses of cisplatin. Similar results have been noted by other investigators,[92] although this finding has not been universal.[93] One precautionary note—the simultaneous use of radiation and drugs can be a double-edged sword because increased host toxicities may ensue, resulting in dose reductions of one or both treatment modalities. Esophagitis and pulmonary toxicities are particularly worrisome in this regard.[76,94,95 and 96] Accordingly, strategies that permit concurrent administration of chemotherapy and radiotherapy and that minimize the likelihood of host toxicity need further exploration.

Treatment	1-Year	2-Year
TRT Alone	41 ± 5.6%	19 ± 5.1%
TRT + Weekly Cisplatin	42 ± 5.7%	30 ± 6.0%
TRT + Daily Cisplatin	59 ± 5.8%	31 ± 6.3%

TABLE 52.6. CHEMOSENSITIZATION WITH CISPLATIN PLUS TRT SURVIVAL WITHOUT LOCAL PROGRESSION

Increased Radiotherapy Dose and Altered Fractionation

The importance of radiotherapy dose and its relationship to the intrathoracic control of NSCLC is well established.[10,11] However, escalating the dose of thoracic irradiation beyond 60–66 Gy in lung cancer has been difficult largely because of the toxic effect on normal tissues, especially the lungs and esophagus. One potential means of increasing total radiation dose without engendering excessive host toxicity is the use of multiple daily fractions of irradiation.[87,97] In theory, giving radiotherapy in many small doses reduces the long-term adverse effects observed in normal tissues with little reduction in effect on most tumors because tumor cell repopulation is minimized.[98] Altered fractionation schemas attempt to exploit the differences in early-responding and late-responding tissues to repair radiation-induced DNA damage. Pilot studies indicate that this approach is feasible in locally advanced NSCLC.[64,99,100]

British investigators recently completed a randomized comparison of *continuous hyperfractionated accelerated radiotherapy* (CHART) and standard once-daily fractionated radiotherapy in NSCLC patients with locally advanced disease.[83] CHART consists of three daily fractions (1.5 Gy) of irradiation given over 12 consecutive days to a total dose of 54 Gy. CHART yielded a statistically significant improvement in overall survival compared to individuals treated with traditional once-daily radiotherapy (Table 52.7). Improved survival appears to have resulted from increased local tumor control because no systemic therapy was administered. Lending support to this conjecture is the observation that CHART imparted its greatest benefit in patients with squamous carcinoma. Squamous carcinomas tend to be localized more commonly than nonsquamous histologies, and because of this tendency, would presumably benefit more from improved local tumor control imparted by CHART. This relationship appears to be the case because squamous histology patients enjoyed a 34% reduction in the relative risk of death with CHART, which translates into an absolute two-year survival benefit of 14% (from 19% to 33%). The principal toxicities of CHART were esophagitis and dysphagia. However,

pulmonary fibrosis also was more common among patients receiving CHART (16% versus 4%) compared to once-daily irradiation. Radiation morbidity accounted for a total of six deaths, three in each treatment arm.

Survival	CHART	Standard RT
1-yr	63%	55%
2-yrs	29%	20%

From Saunders M, Dische S, Barrett A, et al. Continuous hyperfractionated accelerated radiotherapy (CHART) versus conventional radiotherapy in non-small-cell lung cancer: a randomised multicentre trial. CHART Steering-Committee [see comments]. *Lancet* 1997;350:161, with permission.

TABLE 52.7. CHART IN LOCALLY ADVANCED NSCLC

The CHART data are extremely encouraging and correlate with other data derived from randomized trials in which multiple daily fractions of irradiation proved advantageous in NSCLCs and SCLCs.[56],[101] However, the administration of 12 consecutive days of radiotherapy is logistically problematic. Fortunately, both the British group and ECOG investigators have reported equally encouraging results using a less burdensome schedule that avoids weekend radiotherapy treatments.[100],[102] The British investigators refer to their regimen as "CHARTWEL" for "CHART—weekendless,"[102] whereas the ECOG investigators refer to their regimen as "HART," indicating noncontinuous hyperfractionated accelerated radiotherapy.

3-D Treatment Planning

3-D treatment planning provides an ability to increase radiotherapy dose while minimizing normal tissue toxicity.[86],[103] 3-D capabilities are fully discussed in Chapter 48. However, the salient features employ computed tomographic images to better define the target (tumor and perhaps regional nodes), register normal tissues and record doses that they receive, and plan beam directions to optimize dose to the target while minimizing exposure to the adjacent normal organs and tissues. Preliminary studies indicate that this technique permits radiotherapy dose-escalation to levels as high as 85–103 Gy.[85],[104],[105] and [106] Dose-escalation trials have more sharply defined target volumes and even eliminate treatment of mediastinal nodes. In the recent Ann Arbor trial results,[107] 104 patients were treated, none with elective mediastinal irradiation. Toxicity has been moderate; moreover, no grade 3 pneumonitis has been observed despite high doses, and no patient failed exclusively in the untreated mediastinum. If radiotherapy ports can be reduced, and tumor doses increased, then TRT may be a better partner with surgery and chemotherapy in the treatment of NSCLC. Large tumors with multilevel mediastinal nodes may not benefit from these approaches. One study found that prognosis was adversely influenced if more than 20 percent of normal lung volume was included.[106] It remains to be seen if such approaches will prove beneficial in terms of improved local control and enhanced survival.

SUMMARY

The results of the CALGB trial prompted a clear paradigm shift in the management of locally advanced NSCLC.[2],[105] Selected patients are now preferentially treated with combined modality approaches. The optimal means by which these two modalities are combined, however, as well as issues pertaining to optimal radiotherapy and chemotherapy, all require additional study. Newer chemotherapy drugs with higher response rates raise expectations for improved survival, although appropriate clinical studies are needed to validate these expectations.[9] Some of the newer agents—the taxanes, the topoisomerase-targeting drugs, and gemcitabine—also hold promise as radiosensitizers as well as good systemic agents. The methods of improving local control are varied as described previously and each merits continued investigation. Potentially, these techniques will lead to additional modest improvement in the survival of NSCLC patients with locally advanced disease.

CHEMOTHERAPY FOR SMALL CELL LUNG CANCER

RUSSELL F. DEVORE III
DAVID H. JOHNSON

Small cell lung cancer (SCLC) represents the sixth most commonly diagnosed cancer in the United States each year.[1] In comparison to non–small cell lung cancer (NSCLC), small cell carcinoma tends to disseminate earlier in the course of its natural history and displays a more aggressive clinical behavior.[2,3] Untreated patients rarely survive beyond a few months, and local treatment modalities such as radiotherapy or surgery are not effective in prolonging survival beyond a few weeks.[4,5] The cause of death in most instances is systemic disease. The propensity for SCLC to disseminate early is illustrated by a classic study conducted by Matthews and colleagues.[6] These investigators were able to perform a series of autopsies on a group of SCLC patients who had died within one month of an attempted curative surgical resection. In all but a few cases, systemic metastases were identified even though the patients had undergone a preoperative evaluation demonstrating no distant metastases. Given the systemic nature of SCLC, it is not surprising that chemotherapy has become the cornerstone of management. Current chemotherapy approaches are reviewed in this chapter, whereas surgical management and specific details pertaining to radiotherapy for SCLC are covered in Chapter 54 and Chapter 56.

SINGLE-AGENT CHEMOTHERAPY

Small cell carcinoma exhibits sensitivity to a variety of chemotherapy agents (Table 53.1).[7] The chemosensitivity of SCLC was first identified 50 years ago with the recognition that methyl-bis-b-chloroethyl) amine hydrochloride could effect tumor regression in more than 50% of patients.[8] It is now well recognized that numerous antineoplastic agents are capable of effecting objective responses of ³30% in previously untreated patients.[9] Active agents include nitrogen mustard, doxorubicin, methotrexate, ifosfamide, etoposide, teniposide, vincristine, vindesine, nitrosoureas, cisplatin, and its analog carboplatin.[10] In the past decade, several new agents have been found to possess activity against SCLC, including paclitaxel, docetaxel, two topoisomerase I targeting agents topotecan and irinotecan (CPT-11), vinorelbine, and gemcitabine.[11] These newer agents are appealing because of their unique mechanisms of action.

Established Agents	New Agents
nitrogen mustard	paclitaxel
methotrexate	docetaxel
ifosfamide	topotecan
teniposide	irinotecan (CPT-11)
etoposide	vinorelbine
vincristine	gemcitabine
vindesine	
nitrosoureas	
cisplatin	
carboplatin	

TABLE 53.1. ACTIVE SINGLE AGENTS AGAINST SCLC

COMBINATION CHEMOTHERAPY

Despite a plethora of active agents, SCLC is rarely treated with single agents largely because complete remissions are relatively infrequent and remission durations tend to be brief with single agents. Furthermore, in randomized trials conducted in the 1970s, combination therapy was shown to produce superior survival compared to single-agent treatment.[12,13,14] In addition, the simultaneous administration of multiple agents has been shown to be more efficacious than the sequential administration of the same agents.[13] Consequently, for more than 20 years, combination chemotherapy has been the mainstay of SCLC management.

Several chemotherapy combination regimens have demonstrated acceptable activity against SCLC.[7,15] In general, active regimens yield objective response rates in the range of 80% to 90% with complete remissions occurring in up to 50% of patients, depending on stage at presentation. Median survival averages 7 to 9 months in extensive-stage patients and up to 20 months in patients with limited disease.[7,16,17] The best survival is achieved in good performance status patients who present with limited-stage disease and who receive combined modality therapy with chemotherapy plus thoracic radiotherapy.[16,17]

No single induction combination chemotherapy regimen has been found to be ideal for all patients. During the late 1970s and early 1980s, cyclophosphamide-based regimens were most commonly employed, particularly the combination consisting of cyclophosphamide, doxorubicin, and vincristine (CAV). More recently, induction regimens have tended to be built around etoposide either as a substitution for one of the components of the CAV regimen or in combination with cisplatin (with or without additional agents).[7,18] In some randomized trials, induction chemotherapy regimens containing etoposide yielded slightly superior survival compared to regimens without etoposide.[19,20] In direct comparisons to CAV, however, cisplatin and etoposide (EP) failed to demonstrate a clear survival advantage in patients with extensive-stage disease.[21,22] Thus the choice of induction therapy is usually dictated by a patient's coexisting medical problems. For example, even though the EP regimen has a favorable therapeutic index, it may be contraindicated in an individual with renal dysfunction or a preexisting neuropathy (e.g., diabetic neuropathy). Preexisting heart disease also may make it impossible to administer cisplatin because of the requirement for intravenous hydration. In such circumstances, carboplatin represents an acceptable alternative to cisplatin because it is not nephrotoxic nor is it considered cardiotoxic.[23,24,25 and 26] Likewise, doxorubicin may be contraindicated in a patient with preexisting heart disease. In such circumstances, a combination regimen such as cyclophosphamide, etoposide, and vincristine may be preferable.

Toxicity to Combination Chemotherapy

All chemotherapy regimens used to treat SCLC are associated with host toxicities.[7,27] The most common complication of combination chemotherapy is severe myelosuppression, which occurs in 25% to 30% of patients treated with chemotherapy alone and in up to 75% of patients receiving combined modality treatment.[28,29] Culture-positive infections, however, develop in fewer than 5% of patients and fatal infections occur in less than 2%.[29] Other lethal side effects are extremely uncommon. Cyclophosphamide-based therapy is usually associated with the highest incidence of neutropenia, whereas cisplatin plus etoposide generally represents the least myelosuppressive regimen.[2,30,31] With moderate-dose cisplatin (80 mg/m^2) and etoposide (80 mg/m^2 per day for 3 days), life-threatening neutropenia

develops in fewer than 5% of patients.[31]

The recent availability of hematopoietic growth factors (discussed following) has tended to make physicians more sanguine about myelosuppression. However, hematopoietic growth factors must be used judiciously because in selected circumstances, such as when given concomitantly with irradiation, they have proved detrimental.[32] Also, prophylactic antibiotics have not been adequately studied but appear to be effective for the prevention of fever during neutropenia and are considerably less costly.[33,33,34,35 and 36]

The incidence of gastrointestinal side effects varies, although nausea, emesis, esophagitis, and mucositis are relatively common, especially with cisplatin-based therapy or with combined modality programs. The availability of 5-HT, blocking agents can minimize or ameliorate many of the latter complications.[37] Late-developing complications related to chemotherapy also occur and include pulmonary fibrosis, cardiac toxicity, and second malignancies.[29,38] Second malignancies that are treatment related need to be distinguished from second primary malignancies, which are extremely common in long-term survivors of SCLC.[38,40 and 41] Neurotoxicities including mild dementia, ataxia, memory loss, and other neurologic abnormalities have been reported in patients who received prophylactic cranial irradiation, although the exact relationship to this therapeutic intervention has not been well characterized.[42,43,44 and 45]

Although considerable progress has been achieved in the overall management of SCLC, cure remains elusive for the most patients. Considering that fewer than 10% of extensive-stage patients survive beyond 2 years and no more than 15% to 25% of limited-stage patients are alive 5 years after diagnosis, new therapeutic approaches are clearly needed. The discovery of new agents with novel mechanisms of action is important in this regard but so is maximizing the benefits of currently available agents. The lack of curative potential of existing chemotherapy regimens is primarily related to the presence of drug resistance *ab initic* or possibly due to the emergence of drug resistance during chemotherapy administration. Treatment strategies employed to overcome drug resistance have dominated clinical research in SCLC for the past decade and include the following approaches: dose intensification, weekly chemotherapy, and alternating non–cross-resistant chemotherapy.

Dose Intensification

In preclinical tumor models, one of the simplest methods used to overcome drug resistance is drug dose escalation. This approach has been successfully used in a wide variety of murine malignancies, including leukemias and solid tumors.[46] With this knowledge, Cohen and colleagues undertook a randomized trial in the late 1970s, in which SCLC patients were randomized to receive standard dosages of cyclophosphamide, methotrexate, and lomustine or higher dose cyclophosphamide, lomustine, and standard-dose methotrexate.[47] These investigators observed both a higher overall response rate and a prolonged survival in the high-dose chemotherapy group. Furthermore, long-term survivors were observed only among those patients given high-dose chemotherapy. By today's standards, the high-dose regimen used by Cohen and his colleagues would be considered relatively modest. Nevertheless, this trial spawned a series of studies aimed at overcoming drug resistance through dose escalation.

High-Dose Induction Chemotherapy

Several randomized trials have tested the concept of high-dose induction therapy in SCLC (Table 53.2).[9,30,31,48,49 and 50] Based on pilot data demonstrating the feasibility of high-dose induction therapy,[51] the Southeast Cancer Study Group (SECSG) undertook a prospective study in which patients with extensive-stage SCLC were randomized to receive either high-dose CAV for the initial three cycles of therapy or standard-dose CAV.[30] No dose attenuation was allowed during the initial three cycles of therapy. Patients received a mean of ³95% of the planned dosages of cyclophosphamide and doxorubicin during the first three treatment cycles, resulting in a 15% and 67% dose escalation of each drug, respectively. Although the complete remission rate was higher in the high-dose arm (22% and 12%; P < 0.05), overall response rates (63% and 53%) and median survival duration (29.3 weeks and 34.7 weeks) were not significantly different between the two treatment groups. Moreover, the high-dose CAV regimen was substantially more toxic, with a large percentage of patients experiencing life-threatening toxicities (grade 4 neutropenia: 79% and 40%; P < 0.05). Virtually identical results were reported by Figueredo et al. in a Canadian trial.[49]

TABLE 53.2. RANDOMIZED TRIALS OF HIGH-DOSE VERSUS CONVENTIONAL-DOSE CHEMOTHERAPY

Hong and associates randomized both limited and extensive-stage SCLC patients to high-dose cyclophosphamide (2,000 mg/m^2) plus vincristine (CV), standard-dose CAV, or standard-dose etoposide plus cyclophosphamide and vincristine (CEV).[19] A total of 353 patients were studied. In limited-stage patients the complete response rates and median survivals for dose-intensive CV, standard-dose CAV, and standard-dose CEV were 31% and 41 weeks, 42% and 55 weeks, and 38% and 58 weeks, respectively. The median survival duration for all patients was superior in the standard-dose CEV arm (P = 0.01). The inclusion of etoposide in the CEV regimen may have been more important for efficacy than the strategy aimed at overcoming drug resistance.

More recently, Ihde et al. compared standard-dose etoposide (80 mg/m^2 per day for 3 days) plus cisplatin (80 mg/m^2 day 1) to high-dose etoposide (80 mg/m^2 per day for 5 days) plus cisplatin (27 mg/m^2 per day for 5 days).[31] Both regimens were administered every 21 days. The degree of myelosuppression with high-dose therapy was approximately twice that observed with the standard-dose regimen. However, there was no difference in response rates (85% and 81%), median survival (12 months and 11 months) or one-year survival rates (50% and 46%). It is particularly noteworthy that the incidence of grade 4 myelosuppression was just 2% in the standard-dose arm and more than 25% in the high-dose arm. These figures are considerably less than that generally reported for cyclophosphamide-based chemotherapy regimens.

Preclinical studies indicate that a survival benefit may not be observed until the dose of an active agent is increased two-fold or more.[46] Furthermore, the most convincing evidence for a survival benefit to dose intensification in animal model experiments comes from models with curative potential.[52] A two-fold dose intensity increase is not easily achieved in clinical oncology without some type of stem cell support. However, limited-stage SCLC is a curable entity, and efforts to exploit any biological or clinical advantage to dose intensification might better be pursued in this patient subset. Arriagada and colleagues did a retrospective analysis of 131 consecutively treated limited-stage SCLC patients and observed a survival benefit for patients who received higher initial doses of cyclophosphamide and cisplatin.[53,54] Based on this observation, they undertook a phase III trial, in which limited-stage patients were randomly assigned to receive either conventional-dose cisplatin, cyclophosphamide, etoposide, and doxorubicin alternating with thoracic radiotherapy, or the identical treatment regimen except 20% higher doses of cyclophosphamide and cisplatin were given in the first treatment cycle only.[50] The complete response rate (67% versus 54%, p = 0.16) and two-year survival (43% versus 26%, p = 0.02) were superior in the dose-intensive group.

A more recent report by Stewart and colleagues also suggests that dose intensification might effect superior survival outcomes in early-stage patients.[55] These investigators enrolled patients with "good- or intermediate-prognosis" SCLC to a prospective multicenter study that involved a 2 × 2 factorial design, randomizing patients to conventional versus dose-intensified V-ICE chemotherapy (vincristine, ifosfamide, carboplatin, etoposide). Patients were randomly assigned to receive identical doses of all four drugs on either an every-three-week or every-four-week schedule. Both treatment groups were then randomized to receive either granulocyte-macrophage colony-stimulating factor (GM-CSF) or no growth factor support. Eligibility required that patients be classified as good- or intermediate-prognosis as defined by Cerny and colleagues.[50] One hundred and seventy eight of three hundred patients (59%) had limited-stage disease. Although there were greater proportions of limited-stage patients and patients with more favorable prognostic scores in the dose-intensive group, these differences were not

statistically significant. The addition of GM-CSF neither reduced the incidence of complications from myelosuppression nor improved survival. However, patients in the three-week treatment arm experienced statistically superior median and two-year survivals (443 versus 351 days and 33% versus 18%, respectively).

The dose-intensive patients from the Arriagada and Steward trials experienced two-year survival rates of 43% and 33%, respectively. Although the treatment regimens varied significantly between the two trials, an indirect estimate of the relative dose intensity of the two regimens can be made by comparing the incidence of dose-limiting toxicity, that being grade IV neutropenia—59% and 65%, respectively. Turrisi and colleagues recently described the highest long-term survival rates ever observed in a multicenter phase III trial in limited-stage SCLC.[17] Patients were treated with etoposide and cisplatin and concurrent thoracic radiotherapy either by a conventional once-daily or a twice-daily schedule. For the entire patient group, the two-year survival rate was 44% and the grade IV neutropenia rate was 63%, results almost identical to those observed in the dose-intensive patients from the Arriagada and Steward trials. The control regimens used in the latter trials effected grade IV neutropenia rates of only 23% (cycle 1 only) and 49%, respectively. The dose intensity of these regimens might better be considered suboptimal rather than standard. Therefore, dosing initial chemotherapy below the maximally tolerated dose of a given regimen might be detrimental in limited-stage SCLC.

It is safe to conclude that dose intensification of induction therapy is not beneficial to patients with extensive-stage disease. Optimal therapy for limited-stage disease should include doses at or near the maximal tolerated doses of the induction regimen. Compromising dose intensity in these patients may negatively impact long-term survival rates. Whether a survival benefit can be derived by intensifying induction therapy beyond the maximally tolerated doses of conventional outpatient therapy is unknown at this time and is a reasonable area for continued investigation in limited-stage patients.

Weekly Chemotherapy

As described in the preceding section, Steward and colleagues were able to effect a significant improvement in median survival in good- or immediate-prognosis SCLC patients by decreasing the treatment interval from 4 to 3 weeks. This success suggests that increasing dose intensity by more frequent dosing might be beneficial. This may be even better achieved with weekly chemotherapy using standard chemotherapy doses but alternating between myelosuppressive and nonmyelosuppressive agents. Early pilot trials testing this approach have produced promising results, leading to several phase III trials comparing weekly chemotherapy to conventional regimens (Table 53.3).[57,58,59 and 60] The European Organization for Research and Treatment of Lung Cancer (EORTC) conducted a large phase III study comparing a weekly multidrug chemotherapy regimen (doxorubicin, etoposide, cyclophosphamide, cisplatin, vindesine, vincristine, and methotrexate) to a standard chemotherapy regimen (cyclophosphamide, doxorubicin, and etoposide) administered every three weeks.[57] Both limited- and extensive-stage patients were enrolled. Although the response rate in the weekly regimen was higher in limited-stage patients, there was no difference in overall response rate, median survival, and two-year survival. The total relative dose-intensity for the drugs common to both regimens was significantly less in the weekly chemotherapy arm due to frequent treatment delays.

Reference	Regimen	Patient Number	Overall Response %	Median Survival	Two-Year Survival %

[d] Cyclophosphamide, doxorubicin, vincristine alternating with cisplatin and etoposide.
[e] Progression-free survival.

TABLE 53.3. RANDOMIZED TRIALS OF WEEKLY VERSUS EVERY-THREE-WEEK CHEMOTHERAPY

Souhami et al. reporting for the Cancer Research Campaign of the United Kingdom, also found no survival benefit when they compared a weekly multidrug regimen to a standard every-three-week approach.[58] In the U.K. trial, 438 patients with either limited disease or "good prognosis" extensive disease were randomized to receive 12 weekly cycles of ifosfamide and doxorubicin alternating weekly with cisplatin and etoposide or 6 cycles of CAV alternating every 3 weeks with EP. Thoracic irradiation was administered only to limited-stage patients in complete or partial response. There were no reported differences in overall response rates (82.3% and 81.1%), median survival (10.8 months and 10.6 months) or two-year survival rates (11.8% and 11.7%). Hematologic toxicity was greater in the weekly chemotherapy arm and the ratio of intended-to-delivered dose intensity was greater in the standard arm. In both trials the chemotherapeutic agents differed between the two treatment arms. Although the ability to deliver full intended doses was superior in the standard regimens, it was not possible to directly compare dose intensity between the regimens.

Canadian investigators reported promising results from a pilot study of a weekly regimen referred to as CODE: cisplatin (25 mg/m^2 for 9 consecutive weeks); vincristine (1 mg/m^2 weeks 1, 2, 4, 6, 8); doxorubicin (40 mg/m^2 weeks 1, 3, 5, 7, 9); and etoposide (80 mg/m^2 days 1–3, weeks 1, 3, 5, 7, 9).[61] Excluding cyclophosphamide, the CODE regimen contained the same agents and same total cumulative doses as the conventional alternating CAV/EP regimen, but therapy was completed in 9 rather than 18 weeks. Thoracic and prophylactic cranial radiation therapy were also given to selected patients. These investigators were able to deliver close to full intended doses, thus effecting an increase in dose intensity of approximately twofold for the four drugs common to the two regimens. A two-year survival rate of 30% was observed, far superior to the historical rate of less than 10% in extensive-stage patients.

National Cancer Institute (NCI) Canada and Southwest Oncology Group (SWOG) collaborated on a phase III trial comparing CODE to conventional alternating CAV/EP in patients with extensive-stage SCLC.[59] Greater than 70% of intended doses were delivered for both regimens. CODE patients received slightly higher cumulative doses of each of the four common agents but completed their therapy in just 9 weeks rather than the 18 weeks received by the control patients. Therefore, a twofold increase in the dose intensity of the four common agents was achieved. Although rates of neutropenia and fever were similar, 10 of 110 CODE patients versus 1 of 109 CAV/EP patients died during chemotherapy. Response rates were higher for the CODE patients, but progression-free and overall survival were not statistically different. In view of the increased mortality and similar efficacy, CODE was not recommended.

In the Canadian pilot and intergroup phase III trials, CODE patients received aggressive supportive care but were not routinely treated with prophylactic colony stimulating factor. Japanese investigators conducted a small randomized trial of CODE with or without G-CSF in patients with extensive-stage SCLC.[62] Use of G-CSF resulted in increased mean total received dose intensity for all drugs, reduced neutropenia and neutropenic fever, and a significant improvement in survival. This finding led to a phase III trial designed almost identical to that of the NCI Canada/SWOG trial.[60] Two hundred and twenty-seven patients with extensive-stage SCLC were randomized to receive either CODE plus G-CSF or conventional alternating CAV/EP. CODE patients received G-CSF on nontreatment days. The achieved dose intensity for CODE plus G-CSF was twice that of the CAV/EP regimen. The incidence of leukopenia was not different, but anemia and thrombocytopenia were significantly increased in the CODE plus G-CSF patients. The incidence of neutropenic fever was 18.8% versus 8.8% of patients in the CODE plus G-CSF and CAV/EP arms, respectively, and 4/114 (3.5%) of CODE plus G-CSF patients died from therapy-related causes. The response rate was slightly higher (77% versus 84%) in the CODE plus G-CSF arm, but there was no survival difference. Although dose-intensive weekly therapy has not been well tested in limited-stage patients, this approach has failed to effect any benefit for patients with extensive-stage disease.

Colony-Stimulating Factors

As outlined in the preceding sections, the addition of a colony-stimulating factor (CSF) allowed for dose intensification of the V-ICE and CODE regimens.[55,62] Decreasing the dosing interval of V-ICE improved survival, but the addition of GM-CSF had no independent impact on this outcome. The initial Japanese CODE plus G-CSF trial reported by Fukuoka and colleagues was designed to address dose intensity as the primary end point rather than survival. Therefore, only 63 patients were accrued, and median survival was superior for patients who received G-CSF (59 versus 32 weeks, p = 0.0004). Several phase III trials have investigated the impact of CSFs on SCLC chemotherapy (Table 53.4).[32,55,62,63,64,65,66,67 and 68] The primary end point of most trials was the incidence of neutropenia and associated sequelae. Most were not designed to directly address the relationship between dose intensity and therapeutic outcomes. As described previously, Steward and colleagues were able to increase dose intensity by adding GM-CSF to the dosing regimen.[55] Likewise, when Woll and colleagues added G-CSF to the V-ICE regimen,

they were able to increase dose intensity, but the trial was not powered to accurately address survival end points. [67] Pujol and colleagues treated 125 patients with extensive-stage SCLC with either a dose-intensive regimen containing high doses of cyclophosphamide, epidoxorubicin, etoposide, and cisplatin plus GM-CSF or the same chemotherapy at conventional doses without GM-CSF.[63] In this attempt to improve survival by increasing dose intensity with the aid of GM-CSF, these investigators reported decreased dose intensity, worse hematologic toxicities, and inferior median survival (10.8 versus 8.9 months, p = 0.0005) for the high-dose chemotherapy/GM-CSF treated patients.

TABLE 53.4. RANDOMIZED TRIALS OF CHEMOTHERAPY WITH AND WITHOUT COLONY STIMULATING FACTORS (CSF) IN SCLC

The Pujol data further corroborate the overwhelming evidence that attempting to intensify chemotherapy for extensive-stage patients is not beneficial and may be harmful. However, the Arriagada and V-ICE data suggest that dose intensification might be beneficial in limited-stage patients. Although the previously cited trial by Woll and colleagues was not designed to address a primary survival end point, they did demonstrate a statistically significant increase in two-year survival (32% versus 15%) in primarily limited-stage patients receiving dose-intensified V-ICE plus G-CSF. Median survival was not improved (69 versus 65 weeks). Bunn and colleagues conducted a phase III trial in 230 limited-stage SCLC patients to determine whether GM-CSF could be used to reduce the incidence of neutropenic fever and hematologic toxicities of combined chemoradiotherapy. [32] All patients initially received etoposide 80 mg/m^2 and cisplatin 40 mg/m^2 days 1–3. Thoracic radiotherapy consisted of 45 Gy total delivered in 25 daily fractions of 1.8 Gy, 5 days per week given simultaneously with the chemotherapy over the first 5 weeks. GM-CSF was dosed at 250 mg/m^2 subcutaneously twice daily on days 4–18 of each cycle of therapy. There was a statistically significant increase in the frequency and duration of life-threatening thrombocytopenia (p < 0.001), more nonhematologic toxicity, more days of hospitalization, a higher incidence of intravenous antibiotic usage, more transfusions, and more toxic deaths in the patients receiving GM-CSF. There was no significant difference in median survival.

In summary, the addition of CSFs to chemotherapy in patients with SCLC can reduce the incidence of hematologic side effects if chemotherapy is given at conventional doses. Chemotherapy dose escalation or the addition of concurrent radiotherapy to CSFs has resulted in increased toxicity and death rates in some studies. Considering the expense and inconveniences of CSFs, the apparent lack of benefit from dose intensification, and the intolerability of concurrent use with radiotherapy, the routine use of these agents in the management of SCLC cannot be recommended. Indeed, recent pharmacoeconomic analyses have concluded that despite a decrease in hematologic toxicity in most trials, the routine use of CSFs in SCLC is not justified by clinical benefits, improved patient comfort, or economic considerations.[34,35 and 36]

Late-Intensification Chemotherapy

Of the dose-intensification strategies discussed thus far, only the CODE regimen effects a ³ two-fold increase in dose intensity. Some type of hematopoeitic stem cell support is needed to intensify therapy further. Late intensification has both scientific and clinical appeal. [69,70] Because SCLC patients are often ill at the time of presentation, they are often poor candidates for highly aggressive approaches. Patients are generally in better medical condition to be considered for high-dose therapy following induction. Consolidating with high-dose therapy also allows for the prospective identification and selection of patients who are most likely to benefit—those with limited-stage disease, good performance status, and those who obtained a major remission with induction chemoradiotherapy. [70] This approach has been studied by several investigators albeit rarely in a randomized trial. Humblet and colleagues reported the results of the only published multicenter randomized study testing late-intensification chemotherapy in patients responding well to induction therapy. [71] Autologous bone marrow transplantation was used to rescue patients from hematologic toxicities. Of 101 patients receiving standard induction chemotherapy, 45 patients with chemotherapy-sensitive disease were randomized to receive one additional cycle of either high-dose cyclophosphamide, carmustine (BCNU), and etoposide or conventional doses of the same drugs. In this highly selected group of patients, median overall survival after induction therapy was 68 weeks for the intensified group compared to 55 weeks for the conventional therapy group, a difference that is not statistically significant (P = 0.13).

In a large phase II study, SWOG treated 58 limited-stage SCLC patients with induction chemoradiotherapy followed by high-dose cyclophosphamide (150 mg/kg) intensification and autologous bone marrow rescue.[72] Only 21 patients completed the entire course of therapy, and seven treatment-related deaths occurred, four of which occurred during late-intensification chemotherapy. Median survival for all patients was 11.1 months. Nine of the twenty-one patients receiving late intensification were alive in complete remission with a median survival of 27 months.

Dana Farber Cancer Center investigators employed high-dose consolidation chemotherapy in patients with limited-stage SCLC in partial or complete remission following conventional first-line chemotherapy. [73] Patients received cumulative doses of 5,625 mg/m^2 cyclophosphamide, 165 mg/m^2 cisplatin, and 480 mg/m^2 carmustine followed by thoracic and prophylactic cranial irradiation. Of the 36 patients treated in this phase II trial, 29 of whom were in complete or near complete remission before high-dose therapy, 14 remained disease free at a median of 21 months (range: 40–139) after treatment. Actuarial two- and five-year disease-free survival rates were 53% and 41%, respectively. Morbidity was relatively low and most patients were able to return to full-time work. Although the results of this trial are provocative, patients were highly selected and were accrued over a nine-year period. Furthermore, the median age of patients entered into this trial was 49 years, which is several years below the typical average age of SCLC patients. There are few reports of similarly selected patients from which historical control data can be derived and compared. However, the SECSG reported a phase III trial involving a similar subset of selected patients. [74] Patients with limited-stage SCLC were randomly assigned to receive either six cycles of induction chemotherapy with CAV or the same therapy with concurrent radiotherapy. Good performance status patients who had achieved an objective remission at the end of induction therapy were randomized to receive two cycles of consolidation etoposide and cisplatin or no further therapy. Twenty-six patients had received induction chemotherapy and radiotherapy and consolidation with etoposide and cisplatin. From the time of consolidation therapy initiation, these patients achieved a two-year survival rate of 55%, almost identical to the results reported by the Dana Farber group. There are too few data to draw any conclusions about the utility of high-dose consolidation therapy in limited-disease SCLC, but this approach should be considered experimental at this time. The Cancer and Leukemia Group B (CALGB) is now testing the Dana Farber regimen in a multicenter setting.

Dose-intensive induction therapy, weekly chemotherapy, attempts to intensify with CSFs, and high-dose consolidation therapy have all failed to show a convincing survival benefit for patients with SCLC. Intensification of therapy beyond that of conventional regimens has been mostly harmful to patients with extensive-stage disease, and there are no indications that dose intensification in these patients will be beneficial even if advances in supportive care are achieved. The available data suggest that limited-stage patients might benefit from dose intensification. Two randomized trials suggest that administration of combined modality therapy below the maximum tolerated dose (MTD) of conventional outpatient regimens might be detrimental, but no data suggest that intensifying beyond this level is beneficial. The utility of early- and late-intensification therapy for limited-stage SCLC is still not well addressed and remains an area of important research, especially as active new mechanism agents are identified and supportive care is improved.

ALTERNATING NON–CROSS-RESISTANT CHEMOTHERAPY

Theoretically, to obtain optimal antitumor effects, multiple active agents should be administered simultaneously at their optimal single-agent dose. However, because drug toxicities often overlap, strict adherence to this approach is often not possible in the clinical setting. Using mathematical modeling, Goldie and Coldman suggested that alternating two non–cross-resistant chemotherapy regimens of relatively comparable efficacy could potentially minimize the development of drug resistance while avoiding excessive host toxicity. The strategy of alternating two comparably effective chemotherapy regimens was empirically tested in SCLC in the late 1970s and was more rigorously studied in the 1980s following the publications of Goldie and Coldman (Table 53.5).[21,22,75,76,77,78,79 and 80] Most of the more recently

conducted trials compared CAV to CAV alternating with EP. Because CAV and EP are both highly active against SCLC and contain compounds from divergent drug classes, integrating both combinations into an alternating non–cross-resistant regimen is appealing. Unfortunately, CAV and EP are not entirely non–cross-resistant. In CAV failures, EP generally effects response rates between 40% to 50%. Conversely, CAV is generally ineffective in EP failures, typically inducing objective remissions in less than 15% of patients.[21,22,81,82]

TABLE 53.5. ALTERNATING NON–CROSS-RESISTANT CHEMOTHERAPY PHASE III TRIALS

The National Cancer Institute in Canada (NCIC) reported the results of a prospective randomized study in patients with extensive-disease SCLC comparing conventional cyclophosphamide (1,000mg/m^2), doxorubicin (50 mg/m^2), and vincristine (2 mg) (CAV) given every 3 weeks for six cycles to CAV alternating with etoposide (100 mg/m^2 per day for 3 days) and cisplatin (25 mg/m^2 per day for 3 days) (EP) every 3 weeks for a total of six cycles (Table 53.5).[80] The overall response rate was modestly superior for the alternating regimen (80% versus 63%; p < 0.002), as was the overall survival (9.6 versus 8.0 months; p = 0.03). Although alternating therapy was statistically superior in this trial, this outcome might have been more related to the inclusion of EP in the regimen rather than the alternating design. In a similar study, the SECSG compared EP, CAV, and alternating EP and CAV in extensive-disease patients.[22] Response rates and survival were virtually identical for all three regimens. The NCI tested this approach in patients with limited-disease SCLC.[79] Patients were randomized between two induction regimens—either alternating CAV/EP or sequential therapy with three cycles of CAV followed by the same number of cycles of EP. Chemotherapy was followed by radiotherapy in responding patients. Again, no significant differences in therapeutic outcomes were observed between the two arms. The authors concluded that either the differences between the two schedules were too small to detect an advantage for the alternating regimen, or EP is actually a superior regimen and any schedule that includes these drugs produces superior results.

Recently, the EORTC reported a trial testing two relatively non–cross-resistant regimens: CDE (cyclophosphamide, doxorubicin, etoposide) and VIMP (vincristine, carboplatin, ifosfamide, mesna).[83] Previously, they demonstrated that treatment of patients failing therapy with one regimen experienced response rates ³50% when treated with the other.[84] Patients with extensive-stage SCLC were randomly assigned to receive either a maximum of five courses of CDE or five courses of alternating therapy, in which they received CDE cycles 1, 3, and 5 and VIMP cycles 2 and 4. The trial was designed to detect an increase in median survival from 9.2 months to 12 months. Although 360 patients were required to address the planned survival end point with a power of 80% and a significance level of 5%, only 148 patients were accrued. Median survival was 7.6 and 8.7 months for the standard versus the alternating arms, respectively (p = 0.243). Although an inadequate number of patients were accrued to this trial to accurately detect a small median survival advantage, these results suggest there is no major benefit to alternating therapy with conventional agents even when a significant lack of cross-resistance has been demonstrated.

Although the previous EORTC experience demonstrated a relative lack of cross-resistance between the CDE and VIMP regimens, there are no highly active salvage therapies for patients with resistant SCLC (discussed following). A better testing of the Goldie Coldman hypothesis awaits identification of truly active and more significantly non–cross-resistant agents and regimens.

SINGLE-AGENT AND CHRONIC ORAL ETOPOSIDE

Ever since large cooperative group studies conducted in the 1970s demonstrated the superiority of combination chemotherapy over single-agent cyclophosphamide, research efforts have concentrated on combination regimens. Unfortunately, most strategies for improving combination chemotherapy have been unfruitful. Coincident with the conduction of the numerous trials focusing on dose-intensification of combination therapy, single-agent etoposide trials were yielding response rates and survival durations rivaling those of the most active combination regimens. Furthermore, these favorable results were often obtained in patients with advanced age or who were considered medically unfit for combination regimens. When etoposide became available as a soft gelatin capsule, chronic oral regimens were studied and yielded surprising activity in chemotherapy-naïve and recurrent patients alike.[85,86 and 87]

Slevin and colleagues treated chemotherapy-naïve extensive-disease SCLC patients with single-agent etoposide either as a single 500 mg/m^2 24-hour infusion or by a 100 mg/m^2 2-hour infusion for 5 consecutive days.[88] In this randomized study in which the etoposide schedule was the only variable, 89% of patients in the five-day treatment arm versus 10% of patients in the one-day treatment arm achieved an objective response to therapy. Pharmacokinetic measurements were performed, and the total exposure to etoposide, as expressed by area under the concentration versus time curve, was equivalent for both regimens. However, patients receiving the five-day schedule maintained a plasma etoposide level greater than 1 mg/ml for approximately twice the duration as did patients receiving the one-day treatment. The authors concluded that the prolonged maintenance of very low drug concentrations (1 mg/ml) was more important than achieving high peak concentrations. Furthermore, the prolonged maintenance of high drug concentrations was inversely related to antitumor effect; the duration of etoposide blood concentrations greater than 10 mg/ml was greater in the less effective one-day treatment arm. The correlation between the key drug levels characterized in this pharmacokinetic study and those determined in the preclinical cellular studies is remarkable.[89]

In the late 1980s etoposide became available as a 50 mg soft gelatin capsule. A phase I study conducted by investigators at Vanderbilt University led to a recommended phase II regimen of 50 mg/m^2 per day for 21 days of oral etoposide.[90] These same investigators then treated 22 patients with recurrent or refractory SCLC with this regimen.[85] All patients had received at least one prior combination regimen and 18 had received previous intravenous etoposide in combination with other agents. There were two complete and eight partial antitumor responses for an overall response rate of 46%. Prior etoposide exposure did not appear to influence response. However, patients who responded well to induction chemotherapy and those who had been off chemotherapy for more than 90 days prior to disease progression were more likely to respond. Median duration of response was 4 months and median survival was 5 months (range: 1–15 months). The activity of this regimen in recurrent SCLC was confirmed by a group from Indiana University in an even more heavily pretreated patient cohort.[86] Although modest, these results rival those of the most active, multiagent "salvage" regimens used in relapsed SCLC.

Clark and colleagues employed a different regimen of chronic oral etoposide (50 mg total dose, twice daily for 14 consecutive days) in chemotherapy-naïve patients who were ³70 years old and/or who were considered medically unfit for standard combination regimens.[87] An objective response rate of 80% and median survival duration of 8.0 months were observed. Despite the advanced age of the patients and a mean Karnofsky performance status of only 60%, these therapeutic outcomes rival those of the most active combination regimens, the activity of which is generally determined in patients with more favorable prognoses. Not only was this regimen highly active, but it also appeared less toxic than the 50 mg/m^2 per day given for 21 days and substantially less toxic than standard combination regimens such as EP and CAV. Similar results have been obtained in chemotherapy-naïve SCLC patients treated with five-day administration of intravenous or oral etoposide.[91,92]

The early trials of single-agent and chronic oral etoposide indicated that activity was similar to and perhaps even superior to conventional combination chemotherapy. It also appeared to have a more favorable toxicity profile and a lack of cross-resistance with conventional chemotherapy, including the three-day etoposide and cisplatin regimen. It appeared to be superior therapy for elderly and medically unfit patients, and there was reason to believe that integration of chronic low-dose etoposide into combination regimens might lead to therapeutic gains. Unfortunately, none of these characteristics has been confirmed in phase III trials (Table 53.6).[93,94 and 95]

TABLE 53.6. RANDOMIZED TRIALS TESTING ORAL ETOPOSIDE IN SCLC

The first randomized trial testing the efficacy of chronic oral etoposide in SCLC was reported by SWOG in 1995. [93] Patients with chemotherapy-naïve extensive-stage SCLC were randomized to receive conventional etoposide 130 mg/m^2 per day and cisplatin 25 mg/m^2 per day on days 1–3 versus oral etoposide 50 mg/m^2 per day for 21 days plus cisplatin 33 mg/m^2 days 1–3. The intravenous regimen was given every 3 weeks for eight cycles and the oral regimen was given every 4 weeks for a total of six cycles. Three hundred six patients were accrued. There were no differences in response rates and median survival, but hematologic toxicity was greater in the patients receiving chronic oral etoposide. Although the SWOG investigators may have been using the more toxic of the chronic oral etoposide regimens, the complete lack of any therapeutic advantage makes further development of this approach undesirable.

The SWOG chose to test oral etoposide in combination with cisplatin, but phase II trial results suggested that oral etoposide alone might be as active as conventional combination regimens and substantially less toxic. The Medical Research Council Lung Cancer Working Party conducted a randomized phase III trial comparing single-agent etoposide, 50 mg twice daily for 10 consecutive days on a three-week schedule, to a standard intravenous regimen of etoposide and vincristine or cyclophosphamide, doxorubicin, and vincristine. [94] Three hundred thirty-nine chemotherapy-naïve patients with poor performance status (World Health Organization grade 2–4) were accrued. The primary end point was palliation of major symptoms at 3 months after randomization. The palliative effects of treatment were similar in the etoposide and control groups with 41% and 46% of patients, respectively, experiencing an improvement in their palliation score. Grade 2 or worse hematologic toxicity occurred in 29% of etoposide-treated patients and 21% of controls. Controls had a superior overall response rate (51% versus 45%) and a median survival advantage (130 versus 183 days, p = 0.03). These authors concluded that oral etoposide therapy was inferior to standard intravenous multidrug chemotherapy in the palliative setting and that oral etoposide should no longer be used in such patients. Souhami and colleagues reported similar results when they randomly assigned chemotherapy-naïve patients with performance status 2 or 3 to receive either five-day oral etoposide or conventional alternating CAV/EP. [95] After 155 patients were accrued, a planned interim analysis led to early study closure because the one-year survival rate, progression-free survival, overall response rate, symptom control, and quality of life were all inferior in the oral etoposide arm.

The experience with single-agent etoposide exemplifies the importance of randomized multicenter trials in the testing of new therapies in cancer patients. Single-agent therapy has no role in the management of chemotherapy-naïve patients. Chronic oral etoposide has not been extensively studied in the salvage setting and may still have a role in selected patients.

TREATMENT DURATION AND MAINTENANCE THERAPY

The optimal duration of induction chemotherapy for SCLC is not well defined. However, prolonged treatment is generally considered unnecessary because a survival advantage has not been demonstrated in randomized trials (Table 53.7).[96,97,98,99,100,101,102 and 103] In one randomized trial, 687 SCLC patients were treated with five cycles of cyclophosphamide, doxorubicin, and etoposide followed by randomization to seven additional cycles of the same chemotherapy or close follow-up alone. [98] No difference in overall survival or five-year survival was detected between the two treatment arms. Although progression-free survival duration was longer for patients given maintenance chemotherapy, patients not receiving maintenance therapy were more likely to respond to salvage chemotherapy, accounting for the similar survival outcome. Spiro and colleagues compared 4 versus 8 cycles of chemotherapy. [96] Within each treatment group, patients were also randomized to receive salvage chemotherapy at the time of disease progression or to receive no further therapy. Patients who received eight cycles of therapy with or without salvage chemotherapy did no better than patients who received four cycles of induction therapy and salvage therapy at the time of relapse. However, patients who received four cycles of induction therapy and no salvage therapy had an inferior median survival.

TABLE 53.7. PHASE III TRIALS ADDRESSING TREATMENT DURATION AND MAINTENANCE THERAPY

The Medical Research Council Lung Cancer Working Party has conducted sequential phase III trials addressing therapy duration. In the first trial, 497 SCLC patients received six courses of cyclophosphamide, methotrexate, etoposide, and vincristine. [97] Patients still in complete or partial remission at the end of six cycles were then randomized to an additional six cycles of the same regimen or to no further chemotherapy. No survival advantage was achieved with the longer duration of treatment, but maintenance therapy was associated with more toxicity and poorer quality of life. Their second trial attempted to reduce treatment duration even further and compared three to six treatment cycles. Patients were randomized at the beginning of therapy. [99,100] Three hundred six patients were accrued and no difference in overall survival, toxicity, or quality of life was observed. The authors concluded that a small advantage in median survival for the six-cycle regimen could not be ruled out, but there was no apparent advantage to treating patients beyond three cycles of therapy.

The results of the trials described in the previous paragraph along with the results obtained in other randomized trials indicate that an appropriate duration of induction treatment for SCLC is three to six cycles of a standard chemotherapy regimen (Table 53.7). A recently completed Eastern Cooperative Oncology Group/Research Treatment Oncology Group (ECOG/RTOG) trial in patients with limited disease conclusively demonstrates that prolonged therapy duration is not necessary to achieve optimal therapeutic results. [17] Patients with limited-stage disease received just four cycles of cisplatin plus etoposide plus concomitant thoracic radiotherapy and achieved a median survival of more than 20 months and a two-year survival of more than 40%.

In extensive-stage patients, any of several different regimens administered for three to six courses represents adequate induction therapy. Maintenance chemotherapy or continuation of treatment beyond three to six cycles is unnecessary and more likely to produce toxicity than to extend survival or benefit quality of life provided treatment is reinstituted at the time of relapse. [96]

SALVAGE CHEMOTHERAPY

A majority of chemotherapy-treated SCLC patients eventually develop recurrent disease. Although many patients are in excellent physical condition at the time of

relapse, few drugs or drug combinations are capable of effecting tumor regression in this setting. Ebi and colleagues from Japan studied 159 patients with SCLC who received first-line chemotherapy, of whom 123 (77%) were responders.[104] Of the responding patients, 88 relapsed and were eligible for salvage therapy. Forty-eight of the relapsed patients received salvage therapy, of whom sixteen (33%) achieved an objective response. These investigators found the following characteristics to be predictive of response to salvage therapy: (a) more than 90 days since completion of induction therapy; (b) an induction therapy response duration of more than 270 days; (c) and a previous completed response (CR) to induction therapy. Performance status and extent of disease at presentation were not predictive of response to salvage therapy.

Several trials have demonstrated a correlation between the likelihood of response to salvage therapy and the treatment-free interval following induction therapy. Chute and colleagues reported a response rate of 56% in 20 patients treated with salvage therapy after surviving cancer free for ³2 years after initial therapy.[105] In the Vanderbilt phase II chronic oral etoposide study, one of eight patients less than 90 days out from their previous therapy responded to oral etoposide, whereas 9 of 14 patients greater than 90 days since previous therapy responded.[85] Likewise, Giaccone and colleagues administered teniposide to 38 previously treated patients, most of whom had received previous cyclophosphamide, etoposide, and doxorubicin in various regimens.[106] Only 2 of 16 patients who had received chemotherapy £2.6 months prior to starting salvage therapy achieved an objective remission. On the other hand, of the 17 patients who were more than 2.6 months from previous therapy, 9 achieved an objective response. This same study demonstrated the importance of responsiveness to induction therapy in predicting the efficacy of salvage therapy. Ten of twenty-four patients who responded to induction therapy also responded to salvage teniposide, whereas none of the seven patients who failed induction chemotherapy responded to salvage therapy. The same observation was made in the chronic oral etoposide study, in which 10 of 18 patients who were initially chemotherapy-sensitive achieved an objective response to salvage chronic oral etoposide, whereas none of 4 initially resistant patients responded. Finally, some patients can be reinduced with the same regimen if a durable response was achieved from induction therapy.[107,108] Although not well studied, the likelihood of achieving a durable remission with salvage chemotherapy appears to be proportional to the remission duration following induction.

There is no established salvage chemotherapy standard. EP is a reasonable choice in CAV failures, and a likelihood of response of 40% to 50% can be expected.[81,82] Conversely, CAV is often inactive in EP failures.[21,22,109] Chronic oral etoposide induces responses in about 50% of patients recurring following treatment, with regimens that included conventional intravenous administration of the same agent.[85] Even in patients failing both CAV and EP, approximately 25% of patients respond to chronic low-dose etoposide.[86] Unfortunately, remissions with salvage therapy are usually short-lived.

Ifosfamide has been active in the salvage setting when used in combination with chronic oral etoposide and cisplatin.[110] A response rate of greater than 50% has been reported. Unfortunately, this level of efficacy is achieved at the cost of a considerably high incidence of life-threatening toxicities. Kubota and colleagues treated 17 patients with relapsed SCLC with the CODE regimen.[111] Fifteen patients (88%) experienced an objective response, but 76% of patients developed grade IV leukopenia. The median survival was 245 days for the five patients with CR and 156 days for the ten patients with partial response (PR). Although promising, this trial was small and confirmation is needed before such an aggressive approach can be recommended.

Topotecan is perhaps the most carefully studied single agent in SCLC. Activity has been demonstrated in both chemotherapy-naïve and previously treated patients.[112,113,114 and 115] Similar to other active chemotherapies, topotecan is relatively inactive in patients with refractory relapse (those relapsing less than 90 days since induction therapy and those not responding to induction therapy). Ardizzoni and colleagues demonstrated response rates of 6.4% in 47 refractory relapse patients and 37.8% in 45 patients with sensitive relapse.[113] The median survival for sensitive relapsed patients was 6.9 months. These promising results led to a recently completed phase III trial, in which 211 patients who relapsed more than 60 days after completion of induction therapy were randomized to receive either single-agent topotecan (1.5 mg/m^2 per day for 5 days, every 21 days) or conventional CAV.[114] The overall response rates and median survivals were not statistically different: 24.3% versus 18.3% and 25 weeks versus 24.7 weeks for topotecan and CAV, respectively. The proportion of patients who experienced symptom improvement was greater for the topotecan-treated patients. Grade III and IV hematologic toxicities were greater in the topotecan patients, whereas there was no significant difference in nonhematologic toxicities.

Irinotecan (CPT-11) and paclitaxel have also recently been evaluated in previously treated SCLC patients and demonstrated activity.[116,117 and 118] In patients with sensitive-relapse SCLC, irinotecan effects similar response rates and survivals to those of topotecan. Also similar to topotecan, irinotecan has no significant activity in patients with refractory relapse. Paclitaxel is the first agent demonstrating significant activity in patients with refractory relapse. Smit and colleagues treated 24 heavily pretreated SCLC patients relapsing within 3 months of cytotoxic therapy with paclitaxel 175 mg/m^2 intravenously over 3 hours on a three-week interval.[117] Seven partial responses (29%, 95% CI 12 to 51%) were observed, and a median survival of 100 days was reported. This trial was small and requires confirmation. However, a second report of activity in resistant relapse was recently published. Groen and colleagues conducted a phase II trial of paclitaxel and carboplatin in 35 patients relapsing within 3 months of receiving induction therapy with cyclophosphamide, doxorubicin, and etoposide.[118] The median time off treatment was 6 weeks. All patients had an ECOG performance status £1. Of 34 assessable patients, 2 complete and 23 partial responses were observed for an overall response rate of 73.5%. The median survival was 31 weeks. These results are encouraging and suggest that paclitaxel may be a non–cross-resistant regimen with CDE.

In summary, only a few patients benefit from salvage chemotherapy. The choice of therapy and likelihood of response can be accurately predicted based on the timing of disease recurrence and sensitivity to induction therapy. Topotecan is the most extensively studied drug in patients with sensitive relapse and should be considered for these patients. Historically, no therapy has been active in patients with refractory relapse, but paclitaxel-based therapy may offer these patients some chance of another tumor regression. None of the available salvage therapies are adequate, and these patients should always be considered for clinical trials of new therapeutic approaches.

IDENTIFICATION OF NEW AGENTS

Despite the large number of drugs available for treating SCLC, there is an ongoing need to identify additional active drugs, especially agents with unique mechanisms of action. The appropriate setting for new agent testing, however, is controversial.[119,120] Some investigators advocate evaluation of new agents in previously untreated patients arguing that chemotherapy-naïve patients represent the optimal setting.[121,122 and 123] Several new agents have been tested in this setting, including topotecan, paclitaxel, gemcitabine, docetaxel, and vinorelbine.[112,124,125,126 and 127] All but docetaxel were active. Such testing is conducted almost exclusively in patients with extensive-stage disease largely because these patients are rarely cured with conventional treatment. Experience with this approach has demonstrated that if patients are properly selected, those failing to respond to the new investigational agent can be salvaged with cisplatin and etoposide chemotherapy.[112,123,124] Even inactive agents tested in this manner have not resulted in adverse outcome.[122]

In contrast to the aforementioned approach, a cogent argument can be made for continuing the practice of testing new agents only in SCLC patients who have failed a standard induction therapy.[128] Based on a review of the SCLC phase II literature published between 1970 to 1990, investigators at Memorial Sloan Kettering Cancer Center concluded that a response rate greater than 10% in previously treated SCLC patients was adequate evidence that an agent was potentially active against SCLC.[129] They proposed a two-stage sequential design for phase II trials in SCLC using a response rate of 10% as an end point. A target enrollment of 20 patients in the initial phase of the study would allow for early termination of the trial if four or more patients responded because the agent under investigation would be expected to effect an objective response rate of at least 10%. On the other hand, if none of the initial 20 patients responded, the agent in question would not be subjected to further analysis because a true response rate greater than 10.9% would be excluded at the 90% confidence level. If one to three of the first 20 patients respond, an additional 15 patients would be entered to better estimate the agent's activity level. A maximum of 35 previously treated patients would be required to adequately assess the activity of a phase II agent against SCLC. This strategy maximizes the likelihood of identifying truly active agents and only slightly increases the possibility of mislabeling an inactive agent as active.

A compromise approach might be to test new agents in *selected* relapsed SCLC patients.[85,106,130] Topotecan, irinotecan, and vinorelbine have been tested and demonstrated activity in this setting.[116,131,130] Ideal candidates might include patients who maintained a good performance status, who do not have significant visceral metastases necessitating a rapid response, and who had not been treated for some interval prior to receiving the investigational agent. How long an interval should have transpired is not known with certainty but should probably be at least 90 days. Using these carefully defined guidelines, it would appear that new agent activity can be assessed in either previously treated or untreated SCLC patients without putting patients at increased risk.

CONCLUSIONS

Chemotherapy for SCLC is rarely curative except in limited-stage patients who are candidates for bimodality therapy with chemotherapy and thoracic radiotherapy. Although survival is significantly improved with chemotherapy, most patients succumb to their disease within one year of diagnosis. Thus, in SCLC, chemotherapy should be considered primarily a palliative treatment. The optimal induction regimens are either EP- or CAV-based. Multiple strategies designed to improve treatment

with these agents have not yielded significant breakthroughs. Fortunately, several new drugs have recently been identified and given the exquisite chemosensitivity of this neoplasm, there is reason to expect improvements in therapy in the coming years. Furthermore, SCLC expresses a unique biology, thus making it an excellent disease in which to test emerging biologic and targeted therapies. Large strides forward will depend on our ability to translate new breakthroughs in our understanding of the biology of this neoplasm into clinically feasible therapeutic strategies.

MULTIMODALITY THERAPY FOR LIMITED-STAGE SMALL CELL LUNG CANCER: COMBINING CHEMOTHERAPY AND THORACIC IRRADIATION

NEVIN MURRAY
DAVID G. PAYNE
ANDREW J. COLDMAN

Within less than one month of starting treatment, relief of symptoms and improvement in the chest radiographs of small cell lung cancer (SCLC) patients are usually obvious and often dramatic. For the patient, this miraculous development understandably nurtures hope that the probability of curing this malignancy is high. Indeed, reviewing the x-rays with the patient and family is an effective way to enhance their morale and encourage them to soldier on through a vigorous treatment program. Frank oncologists must acknowledge that it is easy to make the chest x-ray look better with chemotherapy or thoracic irradiation. The unpleasant reality of the situation is that despite a satisfactory regression of the tumor, most patients harbor persistent elements of disease and are destined to experience the disappointment of an incurable recurrence. The challenge in the treatment of limited-stage small cell lung cancer (LSCLC) is to combine chemotherapy and thoracic irradiation in a more efficacious fashion so that the proportion of long-term survivors is increased.

The Veterans Administration Lung Group system[1] that divided patients into either limited or extensive stages has persisted for SCLC because of its simplicity, reliable prognostic value, and practical utility. [2,3,4,5 and 6] SCLC is defined as tumor confined to one hemithorax and the regional lymph nodes, whereas extensive-stage disease (ESCLC) is defined as disease beyond these bounds. The original operational definition of limited disease was tumor quantity and configuration that could be encompassed by a "reasonable" radiotherapy treatment volume. Because long-term survival is uncommon (7% to 9%) when chemotherapy alone is used to treat LSCLC,[7,8] the "reasonable" radiotherapy port rule continues to be of practical importance in the design of combined modality therapy.

The term "reasonable" lacks precision in this heterogeneous patient group. Using simple staging techniques, the University of Toronto Lung Oncology Group [9] identified a subgroup of patients with "very limited" SCLC without mediastinal node involvement who had a significantly better prognosis and a five-year survival of 18% with combined modality therapies used between 1976 and 1985. The five-year survival for patients with evidence of involved mediastinal nodes was 6%. Only 2% survived 5 years when pneumonic consolidation, atelectasis, pleural effusion, or involved supraclavicular nodes were present. The utility of a refined staging system may be greater with integrated chemotherapy and thoracic irradiation that generates a larger proportion of long-term survivors. The toxicity of thoracic irradiation volumes including all known disease may not be "reasonable" for patients with peripheral primary tumors or bulky mediastinal lymphadenopathy.

The necessity for accurate staging may be influenced by the sequence of chemotherapy and thoracic irradiation. Because expensive staging procedures delay symptom-relieving treatment and because chemotherapy is recommended for all fit patients anyway, some clinicians prefer not to bother with standard staging procedures outside the context of clinical trials. This pattern of practice may not be associated with negative consequences if the best model of treatment consisted of initial treatment with multiple chemotherapy cycles followed sequentially by administration of consolidative thoracic irradiation after drug treatment was finished. However, if patients with bona fide LSCLC benefit from early delivery of thoracic irradiation concurrent with combination chemotherapy, then careful staging determines the structure and intent (curative versus palliative) of the treatment program. [10] LSCLC patients have curative potential, which justifies the complexity and toxicity of integrated thoracic irradiation and combination chemotherapy. Such hopeful expectations cannot be entertained for palliation of extensive SCLC patients, and the vigor of noninvestigational therapy should be adjusted accordingly. Despite modern technology, the stage of some patients remains equivocal and clinicians must use their judgment.

Although the limited versus extensive stage system was created for practical purposes, its utility clearly reflects important biologic characteristics of the disease. When SCLC is overtly metastatic (ESCLC), we observe an underlying aggressiveness in the tumor that transcends the importance of the simple physical distribution of cancer cells within the body. Potentially curable LSCLC is quantitatively and qualitatively different from incurable ESCLC.

Therapeutic endeavors must contend with bulk concentrations of locoregional disease and a smaller metastatic population in widely different sites. These tissues vary in their tolerance of therapeutic interventions, just as the various tumor populations vary in their ability to resist the agents sent to destroy them. These clinical considerations and the biologic factors underlying them have led directly to modern concepts of multiple modality therapy for this disease.

HISTORY OF THE EVOLUTION OF COMBINED MODALITY THERAPY

The evolution of treatment for LSCLC can be described as a series of treatment paradigms. [11] The sequence of the paradigms did not always follow the chronologic order of the publication of important hypotheses or pilot studies. The evolution of treatment was determined by controlled trials of crucial issues of therapy and

consensus by lung cancer investigators.

Paradigm 1: Surgery as Standard Treatment

World Wars I and II have had a large influence on the history of lung cancer. The stressful circumstances of wars, availability of tobacco products, and permissive attitude toward tobacco consumption during both wars were associated with a large increase in smoking among servicemen. The prevalence of smoking among women increased greatly during World War II. Surgical treatment of penetrating wounds to the chest during World War II resulted in advances in thoracic surgery, and the cadre of expert chest surgeons trained during the war had to contend with the increasing numbers of lung cancer casualties among veterans in the 1950s and 1960s.[12,13 and 14] In the post–World War II era, surgery was the treatment of choice for patients with all types of lung cancer, including SCLC.

Paradigm 2: Thoracic Irradiation Better than Surgery

The epithelial origin of SCLC was described in 1926,[15] and the separation of this virulent pathologic subtype on morphologic grounds was established in 1959.[16] From the earliest reports,[17] impressive regressions of SCLC induced by radiotherapy suggested an integral role of this modality in definitive management.

The median survival in surgically unresectable LSCLC patients randomized to supportive care alone in a trial conducted in the 1960s was 12 weeks.[18] A randomized trial comparing surgery alone to thoracic irradiation alone for SCLC patients was carried out by the Medical Research Council in the United Kingdom.[19,20] Eligibility criteria included (a) SCLC on bronchial biopsy; (b) no evidence of extrathoracic metastasis; (c) the tumor was regarded as operable on clinical examination and chest radiograph; (d) the patient was considered fit enough for resection; and (e) the patient was considered fit enough for radical radiotherapy. Although this study was done in an era before the availability of modern staging techniques, the intrathoracic extent of tumor was probably less than in most contemporary LSCLC trials. Of the 144 patients included in the main analysis, 71 were allocated to surgery and 73 to radical radiotherapy. A complete resection of all visible growth was performed in 48% of the surgical group, all of whom had a pneumonectomy. Thirty-four percent were unresectable and 18% had no operation because of preoperative deterioration or refusal of surgery. In the radiotherapy group, 85% had radical thoracic irradiation, 11% had palliative radiotherapy, and 4% had no radiotherapy because of deterioration or refusal. The median survival was 28.5 weeks for surgery and 43 weeks for radiotherapy (p = 0.04). Five-year survival was 1% for the surgical arm (the sole survivor refused surgery and was given radiotherapy) and 4% for radiotherapy. Outcome for both groups was poor, but treatment feasibility, toxicity, and survival all favored thoracic irradiation. The standard of treatment for LSCLC shifted from surgery to thoracic irradiation. The main aim was to give patients relief of local symptoms until their death from metastatic disease.

Paradigm 3: Thoracic Irradiation With Adjuvant Chemotherapy

The systemic nature of SCLC was emphasized by the rapid tempo of systemic relapse and low probability of long-term survival in patients with apparently localized disease given definitive local therapy only. In a classic study[21] of 19 patients subjected to potentially curative surgical resection who died within 30 days of operation of non–cancer-related causes, 13 were found to have persistent disease at autopsy. Moreover, metastases were distant in 12 of 13 cases. Although not all LSCLC patients have subclinical metastatic disease, the actual proportion is so high that the assumption of metastases is suitable for treatment planning.

A major step in the systemic treatment of SCLC was reported in 1969.[1] This randomized study[1] compared alkylating agents at several dose schedules to an inert compound in approximately 2,000 lung cancer patients at a group of Veterans Administration hospitals. Antitumor effects of chemotherapy were analyzed according to cell type, and improvement in survival was the sole criterion of drug activity. The four-month median survival for SCLC patients treated with high intermittent doses of cyclophosphamide was only somewhat better than the 1.5-month median survival of placebo-treated patients (p = 0.0005). Nevertheless, the documentation of a survival improvement with chemotherapy for lung cancer patients was a notable development in cancer medicine, and cyclophosphamide became the cornerstone in SCLC chemotherapy regimens for decades. The credibility of cyclophosphamide efficacy in SCLC was augmented by randomized trials that showed prolonged survival for that agent as adjuvant chemotherapy compared to no further treatment after surgical resection.[12,13,22] Curiously, the lack of survival benefit for cyclophosphamide and other alkylating agents for non–small cell lung cancer (NSCLC) in these and other lung cancer trials[23,24,25,26 and 27] did not prevent them from being incorporated into combination chemotherapy regimens over the next 20 years.

The prescient observations of Watson and Berg[17] suggested thoracic irradiation coupled with chemotherapy as a model for treatment of SCLC. This hypothesis was first tested in a randomized trial by Bergsagel and colleagues from Toronto, Canada.[28] Patients with nonresectable lung cancer confined to the central area of the thorax were randomly assigned treatment with radiotherapy to the primary lesion and mediastinum or radiotherapy plus two schedules of intermittent intravenous cyclophosphamide. One-third of 123 patients in the study had SCLC, and both progression-free survival (29 weeks versus 16 weeks) and overall survival (42 weeks versus 21 weeks) were significantly superior for patients receiving combined modality therapy.

Two other randomized trials[29,30] showed significantly superior survival for thoracic irradiation and adjuvant chemotherapy versus radiotherapy alone. Median survival for LSCLC patients treated by radiotherapy alone was consistently about 5 to 6 months. Two additional controlled trials[31,32] showed some advantage for combined modality therapy, but survival differences between the groups were not statistically significant, probably because many patients on the radiotherapy arms received chemotherapy at the time of disease progression.

Paradigm 4: Combination Chemotherapy with Adjuvant Thoracic Irradiation

The success of combination chemotherapy in leukemia and lymphoma and the recognition of SCLC as a type of lung cancer with unique chemosensitivity stimulated exploration of multidrug regimens. The first published study of combination chemotherapy for lung cancer was published by Hansen and associates[33] using a regimen including cyclophosphamide, methotrexate, dactinomycin, and vincristine. All eight patients with SCLC subtype responded; combination chemotherapy for SCLC was off to a promising start. High response rates for cyclophosphamide and vincristine were reported by Eagan et al.[34] and Holoye and Samuels.[35] By combining cyclophosphamide, doxorubicin, vincristine (CAV), and bleomycin, Einhorn et al.[36] produced not only high response rates in SCLC, but complete responses were also seen in 20% of cases. Bleomycin was discarded because of pulmonary toxicity, especially when combined with thoracic irradiation,[37] and the CAV regimen persists to the present as a standard regimen for SCLC.

By using principles of combination chemotherapy[38] and incorporating more and newer active agents, the search for a regimen with a high complete response rate for SCLC was intense during the 1970s. Combination chemotherapy was shown to be better than single-agent chemotherapy in three early randomized trials,[39,40 and 41] but a clearly superior regimen did not emerge. Nevertheless, in the early 1970s, a change in philosophy occurred. Because of the high response rates associated with multiagent chemotherapy, this modality became the primary therapy in LSCLC, and thoracic irradiation was relegated to an adjuvant or "consolidative" treatment.[42]

However, programs giving aggressive combination chemotherapy without thoracic irradiation[43] appeared to yield survival results similar to combined modality therapy. Median survival was in the range of 12 to 15 months, and projected long-term survival was usually in the range of 10 to 20% whether radiotherapy was given or not. Many published reports were difficult to interpret regarding long-term survival because of small trial size and inadequate follow-up. Regimens including thoracic irradiation produced a higher rate of complete remission, and an increased proportion of complete responses was felt to be essential in the evolution of therapies with curative potential.[44] However, combined modality therapy was also consistently associated with more acute and chronic toxicity, and selection of patients fit enough to receive this more demanding treatment in nonrandomized reports may have biased results against chemotherapy alone. Many investigators began to speculate that radiotherapy might not be necessary at all in LSCLC.

This debate persisted throughout the 1980s,[45,46] and many randomized trials were performed attempting to settle this vexing issue.[47,48,49,50,51,52,53,54,55,56,57 and 58] It was not until 1992 that metaanalyses[7,8] were published concluding that combined modality therapy moderately improves survival in patients with LSCLC.

Paradigm 5: Integrated Chemotherapy and Thoracic Irradiation

In 1976, investigators from the National Cancer Institute (NCI) in Bethesda, Maryland, performed an exploratory study that boldly went where no oncologist had gone before.[59,60,61 and 62] Although the protocol was influenced by the successful model of combined modality therapy for childhood lymphocytic leukemia,[63] the vigor of therapy was unprecedented in SCLC protocols. It involved initial simultaneous irradiation to the brain, primary tumor, and mediastinum and aggressive concurrent chemotherapy (cyclophosphamide 1.5 g/m^2, doxorubicin 40 mg/m^2, and vincristine 2 mg). The drugs were repeated as soon as the leukocytes increased to 3.5 × 10^9/L.

All therapy was complete in 3 to 4 months.

The toxicity of this regimen was truly formidable. Radiation pneumonitis occurred in 38%, and a combination of pneumonitis and neutropenic sepsis was fatal in 24%. Severe esophagitis requiring nasogastric or parenteral nutrition occurred in 14%, and permanent strictures were observed. [64] Additionally, a previously undescribed neurologic syndrome of somnolence, poor attention span, recent memory loss, and action tremor was seen. The symptoms became evident within 2 to 4 months of starting treatment and were reversible within 4 months of onset.

The first reported survival results for LSCLC treated in this manner were spectacular, with 100% complete remissions and projected 80% long-term survival. [59] With longer follow-up, the survival curves dwindled and this trial was criticized for generation of false optimism by preliminary data reporting and unacceptably severe toxicity. Nevertheless, mature results demonstrating an 80% complete remission rate and 25% survival at 4 years in LSCLC were provocative and unprecedented. [62] Thirteen percent died without evidence of tumor at autopsy; it is speculative whether the cure rate could have been higher had modern supportive care been available. In an analysis of treatment factors contributing to long-term survival, it was concluded that concurrent chemotherapy and radiotherapy achieved better local tumor control than sequential therapy. [62] The data also suggested that if the duration of concurrent therapy is prolonged beyond three weeks, then the enhanced local tumor effect can be lost in a flood of treatment-induced toxicity.

This body of work is important because it clearly recognized the deleterious consequences of tumor repopulation permitted by sequential therapies as predicted by experimental models.[65] A generation of lung cancer investigators was both intrigued by the possibilities of early concurrent chemoradiation and troubled by a foreboding concern about the toxicity their patients would face in the quest for improved therapy.

It was evident that the combined chemoradiation model could not progress unless chemotherapy and radiotherapy could be integrated with less dire normal tissue interactions that did not compromise delivery of either modality. Sequential regimens giving thoracic irradiation during a gap in chemotherapy [66] (the "sandwich" technique) were less toxic, but efficacy was not improved, possibly because the interruption of the cadence of chemotherapy allowed tumor regrowth in unirradiated sites. Phase II results of a less aggressive CAV regimen [67] with concurrent thoracic irradiation led to a large randomized trial comparing simultaneous chemoradiation to CAV chemotherapy alone, but a significant survival benefit was not observed. [68] This may have been because toxicity impaired drug delivery. Another controlled trial of CAV alone versus a tripartite split course of thoracic irradiation between CAV pulses demonstrated a survival benefit for combined modality therapy. [49] However, gastrointestinal and hematologic toxicity continued to be problematic. The severity of morbidity to normal tissue from the interaction of doxorubicin and radiotherapy has limited the utility of these approaches. Concurrent thoracic irradiation with chemotherapy containing cyclophosphamide, methotrexate, and lomustine was superior to chemotherapy given alone [47] in inducing remission and prolonging survival in patients with LSCLC, but the benefit was offset by unacceptable pulmonary toxicity. Similarly, concurrent cyclophosphamide, etoposide, and vincristine and radiotherapy have demonstrated superiority to chemotherapy alone, [48] but unacceptable chemotherapy attenuation from myelosuppression was associated with combined therapy.

The development of cisplatin and etoposide[68] as a potent combination for SCLC allowed the next step forward. Cisplatin produces no esophagitis or stomatitis and little myelosuppression at normal doses. Etoposide at standard doses has myelosuppression as its only serious side effect. More important, although cisplatin has some weak radiosensitizing properties,[69] normal tissue toxicity from concurrent chemotherapy and irradiation is not nearly so severe as with doxorubicin, nitrosoureas, or cyclophosphamide. Additionally, neither cisplatin nor etoposide have been implicated in "radiation recall" [64] toxicity. An important development in the evolution of therapy occurred when cisplatin and etoposide were integrated with thoracic irradiation. Pilot studies were independently performed at the British Columbia Cancer Agency[70,71] and by investigators associated with the Southwest Oncology Group (SWOG). [72,73] From the first report[70] in 1984, it was clear that etoposide-cisplatin chemotherapy and thoracic irradiation could be administered concurrently with manageable toxicity and little compromise in drug or radiation delivery.

The National Cancer Institute of Canada (NCIC) further improved the integration of chemotherapy and thoracic irradiation by demonstrating in a controlled trial that early concurrent cisplatin-etoposide and thoracic irradiation was superior to delayed thoracic irradiation given concurrently with cisplatin-etoposide. [74] A delay of as little as 12 weeks in the administration of thoracic irradiation for LSCLC patients resulted in an approximate 50% decline in the probability of five-year survival from 22% to 13%. The benchmark five-year survival rate for LSCLC shifted from about 10% to about 20%. Other randomized trials [45,75,76 and 77] of thoracic irradiation timing have been reported, and although not all support the superiority of early chemoradiation, the negative trials [48,74] consistently have long-term survival rates of only 10%, and the early chemoradiation arms of the positive studies[74,76,77] report long-term survival rates of 20% to 30%.

The search for improved treatment for LSCLC continues within the integrated chemotherapy and thoracic irradiation paradigm. The foci of research are the generation of more potent chemotherapy regimens and improvement in design and delivery of radiotherapy programs. Turrisi et al. [78] reported the first phase III study demonstrating a statistically significant survival advantage for more intensive twice-daily thoracic irradiation delivered early and concurrent with cisplatin-etoposide. Delayed twice-daily thoracic irradiation concurrent with EP failed to produce any evidence of survival benefit when compared to conventional radiation. [79]

Effective innovations of thoracic irradiation or chemotherapy should be more easily demonstrated in patient populations with a higher proportion of curable cases as determined by more accurate staging technology. New drugs with novel molecular targets are being explored intending to increase tumor destruction with induction therapy or prevent relapse for those in remission.

CHEMOTHERAPY FOR LSCLC

Multiagent chemotherapy is superior to single-agent therapy in most cancers for which treatment is sufficiently effective that it is given with curative intent. [38] The aggregate experience indicates that drug combinations alone in LSCLC yield a total response rate of 60% to 80% and complete response rates of 35% to 50%. Monotherapy with etoposide has been demonstrated inferior to combination chemotherapy in the palliative setting and is inappropriate for patients receiving therapy with curative intent. [80,81] There is no evidence that monotherapy with any other agent (new or old) is acceptable systemic therapy for LSCLC; multiagent chemotherapy is a necessity for patients fit enough for treatment where the goal is long-term survival. [82,83]

It is a common opinion that improvements in chemotherapy should be demonstrated in extensive-stage patients before they are adapted to LSCLC protocols. Such clear-cut evidence of increased treatment power is highly desirable, but this guideline cannot be interpreted to mean that a treatment strategy that does not improve results for incurable ESCLC patients must necessarily fail in the curable LSCLC population. Because LSCLC has a lower likelihood of drug resistance than ESCLC, the tumor burdens of SCLC patients based on stage are fundamentally different with respect to the impact of changes in both systemic and local therapy.

Median survival and rates of complete remission may not be adequate measures to judge differences between chemotherapy protocols for LSCLC. [84] When a large proportion of the patient population achieves complete remission, a therapy that produces more cures may have unimpressive differences in response rates and median survival when compared to a less efficacious treatment. Only long-term survival as shown on the "tail" of the curve may be different. Although this parameter is the outcome of greatest interest, many reports are difficult to interpret because of short follow-up and insufficient patient numbers. For these reasons, this review of chemotherapy is restricted mainly to LSCLC patient populations randomized in studies including at least 50 LSCLC patients per arm. Chemotherapy innovations include the choice of drugs, the number of drugs, and the amount to be administered.

Standard Regimens

The most commonly used programs include cyclophosphamide, doxorubicin, and vincristine (CAV), etoposide and cisplatin (EP), alternating CAV and EP, and CAV with etoposide (CAE or CAVE).[82] Chemotherapy cycles are typically given every 3 weeks for six to eight cycles. Major areas of clinical research include duration of chemotherapy, diversity of drugs within chemotherapy regimens, dose and dose-intensity escalation, and introduction of new agents.

Duration of Chemotherapy Administration

The studies by the Radiation Oncology Branch of the NCI [59,60,61 and 62] were provocative for several reasons, including brief duration of chemotherapy. Although toxicity may have precluded a more lengthy period of chemotherapy, durable unmaintained remissions were nevertheless demonstrated after chemotherapy duration of only 3 months.

A Cancer Research Campaign trial[85] from the United Kingdom randomized 610 patients, including 190 LSCLC patients, to receive either four or eight courses of

cyclophosphamide, vincristine, and etoposide. A second randomization compared second-line chemotherapy (methotrexate and doxorubicin) on progression with symptomatic treatment only. Thoracic irradiation was used for palliative purposes only. When the effects of the treatment policies were separated according to disease extent, survival was adversely affected in patients with extensive disease who were treated with four cycles of initial chemotherapy only (no salvage chemotherapy). A similar trend was observed for LSCLC patients, but the effect was not statistically significant.

The Medical Research Council Lung Cancer Working Party [86] compared six versus twelve courses of chemotherapy (etoposide, cyclophosphamide, methotrexate, and vincristine in 497 patients, 74% with LSCLC). Limited-disease patients received thoracic irradiation between the second and third course of chemotherapy (sandwich technique). No worthwhile clinical advantage was achieved by the policy of continuing chemotherapy beyond six courses.

The European Organization for Research and Treatment of Lung Cancer (EORTC) Cooperative Group investigated 5 cycles of cyclophosphamide, doxorubicin, and vincristine versus 12 cycles in a large study [87] including 341 LSCLC patients. Chest irradiation was not routinely given. Progression-free survival (PFS) was significantly longer for patients receiving prolonged versus short chemotherapy (p = 0.01). However, PFS at 5 years was the same at approximately 8% in both arms, and overall survival was not increased by prolonged chemotherapy.

The experience from cooperative group studies with six cycles of chemotherapy is large. [74,88,89] It is improbable that useful incremental benefit can by demonstrated by administering more than six cycles of chemotherapy. In any case, compliance with additional cycles becomes increasingly problematic. Excellent phase II and III study results have been generated with as few as four cycles of cisplatin-etoposide combined with thoracic irradiation. [78,90] A comparison of four versus six courses may not be a research priority. It may be more useful to examine treatment duration on the basis of total cumulative drug doses rather than time alone.

Drug Diversity

The somatic mutation theory for drug resistance[91] suggested that drug combinations could improve the probability of overcoming resistant tumor clones by early introduction of therapeutic diversity into the treatment program. Because overlapping toxicity precludes administration of more than a few active agents at full dose at one time, the alternation of equivalent non–cross-resistant combinations was recommended. Current opinion of alternating chemotherapy in SCLC is based mainly on the outcome of large randomized studies in ESCLC. [92,93 and 94] The ESCLC experience was disappointing, showing a small or no survival advantage. The probability of resistance to all alternations tried to date is almost universal for ESCLC as revealed by the absence of a consistent proportion of long-term survivors. However, a review restricted to large LSCLC trials of alternating versus sequential chemotherapy combinations does not reach conclusions as clear-cut as ESCLC.

A randomized German multicenter trial[95] showed significant benefits for alternating chemotherapy when 306 patients (104 LSCLC) were randomized to eight cycles of CAV versus three cycles of ifosfamide, vindesine, and etoposide (weeks 1, 3, 5); three cycles of cisplatin, doxorubicin, and vincristine (weeks 2, 4, 6); and two cycles of cyclophosphamide, methotrexate, and lomustine (weeks 7, 8). Responding patients received chest radiotherapy after eight cycles of chemotherapy. In limited disease, the complete response (CR) rate was 33% in the sequential arm versus 52% in the alternating arm; median survival was 11.1 months for sequential therapy versus 13.4 months for patients receiving the more diverse regimen.

Another German multicenter study[96] compared a fixed alternation of ifosfamide/etoposide (IE) and CAV chemotherapy and response-oriented treatment with IE to maximal response and subsequently an immediate switch to CAV. After six cycles of chemotherapy, limited-stage patients (n = 140) received thoracic irradiation. The CR rate for LSCLC was slightly higher in the alternating arm (40 versus 35%). Survival in the arms was similar, with median survival at 12.5 months versus 12.3 months and two-year survival at 21% versus 18%. However, because only a few patients achieved CR with IE, the response-oriented approach used in this trial exposed most patients in this trial to diverse chemotherapy.

The NCIC Clinical Trials Group studied 300 limited-stage patients, comparing an immediate versus a delayed alternation of CAV and EP. [88] Thoracic irradiation was given to responders after six cycles of chemotherapy in a consolidative fashion. Neither complete responses (52% versus 44%) nor median survival (14.2 versus 13.7 months) was different. The five-year survival rates for immediate and delayed alternating arms were 10% and 6%, respectively. Chemotherapy diversity between arms was similar with respect to the number of agents used.

In another large study that primarily focused on the value of thoracic irradiation in LSCLC, [58] The Southeastern Cancer Study Group (SECSG) assessed the value of the addition of two cycles of EP in responding patients after completion of six cycles of CAV (with or without thoracic irradiation). Patients randomized to receive more heterogeneous chemotherapy with "consolidative" EP experienced superior median (21.1 versus 13.2 months; p = 0.08) and two-year survival rates (44% versus 26%; p = 0.028). This result could be interpreted as an advantage for more diverse chemotherapy or simply attributed to the superiority of the EP regimen. The administration of CAV after induction with EP (first described in 1984) [97] was reexamined in an often cited but unpublished trial from Australia. [96] No advantage for the addition of CAV could be demonstrated in the total patient population, but too few limited-disease patients were included for analysis of this subgroup.

The largest randomized study (388 patients) comparing sequential and alternating chemotherapy for LSCLC was performed by the SWOG. [89] The alternating regimen was CAV and EP. The sequential regimen was CAV plus etoposide (EVAC). After six courses of chemotherapy, consolidative thoracic irradiation was given to responders. There were no significant differences in complete response (CAV/EP 51%; EVAC 48%). The survival curves overlap with median survival of 16.5 versus 15.1 months and identical long-term survival (about 10%). This study does not support the value of alternating chemotherapy, but it may not be interpreted as evidence against potential value of chemotherapy diversity. The chemotherapy in the EVAC sequential arm was not the same as either regimen used in the alternation. The drug diversity supplied by the alternating chemotherapy amounts to the addition of one agent (cisplatin) at intervals of 6 weeks on three occasions over the entire treatment program. Moreover, the dose intensity of the other drugs in the alternating regimen (cyclophosphamide, doxorubicin, etoposide, and vincristine) were reduced substantially compared to the sequential arm by the longer cycle time of the alternation.

The addition of etoposide to CAV has been examined in a controlled trial for LSCLC patients by the North Central Cancer Treatment Group (NCCTG). [99] Thoracic irradiation was given with the fourth cycle of chemotherapy (doxorubicin deleted from this cycle) in a trial in which 118 patients were randomized to CAVE and 113 to CAV. Measures of outcome for CAVE versus CAV were median survival 15 versus 13.3 months, three-year survival 17.2 versus 9.7%, and five-year survival 12.1% versus 7.0% (p = 0.13). The difficulty in interpreting studies in which the sample size is modest can be seen here because if the true effect of the addition of etoposide was to double the five-year survival, then the probability that would be declared significant in a trial of this size is only 0.32.

Only the Japanese Lung Cancer Chemotherapy Group has directly compared CAV, EP, and CAV alternating with EP in a study including LSCLC as well as ESCLC. [100] Unfortunately, the arms were not stratified by stage, so examination of LSCLC outcomes is a subgroup analysis. Each arm included about 50 LSCLC patients. Consolidative thoracic irradiation was given after four cycles of chemotherapy. The complete response rates for initial chemotherapy were similar (CAV 16%, EP 18%, and CAV/EP 22%). The median survival of the alternating regimen (16.8 months) was superior (p = 0.014) to either CAV (12.4 months) or EP (11.7 months). Mature results for the proportions of long-term survivors have not been published, but the actuarial projections appear better in the alternating chemotherapy subgroup.

Overall, the data suggest that drug diversity may be more important in LSCLC than ESCLC. However, the efficacy of EP and the ease with which it can be administered with thoracic irradiation without serious toxicity from interaction between radiation and chemotherapy on normal tissue has led several cooperative groups (Table 54.1) to simplify chemotherapy to this two-drug combination in phase III trials. It is unclear whether the loss of "therapeutic diversity" by using EP alone rather than EP plus other agents will result in negative consequences. The fact that these trials were conducted using EP chemotherapy is a powerful statement that many lung cancer experts consider this regimen to be state-of-the-art. This may be true; however, it is a poignant curiosity that, to date, EP has never demonstrated superior survival compared to any other chemotherapy regimen in a published phase III randomized trial of LSCLC or ESCLC. A standard regimen for a curable disease should have better credentials.

TABLE 54.1. PHASE III LSCLC TRIALS USING ETOPOSIDE PLUS CISPLATIN/CARBOPLATIN CHEMOTHERAPY

Dose and Dose-Intensity Escalation

The evidence that more intensive drug treatment can increase complete responses and long-term survival in animal models with curative potential is compelling.[101] However, the SCLC group most often studied with controlled trials of more intense therapy has been incurable extensive-stage patients.[102,103,104 and 105] A metaanalysis of the outcome in LSCLC patients treated with dose and dose-intensity variations of CAV, EP, and CAVE showed no consistent evidence for better response rates or median survival for more intense regimens.[106] However, the range of dose intensities was narrow and many studies included small patient numbers. Only two randomized trials[107,108] of chemotherapy intensity in LSCLC involving more than 50 patients per arm have been reported. Both demonstrate significant survival benefits for more intensive chemotherapy.

The Eastern Cooperative Oncology Group (ECOG)[107] randomized 349 patients with SCLC (38% limited stage) to induction chemotherapy with cyclophosphamide 1,500 mg/m^2 days 1 and 22, lomustine (70 mg/m^2) day 1, and methotrexate 15 mg/m^2 twice per week on weeks 2, 3, 5, and 6 (without dose modification for hematologic toxicity) or to the same drugs with cyclophosphamide 700 mg/m^2. The abstract does not mention use of thoracic irradiation. Median survival for all intensively treated patients was 41 weeks versus 36 weeks (p = 0.04). The effect was most pronounced for limited-stage patients with median survival of 56 weeks for the intensive arm versus 42 weeks for the standard arm (p = 0.02). Long-term outcomes are not reported.

After retrospective review of treatment data on alternating chemotherapy and radiotherapy regimens for LSCLC, investigators at the Institut Gustave-Roussy concluded that the impact of the size of the initial dose of cyclophosphamide and cisplatin should be assessed in a controlled trial.[108] Patients were randomly assigned to receive a different dose of cisplatin and cyclophosphamide (100 mg/m^2 day 2 and 300 mg/m^2 days 2–5) versus (80 mg/m^2 day 2 and 225 mg/m^2 days 2–5). The doses of doxorubicin (40 mg/m^2 day 1) and etoposide (75 mg/m^2 days 1–3) were held identical. The higher doses of cisplatin and cyclophosphamide were given for the first cycle only. Subsequently, all patients received the same schedule of alternating chemotherapy and radiotherapy with the lower cisplatin and cyclophosphamide doses. The complete remission rate for the 55 patients in the high-dose group (67%) was not significantly better than the 50 patients in the lower initial-dose group (54%). However, a significant difference in overall survival (p = 0.01) was observed in favor of the patients who received the single escalated dose of cisplatin and cyclophosphamide. Survival rates at 18 months were 52% and 32%, respectively. Although mathematical models[109] predict a disproportionately large contribution from early treatment events, the effect of escalation of the dose size for only two drugs given on one occasion is so provocative that this finding requires confirmation in trials that include more patients.

An extension of the dose-escalation rationale is that tumor resistance can be overcome by large dose size. High-dose chemotherapy with special support during severe myelosuppression, such as autologous bone marrow transplantation, peripheral blood stem cell transfusion, and hemopoietic growth factors, is commonly tested in malignancies that resist conventional strategies. This approach is an assessment of the dose-response (mg/m^2) effect rather than an investigation of dose intensity (mg/m^2 per week); the difference is not semantic. In LSCLC, high-dose chemotherapy is usually given after induction with standard-dose chemotherapy.[110,111,112,113 and 114] Trials that report the number of patients potentially eligible for such therapy[110,111,112 and 113] indicate that less than 40% respond well enough, remain fit enough, and consent to the high-dose treatment. Results of these investigations make it difficult to separate "late intensification" from the patient selection process. Prospective trials testing this concept must include a complete account of the overall patient population from which the randomized patients were drawn. Even if positive studies emerge, the characteristics of the overall LSCLC population restrict applications of ablative chemotherapy doses to a small subgroup.

New Cytotoxic Agents

Because analogues of existing drugs have not demonstrated convincing advantages over the parent compounds in controlled trials, chemotherapeutic agents with different structure and novel mechanisms of action are imperative to improve outcome for this systemic disease. Several new drugs with activity against SCLC have been recently described, including the taxanes,[115] gemcitabine,[116] and the topoisomerase I inhibitors.[117,118] The characteristics that new agents should have to join or displace standard therapies such as the combination of etoposide/cisplatin are demanding. Not only must the new drug be highly active in previously untreated patients with high response rates and a proportion of complete responses, but demonstration of at least partial non–cross-resistance with existing agents is mandatory. Improved survival will not be associated with new drugs that kill the same cancer cells as the old ones. Moreover, in accordance with the theme of this chapter, it should be possible to give the new agent either concurrently with or adjacent to thoracic irradiation for LSCLC without radiotherapy-chemotherapy interactions that cause serious normal tissue toxicity; a preferential radiosensitizing effect on the tumor would be a great advantage. Activity should be present over a range of schedules so that dose-response and dose-intensity characteristics can be defined. Because it is already obvious that the new drugs are not conspicuously superior to older agents, the useful newcomer must combine with older agents with additive or preferably synergistic effects. An obvious corollary is that the new drug must have a toxicity profile that does not preclude its administration at full therapeutic doses when combined with the best standard agents or thoracic irradiation. Moreover, cumulative toxicity should not decrease the likelihood of completing the entire treatment program at full doses on time. The well-being of long-term survivors must not be endangered by chronic toxicity. The ultimate criteria will be the demonstration that the program incorporating the new drug is unequivocally superior to the best standard therapy in reproducible randomized comparisons. At this time, no phase III trials of new cytotoxic agents for LSCLC have been reported.

THORACIC IRRADIATION FOR LSCLC

Thoracic irradiation for LSCLC has long offered an attractive approach for several reasons beyond its ability to produce early responses. Because its mechanism of action is different from chemotherapeutic agents, the potential exists for additive or even synergistic damage to tumor cells. Toxicity to normal tissues is somewhat different from that produced by drugs. More important, because of its physical nature, "dose" can be administered in a focused fashion to regions containing or at high risk of tumor involvement. Most organs are thus excluded from the radiation beams, and tolerance is limited only by relatively modest volumes of normal tissue. The tumor may receive doses, which exceed by 10- to 20-fold what can be tolerated by the whole body, and the dose concentration greatly exceeds the dose concentration achievable by chemotherapy. Radiation dose is expressed in units of energy absorbed per gram of irradiated tissue (Gray), a unit of concentration or density, rather than units expressing a total body dose calculated without reference to tumor size. This capacity to strike hardest at the most populous and hence most dangerous concentration of tumor improves the probability of controlling local disease that may evolve more resistant progeny and metastasize systemically. It is intuitively reasonable that combined modality approaches including radiotherapy should improve results in the clinic.

Metaanalysis of Randomized Trials of Chemotherapy With or Without Thoracic Radiotherapy

There have been many published studies[42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57 and 58, 119,120,121 and 122] in which this study design has been implemented (Table 54.2). There are several differences in detail between them. For example, the precise definition of "limited" stage disease varied with respect to inclusion of patients with pleural effusions. Other selection factors such as tumor size or pulmonary function were sometimes introduced. Some studies specified a requirement that patients show a complete response to chemotherapy, perhaps in the belief that thoracic irradiation could not be withheld from partial responders. The chemotherapy regimens varied widely. Most studies were initiated before 1981 when cisplatin-containing regimens were not prevalent; none of the trials included this agent. The thoracic radiotherapy protocols were also diverse because four trials employed split-course treatment, fraction sizes ranged from 1.8 to 4.0 Gy, and total dose ranged from 40 to 55 Gy. The treatment volumes all encompassed the primary tumor with a margin of 1 to 2 centimeters. Most included the mediastinum and some treated the supraclavicular fossae electively. Most studies were designed to permit a chemotherapy response evaluation, which allows the possibility of a reduction in the

radiotherapy field size. The timing of thoracic irradiation was most often after three to six cycles of chemotherapy but was concurrent with the first cycle of chemotherapy in four studies. Prophylactic brain irradiation was part of most protocols, usually at the end of induction therapy.

TABLE 54.2. RANDOMIZED TRIALS OF CHEMOTHERAPY ALONE VERSUS COMBINED MODALITY THERAPY IN LIMITED-STAGE SMALL CELL LUNG CANCER

Nevertheless, all of these studies were designed to treat patients with regional disease in order to determine whether regional therapy would improve survival. The study populations were less than 75 in three studies, but three others included more than 290 patients. Consequently, the statistical power to detect differences varied widely and it is not surprising that many trials were negative.

The method of metaanalysis is used to study a collection of trials of similar design where each generates an estimate of treatment effect. This set of treatment effects is then subjected to statistical analysis to determine whether the average therapeutic effect can be attributed to chance alone. [123] The treatment effect can be represented by the difference between the number of events observed and the number expected if the treatment had no impact (method of Peto). The "log odds-ratio" has an approximate normal distribution and permits an estimate of the probability that an observed treatment effect could have been found by chance alone. [124] By a different calculation, [125] each study yields an estimate of the absolute magnitude of the effect observed, termed the *event rate difference.* One may then judge on clinical grounds whether observed effects are of practical value.

Two metaanalyses that examine the role of thoracic radiotherapy in LSCLC have been published. [7,8] One was based on published data (1,911 patients) and looked at two-year survival rates, local control, and toxicity. [7] The other included 2,140 patients and examined only survival at 3 years and prognostic factors for survival. [8] The study by Pignon et al. [8] assembled updated individual patient outcomes from the trial investigators, which yielded comprehensive reporting and more mature results than could be derived from the literature alone.

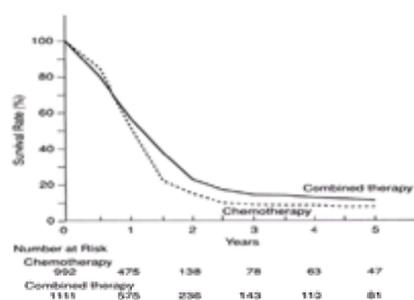
Because the majority of data in each metaanalysis was derived from the same studies, the conclusions are consistent and complementary despite differences in the methods used in the metaanalyses. Both show a modest improvement in survival rates in those patients given thoracic radiotherapy (Figure 54.1). The survival benefit becomes evident at about 15 months following start of treatment and persists beyond 5 years. At 3 years about 9% of the chemotherapy-only group are alive compared to about 14% of the combined modality group. The relative rate of death in the combined modality group as compared to the chemotherapy group was 0.86 (95% confidence interval, 0.78 to 0.94; P = 0.001), corresponding to a 14% reduction in the mortality rate. The analysis of local control was based on 1,521 patients for whom data were reported and showed marked reduction in the absolute two-year local failure rate from 23% in irradiated patients compared to 48% in nonirradiated patients (p = 0.0001). These benefits were obtained at the cost of an increase in treatment-related deaths of 1%.


FIGURE 54.1. Survival curves for the Combined Therapy Group and the Chemotherapy Group. The three-year survival rates were 14.3% ± 1.1% in the combined-therapy group and 8.9% ± 0.9% in the chemotherapy group (for a difference of 5.4% ± 1.4%: p = 0.001 by stratified log rank test)

The relative rate of death between the two groups was not influenced by gender or performance status. However, the improved survival of irradiated patients was largely confined to patients less than age 55; survival benefit for older patients in this data set could not be demonstrated. Similarly, treatment factors such as radiotherapy timing or chemoradiation integration (sequential, concurrent, or alternating) were not significant in the metaanalyses. An explanation for not demonstrating a benefit for older patients or the importance of timing of integration of thoracic irradiation may be found in the shape of the survival curve and the statistic methodology used in this analysis. Initially, the overall survival graph begins in favor of chemotherapy, but the curves cross at about 1 year and later demonstrate a long-term survival advantage for chemoradiation. The initial separation of the curves is not large, but many events occur on this steep portion of the curves (Figure 54.1). Because early concurrent thoracic irradiation with regimens other than EP adds excessive toxicity and may diminish chemotherapy delivery, the relative risk of death is not constant over time. The short-term mortality increase from toxicity or poor chemotherapy delivery may cancel out the long-term survival gain as measured by relative risk. Reexamination of this data set for an effect of thoracic irradiation timing on long-term survival rather than relative risk of death may be useful.

Most studies in the metanalyses began before 1981, and none delivered cisplatin and etoposide concurrently with thoracic irradiation. The safety and efficacy of early concurrent chemoradiation has been markedly improved with the administration of etoposide/cisplatin chemotherapy rather than cyclophosphamide, nitrosourea, or doxorubicin-based regimens. From the first report, [7c] etoposide and cisplatin clearly could be delivered concurrently with thoracic irradiation without dire normal tissue toxicity or the need to compromise the dose of either modality. Concurrent etoposide plus cisplatin or carboplatin with thoracic irradiation has become a prevalent theme in current LSCLC regimens (Table 54.1). Lack of data of this type in the metaanalyses[7,8] reduces the capacity of these reports to provide guidance on optimal integration of chemoradiation or management of LSCLC patients that is relevant to the modern era.

Volume of Radiation

The usefulness of radiotherapy comes from its ability to be directed to target tissues of interest, sparing areas beyond the treated volume, which might otherwise limit the dose delivered to the tumor. One must "see" the tumor to target it. We "see" through the use of imaging technology, knowledge of lymphatic anatomy, and experience with patterns of spread and treatment failure, but these methods have limitations.

LSCLC usually involves the mediastinal lymph nodes. Consequently, radiotherapy volumes almost always must encompass the primary node and most of the mediastinum. However, it is not clear where to draw the line. Most protocols treat the primary and clinically involved nodes; these definitions depend on imaging technology. Margins of 1.5 to 2 centimeters are commonly recommended to account for uncertainties in imaging, patient motion, and microscopic extension. Large

volumes are limited as higher cumulative doses reach neighboring structures (lung, esophagus, and spinal cord). Retrospective radiation therapy quality control analysis, including dosimetric reconstruction and port film review, demonstrate lower response rates, higher chest failure rate, and statistically worse survival for patients who were considered major protocol violations.[126] Analyses suggesting that local control deteriorates with violation of thoracic irradiation protocol guidelines may be confounded by the difficulty associated with encompassing large tumor burdens.

The extension of prescribed fields to cover bilateral hila, mediastinal, and supraclavicular nodes with curative aims suggests that the disease spreads in an orderly fashion. The behavior of SCLC is characterized by disorder. The attempt to increase treatment volume may lead to two adverse consequences: Toxicity to normal tissues will increase and the dose delivered to bulk disease will be compromised. An alternative tactic is to protect normal tissue by focusing on gross disease only using radiotherapy techniques that ensure full dose to all of the target volume, leaving chemotherapy to deal with subclinical tumor.

The simulation process for trials of early integration of chemoradiation [45,74] have targeted the prechemotherapy extent of disease. When tumor has responded to chemotherapy, an opportunity exists to "trim" the volume. The SWOG performed a randomized trial of induction combination chemotherapy with or without thoracic irradiation in complete responders and with wide-field versus reduced-field radiation in partial responders. [62] Late administration of thoracic irradiation did not change survival for complete responders, but local control was better for irradiated patients. Field size of consolidative radiotherapy for partial responders influenced neither survival or local control.

Even if thoracic irradiation is given after only one cycle of chemotherapy, tumor reduction is usually evident at simulation. No scientific rationale exists for the presumption that chemotherapy-resistant elements are confined to the diminished volume.

Wide-Field Irradiation

An extension of larger radiotherapy volumes is the investigation of "systemic" radiotherapy by either whole-body or sequential half-body irradiation. This approach has been demonstrated to be feasible by Powell[127] and Urtasun.[128] In a German study, 91 LSCLC patients were randomized to receive 6 Gy sequential half-body fields alternating with chemotherapy or chemotherapy alone.[129] Outcome differences were not significantly different, but trends in time to progression and survival favored the chemotherapy-alone group.

Dose and Fractionation of Irradiation

These two parameters of radiotherapy are best considered together for radiobiologic reasons. The linear-quadratic method will not be discussed here, but the principle that dose not be considered in isolation from fractionation will be respected. [130] Major issues of thoracic irradiation dose and fractionation include the existence of a dose-response effect on outcome using conventionally fractionated treatment and the utility of unconventional fractionation schemas such as multiple fractions per day and split-course treatment (alternating with chemotherapy).

Local control is an alternative end point to survival in trials of thoracic irradiation dose. Several methodologic problems are associated with measurement of local control. Thoracic diagnostic imaging initially normalizes for complete responders, but patients receiving thoracic irradiation develop radiation fibrosis, which renders it more difficult to recognize relapse until it is moderately large. The method of locoregional failure reporting also varies. An absolute percentage of local relapse is the only information provided in many reports. A shortcoming of using the percentage with local control as an end point is that patients with brief survival and those with systemic failure may be censored from local control analysis, creating an illusory improvement in local control. The actuarial method is preferred because it shows cumulative local relapse rates as a function of time and considers the duration of exposure in the risk period.

Conventional fractionation (1.8 to 3.0 Gy/fraction) administers a dose 5 days a week, usually with no treatment on Saturday and Sunday. Because of the toxicity of combined modality therapy, the range of conventional fractionation doses employed in large studies has been narrow (Table 54.2). Thoracic irradiation dose was examined in a Canadian multicenter trial[131] that initially randomized patients to either immediate or delayed alternation of CAV/EP. After six courses of chemotherapy, responders were randomized to either 25 Gy in 10 fractions or 37.5 Gy in 10 fractions of consolidative radiotherapy. The prechemotherapy disease was treated with a 2 cm margin around the primary tumor. The spinal cord was shielded after 32 Gy. Of 333 patients enrolled in the study, 168 were randomized (88 to 25 Gy, 77 to 37.5 Gy). The complete remission rates for combined modality therapy were 65% and 69%, respectively. The actuarial incidence of local progression by 2 years was not significantly different (80% for 25 Gy and 69% for 37.5 Gy).

A retrospective analysis[132] of a broader range and larger doses of consolidative thoracic irradiation from a single institution suggest a dose-response effect for cumulative risk of locoregional failure. However, the nonrandomized nature of the data and small numbers in each subgroup allow only tentative conclusions. A relatively poor survival outcome from late thoracic irradiation (median 12 months, 5-year 8%) indicate that few LSCLC patients in this data set were at risk of local relapse by 3 years.

Altered fractionation has attracted much interest in recent years because of two biologic observations, one general and one specific. Fractionation studies have shown that late-responding normal tissues (microvasculature, neurons, etc.) are sensitive to the dose per fraction used in radiotherapy regimens with an equivalent total dose. This finding leads to the general principle that regimens with smaller doses per fraction may permit an increased dose to tumor while continuing to respect the tolerance of critical normal tissues. [133] In the specific case of SCLC, its rapid growth and responsiveness to therapy are associated with the lack of a "shoulder" on its *in vitro* cell survival curve in response to irradiation. [134] This pattern implies an inability to repair low levels of radiation damage and cell kill at exponential rates even with small doses per fraction. Multiple fractions per day potentially achieve greater kill at the expense of less late toxicity. Because these tumors exhibit high growth fractions *in vivo,* the compensatory repopulation response must be avoided by delivering multiple fractions per day to limit overall treatment time to 3 to 4 weeks. Most normal tissues are able to repair the damage of low doses in an interval of 4 to 6 hours, at least *in vitro.* As a practical matter, only two or three fractions per day are possible, two being the usual. Further therapeutic potential may arise from the tendency of surviving cells in a rapidly dividing tumor to redistribute themselves into more radiosensitive phases of the cell cycle prior to the subsequent treatment.

An influential pilot study of accelerated fractionation for LSCLC was performed by investigators at the University of Pennsylvania. [135,136] Cisplatin/etoposide chemotherapy was integrated with concurrent thoracic irradiation (1.5 Gy twice daily, total dose: 45 Gy in 3 weeks). After thoracic irradiation, patients received six further cycles of chemotherapy alternating CAV with EP. Mature results[136] from the phase II study of 32 patients show a median survival of 23 months and long-term survival of about 30%. Local failure occurred in less than 10% and occurred mainly in patients with "variant" histologic subtype, which have a shoulder on the *in vitro* cell survival curve.[137]

An intergroup phase III study,[78] including more than 400 patients has now been completed comparing accelerated fractionation to conventional fractionation while holding total dose constant. The conventional fractionation irradiation arm was 1.8 Gy once per day, five fractions per week for 5 weeks (total dose 45 Gy). The investigational arm included 1.5 Gy twice per day, 10 fractions per week for 3 weeks (total dose, 45 Gy). Both schedules of thoracic irradiation were given with initial concurrent cisplatin/etoposide. Four cycles of chemotherapy were administered. Response rates were not significantly different, but survival was significantly improved (p = 0.04) on the twice-daily treatment arm. Median survival was 23 months for twice daily versus 19 months for once daily; actual five-year survival rates were 26% versus 16%, respectively. Grade 3 esophagitis induced by twice-daily thoracic radiotherapy was significantly worse: twice-daily patients, 26% versus 11% (p = 0.001). Intrathoracic failure was 52% in the once-daily group and 36% in the twice-daily group (p = 0.06). This important trial was the first in SCLC to demonstrate an improvement in survival and local control by the sole stratagem of altering the fractionation. Improved effectiveness with approximately equal toxicity was expected on the basis of biologic considerations; the clinical result is encouraging, particularly in a disease so dominated by metastatic events. A logical next step would be to increase the total delivered dose using a similar fractionation.

Notably, twice-daily thoracic irradiation had no impact on median or long-term survival when compared to once-daily radiation in a randomized trial by Bonner et al. [79] that delivered radiotherapy in a delayed fashion (beginning concurrently with the fourth etoposide-cisplatin chemotherapy cycle).

Technical Factors

Potentially important technical radiotherapy factors include (a) the nature of imaging procedures used to specify target volumes, (b) the therapy equipment parameters, and (c) quality assurance procedures. Careful imaging and computed tomography (CT) based planning generate greater confidence in the volume definitions and tend to lead to tighter volumes and less toxicity. Recent studies using concurrent therapies have relied heavily on information provided in this way. [138] Newer planning technologies employ CT simulations (beam's-eye view) to facilitate the shielding of critical normal structures, and even dynamic methods with

collimators, couch, and other equipment moving during the actual treatment exposure.[138] It is not known to what extent these technical advances will translate into clinical improvements; they do seem to improve the ability to safely deliver high doses to tumor and minimize normal tissue exposure.

Megavoltage machines are invariably used, usually linear accelerators. Pulmonary tissue is of low density compared to normal tissue, particularly in patients with chronic obstructive changes. The resultant inhomogeneities produce considerable variations in absorbed dose at high energies.[139] The importance of corrections for the distribution of lung density is unknown, but variations can produce substantial differences in the dose absorbed in the tumor.[140] This inhomogeneity is reduced with the use of higher energy photons, but another problem arises at energies above 10 MV. At the reduced tissue densities found in lung, electronic equilibrium (the condition required for "well-behaved" dose calculations), is not present.[141] Computation and image-intensive algorithms exist to perform these calculations, but they are not widely available. Dose inhomogeneities are accounted for by standard algorithms, but this remains a source of uncertainty in interpreting clinical results.

More traditional concerns have focused on issues of quality assurance of radiotherapy such as appropriate treatment of intended target volumes and shielding. Retrospective studies suggest that failure patterns can be influenced by these factors.[126,142] With the emergence of CT-directed treatment planning, it is relatively easy to apply a tumor dose to the primary tumor site and the mediastinum while avoiding excessive dose to the spinal cord through the use of oblique fields, lateral fields, or rotational techniques. When portals are delivered anteroposteriorly and posteroanteriorly (AP/PA), it is necessary to limit the spinal cord dose by a spinal cord block. Spinal cord blocks may shield centrally located SCLC. A Canadian study[131] of radiotherapy timing used anterior and posterior opposed fields to deliver 40 Gy in 15 fractions over 3 weeks. Posterior cord shielding limited the spinal cord dose to 35 Gy. A CALGB study[48] administered 40 Gy in 20 fractions during a four-week period, and a further boost of 10 Gy was given over 5 days to a "coned-down" volume. The AP/PA parallel opposed portals were used for the initial 36 to 38 Gy, then oblique portals were used for the final 12 to 14 Gy. Despite the more sophisticated treatment planning and higher total dose in the CALGB study, the cumulative risk of local relapse was about 50% at three years in both studies. The superior dose distribution and theoretical benefits of complex beam arrangements are self evident, but large trials will be needed to demonstrate a survival benefit.

Radiotherapy-Chemotherapy Interactions

Compression of combined modality therapies in time and increase in their intensity has taken them to the limits of patients' tolerance. To achieve greater antitumor effect in this way, benefits of temporal and spatial independence, which have traditionally been exploited to minimize toxicity, are partially disregarded. Additive interactions will not accrue meaningful benefits unless normal tissues are spared toxicity relative to the antitumor effect. Various mechanisms of interactions have been reviewed.[143] Comments here are restricted to those relevant to LSCLC therapy.

Radiation damage to lung is well known, and typical doses to tumor exceed the tolerance of any included lung. Oblique fields irradiate more pulmonary tissue than parallel opposed fields. When chemotherapeutic agents such as doxorubicin are given close to AP/PA thoracic irradiation, risk of pneumonitis is low.[74] Pulmonary toxicity can be severe when doxorubicin is given after three-field thoracic irradiation.[144] Lung injury from chemoradiation interaction exists for other drugs as well such as nitrosoureas and cyclophosphamide.[145] Reactions can be diminished if chemotherapy is limited to drugs that have little sensitizing effect on normal tissue, such as cisplatin and etoposide. Whether new cytotoxic agents such as the taxanes, topoisomerase I inhibitors, or gemcitabine can be incorporated into LSCLC concurrent chemoradiation protocols with an acceptable therapeutic index is unclear.

Thoracic irradiation techniques that irradiate large volumes of bone marrow increase hematologic toxicity and may reduce the intensity of ongoing chemotherapy. Larger fractions of cardiac output contained in the treatment volume may worsen myelosuppression disproportionately by irradiating hematopoietic progenitor cells.[146] Use of colony-stimulating factors during radiotherapy has been associated with an increase in the severity of thrombocytopenia,[147,148] and an increase in circulating hematologic stem cells has been proposed as the cause.[149] Marrow and blood stem cell irradiation may contribute to the documented worsening of hematologic toxicity from chemotherapy given after cranial irradiation.[150] Unless it can be convincingly demonstrated that there are advantages to giving prophylactic cranial irradiation early in the treatment program, chemotherapy attenuation from myelosuppression and risk of neurologic damage[151] should be less when elective brain irradiation is delayed until the chemotherapy is complete. Colony-stimulating factors as a supportive technique during radiotherapy requires further research because enhanced killing of circulating progenitor cells and depletion of myelopoeitic reserve may not be temporary.

Esophageal toxicity may be dose limiting. Acute esophagitis is common. Concomitant doxorubicin greatly exacerbates the reaction, and some radiation-recall esophagitis is commonly observed with doxorubicin-containing chemotherapy cycles given after thoracic irradiation.[54] Radiation-recall esophagitis is a manageable cause of morbidity, but a therapeutic effect from such a reaction on the tumor is difficult to investigate. Late strictures appear to be uncommon with standard treatment programs.

OPTIMAL INTEGRATION OF CHEMOTHERAPY AND THORACIC IRRADIATION

The rational development of the optimal integration of chemotherapy and thoracic irradiation for LSCLC requires an understanding of the causes of treatment failure and factors associated with long-term survival. In the absence of such insight, oncologists are vulnerable to either conservatively persisting with a logistically simple treatment plan or shifting with the fads and fashions of the latest new drug or appealing innovation. Even when a therapeutic approach seems logical, it must still be proven effective—not by high-profile pilot studies in prominent journals, or the force of persuasive personalities, but by the scientific method and the performance of controlled clinical trials. The intended outcome is to improve survival through reduction of both local failure and distant metastases.

Conceptual Model of LSCLC

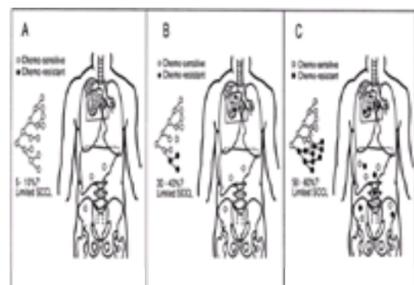
LSCLC patients can be conceptually divided into three patient groups according to the presence or absence of chemotherapy-resistant stem cells and their location (Figure 54.2). A small proportion of patients (about 9%[7,8]) have no drug-resistant variants, and cure can be accomplished with chemotherapy alone provided that treatment is adequate with respect to dose intensity and total dose (Figure 54.2A). Thoracic irradiation for these patients would not make any contribution to cure unless chemotherapy treatment was inadequate and the only persistent disease was within the thoracic irradiation volume. The second group (Figure 54.2B) includes patients in whom drug-resistant disease is present, but the entire resistant clone of cells continues to reside within the principal repository of tumor stem cells at the primary site. Thoracic irradiation may eradicate these clones if it is delivered before they spread outside a reasonable treatment volume. Even if the local tumor mass was not eradicated by radiation, unless the proportion of chemotherapy-resistant cells was high, the effect of the radiation would be to "dilute out" the drug-resistant subpopulation. An appropriate program of chemotherapy could then control the remaining local and distant chemosensitive disease. The event that leads to treatment failure in LSCLC is a very succinct one. It occurs when the first fully chemoresistant stem cell establishes itself where it cannot be destroyed by radiotherapy. Although they cannot be identified *a priori,* the majority of LSCLC patients are in this group (Figure 54.2C). Thoracic irradiation may improve local control, but it cannot change the fatal outcome for these patients.


FIGURE 54.2. Conceptual model of limited small cell lung cancer shows three patient groups according to the presence or absence of chemoresistant tumor stem cells and their location. Disease depicted outside the chest is undetectable by staging procedures. Chemotherapy-resistant disease is absent in **(A)**, localized in **(B),** and disseminated in **(C)**

Thoracic irradiation is acknowledged to be indicated in LSCLC, and no additional trials are underway to further examine this issue. This situation will not change unless dramatic advances are made in systemic therapy. The systemic nature of cancer implies that regional therapy can only influence the long-term outcome in those patients who will have their distant disease cured. Thoracic irradiation improves the long-term prognosis of LSCLC only in those cases where the systemic therapy is successful at treating distant disease (where present) but fails to eliminate regional disease. Thus the effect of radiation on improving long-term outcome is mathematically bounded by the effectiveness of chemotherapy. The contribution of thoracic irradiation to the cure of LSCLC depends on chemotherapy being only moderately effective. If chemotherapy is absent or weak, thoracic irradiation has trivial curative potential. If chemotherapy had the power to cure most patients, it could be difficult to demonstrate efficacy of local therapy.

Strategic Considerations for Assembly of Chemotherapy and Thoracic Irradiation

Arbitrary assembly of chemotherapy and thoracic irradiation is unlikely to yield the best results. Before review of clinical investigations of chemoradiation integration, it would be useful to examine the scientific basis for various sequences of systemic and local therapeutic modalities. The goal of optimal treatment modality assembly is to maximize the probability of elimination of the last cancer stem cell, thereby attaining a durable complete remission.

A simplified overview of strategic considerations for combined modality therapy would identify two distinct plans for combining chemotherapy and thoracic irradiation (Table 54.3). The strategy of the first plan must attempt to destroy as many cancer cells as possible in the shortest period. Such front-end loaded therapy would involve using the most effective modalities early in the treatment program. Four concepts support early chemoradiation, including (a) decreased probability of metastatic events, (b) lower probability of development of chemotherapy resistance, (c) lower probability of development of resistance to radiotherapy, and (d) diminished accelerated repopulation.

TABLE 54.3. CONCEPTUAL BASIS FOR EARLY INTEGRATION VERSUS SEQUENTIAL DELIVERY OF THERAPEUTIC MODALITIES IN THE ASSEMBLY OF MULTIMODALITY CANCER TREATMENT PROGRAMS

The alternative model requires rationalization of the strategic superiority of deploying modalities in a sequential fashion (Table 54.3). Sequential rather than concurrent use of modalities in oncology has been prevalent for the obvious reasons of simplicity and lower toxicity. However, simplicity and low toxicity do not provide a scientific rationale for optimal tumor eradication. Existence of reversible resistance is a concept that could support sequential therapy. Additionally, if a definitive local therapy was originally impossible but was rendered feasible by neoadjuvant therapy, this concept would also support the sequential therapy model.

Concepts that Favor Early Integration of Thoracic Irradiation with Chemotherapy

The concepts that scientifically favor early integration of effective therapeutic modalities have clear-cut characteristics. The probability of treatment failure events associated with these concepts must increase fairly quickly with the elapse of time (weeks). Therefore, the chance of avoiding treatment failure should be minimized by eliminating as many tumor cells as possible in the shortest period. Rapid eradication of tumor cells requires the early integration of definitive local treatment(s) with systemic chemotherapy.

Decreased Probability of Metastatic Events

Experimental work by Hill[152],[153] indicates that tumor cells mutate spontaneously and randomly to acquire metastatic potential. Moreover, once tumors reach a critical size or volume, metastatic phenotypes are generated "explosively." The cumulative probability of the existence of metastases and the number of metastases increases in proportion to elapsed time. The best way to decrease metastatic events is to quickly eliminate as much tumor as possible.

Lower Probability of Chemotherapy Resistance

A large body of experimental and clinical data exists that support the observation that variability exists for chemosensitivity within tumor cell populations. [154],[155] Moreover, tumor cells display a capacity to resist many drugs concurrently.[156] The biologic basis of this evolution of resistance originates during tumor growth from mutations in the cancer genome.[157] The development of resistant mutants is a random process, and the probability of their appearance increases with time in proportion to the total number of cell divisions the neoplastic burden has undergone. The somatic mutation theory of drug resistance[109] predicts that once a tumor has reached a critical size, the probability of cure is lost over a small additional size increase in a short time period. The best way to minimize the probability of chemotherapy resistance is to eliminate as many cancer cells as possible in the shortest time.

Lower Probability of Resistance to Radiotherapy

Local control rates with radiotherapy are inversely related to tumor size. [158],[159] Although microenvironmental effects such as hypoxia[160] may be relevant, increasing evidence indicates that tumor cell populations are heterogeneous with respect to inherent radiosensitivity and similar to chemotherapy resistance, resistance to ionizing radiation may be genetically determined and a stochastic process. [161] Epigenetic mechanisms for radiotherapy resistance also exist, including upregulation of DNA repair enzymes.[161] Induction of DNA repair enzymes by chemotherapy is a plausible reason why thoracic irradiation delivered after chemotherapy may be less effective. Cells that are resistant to specific chemotherapeutic agents can be very resistant[162] (a factor of several hundred compared to sensitive cells), whereas radioresistant cells are likely to be only moderately resistant (dose increase of only a factor of two or three over what is necessary for sensitive cells). [163] SCLC is less responsive to irradiation when recurrent after chemotherapy, and mechanisms of resistance may overlap; however, cross-resistance is not complete. [164] The probability of mutation to radiotherapy resistance or radioresistance as a consequence of enhanced DNA repair efficiency secondary to previous chemotherapy should be minimized by the early deployment of both modalities.

Diminished Accelerated Repopulation

"Outbursts" of cancer progression after perturbation of a tumor are not a novel observation. [165] Accelerated proliferation of tumors undergoing radiotherapy has been proposed[166],[167] to explain the clinical observation that extended therapy regimens often require increased radiation dosages to achieve an isoeffective result. [168],[169] Accelerated tumor growth has been reported after surgery[170] and chemotherapy[171] in animal models. Accelerated repopulation decreases local control, but additionally increased mitotic activity with larger burden of residual tumor may also hasten the tempo of metastatic events and increase the probability of developing drug and radiation resistance. Noncurative perturbation of the primary tumor may have detrimental effects (possibly mediated by cytokines) on existing metastatic lesions.[172] Accelerated repopulation is independent of modalities and an obvious form of cross-resistance. This phenomenon has not been mathematically modeled, but it appears to be well established within a few weeks after initiation of therapy. [166]

The original rationale of consolidative radiotherapy included the opinion that the smaller quantity of local disease remaining after chemotherapy would enhance the

feasibility and effectiveness of local therapy. The phenomenon of repopulation imposes a different reality. Because the quantity of tumor repopulation between chemotherapy treatments depends on the size of the residual stem cell population, rapid destruction of as much cancer as possible by early integration of chemoradiation minimizes the amount of tumor capable of repopulation.

Concepts that Favor Sequential Application of Radiotherapy and Chemotherapy

Simplicity has great appeal. The model of a medical oncologist administering a series of chemotherapy treatments, assessing response, and subsequently referring the LSCLC patient for consolidative thoracic irradiation when toxicity has subsided is undoubtedly simple. This approach is also associated with fewer side effects. However, is sequential or delayed administration of thoracic irradiation after chemotherapy scientifically sound?

The strategic concepts favoring *early* combined modality have a simple rule for the timing of effective modalities; any delay is potentially detrimental because the probability of treatment failure increases as a function of time. The rules are more arcane for concepts that favor sequential modalities because an additional element of information is required. It is necessary to know the most advantageous amount of delay required for the optimum sequence of modalities. This crucial knowledge must be supplied by the concept itself or learned by the conduct of controlled clinical trials. Two strategic concepts may favor sequential therapy.

Originally Impossible Local Therapy Rendered Feasible by Neoadjuvant Therapy

An unambiguous scenario where sequential therapy would offer an advantage would be when a locally advanced tumor was originally untreatable by a definitive local therapy but such therapy was rendered feasible by downstaging. This rationale is classic for neoadjuvant chemotherapy before surgery. However, LSCLC is rarely considered for surgery, and the definition of this stage indicates that all original tumor should be encompassable within a reasonable radiotherapy treatment volume at the outset. No obvious scientific reason indicates that chemotherapy-resistant residual tumor should be confined to the postchemotherapy tumor volume.

Reversible Resistance

Sequential application of modalities could be strategically superior if resistance to a particular therapy (chemotherapy or radiotherapy) was present at one point in the treatment program but the resistance reversed later, allowing successful use of that modality. Once genetically determined resistance to chemotherapy has been acquired by a tumor, it is improbable that such elements would disappear by spontaneous mutation. [109] However, resistance to chemotherapy with an epigenetic basis could occur and would be a possible form of reversible resistance. Kinetic resistance is another type of reversible resistance. The potential superiority of sequential therapies as predicted by the Norton-Simon hypothesis [173] is based on the possible existence of kinetic resistance.

The arguments supporting either early integration of chemoradiation or sequential utilization of chemotherapy and thoracic irradiation are hypothetical and must be supported by clinical data. The most important clinical data for optimal chemoradiation integration are from randomized trials of thoracic irradiation timing.

Randomized Trials of the Timing of Thoracic Irradiation

To date, five trials [48,74,75,76 and 77] of thoracic irradiation timing have been performed; four trials are published in peer-reviewed journals [48,74,75 and 76] and one is currently available as an abstract. [77] Because of the importance of these trials, each study is discussed separately and summarized in Table 54.4.

TABLE 54.4. RANDOMIZED TRIALS OF THORACIC IRRADIATION TIMING IN LIMITED-STAGE SMALL CELL LUNG CANCER

The Cancer and Leukemia Group B Trial

This large trial [48,174] performed from 1981 to 1984 included 399 evaluable LSCLC patients distributed between three arms, including chemotherapy alone (cyclophosphamide, etoposide, vincristine, and doxorubicin), initial chemoradiation (50 Gy thoracic irradiation and whole-brain irradiation concurrently with the initial cycle of chemotherapy), and delayed chemoradiation (chest and brain irradiation concurrently with the fourth cycle of chemotherapy at week 9). Both arms that included thoracic irradiation had significantly superior response rates, time to progression, and overall survival rates compared to chemotherapy alone. However, no significant differences were found between the initial and delayed thoracic irradiation arms; the insignificant trend that existed favors the delayed thoracic irradiation arm. The rationale of a randomized trial is to hold all variables constant except the experimental one. Unfortunately, the interpretation of the Cancer and Leukemia Group B (CALGB) study is confounded because potential differences in outcome from thoracic irradiation timing may be obscured by unequal chemotherapy delivery. Myelosuppression from initial thoracic irradiation, brain irradiation, and concurrent CEV chemotherapy resulted in an unplanned attenuation (50% reduction) in doses of cyclophosphamide, etoposide, and doxorubicin after the first cycle. This trial clearly supports the addition of thoracic irradiation to chemotherapy in LSCLC, but the utility of the study to provide guidance for optimal integration of chemoradiation is doubtful. [174] The long-term survival rates for chemoradiation in the CALGB study are low (<13%). [174]

The Aarhus Lung Cancer Group Trial

In this Danish trial [75] performed between 1981 and 1989, 199 patients with LSCLC were randomly allocated to initial chest irradiation or late chest irradiation delayed by 18 weeks. Both groups received nine cycles of combination chemotherapy: three cycles of EP and six cycles of CAV. Initial thoracic irradiation was delivered sequentially rather than concurrently with EP. The timing of radiotherapy (40–45 Gy) had no significant effect on the median survival (about 1 year) or long-term survival (about 10%).

The doses cited for the etoposide/cisplatin regimen in this study were cisplatin 60 mg/m^2 and etoposide 120 mg/m^2 on 1 day only. Conventional etoposide-cisplatin regimens deliver etoposide on at least 3 sequential days. The published doses of etoposide and cisplatin in the Aarhus study [75] do not respect the well-documented schedule dependency of this agent [175] and diminish the etoposide dose intensity to about one-third of standard levels. This trial also had an irregular randomization to prophylactic cranial irradiation.

The National Cancer Institute of Canada Trial

In 1993, the NCIC published results of a randomized trial [74] (accrual period 1985–1988) comparing early versus late thoracic irradiation that demonstrated a significant improvement in survival for early thoracic irradiation in the combined modality therapy of LSCLC. All 308 eligible patients received CAV alternating with EP for three cycles of each regimen. Patients randomized to early thoracic irradiation received 40 Gy/15F to the primary site concurrent with the first cycle of EP (week 3), and the late thoracic irradiation arm received the same radiation concurrent with the last cycle of EP (week 15). Dose intensity and total dose of chemotherapy was uniform in both arms (85 to 90% delivery according to protocol).

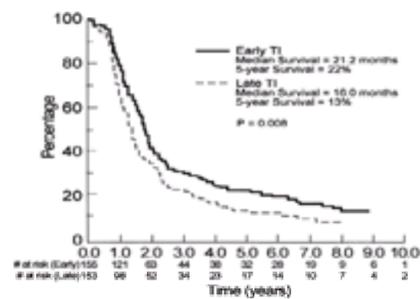
Although complete response rates were not significantly different (CR early arm 64%, CR late arm 56%, P = 0.14), the overall survival was significantly superior (P = 0.013) in the early thoracic irradiation arm (Figure 54.3). Median survival was 21.2 months in the early arm and 16.0 months in the late arm; actual survival at 5 years was 22% in the early arm and 13% in the late arm. A delay of thoracic irradiation by 12 weeks was associated with a 50% decrease in the probability of long-term survival. This trial was the first phase III study to demonstrate that actual five-year survival rates of more than 20% were achievable using early integrated chemoradiation in LSCLC.


FIGURE 54.3. Updated analysis of overall survival for the National Cancer Institute (NCIC) in Canada BR6 study. (From Murray N, Coy P, Pater J, et al. Importance of timing for thoracic irradiation in the combined modality treatment of limited-stage small-cell lung cancer. *J Clin Oncol* 1993;11:336, with permission.)

The Yugoslavian Trial

This extraordinary phase III study[76] performed between 1988 and 1992 achieved outcomes in LSCLC that were not only superior to any other phase III study, but survival was also better than any published phase II trial. All patients received accelerated hyperfractionated thoracic irradiation with 1.5 Gy twice daily to 54 Gy plus concurrent daily carboplatin/etoposide and four sequential cycles of EP. Early thoracic irradiation was delivered between weeks 1 to 4, and late thoracic irradiation patients received concurrent chemoradiation between weeks 6 to 9. The difference in timing of the initiation of thoracic irradiation between the two arms was only 6 weeks.

The median survival was 34 months for initial chemoradiation versus 26 months for delayed chemoradiation; five-year survival was 30% and 15%, respectively. The difference was significant on multivariate analysis (P = 0.027). This study by Jeremic and colleagues [76] shows that early integration of chemotherapy with intensive radiation for LSCLC may generate median survival times of almost 3 years, and long-term survival rates may approach 30%.

The Japan Clinical Oncology Group Trial

This study[77] by the Japan Clinical Oncology Group (JCOG) also examined the optimal sequence of chemoradiation for LSCLC by randomizing patients to initial concurrent versus sequential chemoradiation. The chemotherapy prescription was EP (four cycles), and thoracic irradiation consisted of 45 Gy over 3 weeks (two daily fractions of 1.5 Gy). Two hundred twenty-eight patients were entered between 1991 and 1995.

Initial concurrent chemoradiation was significantly superior (P < 0.05) to sequential therapy, with median survivals of 31.3 months and 20.8 months and projected five-year survival rates of 30% and 15%, respectively. These results strengthen the conclusion that long-term survival rates of more than 20% for LSCLC are obtainable with early chemoradiation.

Why Are the Randomized Trials of Thoracic Irradiation Timing Discordant?

Of the five controlled trials of thoracic irradiation timing performed, three (NCIC, [74] Yugoslavian,[76] JCOG[77]) support the concept that the optimal integration of chemotherapy and thoracic irradiation is early concurrent chemoradiation; the CALGB [174] and the Aarhus[75] studies suggest that the timing of thoracic irradiation does not influence outcome. Why are the results discordant? Three possible reasons are as follows:

1. The timing of thoracic irradiation is unimportant and the discordant results are caused by the play of chance.
2. Delivery of chemotherapy or thoracic irradiation was inadequate in the negative trials.
3. The patient populations differ.

The influence of chance cannot be discounted, but other explanations may be more plausible. Both the CALGB study [174] and the Aarhus trial[75] were associated with compromised chemotherapy delivery. Thoracic irradiation can improve the long-term prognosis of LSCLC only in those cases in which the systemic therapy successfully controls distant subclinical disease. Suboptimal systemic therapy unavoidably decreases the impact of a change in the timing of local therapy for a systemic disease. However, the most important reason for discordance of results probably is associated with differences in the trial patient populations. The prevalence of metastatic drug-resistant tumor outside the thoracic irradiation volume in the study population (Figure 54.2C) strongly affects the likelihood that thoracic irradiation or an innovation of it (timing or dose) will result in a survival advantage. If a poor prognosis LSCLC population (as evidenced by short median survival) is studied, then the proportion of cases that can have their prognosis improved by better integration of chemoradiation will be low and the benefit of early thoracic irradiation timing will be diluted out by most incurable cases. That the study populations in the CALGB [174] and Aarhus[75] trials, which fail to show superiority of early chemoradiation, were a poor prognostic group is strongly suggested by the short median survivals reported (Table 54.4). Long-term survival in these reports is also low. Adverse prognostic factors in these patients accrued to studies beginning in 1981 may have been caused by staging procedures that were less accurate than more recently reported trials. Median survival in the early chemoradiation arms of the NCIC, [74] Yugoslavian,[76] and JCOG[77] trials ranges from 21.2 to 34 months, which is two to three times longer than the median survival times in the CALGB[174] and Aarhus[75] studies. Median survival in the delayed chemoradiation arms of the trials that support early chemoradiation[74,76,77] ranges from 16 to 21 months, which indicates that *all* patients in these trials had better prognostic factors than the negative trials.[174,75] More important, long-term survival for early chemoradiation consistently exceeds 20% at 5 years.[74,76,77] Delayed chemoradiation has never approached the 20% long-term survival milestone, which should be considered minimum standard for LSCLC at this time. Delayed chemoradiation usually is associated with a long-term survival rate of approximately 10% (Table 54.4), which is not much different from the 9% rate expected from chemotherapy alone, as reported in the metaanalysis[8] of randomized trials performed in a similar era.

Ongoing or accelerated metastatic behavior of tumors that are responding to chemotherapy is counterintuitive. The data from randomized trials of thoracic irradiation timing in LSCLC suggests that the satisfaction medical oncologists experience when reviewing radiographs showing an LSCLC patient responding to drug treatment should be replaced with a sense of urgency that definitive local treatment must begin as soon as possible.

Alternating Chemotherapy and Thoracic Irradiation

Sequential and concurrent chemoradiation have previously been discussed in relation to the temporal arrangement of therapies. If interruptions in the radiotherapy sequence are permitted (split-course), then strategies of alternating chemotherapy and radiotherapy become possible, in which short courses of radiotherapy are interposed between cycles of chemotherapy without disrupting the schedule of drug treatment. Alternating chemoradiation was developed to reconcile the needs for early administration of both agents and for sequential delivery of each modality without a long break. [176] Although split-course radiotherapy in the absence of chemotherapy is believed to be detrimental, experimental evidence suggests that an alternating approach may be effective. Alternating chemotherapy and radiotherapy in the rat hepatoma model produced cures in a proportion of animals that could not be achieved by either modality administered sequentially. [177] Similar results were predicted by computer simulation studies.[178]

Clinical investigation of alternating chemoradiation for LSCLC was performed independently of the animal model and computer studies. This approach was used in

one of the largest controlled studies, demonstrating superiority of combined modality therapy over chemotherapy alone. [49] The group at the Institut Gustave-Roussy[179] has performed a sequence of pilot studies pursuing an improved schedule. The alternating plan consisted of six courses of chemotherapy (doxorubicin, cyclophosphamide, etoposide, and cisplatin) and three courses of thoracic irradiation, delivering a total dose of 45, 55, and 65 Gy in consecutive protocols. Radiotherapy was started after the second cycle of chemotherapy with a gap of 1 week between modalities. Seventy percent of patients achieved complete remission. The actuarial five-year local control rate was 60% and five-year overall survival was 18%. No apparent improvement in local control or survival was achieved with higher total thoracic irradiation doses.

Lebeau et al.[180] randomized 156 eligible patients to either concurrent thoracic irradiation initiated immediately after the second cycle of chemotherapy (cyclophosphamide, doxorubicin, etoposide) versus alternating thoracic irradiation in three courses between the 2–3, 3–4, 4–5 chemotherapy cycles. Unfortunately, the conduct of the trial was frustrated by the occurrence of pulmonary toxicity that resulted in termination of the trial with less than one-half of the planned sample size. Moreover, the median survival (13 to 14 months) and three-year survival (4% to 7%) was poor and similar in both arms. Comparison of concurrent versus alternating chemotherapy may be worthwhile in a trial using more compatible chemotherapy (EP).

The concept of alternating chemotherapy was put to a direct test in a study[181] by the EORTC using the three-drug CDE (cyclophosphamide, doxorubicin, etoposide) regimen. Thoracic radiotherapy was given as 2.5 Gy daily, 5 days per week. A continuous four-week consolidation regimen given after five cycles of CDE was compared to an "alternating" regimen in which one week (12.5 Gy/5 fractions) of radiotherapy was associated with each of four chemotherapy cycles after the first. In this randomized study of 335 patients, the alternating regimen was associated with hematologic toxicity severe enough to compromise delivery of both radiation and chemotherapy. No differences in outcome were noted.

LSCLC in the Infirm and Elderly

The experience of elderly patients in two large randomized trials performed by the NCIC has been reviewed, and also discussed in Chapter 64.[182,183] The two trials included 88 patients aged 70 to 80 years in the total group of 608. The elderly subset was found to have received significantly less total drug than the younger patients, largely because of dose omissions rather than dose reductions. Dose omissions were not clearly associated with an increased rate of grade 3–4 toxicity events. Thoracic irradiation (most received 35–40 Gy), even when administered with concurrent chemotherapy, was also well tolerated by the elderly. No increased rate of treatment interruptions occurred, although when irradiation was performed late in the regimen, the elderly were slightly less likely to complete it. The overall rates of response, local relapse, and survival were similar, and age was not a significant prognostic factor. However, the elderly patients represented in these randomized trials may not be representative of elderly patients with LSCLC in general.

Elderly patients with cancer are just as likely to agree to treatment given with curative intent as younger patients, but they are more conservative with respect to trading toxicity with survival. [184] Fit elderly patients should not be denied treatment with standard regimens or access to clinical trials simply on the basis of their age. However, standard protocols are difficult for frail elderly patients or patients of any age with serious co-morbid illness. Rather than abandoning hope for long-term survival in such patients, evidence suggests that abbreviated chemotherapy (two cycles) plus thoracic irradiation has the potential to achieve the therapeutic goals of symptom palliation, prolongation of median survival, and chance of long-term survival.

In a pilot study with mature results, Murray et al.[185] reported on 55 patients with a median age of 73 years who received only two chemotherapy cycles (one CAV, one EP) plus thoracic irradiation concurrently with the EP cycle. The median survival was 54 weeks and actual five-year survival was 18%. Jeremic et al. [186] reported a median survival of 15 months and five-year survival of 13% for a regimen consisting of two cycles of carboplatin and oral etoposide concurrent with hyperfractionated thoracic irradiation. These observations provide some data that may allow realistic reassurance for LSCLC patients who are unable to complete all planned chemotherapy that a large portion of chemotherapy benefit is conferred by the first two cycles and thoracic irradiation. Abbreviated regimens should be compared to standard duration regimes in the large and increasing LSCLC patient population.

TREATMENT RECOMMENDATIONS

After the diagnosis of SCLC, accurate staging should be completed as expediently as possible. Patients with LSCLC should have consultation from both medical and radiation oncologists prior to commencing treatment. If an appropriate clinical trial is available, it should be offered to the patient. Noninvestigational therapy should be given according to a published protocol rather than assembled in an arbitrary fashion. The treatment plan should be commenced without unnecessary delay.

Integration of Chemotherapy and Radiotherapy

Theoretical and clinical data suggest that the best results are obtained with a combination of multiagent chemotherapy and radiotherapy. Thoracic irradiation should be integrated concurrently with chemotherapy early in the program in a way that allows reliable delivery of both modalities.

Chemotherapy Prescription

Standard regimens include EP and alternating CAV/EP. The standard interval between cycles is 3 weeks. The EP combination should be administered concurrently with thoracic irradiation. Chemotherapy doses should not cause more than moderately severe myelotoxicity, and no more than four to six chemotherapy cycles are necessary. Elderly, frail, or noncompliant LSCLC patients who are unable to receive standard-duration chemotherapy may have useful palliation and potential for long-term survival with abbreviated chemotherapy (two cycles) and thoracic irradiation.

Thoracic Irradiation

Evidence suggests that irradiation is best administered concurrently to (or in close association with) one of the early chemotherapy cycles (first or second). The radiotherapy volumes should encompass all areas of gross primary and mediastinal disease, based on CT planning. Through tight initial definitions or the use of volume reductions, normal tissues may be spared; it is not possible to administer full dose to all sites of potential mediastinal spread. Application of newer imaging and conformal radiotherapy planning techniques offers the possibility of improved sparing of normal tissue and of escalating the dose to known tumor. Dose-fractionation regimens may range from 40 Gy in 15 fractions to 50 Gy in 25 fractions (based on evidence from randomized trials). Twice-daily fractionation (1.5 Gy to 45 Gy) is also an appropriate standard of care. Standard regimens should start on Monday to minimize weekend interruptions. Unnecessary treatment breaks should be avoided. In the absence of evidence of infection, thoracic irradiation should not be interrupted for neutropenia, regardless of its severity.

Supportive Care

Until lung cancer symptoms are controlled by antineoplastic therapy, appropriate symptomatic treatment is essential not only for patient comfort but also because these measures may enhance the fidelity of the combined modality program. Similarly, prevention and treatment of side effects and complications minimizes protocol violations.

Standard chemotherapy regimens can be given with a good margin of safety without colony-stimulating factors. Administration of granulocyte colony-stimulating factor (G-CSF) to patients who have treatment delays or reductions because of neutropenia is reasonable when treatment is potentially curative. Because increased thrombocytopenia has been observed when CSFs are given with concurrent chemoradiation, [147] cytokine supportive care in this setting should be avoided.

Clinicians must assess the psychosocial needs of lung cancer patients and use the expertise of their health care colleagues specializing in this area. Inadequate psychological support of the patient can undermine the best treatment plan. Smoking cessation after successful treatment of SCLC is associated with fewer smoking-related second primary cancers.[187] These patients must be actively encouraged and assisted to stop smoking.

Restaging of Responding Patients

LSCLC patients who achieve a satisfactory radiographic response of thoracic disease from combined modality therapy do not require restaging. [188] Repeat bronchoscopy may identify a small proportion of complete radiographic responders with residual disease, which may be of academic interest. However, in the absence of a proven therapy that can convert partial responders who have already received both chemotherapy and thoracic irradiation into complete responders with

potential for long-term survival, the patient discomfort and additional costs mitigate against restaging bronchoscopy.

RESEARCH PRIORITIES

Unlike breast and bowel cancer, no large trials (more than 1,000 patients) have set out to definitively answer important questions in the treatment of LSCLC. To a limited extent, the lack of large trials can be augmented by the metaanalysis of smaller trials, which have used similar protocols. However, heterogeneity of trial design, drug usage, and radiotherapy application among trials reduces the likelihood that differences will be seen when study patients are distributed across several studies compared to their consolidation within larger studies. The potential increase in plausibility obtained by the demonstration of a therapeutic effect in various trials is offset by the likelihood that a small but meaningful therapeutic advance will go unproven. A second concern with the results of metaanalyses of multimodality therapy is that multiple protocol differences may permit several interpretations of the reason(s) for any observed differences. The rationale for the creation of large intergroup trials is particularly strong in LSCLC, where modest therapeutic advance seems possible.

Lung cancer investigators must decide how much of change in long-term survival is important enough to warrant a clinical trial large enough to prove it. Most would probably agree that an increase in the cure rate of 10% is worthwhile. What about 5%? Many would reply affirmatively. For a disease this common, a true increase in the cure rate of 5% would save many patients. What about less than 5%? Probably not. Table 54.5 gives the sample sizes for trials where clinical parameters are in the range of those likely to be seen in LSCLC trials in the future. Examination of this table shows that only a few of the trials conducted to date have sample sizes that exceed the smallest of those in the table. Although most trials are small, metaanalyses have been able to demonstrate value in the use and timing of radiation. However, it will never be apparent what improvements will be missed because of the lack of large meaningful clinical trials. A substantial improvement from a succession of small advances is realistic.

Control Arm Survival Rate (%)	Total Sample Size Required for Improvement in Survival Rate		
	5%	10%	15%
10	1,290	394	134
15	1,894	544	208
20	2,444	676	328
25	2,926	788	374

α, 0.05; power, 0.90
Allow for ineligibility, loss to follow-up, and late events.

TABLE 54.5. TOTAL SAMPLE SIZE REQUIRED FOR TWO-ARM PHASE III TRIALS AS A FUNCTION OF OVERALL SURVIVAL RATE AND IMPROVEMENT IN OVERALL SURVIVAL RATE

Research priorities for LSCLC may include (a) further studies confirming the importance of timing of thoracic irradiation in combined modality therapy, (b) evaluation of more effective thoracic irradiation, (c) and modification of drug resistance. Investigation of chemotherapy regimens including a new drug should consider whether the combination regimen can be given concurrently or adjacent to thoracic irradiation. A large array of drugs with novel molecular targets provides welcome relief from an increasingly tedious cytotoxic drug agenda.

The clinical work performed to date appears to allay one important and serious concern. With dosage adjustments and modern methods of supportive care, it is possible to put patients through fairly rigorous combined modality treatment programs without unacceptable morbidity. Thus ethical concerns that might otherwise have impeded the clinical testing of these concepts appear satisfied. The ethics of phase II and III studies for LSCLC patients must consider that standard combined modality therapy may achieve a five-year survival rate of 20% or more.

CONCLUSION

The opportunity for demonstrating treatment improvements for LSCLC would appear to be greater for systemic chemotherapy, where a large array of drug permutations and dosing variations is used. Additionally, the entire LSCLC population is a potential beneficiary of bona fide improvements in chemotherapy. For radiotherapy, the entire group is eligible for better local control, but only patients without drug-resistant metastases outside the radiotherapy volume are eligible for a contribution of thoracic irradiation to cure. It is disappointing that an advance in the efficacy of chemotherapy for SCLC has not been convincingly shown for more than 20 years. On the other hand, several radiotherapy interventions have shown significant contributions to LSCLC median and long-term survival in phase III randomized trials or metaanalyses, including (a) addition of thoracic irradiation to chemotherapy, (b) importance of early timing of thoracic irradiation, (c) increase in thoracic irradiation intensity, and (d) addition of prophylactic cranial irradiation to complete responders. Progress in the integration of modalities for LSCLC probes fundamental aspects of tumor biology. The LSCLC treatment model of early integration of local and systemic therapy should be considered for other rapidly growing cancers for which local and systemic therapy are combined with curative intent despite a high probability of the presence of metastases and chemotherapy resistance.

SURGICAL MANAGEMENT OF SMALL CELL LUNG CANCER

FRANCES A. SHEPHERD

HISTORICAL BACKGROUND

Although small cell lung cancer (SCLC) accounts for 20% to 25% of all primary bronchogenic carcinomas, this tumor represents less than 5% of cases in most surgical series. The discrepancy can be explained by the biologic behavior of SCLC, which results in dissemination to regional lymph nodes and/or distant metastatic sites in more than 90% of patients at the time of initial presentation. [1] Even patients with apparently "limited"-stage tumors probably have micrometastatic disease at distant sites, which has the potential to proliferate if only local therapeutic modalities, such as surgery or radiotherapy, are employed. This explains why almost all surgical series from the prechemotherapy era reported five-year survival rates approaching zero for patients with small cell carcinoma. [2]

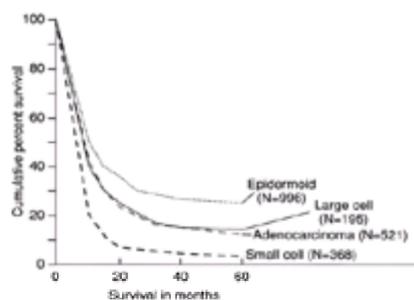
Mountain reviewed the experience of the M.D. Anderson Hospital and Tumor Institute in the surgical management of 368 patients with pathologically proven SCLC [3] and found that only one patient survived longer than 5 years compared to 15% to 25% of non–small cell lung cancer (NSCLC) patients (Figure 55.1). Less than 15% of the tumors presented with a peripheral tumor mass, but no survival advantage could be identified even for this favorable subgroup. Surprisingly, the survival of the SCLC patients without lymph node involvement was not superior to those with bronchopulmonary and/or hilar nodes, or even to those with mediastinal nodal involvement (Figure 55.2). The size of the primary tumor did not seem to be prognostic, nor was the presence of atelectasis and/or pneumonitis associated with a significantly poorer outcome.


FIGURE 55.1. Bronchogenic carcinoma. Cumulative percentage of patients surviving according to morphology. (From Mountain C. Clinical biology of small cell carcinoma: relationship to surgical therapy. *Semin Oncol* 1978;5:272, with permission.)
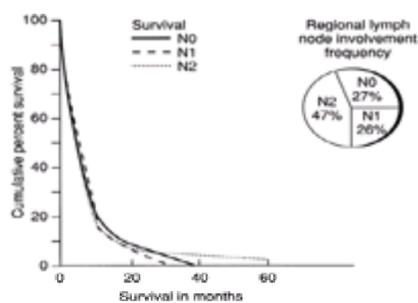

FIGURE 55.2. Undifferentiated small cell carcinoma. Percentage frequency and cumulative percentage of patients surviving according to presence and extent of regional lymph node involvement. (From Mountain C. Clinical biology of small cell carcinoma: relationship to surgical therapy. *Semin Oncol* 1978;5:272, with permission.)

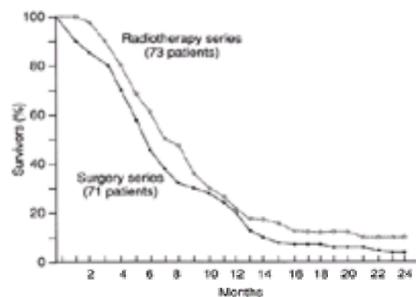
To determine whether it was ever appropriate to undertake surgery as the primary treatment for SCLC, a prospective randomized trial was mounted by the Medical Research Council of Great Britain. [4,5] In this study, 71 patients were randomized prospectively to undergo surgical resection, and 73 to receive a course of "radical radiotherapy" (30 Gy or more over 20–40 days). The median survival was 199 days for patients in the surgical arm and 300 days for patients who received radiotherapy (Figure 55.3). At 5 years, one and three patients were alive in the surgery and radiotherapy arms, respectively (p = 0.04). At 10 years, only the three patients in the radiotherapy arm remained alive. It was concluded from this study that radical radiotherapy was preferable to surgery, but that neither of the treatment policies was really effective. The investigators concluded that other therapeutic approaches (e.g. immunotherapy, chemotherapy, or various combinations) might be more successful, and they also suggested that it would be improbable that any advance in therapy could significantly reduce the overall death rate from this disease in the absence of successful smoking prevention programs. Is it not chastening to realize that 20 years later we could draw exactly the same conclusions from many of our lung cancer clinical research trials?


FIGURE 55.3. Survival in the two treatment series (all patients). (Working Party on the Evaluation of Different. Methods of Therapy in Carcinoma of the Bronchus. Comparative trial of surgery and radiotherapy for the primary treatment of small-celled or oat-celled carcinoma of the bronchus. *Lancet* 1966;2:979, with permission.)

The marginally superior long-term survival rate for patients treated with radiotherapy in the British Medical Research Council trial led some investigators to recommend a policy of preoperative radiotherapy followed by surgery for patients with SCLC. In a prospective phase II trial from the North Middlesex Hospital in London, 49 patients received low-dose preoperative radiotherapy (17.5 Gy) and 24 received higher dose radiotherapy (25 Gy). [6,7] Of the 90 patients who entered the study, 9 were inoperable and did not undergo surgery, and 73 eventually had resection. NSCLC was identified in nine patients. Eight patients survived 5 years, and two remained alive and disease-free more than 10 years postoperatively.

In a similar North American trial of preoperative radiotherapy that included both SCLC and NSCLC patients received higher dose radiotherapy, 30–40 Gy in 2 weeks followed by thoracotomy.[8] No long-term survivors were seen for the small population of patients with oat cell carcinoma in this trial.

It was evident to investigators in the 1960s and 1970s that patients with SCLC were dying from systemic metastases, and that no manipulation of local treatment modalities would result in significant long-term survival in the absence of effective systemic treatment. Bergsagel et al. from the Princess Margaret Hospital were among the first to test the hypothesis that chemotherapy might add to the effects of local radiotherapy, and they showed a modest survival advantage for patients treated with single-agent low-dose cyclophosphamide.[9] The British Medical Research Council Lung Cancer Working Party undertook a similar trial in which 125 patients were randomized prospectively to receive 30 Gy radiotherapy delivered in 15 fractions, or the same radiotherapy with systemic chemotherapy consisting of cyclophosphamide 500 mg/m^2 given every 3 weeks and CCNU (1-(2-chloroethyl)-3 cyclohexyl-1-nitrosourea) 50 mg/m^2 orally every 6 weeks. A significant prolongation of progression-free survival was seen for patients in the chemotherapy arm, although a long-term survival benefit was not demonstrated. [10]

Simultaneously, other investigators were applying the same adjuvant chemotherapy principles to surgical patients. In the United States, large adjuvant chemotherapy trials were conducted by the Veteran's Administration Surgical Adjuvant Group (VASOG). In a trial of 417 patients with all cell types of lung cancer, no survival benefit was identified for patients who received postoperative adjuvant cyclophosphamide alone or cyclophosphamide and methotrexate compared to a no-treatment control group.[11] Eighteen patients with SCLC were included in that trial. Of those, one of six patients in the cyclophosphamide-alone arm and three of nine patients in the cyclophosphamide and methotrexate arm were alive at 3 years compared to no patients in the control group. This was the first report to suggest that adjuvant chemotherapy might prolong survival for patients with SCLC who had undergone complete surgical resection.

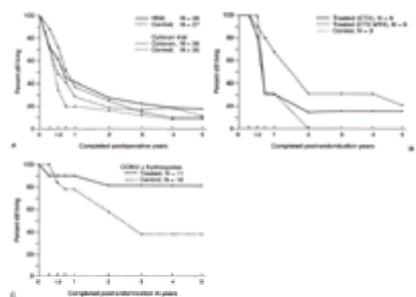
In 1982, Shields reviewed the results of four VASOG adjuvant chemotherapy studies, and undertook a separate analysis of the 148 patients (47%) in those trials who had SCLC.[12] In the first trial, 28 patients were randomly assigned to receive nitrogen mustard and 27 to control, and in the second trial 26 patients were randomly assigned to receive cyclophosphamide and 20 to control. No survival advantage was seen for the patients in the chemotherapy arms of either trial. A small survival advantage was seen for patients in the chemotherapy arm of the three-arm trial, in which patients were randomized to receive prolonged intermittent courses of CCNU and hydroxyurea or no further therapy (Figure 55.4).


FIGURE 55.4. Survival of treated and control patients with undifferentiated small cell carcinoma in the nitrogen mustard (HN$_2$ and cyclophosphamide (Cytoxan) adjuvant chemotherapy VASOG lung trials. B: Survival of treated and control patients with undifferentiated small cell carcinoma in the prolonged intermittent cyclophosphamide (Cytoxan, CTX) and mathotrexate (MTX) adjuvant chemotherapy VASOG lung trials. C: Survival of treated and control patients with undifferentiated small cell carcinoma in the CCNU and hydroxyurea adjuvant chemotherapy VASOG lung trials. (From Shields TW, Higgins GA, Matthews MG, Keehn RJ. Surgical resection in the management of small cell carcinoma of the lung. *J Thorac Cardiovasc Surg* 1982;84:481, with permission.)

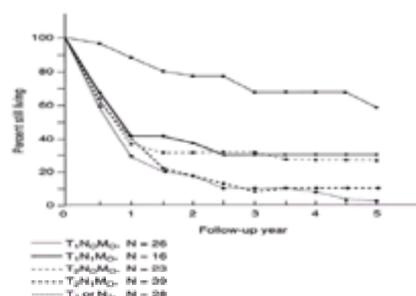
Shields and his co-workers also made other important observations from their analysis of the SCLC patients in the VASOG trials. They demonstrated the importance of TNM (tumor, note, metastasis) staging, which has long been recognized to have prognostic significance for NSCLC. Sixty percent of patients with T1 N0 M0 tumors were alive at 5 years, whereas there were almost no five-year survivors among the patients who presented either with T2-3 tumors or with mediastinal lymph node involvement (Figure 55.5). Patients with small primary tumors with only first-level hilar nodes involved had an intermediate survival of approximately 30%.


FIGURE 55.5. Survival, computed by the life-table method, from post-operative day 30 (early trials) or from randomization (recent trials) by TNM classification for patients with undifferentiated small cell carcinoma who had undergone a "curative" resection in the VASOG lung trials. (From Shields TW. Higgins GA, Matthews MG, Keehn RJ. Surgical Resection in the management of small cell carcinoma of the lung. *J Thorac Cardiovasc Surg* 1982;84:481, with permission.)

Although it had become accepted by the 1970s that surgical resection was not appropriate for most patients with SCLC, the observations of Shields and his colleagues suggested that a subpopulation of SCLC patients might benefit from a surgical approach. In a retrospective review of 40 patients with SCLC who underwent potentially curative resection between 1959 and 1972, Shore and Paneth reported an overall five-year survival rate of 25%. Four of ten patients (40%) without nodal involvement achieved long-term survival compared to nine of twenty-six patients (25%) who had hilar or mediastinal nodal involvement. [13] In a retrospective analysis of 106 resected patients from Japan, 87 cases were of the intermediate cell type and 19 of the oat cell type. [14] The five-year survival for the intermediate cell type was 10.3%, whereas only one of the oat cell type achieved long-term survival. Other investigators have not identified a significant survival advantage for patients with the intermediate cell type, [15] and this designation has largely been abandoned today.

SCLC usually presents with a central mass with associated hilar and mediastinal adenopathy. Lennox et al. observed that patients who had larger or more proximal tumors and who required a pneumonectomy were less likely to achieve long-term survival. Their two- and five-year survival rates for patients who required only a lobectomy were 32% and 18%, respectively, compared to 14.4% and 7.2%, respectively, for pneumonectomy patients. [16] Occasionally, SCLC can present as a solitary pulmonary nodule. Between 1958 and 1963, 1,134 patients with asymptomatic solitary pulmonary nodules were assessed by VASOG members. [17] Only 15 patients (4%) were found to have small cell pathology, and of those, 11 were able to undergo a curative surgical procedure. One-, five-, and ten-year survival rates for those 11 patients were 63.6%, 36.4%, and 18.2%, respectively. Because most of these patients underwent surgery before the chemotherapy era, it may be assumed that approximately one-third of patients were cured by their surgery alone as measured by survival at the five-year mark.

From this historical review it is clear that any local treatment modality alone, whether surgery or radiation, is inadequate therapy for SCLC. If surgery is to have any role to play, it must be in the context of a combined modality treatment program with systemic combination chemotherapy and perhaps radiotherapy as well.

RATIONALE FOR SURGERY IN THE MANAGEMENT OF SMALL CELL LUNG CANCER

IMPROVED CONTROL AT THE PRIMARY SITE

SCLC is a highly chemosensitive tumor (Table 55.1). Response rates of 80% or more are achieved with current chemotherapy combinations, and complete clinical response is achieved in approximately 50% of patients with limited-stage disease. [18,19] Despite this high initial response rate, most patients experience relapse shortly after discontinuing treatment, and the two-year survival rate is 20% or less in most series. For patients with limited disease, the most common site of failure is the area of the primary tumor and its hilar and/or mediastinal draining lymph nodes. Overall, 50% of patients fail at the primary site, and for one-half of those patients, the primary site may be the *only* area of failure. Similar results have been found at autopsy. In a review by Elliott, residual tumor was identified at autopsy in the primary site in 64% of patients and in the hilar and mediastinal lymph nodes in 53% of patients with limited disease who had achieved complete clinical response. [20]

TABLE 55.1. RATIONALE FOR SURGERY FOR LIMITED SMALL CELL LUNG CANCER

Initial attempts to improve control at the primary site focused on the addition of thoracic irradiation. Two metaanalyses of thoracic radiotherapy have been published for SCLC. [21,22] The survival data for almost 2,000 patients in 16 trials were available, and data on local control rates were available for nine studies. Both metaanalyses showed that thoracic irradiation resulted in a reduction in local relapse rate from 47.9% to 23.3% (p < 0.0001). [21] They also demonstrated a small but significant survival benefit for patients who received radiotherapy. [21,22] Indirect comparisons of early to late radiotherapy and of sequential to nonsequential radiotherapy did not reveal any optimal time for the administration of this local treatment. [22]

Based on the results of these metaanalyses, the standard therapy for patients with limited SCLC now consists of combination chemotherapy and thoracic irradiation with or without prophylactic cranial irradiation. Median survival longer than 20 months and five-year survival rates of approximately 20% have been reported. [23] However, even the most successful combined modality treatment programs report isolated relapse at the primary site in 20% to 25% of patients, and a cumulative risk of recurring locally of 50%. This high local failure led several investigators to question whether surgical resection would result in improved local control. They postulated that control of bulk disease in the chest by surgery and eradication of low-volume micrometastatic disease by systemic chemotherapy would result in an increased cure rate. Small studies from several centers suggested that this might, indeed, be the case. The University of Toronto Lung Oncology Group reported only two local recurrences in 35 patients treated with combined modality therapy, which included surgical resection. [24] Similar results were reported by Comis et al., who observed no local recurrences in 16 patients who underwent adjuvant surgical resection after induction chemotherapy. [25]

Mixed Histology Tumors

In approximately 5% to 10% of cases, SCLC is found in combination with other lung cancer histologies such as adenocarcinoma or squamous cell carcinoma. [26] Investigators for the Eastern Cooperative Oncology Group (ECOG) reported that mixed histology tumors were more likely to present as peripheral lesions on chest x-ray, although they found that all other clinical characteristics were similar to those of the pure SCLC patients. When surgical series of SCLC are examined, it would appear that a higher percentage of patients have mixed small cell and non–small cell tumors. The University of Toronto Lung Oncology Group reported mixed histology in 14 of 79 patients (17.7%) who underwent initial surgery followed by adjuvant chemotherapy, and in 3 of 40 patients (7.5%) who had surgical resections after induction chemotherapy. [28]

It may be appropriate to consider a combined modality treatment program for patients with mixed histology tumors if they meet standard surgical criteria and have no evidence of extra thoracic spread. Because NSCLCs are relatively insensitive to chemotherapy, they are not likely to be controlled by systemic treatment. After initial treatment with chemotherapy for the small cell component, the addition of surgery to remove the non–small cell component might contribute to the potential for cure of this small subgroup of patients.

Late Recurrence After Successful Treatment of Small Cell Lung Cancer

Several reviews have now suggested that long-term survivors of SCLC are at high risk of developing second primary tumors, particularly second primary lung cancers. [25,30,31,32] A review of 47 patients who survived longer than 2 years after treatment at the M.D. Anderson Cancer Center identified 14 patients who had second malignancies, and of those, 7 had second primary lung cancers. [29] In fact, their review suggested that a long-term survivor is more likely to have a second primary tumor than a relapse of SCLC. Although the patient population at risk for these second tumors is low because of the low cure rate for SCLC, clinicians seeing patients in follow-up must be aware that a new lesion on chest x-ray may not represent relapse but may be a new primary tumor. Such patients should be investigated similar to any other patient who is presenting with a lung mass for the first time. Histologic or cytologic confirmation of malignancy should be obtained, and if NSCLC pathology is found, then further workup should be directed at determining operability because surgical resection has the potential to be curative for some patients.

ADJUVANT CHEMOTHERAPY FOLLOWING SURGICAL RESECTION OF SMALL CELL LUNG CANCER

The first suggestion that adjuvant chemotherapy after surgery might prolong survival arose from Shields' review of the VASOG trials. [12] There were inadequate numbers of patients in any of these trials for the results to be statistically significant, and the chemotherapy administered would be considered inadequate by today's standards of systemic chemotherapy for SCLC. Nonetheless, the data suggested that, following complete resection of bulk disease at the primary site, systemic chemotherapy had the potential to eradicate micrometastatic tumor deposits.

These favorable results led several investigators to administer combination chemotherapy to all patients following complete resection of SCLC. A summary of 10 such trials is shown in (Table 55.2).[12,33,34,35,36,37,38,39,40,41,42,43 and 44] All of the studies were retrospective reviews, so they suffer from the inherent weaknesses of any retrospective assessment of a treatment policy.

TABLE 55.2. SURVIVAL ACCORDING TO PATHOLOGIC STAGE FOR PATIENTS TREATED WITH ADJUVANT CHEMOTHERAPY AFTER SURGERY FOR SMALL CELL LUNG CANCER

For many of the patients in these series, surgery was undertaken because a preoperative diagnosis of SCLC had not been made. For some, it had not been possible to obtain adequate tissue for any malignant diagnosis, and for others a preoperative diagnosis of NSCLC had been made. Some of those patients were subsequently found to have mixed histology tumors with both small cell and non–small cell components whereas others had pure small cell tumors that had been incorrectly diagnosed preoperatively. Maassen[37] reported that only 18 of 24 patients had a correct histologic diagnosis of SCLC preoperatively. In a series of 63 patients reported by the University of Toronto Lung Oncology Group,[38] only 18 had a correct preoperative diagnosis of SCLC. Postoperatively, SCLC was seen in 54 patients and mixed histology tumors in 9.

For most of the studies, chemotherapy was not standardized, and because most of the reviews included patients seen over a 10 or more year period, multiple chemotherapy protocols were often employed. With the exception of the early trials reported by Shields[12] and Hayata,[33] all patients were treated with combinations of drugs that would be considered adequate even today. The duration of chemotherapy treatment was also variable and ranged from a single course of postoperative therapy to multiple courses for 18 months. Most groups administered approximately six cycles of treatment.

In addition to postoperative chemotherapy, some centers also administered local radiotherapy to the primary tumor bed and mediastinum as well as prophylactic cranial irradiation. Considering the variability in radiation treatment and incomplete reporting in several series, no conclusions can be drawn concerning the advisability of trimodality therapy.

Because so few patients with SCLC are surgical candidates, the TNM staging system is not generally applied to this subtype of lung cancer; instead, patients are classified simply as limited or extensive disease. The patients in the reviews summarized in (Table 55.2) differ from limited-stage SCLC patients overall in that they all underwent pretreatment surgical resection, and therefore detailed pathologic staging is available. From the results shown, it is clear that the TNM staging system that provides such important prognostic and therapeutic information for patients with NSCLC may also be prognostic for patients with limited SCLC. In every study, the best survival was achieved by patients who had *pathologic* stage I tumors, and the poorest survival was seen for patients with *pathologic* stage III tumors. For stage I patients, survival ranged from 22% at 3 ½ years in the Danish series[33] to 61% at 4 years in the International Society of Chemotherapy Lung Cancer Study Group [See Figure 55.6].[39,40] On average, it would appear that approximately 50% of patients with stage I SCLC may be cured with a combined modality approach that includes surgical resection and adjuvant combination chemotherapy. In the early trials, virtually no patients with stage III tumors achieved long-term survival. In the after reviews in which more aggressive combination chemotherapy regimens were employed, long-term survival ranged from 11%[37,42] to 35%.[39,40] (See Figure 55.7). In all series, the survival of stage II patients was intermediate between that of patients at stages I and III. In fact, these survival rates are similar to those seen after surgical resection for similar stage patients with NSCLC (See Figure 55.8).

What may be concluded from these series? All of the studies that employed intensive combination chemotherapy reported survival that appears to be superior to the survival seen in patients following surgery without adjuvant chemotherapy. Although these comparisons are retrospective, it is likely that the improved survival is attributable to the postoperative chemotherapy treatment and not to improvements in surgical techniques or supportive care. It seems appropriate, therefore, to recommend that combination chemotherapy be administered to patients who have undergone resection for limited SCLC because the short-term toxicity of such treatment is usually manageable, and the long-term toxicity is probably minimal. The University of Toronto Lung Oncology Group recommends no more than six treatment cycles[38] because survival does not seem to be superior for patients who receive 12–18 months of postoperative treatment. [36,44] Whether fewer than six cycles may also be adequate is unknown. In the study reported by Hara et al. [42] 11 patients treated between 1972 and 1981 received only one postoperative course of combination chemotherapy, and 26 patients treated from 1982 to 1989 received only two courses of chemotherapy followed by consolidation radiotherapy.

Although the five-year survival rates for patients with stage I and II tumors were excellent, only 10.7% of patients with stage III tumors were alive at 5 years. These results appear to be somewhat poorer than those achieved by other groups that administered a more prolonged course of adjuvant chemotherapy, although firm conclusions cannot be drawn from these retrospective analyses. Littlewood et al. [46] treated two young patients by pneumonectomy followed by a single course of very high-dose chemotherapy and autologus bone marrow transplantation. Both patients relapsed, 118 and 80 weeks after treatment. It would appear, therefore, that a brief course (maximum six treatment cycles) of standard-dose combination chemotherapy should be the treatment of choice for patients at this time.

Although these retrospective trials support the recommendation for adjuvant chemotherapy after surgical resection, it is not possible to state with certainty which patients have the potential to derive most benefit from adjuvant chemotherapy and whether it is necessary to administer such treatment to all patients. Shah et al. [47] reported 43.3% *actual* five-year survival for 28 patients who underwent complete surgical resection without postoperative chemotherapy. The actual five-year survival for patients with stage I disease was 51.1%, and surprisingly, was 55.5% for stage III patients. No patient with stage II disease survived 5 years. More than one-half the patients in this study had peripheral tumors, and their survival was better than that of the patients who had central tumors. Peripheral stage I NSCLC is uncommon. In the VASOG cooperative study of solitary pulmonary nodules, only 11 of 309 patients who underwent curative resection were found to have small cell tumors.[17] Their median five-year survival was 36.4% and their median ten-year survival was 18.2%. The details of postoperative therapy, if any, for these patients were not provided, but it is likely that they did not receive aggressive combination chemotherapy. It is interesting to note that their five-year survival rates were very similar to those of the other lung cancer cell types in the review. The five-year survival rate is less than that reported by Shah et al., and one can only speculate whether superior survival might have been achieved with the addition of combination chemotherapy.

On the other hand, it is not possible to draw firm conclusions concerning the contribution of the *surgery* to the overall survival of these patients. The survival of patients who undergo surgery should not be compared directly to the survival seen in trials of standard chemotherapy and radiotherapy for limited-disease SCLC. It must be remembered that surgical series include only a select subgroup within limited disease from which patients with adverse prognostic factors, such as supraclavicular adenopathy, bulky primary tumors with superior vena caval obstruction, and/or pleural effusions, have been specifically excluded.

Surgery, if it does play a role in the treatment of SCLC will do so by improving control at the primary site. Relapse patterns were reported in only seven of the trials reviewed,[34,38,41,42,43,45,46] but the results from those studies suggest that surgery did contribute to local control because isolated local relapse was seen in only 8 of the 201 patients in those studies (Table 55.3). It must be remembered, though, that these patients represent only a select subgroup of the entire group of limited SCLCs in that they were considered "operable" at the time of diagnosis. It is quite possible, therefore, that this high rate of local control was attributable only to the fact that the patients in these series has less locally advanced tumors and that the local control rate might have been equivalent with a combination of systemic chemotherapy and thoracic irradiation.

TABLE 55.3. PATTERN OF RELAPSE FOR PATIENTS WITH SMALL CELL LUNG CANCER TREATED WITH SURGERY FOLLOWED BY ADJUVANT CHEMOTHERAPY

PROSPECTIVE TRIALS OF INDUCTION CHEMOTHERAPY FOLLOWED BY SURGICAL RESECTION FOR SMALL CELL LUNG CANCER

Phase II Trials

The encouraging results achieved with initial surgical resection followed by adjuvant chemotherapy led several groups to undertake prospective studies of systemic chemotherapy *followed by* surgery for certain patients with limited SCLC. The results of nine such prospective phase II trials are summarized in (Table 55.4).[48,49,50,52,53,54,55 and 56]

TABLE 55.4. PROSPECTIVE PHASE II TRIALS OF INDUCTION CHEMOTHERAPY FOLLOWED BY SURGERY FOR LIMITED SMALL CELL LUNG CANCER

All of the studies administered multiple courses of combination chemotherapy, which included most of the agents that are active against SCLC (i.e., cyclophosphamide, doxorubicin, vincristine, etoposide, and cisplatin). The number of preoperative chemotherapy courses ranged from two to six, and the overall response rate was greater than 88% in all studies except that of Baker et al. [51] In that study, patients received only two preoperative courses of chemotherapy, which may explain the low complete response rate of 3% and overall response rate of only 54%. This finding might suggest that a longer course of induction chemotherapy would be advisable, although in the small study reported by Benfield et al., [52] 88% of patients responded to treatment and 100% were able to undergo complete surgical resection after only two courses of chemotherapy. Not all responding patients underwent thoracotomy. On average, approximately 60% of patients were considered to have responded adequately enough for surgical exploration, and of those, more than 80% could be resected completely. When calculated from the total number of patients who entered the studies, the overall complete surgical resection rate was approximately 50%. Not all studies reported surgical toxicity, but it does not appear that the postoperative death rate or complication rate was significantly increased by the preoperative chemotherapy administered to these patients. Only three postoperative deaths were reported, [51,54,55] all in patients who had required a complete pneumonectomy. Other postoperative complications included infection, bronchopleural fistula formation, and reversible supraventricular tachycardias, but it does not seem that the surgical complication rate was greater than that observed after similar procedures in patients who have not received chemotherapy.

Not unexpectedly, the complete pathologic response rate was considerably lower than the clinical response rate. With the exception of Benfield et al., [52] all authors reported complete pathologic response in a few patients. The rate ranged from 4% [53] to 37% [54] and on average was approximately 10%. It is of interest that this complete pathologic response rate is similar to that which has been reported in studies of induction chemotherapy followed by surgery for patients with locally advanced (stage IIIA or IIIB) NSCLC. [58]

All investigators found that survival strongly depended on TNM stage. Patients with stage I (T1–2 N0) tumors had the best prognosis, with five-year survival rates that approached 70% for completely resected patients. Stage II and III patients fared less well, but all series reported a few patients with stage IIIA tumors (N2) who achieved long-term survival and appeared to be cured by their combined modality treatment program. The median survival for the entire group of patients who entered the trials (including those who did not procede to thoracotomy) was reported for only six studies and ranged from 13 to 33 months. [49,50,52,53,54 and 56] Several authors reported the highest cure rate for patients who required only a lobectomy, [45,56] although this finding was not confirmed by all authors. [48,50] Almost no long-term survival was seen in patients who were found to have unresectable tumors at the time of thoracotomy.

Patients who achieved a complete pathologic response and who had no viable tumor identified at thoracotomy had the best survival. Williams et al. [49] reported that all five patients with a pathologic complete response were cured of their tumors, compared to only 20% of patients who were operable but had viable SCLC present on pathologic review. None of their patients who had inoperable tumors at the time of thoracotomy was cured. [49]

The objective of most of these trials was to assess the feasibility of combined modality therapy, which included chemotherapy and surgical resection, and to determine whether surgery could contribute to long-term survival and cure by reducing the local recurrence rate. Local relapse rates ranged from 0% [48] to 40% of completely resected patients. [51] Most series reported local failure rates ranging from 10% to 20% for patients who were able to undergo successful resection (Table 55.5). [48,50,52,53,54,55,56,59] Not surprisingly, local control was found to correlate with the degree of response to chemotherapy and the completeness of the surgical resection. Of the patients who responded to chemotherapy and proceeded to surgery, approximately 15% of patients had unresectable tumors. When these patients are added to those who relapsed locally, the local failure rate rises to more than 25% of the surgical patients.

TABLE 55.5. PATTERN OF RELAPSE FOR PATIENTS WITH SMALL CELL LUNG CANCER TREATED WITH INDUCTION CHEMOTHERAPY FOLLOWED BY SURGERY*

These phase II trials led to observations that were important in the design of subsequent randomized trials of surgery for limited SCLC. They showed that combined modality treatment was feasible and that the preoperative administration of chemotherapy did not result in excessive postoperative morbidity or mortality. All investigators recognized that the favorable survival achieved in these trials might be caused by patient selection. The Toronto group emphasized the importance of selection bias after their review of limited-stage SCLC treated at their institutions over a ten-year period. [50] They reported a significant survival advantage for patients who had no clinical evidence of mediastinal node involvement. This group, which would include the type of patients who might be considered for surgery protocols, had a 20% cure rate with standard chemotherapy and radiation alone, compared to no long-term survival for patients with more advanced tumors. Prospective randomized trials clearly were needed to determine the true role or surgery for patients with limited SCLC.

Randomized Trials

In an attempt to determine whether the addition of surgery to combination chemotherapy and radiotherapy could prolong survival and improve the cure rate for patients with limited SCLC, the Lung Cancer Study Group initiated a prospective randomized trial of adjuvant surgical resection in 1983. [61] Most patients with limited-stage tumors were eligible for this trial, and it is important to note that patients with clinically evident mediastinal lymphadenopathy were not excluded from the study. Induction chemotherapy consisted of cyclophosphamide, doxorubicin, vincristine, and etoposide in the early phase of the trial, and cyclophosphamide, doxorubicin, and vincristine alone in the later phase. In the absence of toxicity or progressive disease, patients received five preoperative cycles of chemotherapy. They were then restaged and underwent medical assessment to determine their suitability for thoracotomy and pulmonary resection. Eligible patients were randomized to receive either surgical resection followed by radiotherapy to the chest and prophylactic cranial irradiation or to the same radiotherapy alone. Three hundred and forty patients entered the trial. The clinical response rate to chemotherapy was 68% (28% CR, 37% PR), but at the completion of induction chemotherapy, only 144 (42%) patients were randomized, 68 to receive surgery and radiotherapy and 76 to receive radiotherapy alone. Of the 68 patients who were randomized to surgery, six did not undergo thoracotomy, but eight patients had off-study surgery, so a total of 70 thoracotomies were performed. Fifty eight patients

were able to undergo resection of tumor (83%), and after pathologic review, 54 were thought to have had a complete resection (77%). A complete pathologic response was documented for 18% of patients who underwent surgery. Non–small cell pathology was found in 11% of patients. All randomized patients received radiotherapy to the chest, 50 Gy delivered over 5 weeks, and prophylactic cranial irradiation, 30 Gy over 3 weeks.

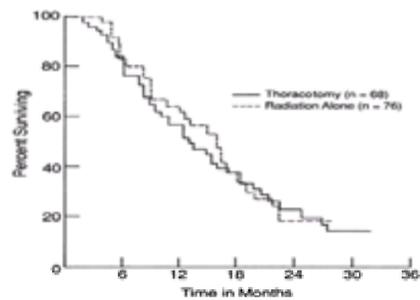
The median survival from enrollment for all patients was 14 months, and for the randomized patients was 18 months, with no difference seen between the groups in either median survival or long-term survival (Figure 55.9). Because only one-half of the randomized patients in this study underwent surgical resection, it is not possible to compare survival based on pathologic stage or TNM subgroup. The Toronto Group was the first to draw attention to the discrepancy between clinical staging and pathologic staging for patients with SCLC;[53] they showed that clinical staging could not identify subgroups of patients with different prognoses (Figure 55.10).[29] Similar results were found in this study in which patients were staged carefully at the time of surgery. For all patients, it was a protocol requirement to submit multiple lymph node samples, and a mean of 10 lymph nodes were submitted for each of the 70 patients who underwent thoracotomy. Clinical and surgical TNM stages after chemotherapy were the same in only 20 patients (29%), and patients most often moved into a more advanced stage.[62] For the surgical group, no difference in *resectability* was identified for patients in any T or N subgroup, although there seemed to be a trend toward unresectability for patients with T3 tumors (p = 0.08). All pathologic T and N subsets in the surgical patients had similar survival.


FIGURE 55.9. A comparison of survival for patients randomized to thoracotomy and radiation or radiation alone. (From Shields TW, ed. General Thoracic Surgery, ed 4. Baltimore: Williams & Wilkins, 1994, with permission.)
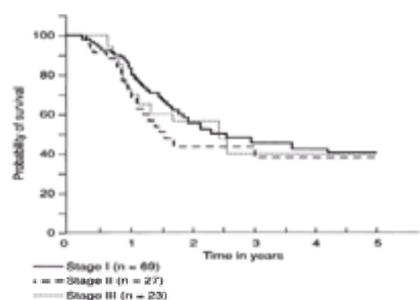

FIGURE 55.10. A comparison of survival by pretreatment clinical stage for 119 patients who underwent surgery for limited small cell lung cancer. (From Shepherd FA, Ginsberg RJ, Feld R, et al. Surgical treatment for limited small cell lung cancer. *J Thorac Cardiovasc Surg* 1991;101:385, with permission.)

Why was survival not improved by surgery, and how should we interpret the results of this Lung Cancer Study Group trial? The survival curves shown in Figure 55.9 were generated on an "intent-to-treat" basis, which is, of course, proper for any prospective randomized trial. It should be noted, though, that 10% of the patients did not receive protocol-specified therapy. Six patients randomized to surgery declined operation, and of perhaps even greater significance, eight patients in the nonsurgical arm underwent thoracotomy and surgical resection. In a small study of this size, a 10% protocol violation of this nature may have masked a small but significant survival advantage in one of the treatment arms.

The next question to be asked is why complete surgical resection was possible for only three-quarters of the patients subjected to thoracotomy. Although the combination of cyclophosphamide, doxorubicin, and vincristine was considered standard therapy at the time, a disappointingly low response rate of only 65% was seen in this study. With newer regimens that incorporate etoposide and cisplatin and concurrent radiotherapy administered early in the course of the disease, response rates of 90% or more are standard.[23,50,52,55,56] Might it have been possible that a more complete response to chemotherapy could have resulted in a higher complete surgical resection rate? The answer, of course, must remain speculative.

Seventeen percent of patients underwent "open-and-closed" procedures with no attempt at surgical resection. For some patients, the residual tumor was clearly unresectable at the time of thoracotomy. For other patients, though, the decision not to proceed to resection was based on scar tissue formation at the area of the primary tumor and in the mediastinum. Response to chemotherapy is often accompanied by an intense local schirrous reaction, which makes surgical resection more difficult. Tumors that may appear initially to be unresectable because of fibrosis may, in fact, be resected safely with careful dissection of the tumor bed and mediastinum. Because of the multi-institution, and indeed multinational nature of this large study, any individual surgeon operated on only a few patients. It is possible that had this study continued longer, the overall resectability rate might have been higher. This possibility is suggested by the observation that the resectability rate was higher for the Lung Cancer Study Group surgeons than it was in other centers that joined the trial at a later date. This difference may have resulted from their greater experience in operating on both small cell and non–small cell patients after induction chemotherapy.

Finally, patient selection undoubtedly played a large role in the ultimate results of this trial. All patients with limited disease were eligible to enter this study, with the exception of those who had supraclavicular lymph node involvement or pleural or pericardial effusions. This criteria meant that most patients had stage III (N2 and/or T3) tumors. It has long been recognized that surgery has very little role to play in the management of stage III patients with NSCLC, and this trial suggests that the same is true for patients with SCLC. Because many if not most patients with limited SCLC have mediastinal node involvement (often bulky) at the time of initial presentation, it is clear that surgical resection will have very little role to play for most patients with this disease. Nonetheless, it still remains possible that patients with early-stage disease (T1–2 NO, and perhaps nonbulky stage II) may benefit from a combined modality approach that includes surgery. Because so few patients fall into this subgroup (likely less than 10%), it will probably never be possible to undertake a prospective randomized trial to prove or disprove that surgery is appropriate in this setting.

SALVAGE OPERATIONS FOR PATIENTS WITH SMALL CELL LUNG CANCER

Treatment for patients who fail to respond to initial therapy, or who relapse after a primary response, remains unsatisfactory, and only brief periods of palliation and prolongation of survival are achieved with second-line chemotherapy and/or radiotherapy. This result has led several groups to evaluate whether surgery might be useful as salvage therapy for certain patients with limited SCLC.

Yamada et al.[59] offered surgery as salvage therapy to nine patients after chemotherapy for limited SCLC. Two patients had failed to respond to chemotherapy, six had achieved partial response, and one had experienced a complete response. Four of the nine patients achieved long-term disease-free survival, which ranged from 3 to more than 11 years. Surgery was undertaken 1 ½ to 2 ½ years after the initial diagnosis, and no details were provided to suggest why it was felt that surgery might be appropriate for this patient population. Three of the long-term survivors had stage I tumors. These results were very similar to another cohort of 11 patients reported in the same article, for whom surgery was offered as consolidation of the primary chemotherapy. Once again, long-term survival was limited almost exclusively to

patients with stage I tumors.

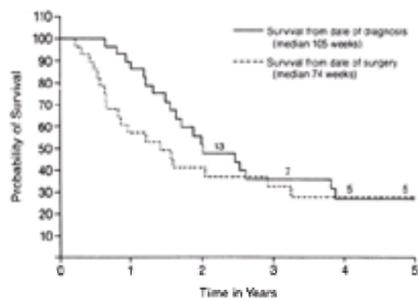
The Toronto Group reported their experience with salvage operations for 28 patients with limited SCLC. [67] Eighteen patients in their series had pure small cell tumors. Their overall median survival was 100 weeks, but only two patients survived 5 or more years (Figure 55.11).


FIGURE 55.11. Survival of twenty-eight patients who underwent salvage operations for small cell lung cancer. (From Shepherd FA, Ginsberg RJ, Patterson GA, et al. Is there ever a role for salvage operations in limited small cell lung cancer? *J Thorac Cardiovasc Surg* 1991;101:196, with permission.)

In view of these small numbers, surgery cannot be recommended for patients with pure small cell tumors that fail to respond or who relapse after initial standard therapy. The only possible exception to this recommendation might be the rare patient with a true stage I tumor. If surgery is contemplated for these patients, mediastinoscopy should be undertaken preoperatively because it is unlikely that any benefit will be derived if the tumor has spread to the mediastinal lymph nodes.

In a few patients, NSCLC may be found in combination with SCLC. In a review of 429 patients seen at Vanderbilt University, mixed histology tumors were identified in only nine (2%) cases. [63] Mixed histology tumors may be seen somewhat more often in patients who have been submitted to surgery, and some reviews have suggested that mixed histology tumors may be seen in more than 10% of cases. [26] In the series of salvage operations reported by the University of Toronto Group, [62] eight patients had mixed histology tumors. The median survival for that group was 108 weeks, and four of the eight patients achieved long-term survival after operation. Three of those four patients had pathologic stage I tumors. Because a few patients with tumors of mixed histologic type may be cured by surgical treatment, consideration should be given to a second biopsy for patients who have *localized* resistant SCLC. Although few patients fall into this favorable subgroup, it is important to take the necessary steps to identify them because curative therapy may be available.

Several authors have now reported that long-term survivors of SCLC are at increased risk of developing second primary malignancies. [29,30,31,32] In fact, a long-term survivor is more likely to have a second primary malignancy than a relapse of SCLC, and many of these tumors arise in the upper aerodigestive tract, in particular the lung. In the University of Toronto series, eight patients underwent surgical resection at the time of "relapse" following a long disease-free interval after initial treatment for SCLC. Two were found to have NSCLC, and both achieved long-term survival after surgery.

It is recommended, therefore, that cytologic or histologic identification should be undertaken for long-term survivors of SCLC who develop a new lung lesion. If NSCLC pathology is documented, then the patient should be staged completely. Surgery should be considered if the standard medical and surgical criteria for resection that would be applied to all patients with NSCLCs are met. Once again, it must be recognized that any individual oncologist will see few of these patients. Nonetheless, it is the responsibility of the medical oncologist to undertake the appropriate diagnostic tests and arrange for a surgical consultation because potentially curative therapy may be available.

SUMMARY

Many lessons have been learned from the retrospective, prospective phase II and randomized trials of surgery for patients with SCLC. It is clear that patient selection is the most important determinant in the results obtained. Almost all authors have emphasized the importance of stage and have shown that, similar to NSCLC the chance of long-term survival and cure is strongly correlated to pathologic TNM subgroup. In fact, any consideration of surgery for patients with SCLC should probably be limited to those with stage I and perhaps a subgroup of stage II patients. Therefore, before surgery is ever contemplated, patients should undergo extensive staging of the mediastinum, including mediastinoscopy. Many groups have now shown that combined modality therapy with surgery either before or after chemotherapy is feasible, the toxicity is manageable, and the postoperative morbidity and mortality rates are acceptable.

The results of the Lung Cancer Study Group trial indicate that surgical resection will not benefit the majority of patients with limited SCLC. In general, the phase II studies suggest that the criteria of operability that are applied to NSCLC are equally valid for SCLC patients. Surgery could be considered, therefore, for all patients with T1–2 N0 small cell tumors. Whether surgery is offered as the initial treatment or after induction chemotherapy does not seem to be important. Similar results were reported by Wada et al. [44] If a small cell tumor is identified unexpectedly at the time of thoracotomy, complete resection and mediastinal lymph node resection should be undertaken if possible. Chemotherapy should be administered postoperatively to all patients, even those with pathologic stage I tumors.

With respect to stage II disease, it is not possible to make generalized recommendations regarding surgery, and treatment decisions must be individualized. If surgery is to be part of the treatment approach, it should probably be offered as adjuvant treatment only to patients who have demonstrated response to initial systemic chemotherapy. As was recommended for patients with stage I tumors, complete resection should be undertaken if SCLC is identified unexpectedly at thoracotomy, even if hilar or intrapulmonary lymph nodes are found to be positive. These patients should then receive a full course of adjuvant chemotherapy when they have recovered sufficiently from surgery.

Surgery has little role to play for patients with stage III tumors. Even though chemotherapy can result in dramatic shrinkage of bulky mediastinal tumors, the addition of surgical resection does not contribute significantly to long-term survival for most patients, as shown conclusively by the Lung Cancer Study Group trial.

The final group of patients who may benefit from surgical resection are those with combined small cell and non–small cell tumors. If a mixed histology cancer is identified at diagnosis, then the initial treatment should be with chemotherapy to control the small cell component of the disease, and surgery should be considered for the non–small cell component. For patients who demonstrate an unexpectedly poor response to chemotherapy, and for patients who experience localized late relapse after treatment for pure small cell tumors, a repeat biopsy should be performed to rule out non-small cell pathology. Complete staging should be undertaken and surgery considered for stage I and II patients who are medically fit.

PROPHYLACTIC CRANIAL IRRADIATION IN SMALL CELL LUNG CANCER

DAVID L. BALL

The hypothesis is simple. Small cell lung cancer (SCLC) is a disseminated disease at diagnosis, best treated by systemic chemotherapy; subclinical disease in the central nervous system (CNS) is, however, in a sanctuary site protected by the blood–brain barrier; relatively low doses of prophylactic irradiation of the CNS may be able to eradicate this disease and so cure some patients who, having achieved a complete response (CR), would have relapsed in the CNS as the sole site of failure. Yet it has taken over 25 years since prophylactic cranial irradiation (PCI) was first tested in a clinical trial by the CALGB [1] before the expected survival advantage in patients with SCLC in CR could be detected by metaanalysis. [2] Even so, the role of PCI remains controversial, mainly because of concerns about late neurologic toxicity in long-term survivors. [3] Other unresolved issues include questions about the optimum dose and fractionation of the radiotherapy prescription, the timing of PCI and the net quality-of-life benefit for treated patients. It is the purpose of this review critically to examine the available randomized and nonrandomized evidence in relation to the role of PCI in SCLC and to make recommendations about its use in practice.

HISTORY

In 1971, Aur and colleagues published a paper which demonstrated that the problem of CNS relapse in children with acute lymphocytic leukaemia could be partly overcome by the administration of cranial irradiation and intrathecal methotrexate early in complete remission. [4] That the success of this approach might be reproducible in the treatment of SCLC in adults was first suggested by Hansen in 1973. [5] In the same article he reported a 40% crude incidence of cerebral metastases in 20 patients following treatment with chemotherapy and thoracic irradiation, with an apparent increase in incidence with greater elapsed time from diagnosis. However, he did not report how many patients had active disease at other sites, although it was mentioned that neurologic manifestations became the major symptomatic feature in eight of the patients with cerebral metastases. Hence, although CNS disease was a major problem for these patients, no evidence was provided to suggest that the CNS was a sanctuary site. At the time Hansen's paper appeared, the first randomized trial comparing PCI with no CNS prophylaxis had already been initiated by the CALGB in December 1972, but the results were not published until 1980. [1] By 1993, 10 randomized trials comparing PCI with no prophylaxis had been published. [1,6,7,8,9,10,11,12,13 and 14] Although PCI appeared to reduce the incidence of cerebral metastases in all studies, none revealed an associated statistically significant survival advantage. In retrospect this is not surprising—most of the studies were small: seven had fewer than 100 patients randomized and therefore had low statistical power. In only two small studies [11,14] was CR an eligibility criterion for randomization. As we shall see, patients in CR are those likely to obtain the greatest survival benefit if prevention of isolated CNS relapse can be achieved. It is now obvious that the early PCI trials suffered from a lack of sound statistical input at the study design stage, and, rather than contributing to a resolution of the controversy, the first generation of trials may have only delayed recognition of the value of PCI. The second generation of trials were, however, based on a knowledge of the magnitude of the problem of isolated CNS relapse as a cause of treatment failure and were, in statistical terms, powered accordingly. This forms the subject of the next section.

CENTRAL NERVOUS SYSTEM INVOLVEMENT AS A CAUSE OF TREATMENT FAILURE IN SCLC

The high frequency with which CNS involvement complicates the course of SCLC is well recognized. [15,16] The incidence will vary depending on the method of detection, according to the following ascending scale of sensitivity: clinical, nuclear brain scan, CT, MRI, and postmortem histopathology. High-quality CT and MRI have become readily available for staging purposes only over the last ten years, and it is conceivable that many of the patients randomized in the trials mentioned in the previous section may have already had brain metastases by current staging criteria. In theory, these patients are least likely to benefit from the relatively low doses of radiotherapy used for PCI, and their inclusion in trials may have tended to obscure the benefits of PCI for those patients whose disease was truly microscopic.

Three main sites of CNS involvement are recognized: brain, leptomeninges, and spinal cord. A review of the postmortem documented incidence of CNS metastases revealed that the brain was most commonly involved (42%) followed by the leptomeninges (14%) and spinal cord (12%). [15] In a large study of 641 patients with SCLC, 210 developed neurologic disorders during the course of their illness, including 178 cases with CNS involvement. [16] The frequency of involvement, as a percentage of the total population, was brain 24.8%, meninges 2.2%, and spinal cord 0.8%. In a nonrandomized study, PCI had no influence on the development of leptomeningeal or spinal cord metastases, although it did reduce the incidence of brain relapse. [17] Since a reduction of the incidence of meningeal or intramedullary disease is not the primary goal of PCI, the remaining discussion will concentrate on brain involvement as a cause of treatment failure.

The development of cerebral metastasis in the course of any malignancy is a catastrophic event because of the associated disabling morbidity and high mortality. The clinical features of brain involvement are likely to overshadow symptoms related to disease at other sites, even though that disease may be of greater bulk. Further, once cerebral relapse has been detected, it is unlikely that the patients will be subjected to a rigorous restaging, leading to an underestimate of the extent of extra-CNS disease. As a consequence, the frequency of the brain as a sole site of relapse may be overestimated.

In a recent review of 17 studies involving 1,202 patients with SCLC who did not receive PCI, the crude incidence of cerebral metastases was 25%. [18] The incidence was even higher (33%) in patients who had achieved a CR, possibly because of the longer survival of these patients and hence increased opportunity to develop brain metastasis. However many patients relapsed at multiple sites simultaneously, and in those studies in which first site of relapse was reported, the brain was the only site in 14%. In theory this is the proportion of patients who are most likely to benefit from eradication of subclinical disease by PCI—either curing those patients who have no disease elsewhere, or delaying death in those patients who do have extracerebral disease but who are more likely, in terms of competing risks, to die of their cerebral metastases. But as we have already seen, additional factors other than PCI—such as duration of survival—can influence the incidence of cerebral metastasis, and these need to be taken into account in any evaluation of the effect of PCI. We shall now consider these independent influences one by one.

Influence of Duration of Survival on the Risk of Cerebral Metastasis

In his original report, Hansen [5] noted an apparent increase in the risk of cerebral metastasis with lengthening survival. This observation was subsequently confirmed

by others.[19,20] In the study of Nugent and colleagues,[19] the overall incidence of CNS metastasis was 49%, but for patients surviving two years, the cumulative probability rose to 80%. In the Komaki study,[20] 32 patients not receiving PCI had a 58% calculated rate of clinical failure in the brain at two years. Arrigada and colleagues[21] using a competing risk approach, reported an overall rate of 67% of patients with brain metastases at two years after achieving CR and 45% with brain metastases as a first site of failure.

The crude incidence of CNS metastases will continue to increase with increasing duration of survival unless there is a time at which the cumulative actuarial incidence reaches a plateau. For example, if the median time to CNS relapse were three years and the median overall survival duration were six months, then, assuming exponential distributions, the expected crude incidence of CNS relapse would be 14% if all patients were followed to death. If the median survival were one, two, or three years, then the expected crude incidence of CNS relapse would increase to 25%, 40%, or 50% respectively. Thus, as systemic treatment improves, CNS relapse will be an increasing cause of treatment failure in the future.

Influence of Systemic Chemotherapy on the Risk of Cerebral Metastasis

On theoretical grounds, the CNS should be impervious to the effects of systemically administered chemotherapy because of the blood–brain barrier. Recent clinical observations suggest, however, that this may not be so, since chemotherapy has been reported to induce responses in cerebral metastases in untreated and previously treated patients.[22] Twelves and colleagues[23] assessed the response in 19 patients with symptomatic cerebral metastases who were treated with chemotherapy (cyclophosphamide, vincristine, and etoposide) and in whom cranial irradiation was withheld. Of 14 patients who had postchemotherapy scans, eight had a partial response and one a complete response; of the others, one had clinical neurological improvement, giving an overall response rate of 53%. The response rate of the intrathoracic tumor in these patients was 79%, suggesting either a partial "sanctuary site" effect or, alternatively, differences in chemosensitivity between primary and metastatic disease. In a study of similar design by Kristjansen and associates[24] in which the chemotherapy consisted initially of cisplatin, teniposide, and vincristine, the CT documented response rate of the cerebral metastases was almost identical at 52%.

In an autopsy study of 85 patients with SCLC, de la Monte and colleagues observed differences in the patterns of failure according to the type of treatment received.[25] No patient had been given PCI. The incidence of CNS involvement in patients treated with chemotherapy with or without irradiation was 50% to 55%; in patients treated exclusively with thoracic irradiation, it was 75%. Since this last group had a shorter survival than the patients treated with chemotherapy, it would have been expected that the incidence of CNS involvement would have been lower rather than higher. One possible explanation for this observation is that the chemotherapy acted directly on subclinical CNS disease to reduce the autopsy incidence. If subclinical CNS disease is as sensitive to chemotherapy as are clinically evident cerebral metastases, the development of CNS involvement in spite of chemotherapy may be at least in part a manifestation of generalized chemoresistance, and not purely a "sanctuary site" phenomenon.

Influence of Thoracic Irradiation on the Risk of Cerebral Metastasis

That thoracic irradiation may have an effect on the subsequent incidence of CNS metastases was suggested by the results of a Canadian trial designed to investigate the importance of timing of thoracic irradiation in patients with limited SCLC.[26] Patients were randomized to receive thoracic irradiation either early (week 3) with chemotherapy, or later (week 15). Complete responders were given PCI when they had finished chemotherapy. Cerebral metastases developed more frequently in patients who were randomized to late thoracic irradiation, even though they had a significantly shorter survival. The authors postulated that this result may have been due, in the early radiotherapy group, to eradication of chemoresistant clones of cells at the primary site before they had the opportunity to metastasize. If radiotherapy is delayed, these cells can disseminate and proliferate outside the radiotherapy target volume, unaffected by chemotherapy. The lower incidence of brain disease contributed to but did not entirely account for the superior survival of patients randomized to early irradiation.

Two other randomized trials have been published addressing the issue of timing of thoracic irradiation and in which the incidence of CNS relapse was reported.[27,28] In contrast to the Canadian result, neither showed an influence of timing of thoracic irradiation on the incidence of cerebral metastasis. It is not possible directly to compare the three trials because of differences in the timing of both thoracic irradiation and PCI, with the result that the contrasting results cannot be easily explained and so the effect of thoracic irradiation on the probability of CNS relapse must be regarded as an open question.

Reseeding of the CNS as a Cause of Cerebral Relapse

The discussion thus far has treated the CNS as a primary site of treatment failure, but it is conceivable that the CNS could be a site of secondary relapse, even after PCI, as a result of reseeding from uncontrolled extra-CNS disease. If this were so, it would have implications for the timing of PCI, in particular whether it is appropriate to administer PCI before complete response is achieved. This issue has been considered by Hoskin and colleagues in a study of 30 patients who had achieved a complete response and who then had PCI (20 Gy in five fractions).[29] Seven patients then relapsed in the brain after first relapsing elsewhere: six initially in the thorax, and the seventh in bone. Cerebral relapse occurred at a mean interval of 4 (range one to six) months after first relapse. Basing their arguments on clinically observed doubling times of SCLC, the authors claimed that a period of 15 months would be required from the time of reseeding until clinical relapse occurred. They therefore concluded that CNS relapse in their study was more likely to be due to inadequate PCI dose rather than secondary failure.

Summary

When patients with SCLC develop progressive disease, they usually do so at multiple sites. In one autopsy study, the mean number of metastatic sites ranged from 9.1 to 11.6, depending on the type of treatment administered[25]; in another, it was 4.2.[30] Cerebral metastasis as a sole site of first treatment failure may occur in fewer than 14% of patients; it is in this subgroup of patients that PCI has the potential to increase the probability of cure (in which case extracranial CR is a prerequisite) or at least to extend survival. Overall some 25% of SCLC patients may fail in the brain. Some survival benefit could be expected from PCI in these patients if more effective treatments of noncerebral metastases were available. Finally, it is now clear that factors other than PCI can influence the risk of CNS relapse, and unless these components of the treatment program are standardized in any comparative study evaluating PCI, their independent influence on the development of CNS metastases may be mistakenly interpreted as an effect of the PCI.

TREATMENT OF ESTABLISHED CEREBRAL METASTASES

If treatment could eradicate cerebral metastases at the time they become clinically or radiologically apparent, there would be less justification for PCI, although the relative morbidity of the two treatment approaches would need to be considered carefully. Of the treatments available, only surgery, radiotherapy, and chemotherapy are theoretically capable of inducing complete response, while corticosteroids are valuable for short-term symptom control. Because brain metastases are usually multiple,[16] surgical resection or stereotactic radiotherapy are seldom options, although they can be useful for solitary metastasis resulting from other histologic types of lung cancer.[31]

Radiotherapy

This is the most frequently used treatment modality. Table 56.1 is a compilation of reports in which the response of cerebral metastases to radiotherapy was reported in patients with SCLC. The overall symptomatic response rate was 68% in 441 patients assessed for response. This represents an overall rate of 57% in the 527 patients treated, many patients dying before an assessment could be made. Complete symptomatic responses were reported in 40% of 203 patients assessed or 32% of 251 patients treated. Response as measured by follow-up CT scanning was available in only two of the studies[32,33]: only 35% of 114 assessable patients were judged to have had a complete response.

First Author	Total No. of Patients	Population	No. Assessed for Symptomatic Response	Symptomatic Response Overall No. (%)	Symptomatic Response Complete No. (%)
Nugent 1979[34]	53	all	53	47 (67%)	NR
Cox 1980[35]	40	all	35	30 (79%)	15 (38%)
Baglan 1981[35]	47	all	35	33 (65%)	26 (65%)
Hirsch 1982[36]	24	all	24	11 (46%)	NR
Lucas 1986[37]	38	all	38	30 (66%)	8 (21%)
Scaler 1987[38]	144	all	85	54 (64%)	NR
Giannone 1987[39]	43	all	43	18 (30%)	NR
Mira 1988[37]	54	all	31	28 (93%)	14 (45%)
Carmichael 1988[38]	53	all	50	37 (67%)	19 (32%)

Nieder 1997[37]	54	all	34*	26 (76%)*	14 (37%)*
Postmus 1998[33]	22	CR	20	12 (60%)	6 (30%)*

NR, not reported; LD, limited disease; CR, complete response.
† includes 7 patients treated with dexamethasone alone.
* measurable response assessed by CT.

TABLE 56.1. RESPONSE TO THERAPEUTIC CRANIAL IRRADIATION IN SCLC

Most studies[34,35,36,37 and 38] included patients whose cerebral metastases were detected at diagnosis, a group for whom PCI could never have been possible and who may have had a better result because they benefit from chemotherapy as well as radiotherapy.[35,40] In one report[38] the complete response rate in patients treated for delayed metastases was only 28%, compared with 39% for patients with metastases at initial presentation. Hence the complete response rate in patients who develop delayed cerebral metastases may actually be 30% or less, taking into account those patients who may never be well enough to have radiotherapy.

Table 56.2 provides a representative list of some recently reported survival data following the diagnosis of cerebral metastases in SCLC. It is important to remember that not all patients actually received or completed radiotherapy, some being too unwell to have treatment, but they cannot be excluded in any evaluation of the impact of radiotherapy on survival. The results are uniformly poor, with most series reporting median survivals of approximately three months following the diagnosis of brain metastases. In the study by Ryan and colleagues,[41] only 8% of patients survived 12 months. The longer median survival of 5.5 months observed by Mira et al[37] can be explained by the selection of their patients, all of whom had their cerebral metastases detected at diagnosis, before chemotherapy. Absence of extracranial disease may also favor improved survival, as observed by Postmus and associates[33] although not observed by others.[42]

First Author	Total No. of Patients	Patient Population	Median Survival (months)
Mira 1988[37]	64	P	5.5
Ryan 1995[41]	122	All	3.3
Bach 1996[42]	101	X	3.6
Nussbaum 1996[46]	110	All	3
Priestman 1996[47]	103	X	2.6
Postmus 1998[53]	22	CR	4.7

P, includes only patients whose brain metastases were discovered at diagnosis; X, includes only patients given whole brain radiotherapy; CR, includes only patients with no evidence of extracranial disease.

TABLE 56.2. SURVIVAL FOLLOWING DIAGNOSIS OF BRAIN METASTASES IN SCLC

Perhaps the clearest picture of what is achievable when patients relapse in the brain is provided by the results of a prospective study (not listed in Table 56.1) in which 127 patients underwent three-monthly brain CT surveillance after the diagnosis of SCLC; PCI was not used, but radiotherapy was begun as soon as cerebral metastases were detected, whether symptomatic or not.[43] Brain metastases were detected in 56 patients: 16 at presentation, nine of whom were asymptomatic, and 40 on follow-up, 27 of whom were asymptomatic (i.e., detected by surveillance). When cerebral relapse was detected, the policy was to give 40 Gy in 20 fractions to the whole brain. Seven patients were never well enough to receive radiotherapy, and of the remainder, 26 died with active CNS disease or within a month of completing radiotherapy; hence 33 of 56 (59%) died because of or with active CNS disease. The patients whose disease was detected by surveillance showed no survival advantage in comparison with the symptomatic group; the authors concluded, therefore, that this approach was not an effective substitute for PCI.

Baglan and Marks[35] and Kristjansen and Kristensen[44] have each undertaken an exercise designed to measure the net benefit of PCI compared with delayed therapeutic irradiation. In both instances the authors concluded that the results of therapeutic radiation were such that the proportions of patients who will be left with neurologic symptoms at the end of their illness is the same whether PCI is given or not. However Baglan's and Marks's symptomatic response rates were estimated from a series including patients whose brain metastases were detected at diagnosis, thus biasing the conclusion in favor of therapeutic irradiation. Further, 17% of patients with brain metastases who either died, were lost to follow-up, or had a craniotomy with subtotal removal of metastasis were excluded from the symptomatic response calculations. The exercise took account of only symptomatic response and did not consider the poor survival (median three months) of patients following treatment of delayed metastases. Similarly, Kristjansen and Kristensen in their calculations used a rather high figure of 40% CR rate following therapeutic irradiation—30% may be more realistic; also they have not allowed for the fact that a percentage of patients who develop CNS metastases despite PCI may obtain a symptomatic CR as a result of subsequent therapeutic irradiation.

To make a realistic assessment of the value of PCI, both duration and quality of life need to be considered. Felletti and associates[45] attempted to assess the morbidity of cerebral relapse by measuring the time spent in hospital by patients who first relapsed in the brain and comparing it with the time spent by those who relapsed in the liver. Both groups had a similar survival from the time of relapse, but the brain group spent significantly more time in hospital; thus the authors concluded that brain relapse was associated with a greater morbidity. They commented that radiotherapy was relatively ineffective in producing an improvement in performance status in their patients, and that even if PCI did not influence survival, it might be justified because of its social and economic benefits.

Chemotherapy

In comparison with radiotherapy, there is much less information available on the efficacy of chemotherapy for cerebral metastases which have developed after previous treatment. In a phase II study of the EORTC Lung Cancer Cooperative Group, response and survival following treatment with teniposide were measured in 80 patients with cerebral metastases from SCLC.[46] The overall response rate was 33%, including 8% complete responses, but there were eight treatment-related deaths. These results appear inferior to those achieved with whole-brain irradiation, which the authors recommend is still the standard treatment.

Summary

The treatment of cerebral metastases which have developed following chemotherapy is unsatisfactory, resulting in short survivals and most patients dying of their cerebral cancer. Thus there appears to be ample justification for exploring ways of reducing the risk of patients' developing cerebral metastases.

RANDOMIZED TRIALS OF PCI IN PATIENTS IN COMPLETE REMISSION

From what has been said previously, it is clear that unless competing risks for death resulting from disease *outside* the CNS can be eliminated, the eradication of disease *inside* the CNS by PCI cannot be expected to increase the probability of cure in SCLC. Effectively this means that the population of patients who stand to gain from PCI, purely in survival terms, are the 14% of patients who, in the absence of PCI, relapse in the brain as the first and only site of relapse. Accordingly, if PCI is to be given "late," only those patients who are in CR should be selected. Yet only two of the early randomized trials specified CR as a criterion for randomization.[11,14] Both studies were too small to detect an influence of PCI on survival, although significant reductions in the incidence of cerebral metastases were seen in patients randomized to PCI. Several nonrandomized studies have suggested a survival advantage for patients in CR having PCI,[17,47,48] but this has not been a universal

finding.[49]

Table 56.3 a compilation of randomized trials of PCI in which only those patients who had achieved a CR were eligible. Only three of these studies were large enough to have some prospect of detecting a survival advantage. [21,50,51] Two of the trials were coordinated by the Institut Gustav-Roussy: the first trial (IPC85) had a more elaborate design and included a mandatory neuropsychological assessment, [21] but the second trial (IPC88) focused on overall survival and allowed for some variation in PCI dose.[50] IPC88 was closed prematurely when the results of IPC85 became available. All studies reported a reduction in CNS metastases in patients randomized to PCI, and this was highly significant in the IPC85 and European trials. [21,51] In the studies in which it was reported, survival was consistently better in the PCI arms, although this did not achieve statistical significance in any individual trial. However, when the results of seven separate randomized trials of PCI in CR were grouped together in a metaanalysis of individual data on 987 patients, there was a statistically significant 16% reduction in mortality in favor of PCI. [2] The survival benefit was consistent across the subgroups defined according to age, performance status, initial disease extent, and type of induction treatment. In terms of survival, however, PCI appeared to be less effective in women than in men. There was a trend for patients having higher doses or earlier PCI to have a greater reduction in risk of brain metastasis, but without an effect on survival. Thus the elusive survival benefit for PCI which had been predicted on the basis of first principles now appears to be supported by the available evidence. Interestingly the magnitude of the effect appears to be similar to what might have been expected based on what is known of the frequency of brain as the site of first failure.

TABLE 56.3. RANDOMIZED TRIALS OF PCI VERSUS NO PCI IN PATIENTS IN COMPLETE REMISSION

THE RADIOTHERAPY PRESCRIPTION: DOSE, FRACTIONATION, TIMING, AND TARGET VOLUME CONSIDERATIONS

The objective of PCI is to eradicate subclinical disease while minimizing the risk of producing injury to normal brain. To achieve the former requires sufficient dose and an adequate target volume. However, the risk of injury is dependent not only on total dose, but also on dose per fraction, especially for late effects. In this section we will consider one by one the individual parameters of the PCI prescription and their relevance to disease control and late toxicity.

Dose

A major advance in our understanding of the dose-response relationship for subclinical disease occurred with the publication in 1995 of an analysis by Withers and colleagues of the rates of reduction of metastatic disease according to dose of elective irradiation for various tumor sites. [52] In essence they were able to demonstrate that the percentage decrease in metastases bore a linear relationship to the dose of radiation administered, and that even very low doses of radiotherapy could be associated with a small reduction in the number of metastases. These observations fitted with a model in which the logarithm of the number of subclinical metastatic clonogens is distributed evenly in any series of patients between log 1 and log M, where M is the maximum number of cells that can remain clinically undetectable. Applying these principles to PCI, one would expect a greater reduction in CNS metastases in patients receiving higher doses, and in the only published study in which patients were randomized to two different dose levels of PCI (24 Gy in 12 daily fractions versus 36 Gy in 18 daily fractions), there was in fact a significantly greater reduction in cerebral metastases in the patients randomized to the higher dose. [51] The lower dose of 24 Gy was not associated with a statistically significant reduction in cerebral metastases, but the numbers in this study were small, with only 68 patients in the comparison. In the much larger French trials involving 505 patients in which the same dose of 24 Gy (given in eight fractions) was used, a highly significant reduction in metastases was detected. [50] The association between higher doses and reduced rates of cerebral metastases was confirmed in the metaanalysis, but there was no influence of dose on overall survival. [2]

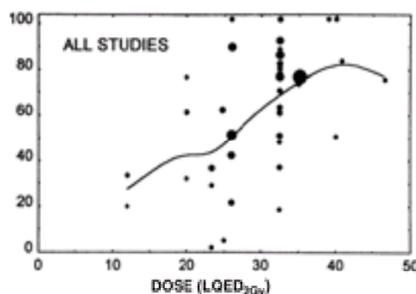
Suwinski and colleagues have performed an exhaustive analysis of the published literature on the dose-response relationship for PCI, using both randomized and unrandomized data[53] and the methodology originally described by Withers and colleagues. [52] Their results are shown in Figure 56.1, in which the reduction in metastasis rate has been plotted against dose normalized to equivalent 2 Gy fractions (LQED $_{2Gy}$), using an a/b value of 10 Gy for tumors. Using a fitted regression curve, there appears to be a shallow dose-response relationship, with doses of 35 Gy or greater being required to achieve a 70% reduction in brain metastasis rate. The authors then divided the data into two subsets: an "early" group, in which PCI was initiated less than 60 days after the start of treatment for the primary, and a "late" group, in which PCI was given after 60 days. The dose of radiation to achieve a 50% reduction in cerebral metastases was approximately 7 Gy greater for the "late" compared with the "early" subset. Further, it appeared that there was a 15 to 20 Gy threshold before any reduction in metastases could occur in the "late" group, unlike the "early" group, in which there appeared to be no dose threshold. The explanation advanced is that the longer PCI is delayed, the greater the increase in subclinical metastatic burden, thus requiring a higher dose to achieve the same effect. When the analysis was restricted to patients who received PCI after achieving CR, a reduction in metastasis rate was again apparent, but there was no clear dose response. The authors suggested that among other things the explanation for this observation may have been the variety of time delays between treatment of the primary and initiation of PCI among the different studies. Although the methodology of Suwinski et al. is open to criticism—particularly the inclusion of data from nonrandomized studies and the use of an assumed standard figure for brain relapse rates in the absence of PCI—their results do fit nicely with radiobiologic theory, and their study represents the best available information on the dose-response relationship of PCI in SCLC.


FIGURE 56.1. Percentage reduction in metastases rate as a function of dose equivalents given in 2 Gy fractions (LQED $_{2Gy}$). (From Suwinski R, Lee SP, Withers HR. Dose-response relationship for radiation therapy of subclinical disease. *Int J Radiat Oncol Biol Phys* 1995;31:353, with permission.)

Dose per Fraction

One of the major disadvantages of higher-dose PCI is the greater duration and cost of treatment. In order to keep treatment times short, it has been common practice to hypofractionate PCI so that there is little or no reduction in total dose. For example, in the aforementioned paper of Suwinski and colleagues, 42 separate studies of PCI were included in their analysis, and in only six of these were fraction sizes of 2 Gy or less used. [53] But the brain is a late-reacting tissue particularly sensitive to

size of dose per fraction, and if the risk of neurotoxicity is to be minimized, treatment should be limited to 2 Gy per fraction. [54]

It is important to remember that dose per fraction can be significantly influenced by the number of fields treated at each session. For example, for a typical skull separation of 14.5 cm, the peak dose (one field per day) for cobalt-60 photons will be approximately 40% higher than the mid-separation dose; for 4 MV photons, it will be approximately 25%. Hence, for a prescribed midplane dose of 2 Gy with cobalt-60, the dose in the peak region will be 2.8 Gy. The effect of fraction size will be amplified even further if the prescribed midplane dose exceeds 2 Gy. If the dose limit of 2 Gy per fraction is to be adhered to, all fields should be treated daily.

One approach to keeping overall treatment time short without increasing fraction size is to use accelerated hyperfractionation. Although this approach has shown promise in the treatment of intrathoracic disease, [55] there are no reports of the use of multiple fractions per day for PCI.

Target Volume

Figure 56.2 is a simulation film of the skull demonstrating the field limits for a typical PCI treatment. The cross wire AB represents a line drawn from the supraorbital margin (by palpation) to the external auditory meatus, which is commonly taken to represent the base of skull, but it can be seen that this provides no margin on the middle or posterior cranial fossae. The lower-level CD is more appropriate, and this example highlights the need to simulate all patients. The value of including a cervical extension to C2 is unknown. In the French trial[21] testing the value of PCI, a cervical extension to C2–3 was specified, but was not required in another European trial.[51]

FIGURE 56.2. Simulation film for prophylactic cranial irradiation.

Timing of PCI

Since the incidence of cerebral metastasis increases with lengthening survival, it could be reasoned that PCI might benefit the greatest number of patients if given at the earliest opportunity after chemotherapy. The analysis of Suwinski and colleagues suggests that the same dose of PCI has a greater effect if given early rather than later.[53] Patients in early PCI groups who achieve CR at the time of irradiation had a significantly longer brain-metastasis-free survival compared with those who had failed to achieve CR. There are two possible explanations for this observation, which has also been made by others. [17] One is that chemotherapy acts on subclinical cerebral micrometastases as well as disease at the primary site. It follows that patients achieving CR may obtain greater benefit from the effect of chemotherapy (over and above any effect of PCI) on any subclinical brain disease compared with patients not achieving CR, whose micrometastases are, like the primary site, partly chemoresistant. The second explanation is that patients not achieving CR have residual disease at the primary site which reseeds the brain *after* the subclinical metastases have been eradicated by PCI.[57] However this seems unlikely, since it has been calculated that it would require 30 months for a single clonogenic cell to become a clinically detectable metastasis. [29]

The most logical argument in favour of delaying PCI until a complete response has occurred recognizes that complete responders are the only patients for whom long-term survival is possible, while incomplete responders and nonresponders will die from uncontrolled extra-CNS disease. If PCI is given at the outset of systemic therapy, there will be additional patients treated who will never achieve CR—approximately 50%—for whom PCI is likely to be of little or no benefit. Further, there are dangers if chemotherapy and radiotherapy are given simultaneously, [58] and it may be safer to delay PCI until at least the first course of chemotherapy has been delivered. Although present indications are that PCI should be administered at the earliest possible opportunity after a CR has been achieved, a 1996 consensus report of a workshop of the International Association for the Study of Lung Cancer conceded that the optimal timing and dose of PCI are not known, and that further studies of these issues are required.[59]

TOXICITY

The acute toxicities of PCI include temporary hair loss, nausea and vomiting, and headache. [21] The risk of headache may be reduced by prophylactic administration of corticosteroids.

Late Neurotoxicity

Therapeutic radiation is a well-established cause of CNS injury. [60] The likelihood and severity of CNS injury are dependent on total dose and also on dose per fraction.[54] Since total doses in the vicinity of 60 Gy given in 2 Gy fractions have been used with comparative safety in the treatment of cerebral tumors, [61] it could not have been anticipated that lower doses in the range of 30 to 40 Gy, as used for PCI, might later be associated with irreversible long-term injury, even allowing for differences in dose per fraction. Of course, patients with brain tumors mostly have neurologic deficits prior to radiotherapy, and any late damage resulting from treatment may be obscured by preexisting deficits or features of recurrent disease. In contrast, patients for whom PCI is prescribed, are neurologically intact—or are they? Van Oosterhout and associates performed pretreatment neuropsychologic tests on 14 patients known not to have cerebral metastases and compared their performance with that of 14 matched controls.[62] The performance of the patients before they received any treatment was significantly inferior to the controls, but there was no deterioration in the performance of the patients when they were retested during and after chemotherapy and one and five months after PCI. Komaki and colleagues performed neuropsychologic tests on 30 patients with SCLC *before* going on to PCI after they had responded to chemotherapy and thoracic radiotherapy.[63] Twenty-nine of the patients had evidence of cognitive dysfunction. Excluding nine patients with a prior neurologic history, 84% had impaired verbal memory, 39% had frontal lobe dysfunction, and 21% had fine motor incoordination. It is not clear if the patients had CT or MRI of the brain at the time of testing to exclude cerebral metastases as a cause for these findings, but further studies on patients with limited disease who had not received any treatment revealed similar levels of impairment.[64] The authors concluded that the disease, rather than the treatment, somehow accounted for the cognitive deficits. However, in a study involving patients with breast cancer, some of whom had received adjuvant chemotherapy, there did appear to be an effect of chemotherapy on cognitive function, particularly in patients having high-dose therapy. [65] Thus the available evidence suggests that both the underlying disease itself *and* chemotherapy may be associated with neurologic complications independent of and preceding the administration of any PCI.

The first report of neurologic toxicity following PCI appeared in 1976 when a syndrome of poor attention span, recent-memory loss, and action tremor was described in 13 patients who had received PCI (20 to 30 Gy in 2 Gy fractions) concurrently with a doxorubicin-containing three-drug regimen. [66] The symptoms appeared within two to four months of commencing treatment and were reversible in all patients within four months of onset. An update published two years later confirmed the original observations in a larger number of patients; the symptoms were particularly severe in patients receiving 30 Gy, but the effects were not permanent. [67] That this syndrome had not been reported previously was probably due to the fact that this was one of the first reports of combined chemotherapy/radiotherapy involving doxorubicin, now recognized as a potent enhancer of radiation toxicity. Follow up of 13 long-term survivors (18 to 48 months) revealed no permanent clinical effects other than mild impairment of mental function in six patients, two of whom had not received PCI.[68] Subsequent reports of neurotoxicity following PCI confirmed the character of the syndrome—memory loss and ataxia—but also documented irreversibility of the symptoms and even fatalities. A review of 16 studies involving 691 patients revealed an overall crude incidence of significant neurologic toxicity in 19%. [16] A puzzling feature of the data was the wide variation in the reported incidence of toxicity—from under 10% in some reports[47,69] to 75% in another.[70] All studies were retrospective and most lacked information on pretreatment neurologic status.

Only a small minority of studies included for comparison a cohort of patients who had not received PCI. In two nonrandomized studies there was a greater incidence of neurotoxicity in patients who had received PCI compared with those who had not.[71,72] Although it is tempting to conclude that PCI was responsible for the syndromes observed, factors such as large fraction size and concurrent chemotherapy may have been contributory. For example, in one of these studies, from the Mayo Clinic, which reported a crude incidence of neurotoxicity of 18%, the majority of patients were given 36 Gy using 3.6 Gy fractions.[71] The incidence of neurotoxicity in the other study (of the SWOG database) was 23%, which was confined to the group that had received PCI, some of whom had received concurrent chemotherapy.[72] Combining all the studies in the review, the use of concurrent chemotherapy was associated with a 26% incidence of neurotoxicity, which was significantly greater than 12% (p = 0.001) in those studies in which it was known not to be given.[18]

The lack of consistency in the reported frequency of neurotoxicity following PCI thus raises questions about a cause-and-effect relationship even though some of the differences might be explained by details of the various PCI prescriptions, some of which would now be regarded as hazardous. The issues raised by the historical data clearly required resolution by carefully conducted prospective studies. One of the French randomized trials[21] and the European trial[51] incorporated a pre- and posttreatment neuropsychologic assessment into the study design. Not all patients underwent evaluation—78% in the French study and 43% in the European study—and so the results must be interpreted with caution. Both studies found high levels of impairment (59% and up to 41% respectively) in patients tested at randomization prior to receiving PCI. Retesting of survivors at two years in the French study and one year in the European study showed no significant differences in the cumulative incidence of neuropsychologic changes between treated and untreated groups. Furthermore, there were no significant differences in the incidence of cortical atrophy and ventricular dilatation on computed tomography scans of the brain between groups at randomization and two years later.[21] These reassuring findings in relation to the safety of PCI have now been supported by the results of recently published nonrandomized studies from the Netherlands,[73] Denmark,[74] and France.[75] Surprisingly, a large single dose of 8 Gy used as PCI in Manchester was not associated with any neurologic problems when assessment was performed at least 24 months after PCI, although 75% of patients were impaired on at least one of the four formal neuropsychometric tests used.[76] Indeed, when, in a collaborative study from the United Kingdom, the performance of the single-fraction patients was compared with that of individuals who had received a more conventional PCI regimen, they did better.[77] While there was a high frequency of impaired performance on formal neuropsychometric testing in the UK study, the majority of patients were well, with 95% having a performance status of one or less. There were insufficient patients who did not receive PCI for comparative analysis; however, the study demonstrated that the tests used were able to detect deficits of cognitive function that would have otherwise gone unnoticed.

It seems reasonable to conclude that late neurotoxicity in patients with SCLC who have received PCI may be multifactorial, and that injudicious choice of fraction size or the use of concurrent chemotherapy may be contributory. However, there is little evidence from randomized studies that PCI alone, delivered up to a dose of 36 Gy with classical fractionation, is a cause of late neurotoxicity. Nevertheless longer follow-up of the French[21] and European[51] studies will be required to confirm these preliminary findings. Since future studies of PCI are likely to focus on dose optimization,[78] the effects of treatment on cognitive and neurologic function will be critical end points. Careful pre- and posttreatment evaluation, including the use of tests capable of detecting subtle decrements in performance,[77] should continue to be part of the study design.

Finally, it should be remembered that neurologic complications of SCLC are common, occurring in 65% of patients in one large prospective study,[79] and that the vast majority of these were due to CNS metastases, which should therefore be carefully excluded before attributing the problem to treatment-related toxicity.

Quality of Life

The ideal evaluation of PCI would be a trial which takes into account not only survival but also the morbidities of treatment and cerebral relapse in both treatment arms. An example of this kind of evaluation is "TWiST" analysis, which measures the total time without disease-related symptoms *and* treatment-related toxicity.[80] None of the randomized trials of PCI has included such an analysis, but the European trial[51] did measure quality of life using the Rotterdam Symptom Checklist in a minority of the patients randomized. For all of the six commonest symptoms reported, deterioration was worse in the "no PCI" than in the "PCI" group, but the numbers were too small to draw firm conclusions.

As it seems likely that future studies of PCI will focus on fine-tuning the details of the PCI prescription, quality-of-life assessment and TWiST-type analysis will be essential components of trial design.

CONCLUSIONS

There is now incontrovertible evidence that PCI reduces the incidence of cerebral metastases in SCLC. There appears to be a shallow dose-response relationship for this effect without a detectable threshold below which some effect does not occur, especially if PCI is given early in the course of the disease. Lower doses may be required to achieve equivalent effects if PCI is given earlier rather than later. However, the only patients who can benefit in terms of cure are those who will achieve or have achieved CR, and so giving PCI early (before CR) increases the number of individuals who will be irradiated without benefit.

Although several randomized trials of PCI in patients who have achieved CR have shown that a reduction in the rate of cerebral metastasis is associated with improved survival, none has shown a statistically significant survival advantage. But when the data from all studies were combined in a metaanalysis, there was a 16% reduction in mortality in favor of PCI which was significant at the level of p = 0.01. Prospective studies of cognitive function using formal neuropsychometric tests in two of the randomized studies has not supported anecdotal observations which suggested that PCI might be a cause of serious delayed neurotoxicity, but further follow-up is required to confirm these early results.

In light of all the preceding considerations, it would seem obligatory for clinicians to inform their patients of the known benefits and potential toxicities of PCI, particularly those individuals who have achieved CR. Then it should be a case of the question being "not who needs PCI but who wants PCI?" as in the title of a recent editorial.[81] Those individuals who then wish to proceed with PCI should be offered a dose in the range of 30 to 36 Gy given in conventional 2 Gy fractions, but only at a time when chemotherapy is not being administered.

PALLIATIVE CHEMOTHERAPY

MARK R. MIDDLETON
NICHOLAS THATCHER
PENELOPE HOPWOOD

The majority of patients with small cell lung cancer (SCLC) or advanced non-small cell lung cancer (NSCLC) will die of their disease. In the United States around 178,000 patients are diagnosed with lung cancer annually, and of these the disease kills 160,000. [1] Thus most treatment is delivered with palliation rather than cure in mind. In NSCLC this has been used as an argument against the use of chemotherapy, which is perceived as providing little survival benefit at the expense of unacceptable toxicity. However, modern chemotherapy has an important role to play in improving quality of life, besides offering modest but important improvements in survival. The recognition of this has required a shift away from solely traditional measures of efficacy in evaluating new drugs. Many studies now incorporate assessments of symptom relief and quality of life, as well as the usual endpoints of response, toxicity, and survival.

In SCLC the benefits of chemotherapy are more clear-cut. Improvements in median survival, even in extensive-stage disease between eight and ten months against an anticipated six to eight weeks untreated, have made chemotherapy the accepted standard for this group of patients. The lung cancer population is largely elderly and often frail as a result of other illnesses. There is therefore a need to improve upon existing treatments, in particular increasing their tolerability so that more patients can benefit from them.

Choosing the optimal palliative therapy is complex. A balance must be struck between the benefits and risks of treatment that is not skewed in favor of the former, as it often is where cure is unrealistically attempted. Patients who often have considerable symptoms from their disease as well as intercurrent illnesses cannot be expected to tolerate the side effects inherent in more aggressive approaches. This is not to promote the selection of the most suitable regimen on subjective criteria. Rather, there is as great a need for objective measures in selecting patients for palliative treatments as there is in the curative scenario.

There are also several new agents available to improve the treatment of lung cancer patients, but further progress will depend upon changes in the nihilistic attitude of nononcology physicians and funding organizations towards chemotherapy. The acceptance of enhanced quality of life as a sufficient criterion for licensing a drug and the continued evaluation and promotion of the cost-effectiveness of the approach are also important.

ASSESSING THE OUTCOME OF PALLIATIVE CHEMOTHERAPY

Response Rate and Survival

These have traditionally been the criteria by which the efficacy of new treatments has been assessed. Although they continue to play a role in the evaluation of palliative therapies, they can no longer be considered in isolation, for palliation of symptoms can occur in the absence of a conventionally defined response to treatment. Objective response to chemotherapy in NSCLC, as measured by WHO criteria, occurs in only 30% to 40% of patients, and survival benefits are modest. [2] However, there are now several studies showing that, with this objective response rate, up to 70% of patients report relief of symptoms with modern chemotherapy. [3,4] and [5]

Toxicity and Disease-Related Symptoms

The assessment of treatment-related toxicity has been codified so that side effects are recorded systematically and different therapies can be compared from trial to trial. Although a powerful tool, the Common Toxicity Criteria scheme ignores the impact of a particular side effect or symptom upon the individual; neither does it measure the combined effect of symptoms. Thus the traditional means of evaluating chemotherapy use end points that bear little relation to patients' experience of treatment. This is not to decry the use of these measures in the evaluation of new therapies, but there is a need to take into account their impact on the patient as well.

Quality of Life

The criteria that define tumor response are straightforward, as are those related to treatment toxicity, and the concepts of time to progression and overall survival are readily understood. Health-related quality of life is a more abstract entity that is much harder to define. It comprises several elements, including physical, psychological, social, emotional, and economic well-being. There are now several instruments that allow systematic collection of quality of life data so that disease-related symptoms, the side effects of treatment and their significance to the patient can be evaluated.

Although observers can readily assess some aspects of quality of life, such as physical functioning and some symptoms, there is evidence to suggest that health professionals' and other carers' interpretation of quality of life differs from that of the patient. [6,7] Since the data collected are largely subjective, it would seem best that the patients provide the information themselves. Initially studies used simple diaries to gather data. This proved very effective, for example, highlighting the (previously unsuspected) differences of dysphagia between radiotherapy regimens providing similar palliation in NSCLC. [8] However, this method is time-consuming to interpret and difficult to generalize between treatments because it does not provide systematic data. The usual method of evaluating quality of life now is by multidimensional self-report questionnaire. Depending on the design used, patients either select one of a limited number of answers to questions on their health or indicate the severity of a symptom on a visual analog scale. Several such instruments are available (Table 57.1) many of which have been validated against other indices of quality of life such as performance status, weight loss, and toxicity of treatment. This approach is acceptable to patients; indeed, many react positively to the chance to become involved in the assessment of their treatment.

TABLE 57.1. SELECTED EXAMPLES OF QUALITY-OF-LIFE INSTRUMENTS

The European Organisation for the Research and Treatment of Cancer (EORTC) QLQ-C30 is a well-developed example of such a questionnaire. [9] This examines quality of life across five functional scales (physical, role, cognitive, emotional, and social), three symptom scales (nausea and vomiting, fatigue, and pain), and a global scale. There are also several other measures, and these core questions are supplemented by disease-specific modules (in the case of lung cancer, designated LC13).[10] This instrument represents only one of a number of valid scales, but the QLQ-C30 has the advantage that it has been tested successfully across several languages and cultures.[11]

There are several problems with quality-of-life assessments, not least the abysmal rate at which they have been incorporated into clinical trials. A review of four oncology journals in the period 1980 to 1995 found only 13 studies out of 871 incorporating quality-of-life assessments—and only four of the 13 were considered adequate in terms of the quality-of-life data gathered. [12] Data collection is often patchy, particularly in the palliative setting, because of limited compliance, patient attrition, and inadequate infrastructure to support studies. [13] Acute toxicities may be missed because assessments are usually made prior to each cycle of treatment, when the toxicity of the last cycle is up to three weeks past. Few trials gather data once interventions have ceased, so there is even less information about the duration of changes in quality of life. Finally, the profusion of instruments for assessing quality of life (over 50 have been used in lung cancer studies published to date) makes it difficult to draw comparisons between studies, and this is further hindered by a lack of agreed criteria for reporting results. [9] Nevertheless, quality-of-life research is critical in the evaluation of the impact of new treatments, particularly in the palliative setting where a limited improvement in survival may not be the patient's sole consideration. [14,15]

Economic Analysis

Part of the resistance to the use of palliative chemotherapy in lung cancer stems from the perception that it is expensive and, by implication, not cost-effective. However, the costs of chemotherapy are small in comparison with those of making the diagnosis and of terminal care. Chemotherapy accounted for less than 10% of the costs of care over one year in the Canadian model of lung cancer management.[16] There is also trial evidence that chemotherapy results in fewer days in hospital or hospice and less need for radiotherapy, saving costs even in NSCLC. [17,18] The need to demonstrate that palliative chemotherapy is worth it to funding bodies will persist, particularly where newer, more expensive, agents with perhaps less toxicity replace established drugs.

PALLIATION OF ADVANCED NON–SMALL CELL LUNG CANCER WITH CHEMOTHERAPY

Patient Selection

Multivariate analyses have identified a number of independent factors that predict the outcome of treatment. The presence of extrathoracic disease, some locations of metastases (e.g., brain), and weight loss are associated with a poor prognosis. However, neither age nor histological subtype has been shown consistently to affect outcome.[19,20,21,22 and 23] Patients suitable for palliative chemotherapy are those with stage IIIB or IV disease and fair performance status (ECOG 0 and 1, and possibly 2). Clearly, some patients with localized disease are not fit for surgery and so will be candidates for radical radiotherapy with or without chemotherapy. Patients with even moderately impaired performance status fare less well with chemotherapy: survival is reduced and the toxicity of treatment increased compared with unimpaired patients.[24] Thus chemotherapy should be offered only to patients in relatively good condition. This may change as new drugs with proven activity and fewer side effects, such as gemcitabine, become available.

Effect on Survival

The first studies, in the 1960s and 1970s, showed no benefit from chemotherapy and, as a result, radiotherapy became the standard treatment for palliating NSCLC. However, these trials used drugs that are now considered inactive. [25,26] More modern regimens have since been tested against best supportive care, with better results (Table 57.2). Supportive care was not consistently defined but was usually taken to mean any palliative therapy offered to the patient, excluding cytotoxic chemotherapy but including radiotherapy and noncytotoxic medication. The trials are difficult to interpret, as the case mix of patients was very variable, with survival times varying between 4.2 and 8.7 months in the supportive-care arms. The duration of chemotherapy also varied considerably, as did the criteria for the discontinuation of treatment. However, large metaanalyses have confirmed that platinum-based combination chemotherapy reduces mortality in advanced NSCLC, with an improvement in survival of around two to three months and an absolute increase of 10% (from 16% to 26%) in the proportion of patients surviving one year.[27,28]

Reference	Regimen	Patients	Responses (%)	Median Survival (months) CT	Median Survival (months) BSC	1-Year Survival (%) CT	1-Year Survival (%) BSC	p Value

TABLE 57.2. CHEMOTHERAPY VERSUS BEST SUPPORTIVE CARE IN LOCALLY ADVANCED OR METASTATIC NSCLC IN OVER 100 PATIENTS

Effect on Symptoms and Quality of Life

Although there have been few trials that measured patient-generated quality of life on chemotherapy and none as yet published with it as the primary end point, there is evidence that most patients either improve or preserve their performance status during treatment. In one report on the MIC (mitomycin C, ifosfamide, cisplatin) regimen, only 9% of patients experienced deterioration in quality of life on treatment, and 30% improved. [4] Similar results have been observed for other platinum-based regimens and with single-agent therapy. [39,40 and 41] It is also well documented that improvements in symptoms are not confined to patients with an objective response. [3,41,42 and 43] Symptoms relief with chemotherapy is comparable with that achieved by radiotherapy (Table 57.3) and decreases the need for palliative irradiation by around one third. [16,18] Trials are now being performed that examine symptom relief over time, improving on the data that are currently available. [18]

Reference	Treatment	Patients	OR (%)	MS (months)	Cough	Haemoptysis	Dyspnoea	Pain	Anorexia
MRC/CLGP	Radiotherapy	369	3	4.4	60	84	63	28	67

OR, overall response; MS, median survival; NR, not recorded; MIC, mitomycin C, ifosfamide, cisplatin; MVP, mitomycin C, vinblastine, cisplatin.

TABLE 57.3. SYMPTOMATIC RELIEF IN ADVANCED NSCLC: STUDIES OF OVER 100 PATIENTS

Combination Therapy

Although there are studies showing significant differences in survival in favor of combination treatment, there is as yet no consistent trial evidence that this is superior to single-agent therapy, other than with vinorelbine. [44] Despite this, most investigators use combination regimens as controls in randomized trials: usually MIC or MVP (mitomycin C, vinblastine/vindesine, cisplatin) in the U.K. and platinum with paclitaxel or vinorelbine in the United States and mainland Europe. Attempts to improve outcome with dose intensification have yielded enhanced response rates but no clear survival advantage. Alternating combinations of chemotherapy have shown no advantage over their sequential administration—with a single exception. [22] Nor has any benefit been shown with increased treatment duration. Indeed, three cycles of the MVP regimen produce the same symptom relief and survival as six, but with considerably less toxicity. [45]

Attitudes to Chemotherapy

There remains a belief among physicians and other health professionals that chemotherapy inevitably causes deterioration in quality of life and performance status. Early trials in NSCLC did not show the improvements in survival seen with SCLC. Indeed, the earliest regimens, based upon alkylating agents rather than cisplatin, appeared detrimental.[25,26,38] Physicians' attitudes to chemotherapy for NSCLC were therefore profoundly negative, and have tended to remain so. [46] Subsequent combination chemotherapies have yielded some improvements in survival, as well as symptom relief as described above. Unfortunately, attitudes have not changed despite the now-abundant evidence that chemotherapy is superior to supportive care: in 1995, 79% of Canadian oncologists felt that there was no specific treatment for advanced NSCLC, a figure little changed from 1986. [47] Furthermore, this study showed that there was a tendency for physicians to overestimate the value of radiotherapy, the main plank of supportive care, and undervalue the potential contribution of chemotherapy. Patients, on the other hand, are prepared to tolerate toxic treatments for even short extensions in survival times, for symptom relief, or for an improvement in quality of life. [14,15,48]

Thus trials comparing chemotherapy with best supportive care have been, and continue to be, essential in promoting the case for palliation of advanced NSCLC with chemotherapy, particularly with reference to poorer-performance-status patients. In the fitter patient, where the benefits of chemotherapy are more clearly defined, research concentrates on the incorporation of new agents into combination regimens to improve outcomes. In either scenario it is vital that future studies assess the quality of life of patients during and after treatment in order to understand and decide upon the best possible palliation.

PALLIATION OF SMALL CELL LUNG CANCER WITH CHEMOTHERAPY

SCLC is exquisitely sensitive to chemotherapy, and this is the treatment modality of choice both for palliative or curative therapy, although radiotherapy too has an important role. Three quarters of patients respond to treatment, but relapse usually occurs within a few months, so that fewer than 10% of patients overall are alive two years after diagnosis.[49,50] Thus chemotherapy for SCLC is largely palliative. Chemotherapy is also effective in improving localized complications such as superior vena cava obstruction and pleural effusion. [50]

Patient Selection

As with NSCLC, the stage of disease and patient performance status are important predictors of prognosis and treatment outcome. [51] However, in SCLC the precise tumor stage is less important than the distinction between extensive and limited-stage disease. Limited-stage disease is defined as tumor confined to one hemithorax, including the mediastinum and/or supraclavicular nodes bilaterally, that is, contained within a single radiation field. This remains a useful distinction, despite evidence that SCLC disseminates early and that systemic metastases are often present in cases where screening for these is negative. [52] There are also several independent biochemical prognostic factors that predict prognosis, including lactate dehydrogenase, alkaline phosphatase, sodium, and bicarbonate. [53,54] These biochemical parameters, the disease stage, and patient performance status have been incorporated in scoring systems in selecting candidates for different therapeutic approaches (Table 57.4).[54,55] Again, age is not a predictive factor[56] but, as in NSCLC, the patient population is often frail: a consequence both of the aggressive nature of SCLC and the frequency of comorbid nonmalignant disease. Thus similar problems of balancing potentially toxic treatments against symptom palliation in a relatively unfit population persist. In general, prognostic factors are taken into account in determining whether treatment will be aimed at long-term survival, at cure, or at palliation, and the patient's performance status will then guide the chemotherapy regimen to be used.

Manchester Score[54] Criteria	Ontario Cancer Institute[55]
+1 if LDH greater than ULN	Algorithm following
+1 if extensive stage	Stage (very limited/limited/extensive)
+1 if sodium is under 132 mmol/L	Gender (male/female)
+1 if KP is under 60	LDH (normal/elevated)
+1 if Alk phos over 1.5 × ULN	WBC (if limited stage)
+1 if bicarbonate is under 24 mmol/L	Alk phos, liver metastases (if extensive)
Groups (median survival in weeks)	
1: score 0,1[50]	A: limited-stage patients only[55]
2: score 2,3[37]	B: limited- or extensive-stage[48]
3: score 4+[14]	C: limited- or extensive-stage[37]
	D: extensive-stage only[24]

TABLE 57.4. SMALL CELL LUNG CANCER: EXAMPLES OF PROGNOSTIC SCORING SYSTEMS

Single-Agent versus Combination Chemotherapy

Combination chemotherapy has proved superior to single-agent treatment in most trials addressing this question. [57,58] Response rates, particularly complete response rates, are higher and median survival is longer. Combinations of the drugs that have shown single-agent activity are used. [59,60,61 and 62] Vincristine excepted, their dose-limiting toxicity is myelosuppression, and therefore combinations of up to four agents have been used (Table 57.5). The success in extending median overall survival with these regimens has meant that, until now, this and response rate have been the criteria in assessing efficacy. Although toxicity has also been well documented with these regimens, there are few studies reporting quality-of-life outcomes with combination treatments.

Regimen	Patient Number	OR (%)	CR (%)	MS (months)
CAV[59]	140	51	7	8.3
ACE[60]	73	59	13	6.4
	89	45	10	5.8
CAVE[61,71]	110	66	26	11.9
PE[59,62]	140	61	10	8.6
	156	57	15	9.5
	150	61	14	9.9

CAV, cyclophosphamide, doxorubicin, vincristine; ACE, doxorubicin, cyclophosphamide, etoposide; CAVE, cyclophosphamide, doxorubicin, vincristine, etoposide; PE, cisplatin, etoposide; OR, objective response; CR, complete response; MS, median survival.

TABLE 57.5. STANDARD COMBINATION CHEMOTHERAPIES IN EXTENSVE SMALL CELL LUNG CANCER

If combination chemotherapy is used, there remains the question of how many drugs are needed to give the best palliation. Most trials that have sought to compare four-drug regimens with three- or two-drug treatment have not addressed palliation specifically, although there are three that have. In a 310-patient randomized trial, the Medical Research Council (MRC) Lung Cancer Working Party compared ECMV (etoposide, cyclophosphamide, methotrexate, vincristine) with EV (etoposide, vincristine) in poor-prognosis SCLC. [63] No differences were seen in median survival (141 versus 137 days) or one-year survival (12% versus 10%), but toxicity was greater with the four-drug treatment, the main differences being in the rates of mucositis and of myelosuppression. Despite this, ECMV provided better symptom palliation and better relief of psychological distress, although patients reported more lethargy. The same group also compared ECMV with EI (Ifosfamide, etoposide) over six cycles, as part of a study that also assessed the effect of three cycles of ECMV. [64] Quality of life was measured by daily diary card and physician report. Survival and symptom palliation were similar in all the arms, but patients on EI reported less dysphagia and better overall condition between cycles of treatment. The third study, conducted in Switzerland, sought to compare weekly carboplatin/teniposide with standard chemotherapy (cyclophosphamide, doxorubicin, vincristine [CAV] alternating with cyclophosphamide, lomustine, methotrexate, and vincristine). This closed early when inferior survival in the less-intensive two-drug arm became apparent.[65] For now, too few data exist to indicate a preferred combination treatment for the palliation of SCLC. CAV and PE (cisplatin, etoposide) are the most widely used and are often included as control treatments in randomized trials.

Since response to treatment relates to dose intensity, it would seem worthwhile to investigate means of attenuating the toxicity of combination treatments while maintaining the latter. In a London study of largely poor-performance-status patients, low-dose/high-frequency ACE (doxorubicin, cyclophosphamide, etoposide) was shown to be as effective as the standard three-weekly schedule in terms of response rate and overall and one-year survival. [66] Although toxicity was unaffected by schedule, quality of life (measured by daily diary card) was better in the low-dose/high-frequency arm. This demonstrates once again the added value of quality-of-life measures in evaluating palliative therapies, for the conventional outcome measures suggested that the schedules were equivalent.

Dose Intensity in Extensive SCLC

Preclinical models show a clear relationship between cure rate and dose intensity in SCLC. [66] Early clinical trials failed to establish this in clinical practice, but although dose intensification was intended, actual dose delivery often differed little between study arms. [67,68] Evidence is now emerging that growth-factor-supported dose intensification can have a significant impact upon survival, [69,70] but this approach to treatment demands a fit patient, usually with limited disease. Indeed, in extensive-stage disease, investigators have been thwarted by their inability to intensify dose owing to excessive toxicity. [71] Where intensification has been achieved in extensive-stage patients, this has had no impact upon survival, as shown in two recent trials comparing CODE (cisplatin, vincristine, doxorubicin, and etoposide) with alternating CAV and PE.[72,73] On the other hand, patients with extensive disease but good performance status benefited from dose intensification of the V-ICE regimen (vincristine, ifosfamide, carboplatin, etoposide). [74] Thus intensified therapy cannot be justified where cure is not sought.

Another approach has been to use alternating non-cross-resistant chemotherapies to enhance response rate, according to the Goldie-Coldman hypothesis. [75] Trials of PE alternating with CAV compared with one and/or other regimen alone have suggested a survival benefit for alternating treatment. [76,77] However, in the Japanese study this was confined to patients with limited-stage disease, and it failed to achieve significance in the Canadian trial of patients with extensive SCLC when those with locoregional disease were taken into account. A large United States study in extensive-stage patients found no difference in response rate or survival between six cycles of CAV, four cycles of PE, or three cycles of CAV alternating with three of PE. [59] Similarly, a German study of alternating CAV and IE (ifosfamide, etoposide) versus sequential IE then CAV found no difference in survival. [78] At present, alternating chemotherapy has no clear role in SCLC.

Duration of Treatment

There have been several studies examining the optimum number of chemotherapy cycles in SCLC, but all have used survival rather than symptom palliation or quality of life as their yardstick. A study by Cullen and others [79] showed a survival advantage for extensive-stage patients who responded to six cycles of CAV chemotherapy if they went on to receive a further eight treatments (372 versus 259 days; p = 0.006). However, this is the only randomized trial in which prolonged chemotherapy has shown an advantage in the palliative setting. Several other studies involving extensive-stage SCLC have shown no advantage either to more cycles of chemotherapy at induction[64,80,81,82 and 83] or to maintenance chemotherapy for responding patients.[84,85,86 and 87] Prolonged chemotherapy is associated with increased toxicity, therefore the weight of evidence favors a short induction treatment (of four to six cycles) with further therapy held back for the treatment of symptomatic disease at relapse (see below).

Treatment of Poor-Prognosis, Poor-Performance-Status Patients

Although intravenous combination chemotherapy is accepted as the optimal approach in SCLC, the assumption that its use inevitably causes quality of life and performance status to deteriorate has led to some reluctance to use it on frail patients. The convenience, tolerability, and activity of single-agent oral etoposide have made this the preferred treatment for the purely palliative setting. Etoposide is schedule-dependent, with an overall response rate of 50% to 70%, depending on the regimen used and the population treated, and median survival is extended to nine or 10 months. [88,89 and 90] There are now three randomized trials comparing single-agent etoposide with intravenous combination chemotherapy, two of which examined symptom palliation or quality of life as well as conventional end points (Table 57.6). The Medical Research Council study was ended early as a result of interim analysis by an independent data-monitoring board. The study recruited patients with poor performance status. Symptom palliation, the primary end point, favored combination treatment (50% versus 39%), as did response rate and median survival.[91,92] Similar results were obtained in the London group's study of patients with extensive-stage SCLC and a poor prognosis or age of over 75 years. Quality of life was assessed using the Rotterdam Symptom Checklist and diary cards, and was shown to favor the combination regimen—with the exception of nausea and vomiting.[93] A smaller Danish study confirmed these findings in patients with extensive disease under the age of 71. [94] Together these studies show that combination chemotherapy is the treatment of choice, even for the less fit SCLC patient.

Reference	Total No. Patients	Therapy	OR (%)	MS (months)	5-Year Survival (%)	p value
MRC[91,92]	370	E	51	4.3	5	0.03
		EV or CAV	77	5.4	14	
London[93]	155	E	33	4.3	11	<0.05

TABLE 57.6. SINGLE-AGENT ETOPOSSIDE VERSUS COMBINATION CHEMOTHERAPY FOR POOR-PROGNOSIS SMALL CELL LUNG CANCER

Salvage Chemotherapy

Patients who respond to induction chemotherapy generally relapse within a few months of completing treatment. There is evidence that chemotherapy can offer useful palliation in these circumstances, and this includes (unusually for SCLC) information on symptom relief and quality of life. Radiotherapy offers useful palliation, better than that achievable with chemotherapy in an early 1980s study,[95] but the increasing use of combined-modality first-line treatments means that this is not always an option. Response to second-line chemotherapy is better the longer the progression-free interval after induction therapy.[96] Normal blood parameters (specifically hemoglobin and lactate dehydrogenase) and good performance status are also associated with better response.[97]

PE can salvage patients treated with CAV chemotherapy—around half will respond.[96] Indeed, this finding is the basis for the alternating chemotherapy approach discussed above. However, with platinum-based regimens taking over from CAV as first-line treatment for limited-stage SCLC, the latter is coming into common use as a salvage therapy—to the extent that it provides the control arm in trials of treatments for relapsed SCLC.[99] The results with CAV are not particularly promising: around 20% of patients have an objective response, although more achieve symptom relief. Thus many of the newer agents discussed below are being tested as single-agent second-line treatment, and have shown activity in this setting. Topotecan, for example, has recently been shown to have similar efficacy, both in terms of symptom control and survival, and tolerability to CAV in the treatment of recurrent SCLC.[99] The taxanes, vinorelbine and irinotecan, have also been studied (Table 56.7).

Agent	NSCLC		ED-SCLC		Relapsed SCLC	
	RR	n	RR	n	RR	n
Gemcitabine[18,100]	20	332	27	29	--	
Topotecan[99,101]	14	153	39	48	19	301
Irinotecan[102-104]	27	138	50	8	33	38
Paclitaxel[102,105-107]	84	317	38	79	29	24

Navelbine[44,112-114]	24	1146	5	22	14	50

NSCLC, non small cell lung cancer; SCLC, small cell lung cancer; RR, response rate; ED, extensive disease; n, number of patients.

TABLE 57.7. ACTIVITY OF NEW AGENTS IN LUNG CANCER

NEW DRUGS IN THE PALLIATION OF LUNG CANCER

There is a pressing need for new drugs to treat lung cancer, and there are six major new agents under evaluation: paclitaxel, docetaxel, topotecan, irinotecan, gemcitabine, and navelbine (Table 57.7). Their activity in NSCLC and extensive or relapsed SCLC has been tested in phase II studies as single agents, and they are now being incorporated into combination regimens and subject to phase II trials. The aim of the latter is to improve cure rates, but even so, the majority of patients with lung cancer will continue to die of the disease for the foreseeable future. It is therefore imperative that studies include assessments of quality of life and that palliation is adequately evaluated in order to select the best of the new regimens.

CONCLUSION

Chemotherapy is accepted as standard treatment for patients with SCLC who are fit enough to receive it. Patients with limited-stage disease are likely to be treated with multimodality regimens aimed at cure, but those with poor prognostic features and/or extensive-stage disease can gain substantial benefits, in terms of both symptom relief and longer survival, from less-intensive treatments. In NSCLC there is now ample evidence that, in selected patients, chemotherapy offers better quality of life and symptom control than supportive care, with some improvement in survival. The incorporation of new agents into current treatment schedules is likely to improve on results to date. However, their utility in palliating lung cancer can be properly evaluated only if data regarding the impact of treatment on the patient is captured along with traditional outcome measures.

PALLIATIVE RADIOTHERAPY

FRANCIS J. SULLIVAN

One of the first and most fundamental principles we are taught when learning the art of radiation medicine is the distinction between radical and palliative care of the cancer patient. In defining the goals of our treatment, we clarify for ourselves and for our patients and their families realistic expectations for the (often all too short) time remaining to them. A thorough knowledge of the natural history of the disease is a prerequisite for this decision. Not infrequently we are surprised when the patient's course runs differently from the expected. Nonetheless, the inadequacies of our current treatments routinely place us in a clinical situation where cure is impossible, and improvement in the quality of life is all that we have left to offer. Some 25% to 50% of all cancer patients will require palliative radiation at some point during their illness. In no disease is this more important than in the care of the patient with lung cancer. In 1993 it was estimated that 170,000 patients would develop cancer of the lung in the United States, and 149,000 (87.6%) will die of their disease. [1] With cure rates so low that the mortality from this disease approaches the incidence, palliative care is more significant an issue in lung cancer than in almost any other single malignancy. For example, the five-year survival rates for patients presenting with locally advanced, inoperable, non–small cell lung cancer (NSCLC) (by far the majority of NSCLC patients) treated with radiation therapy with "curative" intent are 5% to 7%. [2] These figures are low enough to cause intense debate as to whether these patients are best served by aggressive therapies rather than a "palliative" approach. [3],[4],[5] and [6] Thus in lung cancer, even when the patient has locally confined disease, we are faced with a difficult decision which centers around the question of "palliation" and quality of life.

It seems generally true that management decisions for the patient requiring palliative radiotherapy may be more complex and demanding than those involving definitive or "curative" care. The patient is generally more debilitated, often has multiple coincident medical and psychosocial problems, and frequently requires complex treatment planning and support. In this context, radiation therapy is generally acknowledged as one of the most effective weapons in the armamentarium of the physician attempting to treat patients with advanced or metastatic lung cancer. [7] Radiation is capable of improving symptoms in the majority of patients, and can even improve survival in selected cases. However, a wide variety of time dose and fractionation schedules are employed, with relatively little available information to guide the clinician in deciding optimal management strategies. [8],[9],[10],[11],[12],[13] and [14] The final choice of dose and fractionation is often more influenced by the physician's perception of the patient's prognosis and survival, as well as by availability of resources and cultural differences in the approach to the terminal care of the cancer patient, than by clear clinical guidelines. [15] This chapter will outline the general approach to the patient with lung cancer requiring palliation of a symptom or a clinical syndrome and will thereafter focus on selected site-specific problems frequently encountered in the care of such patients.

GENERAL APPROACH TO PALLIATIVE THERAPY IN LUNG CANCER

Given the natural history of the disease, a wide spectrum of clinical conditions may confront the physician dealing with the palliative care of the patient with lung cancer. [16],[17] and [18] It cannot be overemphasized that the treatment of such patients must be individualized. The tendency to categorize patients with metastatic disease as a single group, for example, is not helpful and perhaps should be avoided. For instance, there is a clear difference between the patient with a solitary brain metastasis occurring more than a year after being rendered disease-free [19] and the patient in whom multiple brain metastases occur in conjunction with other sites of extrathoracic disease. [20] A multimodality approach may be required, and physicians subspecializing in oncology should interact with one another in the management of these problems for these patients. No treatise on this topic can be all-encompassing; the following is intended as a general guideline only.

Firm Diagnosis

In the selection of the patient who might be expected to benefit from palliative irradiation, the following factors are critical (Table 58.1). In general the histologic subdivisions of lung cancer [21] are less important in the palliative management of these patients. When the patient with lung cancer requires palliative irradiation, it is often less important to know if the patient has SC versus NSC histology than it is to know that the patient has a malignant cause for the symptom. Tissue diagnosis is usually not a significant problem. The patient will commonly have a firm histologic diagnosis, so histologic reconfirmation prior to a course of palliative irradiation will not always be required. However, two clinical situations deserve mention.

- Firm diagnosis of malignancy
- Adequate life expectancy
- Performance status and coexistent medical conditions
- Clinical radiographic correlation
- Balance of radiation-induced morbidity and expected outcome
- Technical considerations (prior therapy, treatment planning issues)
- Identification and communication of treatment goals

TABLE 58.1. GENERAL APPROACH TO PALLIATIVE CARE

Histologic Confirmation

The first involves the patient who presents with a single or multiple sites of disease in a distribution highly suggestive of a metastatic process but with no prior history of malignancy. Lung cancers not infrequently have as their initial presentation parenchymal brain lesions, spinal cord compression, or superior vena cava syndrome, requiring immediate intervention. [2],[22] In the current management of these patients, it is mandatory to obtain tissue prior to instituting any anticancer therapies, including

radiation.[23]

The second situation involves the patient with a known history of lung cancer who presents with a solitary lesion suggestive of metastatic disease. Table 58.2 summarizes the important issues with regard to management in this situation. Here an important issue may be whether a biopsy is required prior to palliative therapy. Although each patient must be individually evaluated, the following points may be helpful. The commonest clinical problems relating to distant metastatic disease in lung cancer are those relating to brain and skeletal metastasis. [2,16,17 and 18] Solitary lesions may account for 30% to 50% of all cases of brain metastases. [24] In selected patients, surgical resection with postoperative whole-brain radiotherapy offers a group survival benefit. So, prior to a course of palliative irradiation, selected patients may benefit from surgical intervention for both diagnostic and therapeutic reasons.

- Status of primary
- Patient age and performance status
- Interval from primary to development of the metastasis
- Morbidity of biopsy/resection
- Radiosensitivity of the lesion

TABLE 58.2. THE SOLITARY METASTASIS

Solitary bone lesions occur in only 6% to 8% of all patients undergoing screening isotope bone scanning for metastases. [25] Not all bone scan lesions represent metastases. Nonmalignant causes (osteoporosis, Paget's disease, prior trauma, and infection, for example) as well as other malignant entities (lymphoma, myeloma, primary bone tumors) may be characterized as metastatic lesions. The anatomic site of the lesion within the skeleton may be helpful in the differential. Although advances in diagnostic imaging have aided in the evaluation of such lesions, [26] as a rule solitary lesions should be biopsied prior to therapy. In the practical management of these problems, it is recognized that a biopsy may not be safely and easily accomplished (poor performance status or inaccessibility of the lesion). The clinician must judge each situation individually. Clearly, the assumption that a single lesion suggestive of a metastasis may be treated empirically with radiation is to be discouraged. This practice will on occasion lead to the inappropriate use of ionizing radiation for an unrelated (and possibly benign) condition or may lessen the potential for an optimal result from a curative approach (Table 58.2).

Life Expectancy and Performance Status

It need hardly be stressed that the patient's life expectancy must be factored into any decision regarding palliative irradiation. Desperately ill patients in the final stages of refractory malignancy rarely benefit from intervention. Appropriate dose fractionation, including large single fractions, may be appropriate. [11] For example, the patient with significant hemoptysis at the late stages of the disease may benefit from such an approach. The patient performance status continues to be an important prognostic factor predicting response to radiation therapy. [8,12,27] Patients with poor performance status (PS) tend to respond less well to anticancer therapies than those with good to excellent PS.[28] Coexistent medical conditions or pathophysiologic processes (related to the cancer or its treatment) may significantly impact on the patient's ability to tolerate or respond to a course of irradiation (Table 58.3).

- Anemia
- Chronic obstructive pulmonary disease
- Myocardial dysfunction
- Significant bone marrow dysfunction

TABLE 58.3. COEXISTENT CONDITIONS

Clinical/Radiographic Correlation and Target Volume Selection

A critical step in the decision to offer a course of palliative irradiation is the accurate anatomic localization of the cause of the patient's symptom or syndrome. A combination of clinical and radiographic information helps to localize a radiation portal for maximal therapeutic gain. A directed clinical history and thorough physical examination remain the best start. The practice of relying solely on radiographic studies in the selection of a treatment strategy is to be discouraged. The patient cannot always accurately localize the cause of a symptom which may vary depending upon the problem. For example, localized pain is the hallmark of skeletal metastases,[29] and a patient may accurately localize bone in many instances, whereas the ability to accurately localize the site of esophageal obstruction in the cause of dysphagia is less accurate. Clinical presentations with radiculopathy, such as brachial plexopathy from a Pancoast tumor or sciatic nerve pain from a lumbar metastasis, need to be recognized. Not infrequently, physical examinations will uncover previously unrecognized coexistent. For example, a patient with neurologic symptoms from known brain metastases may present with coexistent spinal cord compression from bony metastases. It should further be stressed that repeated clinical assessment, including physical examination, may be required during palliative therapy to ensure that the goals of treatment are being met and that such treatment remains the appropriate course, that is, is not unnecessarily protracted.

However, seldom if ever will a course of palliative radiation be instituted without some radiographic correlation (Table 58.4). The target volume irradiated must include but not necessarily be confined to the demonstrated radiographic abnormality. Knowledge of the pathophysiology and natural history of the symptom or syndrome being palliated is essential. For example, palliation of a brachial plexopathy from a Pancoast tumor requires coverage not only of the visible lesion but also of the vertebral bodies and nerve routes to the plexus. In treating multiple vertebral body metastases, the physician must remember the potential need to treat an adjacent field at a later time.

- Plain radiography
- Bone scintigraphy
- Computerized tomography
- Magnetic resonance imaging
- Other: angiography, myelography

TABLE 58.4. RADIOGRAPHIC EVALUATION IN PALLIATIVE IRRADIATION

In the era of modern imaging, there is a tendency to use MRI or CT imaging techniques as initial screening evaluations prior to or instead of a plain radiograph. While there are certainly clinical situations in which this is clearly appropriate (spinal cord compression, brain metastases, etc.), plain radiographs are very useful screening evaluations in this patient population. They may be very accurate in differentiating metastatic carcinomatous lesions of bone from benign lesions as well as other bone malignancies.[29] Bone metastases from lung primaries tend to be lytic or occasionally blastic lesions localized to the spine, ribs, or metaphyseal regions of the long bones.[30] Plain radiographs of the spine can frequently complement an MRI scan and aid in the accurate localization of a vertebral body collapse or spinal cord compression. Not all bone metastases are painful. Skeletal surveys and bone scintigraphy are a powerful tool in screening for such lesions. [25,31] Scintigraphy is also useful for following responses to treatment.[25] Bone scans do not provide detail of the structural lesion in the bone; for this reason, plain radiographs should be obtained of abnormal areas of tracer accumulation detected on bone scan. In particular, painful areas and those in weight-bearing bones should be radiographed. Computerized tomography (CT) has gained an important role in the radiation management of the cancer patient, including the patient requiring palliative care. [32,33 and 34] CT can greatly aid in the delineation of soft tissue masses, which are often associated with bone metastases and are not easily seen on plain radiographs. Furthermore, the increasing use of ultrasound (US) and CT-guided biopsy to obtain tissue from previously inaccessible locations has made tissue confirmation prior to therapy a much more attainable goal.[35,36 and 37] Lastly, the incorporation of CT dosimetry into treatment planning systems [37] has enhanced the delivery of effective radiation doses with less normal-tissue morbidity.

Recent advances in magnetic resonance imaging (MRI) have greatly aided the palliative care in the cancer patient. MRI, coupled with radionuclide bone scanning, detected occult metastatic disease to the brain or skeleton in 28% of a small series of patients with operable NSCLC. [38] MRI has been shown to be effective in the early detection of vertebral body metastases [39] and is now considered to be the procedure of choice in assessing patients with medullary symptoms and cancer. [40,41] Prospective as well as retrospective studies have shown a high degree of sensitivity and specificity (90% or more) in evaluating patients with suspected metastatic spinal compression syndromes.[42,43] In situations where isotope bone scintigraphy is equivocal or negative, MRI has been shown to be a complementary noninvasive test.[44,45 and 46] With appropriate technique, differentiation between osteoporotic fractures and metastases is possible with MRI alone, and this test is now becoming increasingly useful in obviating the need for biopsy confirmation in this situation. [26] In evaluating patients with suspected spinal cord compression, the MRI has demonstrated ability in precisely characterizing the mass and its relationship to the spinal cord. It allows simultaneous demonstration of multiple sites of involvement and thus can obviate the need for invasive and less sensitive tests such as myelography. [47] MR has also been found superior to CT in the detection of cerebral metastases.[48] Coupled with an increasing role in radiation treatment planning, [49] it has therefore become invaluable in the staging and palliative management of the patient with lung cancer.[50]

The combined use of some or all of the aforementioned techniques, allied to the less frequently used sonography and angiography, generally compliment the history and physical examination in planning a course of palliative irradiation.

Time Dose and Fractionation in Palliative Care

There is perhaps no more important aspect to planning and administering palliative irradiation than choosing an appropriate time dose and fractionation (TDF) schedule (Table 58.5). The generally held assumption is that hypofractionated irradiation, utilizing fewer but larger doses of irradiation, is the appropriate course. Radiobiologically, these fractionation schedules are predicted to be associated with a greater long-term radiation morbidity (see Chapter 12). This approach is considered acceptable because the majority of patients will not survive long enough to experience these toxities. However it has been estimated that some 10% of all cancer patients treated palliatively will survive longer than one year. Therefore, the indiscriminate use of such schedules may cause long-term toxicity in surviving patients. Where possible, patients with a longer life expectancy should be identified because they are at greater risk for long-term morbidity related to their treatment. Because there is relatively little available literature critically analyzing the outcome when various TDF schedules are compared, good studies are needed to address this important question. Reliable and reproducible outcomes allowing comparison of various treatments must be agreed upon (see Table 58.6).

- Natural history of the disease
- Resources for treatment
- Recognizing cultural differences in palliative care
- Identifying meaningful goals for evaluating various treatments
- Communicating with patient and family
- Individualizing treatment approaches

TABLE 58.5. FACTORS IN CHOOSING PALLIATIVE RADIATION SCHEDULES

- Time to symptom response
- Duration of response
- Change in performance status
- Tumor volume changes
- Functional independence
- Quality of life

TABLE 58.6. POSSIBLE PALLIATIVE CARE STUDY END POINTS

In this context, the work of patterns of care studies (PCS) and cooperative study groups such as the Radiation Therapy Oncology Group (RTOG) should be acknowledged. Recent physician-targeted studies have identified important international differences in the approach to these patients. [15,51,52 and 53] Such studies highlight as significant the availability of resources (government-funded versus private), physician and patient expectations, as well as a lack of reliable patient prognostic factors. For example, physicians who are funded privately tend to choose longer treatment courses with higher total radiation doses, as opposed to government-funded doctors, when they (the physicians) believe their treatment will prolong life or prevent the occurrence of future symptoms ("prophylactic" palliation). Further differences are seen depending on which physician has the responsibility for the terminal care of the patient. [54] These choices are often made in the absence of any demonstrable benefit in terms of survival or quality of life. As a final point, it is worth remembering that the palliative care of the patient with cancer is not necessarily synonymous with cytotoxic therapy. It is often appropriate to care for the patient with general medical treatments (analgesics etc.), allowing them to *live with* their cancer in a way that preserves their comfort, independence, and dignity for as long as possible.

SPECIFIC PROBLEMS IN PALLIATING LUNG CANCER WITH RADIATION

Brain and Central Nervous System Metastasis

Incidence

Metastasis to the central nervous system (CNS) occurs in 25% to 35% of all cancer patients. [55,56] It presents in three distinct temporal patterns relative to the primary lesion: precocious (occult primary), synchronous (simultaneous primary), and metachronous (antecedent primary). It has been estimated that lung cancer is the most common cause, accounting for 40% to 60% of all parenchymal metastases, translating to almost 45,000 cases in the U.S. in 1992. [57] In addition to being a frequent occurrence in newly diagnosed lung cancer, brain metastases constitute more than 25% of all recurrences in patients with resected NSCLC. [58] Brain metastases are present at the time of diagnosis in approximately 10% of patients with SCLC and occur at some point during the illness of a further 25% to 35%. [59] In fact, the incidence in SCLC increases with length of survival, so that 50% to 80% of patients surviving two years will develop brain metastases if no therapy is directed at their prevention. [60] The use of prophylactic cranial irradiation (PCI) in lung cancer is dealt with in Chapter 56. Brain metastases are often dramatically symptomatic and distressing to the patient and family. It is thought that as many as 50% of patients will die of progressive CNS metastases. [61,62] Thus parenchymal brain metastases represent a significant cause of morbidity and mortality in the patient with lung cancer and require careful evaluation and therapy. However, the prognosis of patients with brain metastases varies widely, once again emphasizing the need for individualized management depending on the clinical setting.

Natural History and Prognostic Factors

CNS metastases arise either from hematogenous dissemination or from direct extension from adjacent sites (skull, soft tissues of head and neck, vertebral column, etc.). This section will deal only with parenchymal brain metastases. Clinical series estimate that 53% of brain metastases are multiple, though autopsy examination would suggest an even higher frequency. [55,63,64] Lung cancer more typically presents with multiple rather than single brain metastases. Although synchronous presentations are not uncommon, the usual occurrence in lung cancer is that of metachronous presentation. In contrast to other histologies (breast, colorectal), the time interval to the development of brain metastases is relatively short in lung cancer. [56] Without treatment, the median survival for all patients is four to eight weeks. [65] With active therapy, the median survival is increased to three to six months, with measurable if modest one- and two-year survival rates. For example, of 1,292 patients with CT-documented brain metastases, the survival rates at six months, one year, and two years were 36%, 12%, and 4%, respectively. The authors identified performance status, response to steroids, systemic tumor activity, and serum LDH as independent prognostic factors with the strongest impact on survival, second only to treatment modality. Patients treated with steroids only had a 1.3-month median survival, while those receiving radiation had a 3.6-month median survival. [66] The presence of symptoms related to the primary lung tumor has also been associated with a poorer outcome. [67] The RTOG has identified a series of prognostic factors for patients with brain metastases from all causes (Table 58.7). [68] The presence of four favorable prognostic factors is associated with a 52% predicted probability of surviving six months (10% of patients), while the absence of any of these factors is associated with a dismal prognosis—less than 10% chance of six-month survival. Approximately 10% to 15% of patients will live more than one year, emphasizing the need for careful patient selection and appropriate choice of therapy so as to minimize long-term morbidities in such patients.

- Karnofsky Performance Status (70–100)
- Status of primary (absent or controlled)
- Patient age (under 60 years)
- Histology (breast better than other)
- RTOG Neurologic function (class I = 6.6 months versus class IV = 1.2 months)
- Brain only site of metastasis (4.8 months versus 3.4 months)
- Number of metastases (single versus multiple and under 4 versus 4 or more)

TABLE 58.7. PROGNOSTIC FACTORS IN BRAIN METASTASES

Presentation

The diagnosis of brain metastases in cancer patients is based upon patient history, neurologic examination, and diagnostic radiologic procedures. Patients may describe headaches (over 50%), focal weakness (40%), seizures (15%), loss of sensation, or difficulties with gait or balance. [56] Often, however, patients are brought by family members or friends who have noticed the patient's lethargy, emotional lability, or personality change. Physical examination may demonstrate objective neurologic signs, but often only minor cognitive signs are present. The definitive diagnosis cannot be based solely on clinical examination alone, because the presenting symptoms and signs are not distinct from those of other intracranial space–occupying lesions. In addition, metabolic disturbance, carcinomatous meningitis, and paraneoplastic conditions may also present with CNS symptomatology, and these must be distinguished. CT and MRI scanning are the most sensitive and specific diagnostic tests. [69] They are useful not only for diagnosis but also for treatment planning (surgery as well as radiation), to follow response, and to detect recurrence or complications of therapy.

Management

Prompt and often urgent intervention is required in the management of brain metastases to avoid or minimize progressive neurologic injury. It is far more effective to prevent neurologic deterioration than to regain deficits already lost. The quality of survival is greatly improved if clinical control of intracranial metastases is achieved. Initial management is generally directed at controlling raised intracranial pressure (ICP) if present. Steroid preparations (dexamethasone, methylprednisone, prednisone) are rapidly effective (six to 48 hours) and have long been the cornerstone of initial management. [70,71] The use of steroids alone is associated with a modest survival benefit (2.5 months median) when compared with no treatment. A common regimen is dexamethasone 4 to 6 mg q.i.d. (per oram [po] or intravenously) with or without a loading dose of 10 mg. Equivalent dosages of other steroids may be used. Higher doses are sometimes effective where lower doses have failed. This is especially true in the treatment of chronically raised ICP in patients with end-stage disease. [72,73] After radiation, steroids are tapered to the lowest dose necessary to suppress neurologic symptoms, and can often be discontinued. No specific tapering schedule is preferred, and the clinician must judge on an individual basis. Other maneuvers to reduce ICP, including diuretics (furosemide, mannitol) and hyperventilation, are far less frequently required in general oncologic practice and will not be further discussed here. [56] Not all patients will show clinical evidence of raised ICP, and therefore many patients may be safely managed with radiation therapy without the use of steroids. Anticonvulsant therapy (phenytoin, carbamazepine) is recommended only if seizures occur, and is not required on a generalized basis.

Radiation Therapy of Brain Metastases

Therapeutic irradiation is used in virtually all referred patients with brain metastases, either as primary therapy or as an adjunct to surgical excision of a single lesion. The basis for the use of radiation is outlined in Table 58.8.

- Median survival modestly improved to 4 to 6 months
- Selected patients with long-term (1- and 2-year) survival
- Improves symptoms 69% to 90% (RTOG)
- Improvement in KPS of 10 to 20 points
- 2 of 3 of patients with serious neurologic dysfunction improve
- 1 of 3 of patients with moderate neurologic dysfunction improve

TABLE 58.8. BASIS FOR RADIATION THERAPY IN BRAIN METASTASES

The commonest technique is the use of whole-brain external-beam irradiation, generally administered using 4 to 6 MV photons from a linear accelerator. [60]Co teletherapy is also appropriate. Opposed lateral technique with customized shielding of the ocular lens and soft tissues of the oropharynx and anterior neck is preferred by some. The inferior margin may be placed at the base of brain, but for ease of possible future field matching this border may also be placed to include the second cervical vertebra. The optimal time dose and fractionation schedule has been studied by the RTOG in a series of randomized prospective clinical trials. [74,75] All schedules studied were comparable in terms of frequency of improvement of symptoms and time to progression, but the duration of response and rate of complete disappearance of neurologic symptoms were not as good for ultrarapid schedules using one or two large fractions. Even where more favorable prognostic patients were evaluated using more protracted radiation courses (50 Gy in four weeks) no advantage was seen over the shorter treatment schedules. [68,76] Relatively little data exists on the long-term toxicity of these treatment regimens for obvious reasons. One report suggests a 10% to 15% dementia rate amongst long-term survivors treated with 30 Gy in two weeks.[77] More recently the RTOG has evaluated accelerated fractionated radiation schedules at 1.6 Gy b.i.d. to doses up to 54.4 Gy, and found improvements in survival (not reaching statistical significance) at the higher dose levels, with acceptable toxicity rates. [13] This higher dose will now be the subject of a randomized comparison versus standard therapy. Until the results of this and similar studies are available, the standard recommended time dose fraction schedule for palliative whole-brain radiotherapy in the United States continues to be 20 to 30 Gy in five to 10 fractions over one to two weeks. These are cost-effective regimens offering maximal palliative benefit with acceptable long-term morbidity rates.

The Solitary Brain Metastasis

Solitary lesions account for 30% to 50% of all cases of brain metastases. [24,63] There is emerging evidence in selected patients that surgical resection with postoperative whole-brain radiotherapy offers a potential survival benefit. [8,78,79,80,81,82,83 and 84] Patients with cancer and single metastases to the brain who receive treatment with surgical resection and postoperative radiotherapy have fewer recurrences of cancer in the brain and are less likely to die of neurologic causes than similar patients treated with surgical resection alone. [85] While the argument for resection is less strong in patients with highly radiosensitive histologies and those with other sites of disease systemically, those patients with a good performance status presenting with metachronous brain metastasis and control of the primary tumor gained maximal benefit from the combined approach. Advances in neuroanaesthesia, surgical technique, and perioperative care have broadened the availability of neurosurgical intervention in this patient population. However, even with such improvements, less than half of the patients with solitary metastases will be able to undergo such an aggressive approach. [86] Factors associated with the best short-term results from the combined approach are listed in Table 58.9.[87] One of the more influential recent studies has been that of Patchell and colleagues [80] which suggested a modest survival benefit with combined surgery and postoperative irradiation versus radiation therapy alone in a selected population with biopsy-confirmed single brain metastases. Of note was that as many as 11% of the patients entered were ineligible because they were found to have other than metastatic lesions (glioma, abscess, etc.), reinforcing the need for biopsy confirmation in the setting. A prolonged median survival (40 versus 15 weeks) and improved local control rate (80% versus 48%) was initially observed in the combined arm. However, by 90 weeks the overall survival in both arms was less than 10%, confirming the still-poor prognosis in these patients irrespective of treatment. Patchell and associates extended these observations in a multicenter randomized trial, [85] noting that recurrence of tumor anywhere in the brain was less frequent in the radiotherapy group than in the observation group (nine [18%] of 49 versus 32 [70%] of 46; p = less than 0.001). Postoperative radiotherapy prevented brain recurrence at the site of the original metastasis (five [10%] of 49 versus 21 [46%] of 46; p = less than 0.001) and at other sites in the brain (seven [14%] of 49 versus 17 [37%] of 46; p = less than 0.01). Patients in the radiotherapy group were less likely to die of neurologic causes than patients in the observation group (six [14%] of 43 who died versus 17 [44%] of 39; p = 0.003). Again, there was no significant difference between the two groups in overall length of survival or the length of time that patients remained functionally independent.

- Preoperative neurologic status
- Presence or absence of systemic disease
- Patient age
- Time interval from primary to metastasis

TABLE 58.9. PROGNOSTIC FACTORS IN SINGLE BRAIN METASTASES

The optimal postoperative radiation technique has not been defined. The initial study by Patchell and associates used whole-brain radiotherapy, 3 Gy per day to 36 Gy. The dose was delivered via opposed laterals using a ^{60}Co machine. One large retrospective review suggested a radiation dose response, with improved results in patients receiving 39 Gy or more (89% local control) versus less than 39 Gy (69% local control) in the adjuvant setting. [79] Another reported treatment schedule with similar results was 2.5 Gy per day to 40 Gy whole-brain, followed by a 10 Gy boost to the metastatic lesion. [8] There is increasing acceptance for the use of combined surgery and postoperative radiation therapy in the management of selected lung cancer patients with isolated intracranial metastases.

Specialized Radiation Techniques in Brain Metastases

Retreatment

Since 30% to 50% of patients with brain metastases will develop progressive or recurrent intracerebral disease, selected patients will be considered for reirradiation. Limited data exist on the use of external beam radiation in retreating patients who have received prior whole-brain therapy. [82] Cooper and colleagues have shown that if patients are carefully selected (Table 58.10), they can benefit from reirradiation, either partial or whole-brain, in dosages up to 25 Gy in 10 fractions. [88] Patients so chosen had a mean survival time of 5.6 months postretreatment and demonstrated improved average neurologic function. Less favorable reports show median duration of survival of only two to 3.5 months after retreatment and little improvement in neurologic status, illustrating that the margin of benefit is probably slim and careful patient selection is likely the key factor. [89,90]

- At least 4 months from initial irradiation

- Neurologic deterioration as their primary clinical problem

TABLE 58.10. SELECTION OF PATIENTS FOR REIRRADIATION

Focal Irradiation Including Stereotactic and Brachytherapy Techniques

The ability of these techniques to limit the dose of radiation to surrounding tissues has led to their evaluation in the setting of retreatment of cerebral metastases. Stereotactic "radiosurgery" uses sophisticated computerized techniques to identify targets and to focus multiple nonplanar radiation beams on these targets, allowing the delivery of large (usually single) doses while minimizing irradiation of surrounding tissue. Therapeutic gain is maximal when the ratio of the tumor volume to that of the surrounding normal tissue is large. In practice, small (3.5 cm or less), single, favorably located lesions are suitable for this approach. Therefore the impact of this technique on cerebral metastases, frequently large, and usually multiple, will be limited. However, selected patients with single recurrent lesions appear to benefit. [91,92] A similar rationale, and therefore limitation, holds for the use of brachytherapy in this setting. This approach has been used as a boost technique in selected cases and as retreatment in patients with recurrent disease. [93,94]

Radiation Sensitizers and Chemotherapy

The high response rates of SCLC to chemotherapy has led to the observation of regression of intracerebral metastases in patients responding to primary therapy. [95,96] and [97] The response of cerebral metastases to "salvage" chemotherapy is less impressive. The fact that patients presenting with brain metastases as their only site of "extensive"-stage disease fare as well as patients with limited-stage disease is a testament to this phenomenon. [20] The response rates for brain metastases from NSCLC is obviously less striking. No studies address the role of combined chemotherapy or neoadjuvant chemotherapy with radiation. [56] Although responses may occur, this approach cannot yet be endorsed outside of a study setting. Lastly, the use of radiation sensitizers has been evaluated but shown to be of no benefit in the management of the patient with brain metastases.[9,98] There is much need for the investigation and development of novel effective approaches in the management of this important clinical problem.

Bone Metastases and Related Clinical Problems

Incidence

Annually more than 100,000 people in the U.S. suffer with painful bone metastases. [99] Bone metastases occur in 20% to 40% of patients with lung cancer,[100] amounting to almost 70,000 cases in the U.S. in 1993. Lung cancer accounted for one third of the bone metastases in one large autopsy series of patients dying of epithelial neoplasms.[101] The commonest sites are the vertebrae, pelvis, and femora, with the skull and distal extremities being less frequently involved. [101,102] When long bones are involved, it is most usually the metaphyseal and less often the mid-diaphyseal regions which are affected. Pathologic fractures requiring surgical intervention occur in less than 10% of patients with metastatic disease but are an important cause of morbidity in the cancer patient. [103] Interestingly, lung cancer less frequently accounts for such fractures than other histologies, possibly relating to the short life expectancy in this disease. [29]

Pathophysiology and Presentation

Normal bone remodelling is a coupled process balancing resorption by osteoclasts and regrowth by osteoblasts. [104] Bone metastases are either osteolytic, osteoblastic, or mixed. The osteoblastic variety is uncommon in lung cancer and will not be further discussed here. The typical bone metastasis from lung cancer is osteolytic. The mechanism of bone destruction is not completely understood and is the subject of intense research. [29] Evidence is emerging that both tumor cells and bone itself are capable of secreting factors that can stimulate osteoclastic activity. Several of the factors (TGF, OAF, IL-1, IL-6 etc.) are being evaluated as target molecules in the systemic treatment of bone metastases.[104] Skeletal metastases occur via hematogenous spread possibly through a low-pressure venous plexus described by Batson in 1940.[105] The important clinical consequences of bone metastases are pain and bony destruction. The pain is generally well localized, initially intermittent, but eventually constant and unremitting. Depending on the location of the lesion, the pain may be referred to a nearby joint (e.g., "frozen shoulder"), the anterior chest or abdominal wall, or extremity. Bone destruction may compromise the biomechanical strength of the bone and lead to pathologic fracture. The strength of normal bone depends on an intact cortex and underlying medullary system. [29] Typical metastatic lesions destroy a segment of both the cortex and medulla. Cortical defects weaken the bone, especially to torsion or rotational forces. It has been estimated that such a defect whose length is greater than the diameter of the bone may weaken the bone by as much as 90%.[106]

The consequences of pathologic fracture may be severe and debilitating. This is especially true of fractures involving weight-bearing bones, humerus, and the spine, where epidural compression of the spinal cord may be a paralyzing and even a preterminal event. Pathologic fractures from metastases will not heal without anticancer therapy. The rate of subsequent union has been shown to vary with histology (poor in lung metastases), as well as type of intervention (orthopedic, radiotherapy, or chemotherapy) employed. [107] The following sections will deal with the use of radiation for clinical syndromes common in patients with lung cancer metastatic to bone. Unlike other histologies such as breast and prostate cancer, where systemic treatment with hormonal therapies and novel agents such as bisphosphonates[108,109] and pamidronate[110,111] can bring about valuable responses and palliation, radiation therapy (with or without surgery) is often the only therapeutic option available to lung cancer patients. The aims of such treatment are pain relief, maintenance of normal function including ambulation, and prevention or management of complications of bone destruction such as pathologic fracture or cord compression. At present the role of radiation in preventing the progression of subclinical disease is being explored.

The Radiation Management of Painful Bone Metastasis

Localized Radiotherapy

Focal external-beam radiotherapy is the commonest technique used to treat bone metastases. Factors associated with optimal radiotherapy treatment planning are listed in Table 58.11. It need hardly be stressed that any prior radiation treatments must be accounted for and the portals and techniques used should be reviewed prior to initiating therapy. It is useful practice at simulation to localize any prior portals with reference to skin tattoos and prior documentation, and delineate such portals with a wire placed on skin, to minimize the likelihood for unexpected overlap of radiation fields. The choice of the most appropriate TDF schedule for the palliation of bone metastases is a complex topic. Physician bias influences therapy selection in palliative care. [15,51] Although patients with lung cancer metastatic to bone have a median survival of less than six months and a good outcome is thought less likely with lung than other histologies, [112,113] there is sufficient heterogeneity even in this patient population to warrant careful selection in the choice of technique.

TABLE 58.11. RADIATION TREATMENT PLANNING FOR BONE METASTASES

Several retrospective reviews[114,115 and 116] and a number of prospective randomized controlled trials, including those of the RTOG and others[112,117,118,119,120,121,122 and 123] are available to document the rough equivalence of single-dose to fractionated radiotherapy, as well as a number of multifraction schedules (10 Gy in 2 to 2.7 Gy in 15 fractions). A prospective nonrandomized study has also compared various TDF schemes in this context.[113] A number of general statements may be made. Some 80% to 90% of patients can anticipate at least partial pain relief, irrespective of the schedule used.[29,119] As many as 50% to 62% of patients experience complete pain relief.[112,113] The majority of patients will respond within two to 12 weeks from start of therapy. Some authors have argued for more protracted treatment courses and higher radiation doses, on the basis that they are more likely to produce complete responses with full withdrawal of narcotic medications than shorter courses,[118] a greater likelihood of complete pain relief, and a longer time to progression.[113] A second argument for more protracted treatment points to the increased frequency of reirradiation among patients treated with single doses, inferring less therapeutic effect. However, as has been pointed out by Malawar and Delaney,[29] this may simply reflect the reluctance of radiation oncologists to retreat areas that have received prior high-dose (tolerance dose) schedules. It has been our practice to avoid the use of large single doses of radiation in anatomic locations where potential toxicity to surrounding structures may limit the effectiveness of the therapy. Thus, for bone metastases to the skull and spine, fractionated doses are preferred, minimizing the risk of injury to the brain, spinal cord, and major organs. In the United States, 30 Gy in 10 fractions is probably the commonest schedule used. When very large spinal column fields are required, we have found 30 to 35 Gy in 12 to 14 fractions a useful alternative with acceptable acute gastrointestinal morbidity. Careful individualization is required.

Single or Limited-Number Bone Metastases

As described above, histologic confirmation is frequently required prior to irradiation. Although uncommon in lung cancer, such patients may enjoy relatively long disease-free and overall survival periods.[26] Although no clear evidence of dose response exists in palliating bone metastases, there are suggestions that doses in excess of 40 Gy may be beneficial[124] and may therefore be considered in this circumstance.

Spinal Cord Compression (SCC)

Incidence

After brain metastasis, SCC is the second most common neurologic complication of malignancy and the most common malignant lesion to affect the spinal cord. Lung cancer is its most frequent cause.[125,126] SCC is the commonest radiation emergency in the cancer patient. Although it may be the presenting feature of malignancy in lung cancer, it more typically occurs at an interval following the diagnosis.[127] The main determinant of neurological outcome after treatment is the pretreatment neurological status, whereas the prognosis for survival is related more to the underlying disease.[128,129] The relationship between functional outcome and pretreatment neurologic status deserves emphasis. Even with modern approaches, it has been reported that zero to 16% of paraplegic patients will regain ambulatory status with treatment.[130,131 and 132] Additionally, in a retrospective analysis of patients with lung cancer and SCC, all ambulatory small cell lung cancer patients retained function with therapy, while only 15% of the nonambulatory small cell patients regained walking ability. Similarly, 95% of patients with non–small cell lung cancers retained ambulatory function, while only 22% of nonambulatory patients were able to walk posttreatment.[133] Early recognition of the problem is essential so that therapy may be initiated and neurologic deterioration avoided.[134,135] Despite increasing awareness of the presenting features of this syndrome among oncologists as well as general physicians, 75% to 80% of patients still present with significant neurologic compromise, and these patients uncommonly recover function even with aggressive multimodal therapy.[129,136] However, it should be borne in mind that with appropriate recognition and treatment, 40% to 60% of patients will remain ambulatory.[126] Posttreatment physical therapy is also important. Functional improvements in mobility and self-care can be obtained and maintained in appropriate patients.[137]

Pathophysiology and Presentation

Although metastases to the cord itself or the epidural space can occur, by far the commonest mode of compression is that due to expansion or collapse of the vertebral body (85%) or neural arch.[126] Lung cancer may also directly invade the spinal column and epidural space, producing SCC.[138,139] With the advent of high-resolution tomography and MRI, cord compression with associated paravertebral mass is being recognized with increasing frequency.[132] The anatomic distribution of SCC reflects the number of vertebral bodies at risk (70% thoracic, 20% lumbosacral, and 10% cervical).[126] Increasing use of MRI in the diagnosis of SCC has highlighted the fact that multiple levels may be involved.[47] The clinical syndrome is summarized in Table 58.12. Pain usually precedes other symptoms and must never be ignored in the cancer patient. Sensory changes may follow or accompany motor loss. Findlay proposed a motor grading system that is useful in categorizing patients pretreatment and predicting outcome (Table 58.13).[131,134]

TABLE 58.12. SPINAL CORD COMPRESSION

Grade I: ambulant with or without use of walking aid

Grade II: paraparetic and nonambulant

Grade III: complete paraplegia

TABLE 58.13. FINDLAY MOTOR GRADING SYSTEM IN SCC[134]

The evaluation of the patient with SCC must be speedy and decisive. Delay may allow the development of irreversible neurologic deficit. Although 80% of patients will show abnormalities on plain spinal radiography, normal spine films do not exclude epidural metastases. MRI with gadolinium enhancement is now being increasingly recognized as the diagnostic method of choice in SCC (see Table 58.14.[126] Figure 58.1 illustrates an algorithm which allows for the practical evaluation of the patient with suspected SCC.

- Excellent sensitivity and specificity rates (over 95%)
- Selected patients may be spared the need for biopsy confirmation
- Noninvasive, avoiding need for lumbar puncture
- Rapid (usually less than 90 minutes)
- Entire spine may be imaged, detecting multiple-level involvement
- Accurate anatomic localization
  intramedullary versus subdural or epidural
  paravertebral masses
- Vital treatment planning information (radiation therapy and surgery)
- Progress and response to treatment

TABLE 58.14. MRI ADVANTAGES IN DIAGNOSING/MANAGING SCC

FIGURE 58.1. This figure illustrates an algorithm which allows for the practical evaluation of the patient with suspected SCC.

Management of Spinal Cord Compression

Appropriate assessment and management requires close cooperation among subspecializing physicians. Primary physicians and medical oncologists, neurologists, neurosurgeons, orthopedists, and radiation oncologists may all contribute to a successful outcome. It is incumbent on each, however, to be aware of the indications and limitations of the techniques available. Absolute management recommendations cannot be made. However, most patients will require radiation with or without surgical intervention. Selected patients with chemosensitive tumors may also require chemotherapy. Initial therapy generally consists of corticosteroid administration. Steroids can reduce pain and limit neurologic progression prior to definitive therapy. The presumed mechanism of action is reduction of edema. The optimal dose has not been established. Typically 10 mg of dexamethasone given intravenously at diagnosis is followed by 4 mg t.i.d. or q.i.d. (either intravenously or by mouth). There is no clearly established benefit to exceeding these doses, although doses up to 100 mg have been evaluated. [140]

Although a full discussion of the neurosurgical aspects of managing SCC is beyond the scope of this chapter, certain points should be made. The optimal timing of neurosurgical intervention has yet to be defined, but it would seem logical that, if surgery is contemplated at all, the sooner the better. At least one retrospective review of 84 cases showed improved functional outcome (61.5% versus 25%) if the surgery was performed within 24 hours. Improvement was even seen in patients incontinent and immobile prior to intervention. [141] There has been a reevaluation of the role of posterior laminectomy in the surgical approach to these patients, and the radiation oncologist must be aware of the indications and contraindications for this procedure. Formerly, when the combined approach was used, laminectomy was the preferred neurosurgical intervention. Some series report good results with this technique. [142] Recent neurosurgical literature, however, emphasizes the importance of a selective operative approach based on the anatomic location of the tumor. Since 85% of epidural compressions are anteriorly located, the focus of the surgery should be the vertebral body. [126] There is evidence that posterior laminectomy may fail to deal adequately with this problem and may in fact worsen the neurologic outcome. [130,134] It has been reported that less than 10% of patients with anteriorly based lesions benefit from laminectomy. [126,143] Removal of the spinal arches in a patient with vertebral body involvement or collapse can greatly increase spinal instability and worsen neurologic function. Anterior approaches can allow stabilization of the spine. Using optimal neurosurgical approaches, as many as 94% of patients retain ambulation after treatment. [126] The indications for neurosurgery in SCC are listed in Table 58.15.

- Appropriate surgical candidate
- Pathologic fracture of the vertebral body
- Spinal instability
- Compression of the cord by bone fragments in the canal
- Requirement for tissue diagnosis
- Radioresistant primary (progressive deterioration on or following radiation)

TABLE 58.15. INDICATIONS TO CONSIDER NEUROSURGERY IN SCC

Radiation Management of Spinal Cord Compression

The role of radiation therapy alone in the management of SCC is well established. Retrospective reviews comparing radiation alone versus radiation and surgery combined are fraught with selection bias, precluding meaningful statements regarding the benefit of one versus the other. However, there is evidence of comparability in selected series.[144] Only one small randomized trial of radiation alone versus surgery and radiation has been published, and shows no significant difference between the two.[145] It is hardly surprising that radiation therapy alone is associated with better results in the more radiosensitive malignancies. [144,146] Although SCLC might be expected to exhibit a somewhat better response to radiation than NSCLC, when analyzed, histologic subtype has not proven to be important. [129] A tendency for patients with NSCLC in this study to do better with the combined approach is probably the result of patient selection. In general, response rates to radiation alone in this situation are in the 40% to 60% range. As is true in surgical and combined series, the pretreatment neurologic status is the principle prognostic marker of response to radiation.[126,129] The radiation portal should be based on all available clinical and radiographic information. Paravertebral extension should be included in the portal. Since lung cancer is commonly associated with paravertebral masses, imaging must assess for such problems. [132] By time-honored practice, the typical radiation portal includes the affected vertebral body, including two vertebral bodies above and below. Cervical spine fields are generally arranged laterally and opposed. A single posterior (PA) is used for upper- and mid-thoracic levels, while lower thoracic and lumbosacral lesions may be optimally dosed via the anteroposterior (APPA) approach.

Energy and prescription depths must be individualized. The optimal radiation TDF schedule for spinal cord compression has not been clearly established. Spinal cord tolerance to radiation must be respected, and there is no objective evidence that this tolerance varies from cervical to thoracic levels. [147,148] There appears to be no clear dose response relationship in lung cancer patients irradiated for SCC. [126] Attempts to treat lung cancer patients with associated paravertebral masses to doses of 40 Gy in 16 fractions have yielded no improvement. [132] Limited experimental data in a rat model suggesting a benefit to using large initial fractions (300 to 500 cGy) has no human clinical evidence in support but is a frequently utilized regimen. The standard TDF schedule for radiation therapy alone in lung cancer SCC is 30 Gy in 10 fractions. No clear consensus on the optimal postoperative radiation TDF schedule exists. When the SCC lesion represents the only site of metastatic disease, it has been our practice to employ doses in the 40 to 50 Gy range at standard fractionation, in view of the somewhat better prognosis expected in such cases.

Prevention and Management of Pathologic Fracture

Radiation therapy is capable of halting osteolytic bone destruction and even of promoting reossification in up to 80% of lesions. [149,150] Although pathologic fracture has been thought less commonly a problem in the patient with lung cancer than in osteolytic metastases from other histologies, this clinical issue is frequently presented to the radiation oncologist for consideration. The commonest anatomic locations are the femur and humerus. Both are extremely important clinical issues, since fracture in these locations can bring about major functional impairment. Prognostic factors predicting patients at high risk for subsequent fracture have been published and used as a guide for prophylactic management,[29] both surgical and radiotherapeutic. The question as to whether the patient at high risk for pathologic fracture should be managed surgically or with radiation is a difficult one. Since radiation will take time to bring about reossification, any patient considered at imminent risk for fracture should be considered for surgery. The criteria used for operative repair of lesions of the hip and femur at Memorial Sloan-Kettering (MSK) have been published (Table 58.16).[151]

- Painful intramedullary lytic lesion 50% or more of the cross-sectional diameter of the bone
- Painful lytic lesion involving a length of cortex equal to or greater than the cross-sectional diameter of the bone
- Painful lytic lesion involving a length of cortex 2.5 cm or more in length
- Lesion of bone in which pain is unrelieved after radiation

TABLE 58.16. CRITERIA FOR PROPHYLACTIC SURGERY TO PREVENT FRACTURE (MSK)

Radiographic criteria alone may be insufficient, and Mirels has described a clinico-radiographic scoring system based on four clinical factors (Table 58.17).[152] The author suggests that lesions of the long bones with scores of 7 or less could be irradiated, while those of 8 or more should be fixed surgically with postoperative irradiation.

Factor	Score (Range 3–12)		
	1	2	3
Site	Upper limb	Lower limb	Peritrochanteric
Pain	Mild	Moderate	Functional
Lesion	Blastic	Mixed	Lytic
Size*	<1/3	1/3–2/3	>2/3

* Relative to the diameter of the bone.

TABLE 58.17. SCORING SYSTEM FOR PATHOLOGIC FRACTURES

The principles and techniques for irradiation, be it prophylactic palliation or definitive therapy, do not differ form those relating to bone metastases described above. The entire bone should be evaluated radiographically and with scintigraphy so that coexistant lesions do not go unrecognized. All patients treated with surgical intervention should be irradiated postoperatively to aid in bone healing. Postoperative irradiation is usually commenced two to three weeks after surgery to allow wound healing. Doses of 20 to 30 Gy in 5 to 10 fractions are customary, with boost doses of 600 to 900 cGy where appropriate. As before, the isolated bone lesion may be considered for a more protracted TDF course.

SPECIALIZED RADIOTHERAPEUTIC TECHNIQUES IN BONE METASTASES

Wide-Field and Systemic Irradiation

The ability to deliver tumoricidal doses of ionizing radiation systemically or at least to wider "fields" requiring treatment is an extremely appealing concept in the management of patients with or at high risk of developing overt metastatic disease. Radiation remains the most effective single anticancer agent in solid malignancies. However, the toxicities of such approaches have traditionally rendered them less desirable in this context in the opinion of most clinicians. The use of "hemibody" irradiation (HBI) or sequential double-hemibody irradiation (DHBI), either in single or multiple fractions, is not new. [153,154,155 and 156] With the advent of radioprotectors

such as interleukin-1 and nitroxides, [157,158] along with recombinant growth factors allowing a degree of bone marrow protection, the use of HBI/DHBI with these agents is enjoying a revival in the investigative management of systemic malignancies. Included are those cancers affecting bone marrow (multiple myeloma and non-Hodgkin's lymphoma) as well as bone metastases from solid malignancies (primarily prostate and breast).

Although response rates are less than those usually expected from fractionated local-field irradiation (complete responses 20% and partial responses 50%), the pain relief may be rapid (24 to 48 hours). The use of fractionated (30 Gy in 10 fractions) versus single-dose (600 to 800 cGy in 1 fraction) may be more effective in terms of time to and duration of response, as well as toxicity, but offered no survival benefit where evaluated. [155] The optimal fractionation scheme for HBI has not yet been defined but has been evaluated by the RTOG in a phase I-II trial. [156] The dose-limiting toxicity appeared to be hematological, but gastrointestinal toxicities were also significant.

The RTOG also assessed the role of wide-field irradiation in delaying the progression of subclinical disease. A randomized prospective study found that the addition of wide-field to local irradiation delayed the onset of new disease in the targeted hemibody field, with a doubling of time to progression (6.3 to 12.6 months). [10] The same investigative approach was used in the evaluation of radionuclides in the therapy of bone metastases. Injectable radionuclides such as phosphorus-32, strontium-89, iodine-131-diphosphonates, rhenium-186, and samarium-153 are bone-seeking compounds which have been shown to be effective in relieving pain from bone metastases. [159] Much attention has been recently focussed on strontium-89 (^{89}Sr). Randomized comparisons of local field irradiation and local field plus ^{89}Sr have shown a benefit in terms of improvements in quality of life and reduction in analgesic requirements, as well as delaying the requirement for further radiotherapy in prostate cancer. [160,161] Current trials are evaluating the combination of HBI/DHBI with radionuclides and may bring about improvements applicable to treatment of bone metastases from lung cancer.

PALLIATING LOCOREGIONAL PROBLEMS IN LUNG CANCER

Superior Vena Cava Syndrome (SVCS)

Modern reports show that obstruction to the flow of blood through the superior vena cava is due to intrathoracic malignancy in almost 90% of cases. [162] Lung cancer (usually the right lung) is the commonest malignant cause, accounting for 70% of all cases. [163,164] Although SVCS occurs in less than 5% of all patients with lung cancer, [165,166] it is an important syndrome requiring recognition and relatively urgent management. Small cell (40%) and squamous cell (25%) are the commonest histologic culprits. [163,167] The SVC is a large, thin-walled vessel in the middle mediastinum and is intimately related to the right bronchus, hilum, and paratracheal lymph nodes, draining the entire right and left lower thoracic contents. It is not surprising, therefore, that it is vulnerable to compression in lung and other intrathoracic malignancies. The rapidity of onset of the obstruction is an important determinant of the type of clinical syndrome produced. Rapid occlusion of the vessel produces acute and at times dramatic clinical signs. Gradual occlusion allows time for the development of collateral vessels. This syndrome has been modeled in animals. [168] The commonest presenting symptoms and signs are listed in Table 58.18. It is important to bear in mind that the syndrome varies from an acute and dramatic presentation to a more insidious and indolent picture. Frequently, the facial and neck swelling may be apparent only on comparing appearances with an old photograph or driver's license. Although SVC has long been considered a "medical emergency," it should be emphasized that in general the only threat to the patient's life is when the patient's airway is impeded, either from the mass itself, from laryngeal edema secondary to venous hypertension, or from raised intracranial pressure.

- Dyspnea aggravated by lying flat
- Facial swelling/fullness
- Cough
- Sensation of fullness in chest
- Orthopnea
- Venous distension of neck and chest wall
- Facial swelling and plethora

TABLE 58.18. COMMON SYMPTOMS AND SIGNS IN SVCS

Diagnosis and Management of SVCS

The practice of irradiating the patient with SVCS without a tissue diagnosis is inappropriate. [23,163,169] The presence of SVCS itself does not preclude a curative therapeutic strategy. The prognosis of this syndrome is strongly correlated with that of its underlying cause. On assessing the patient clinically, particular attention should be paid to the presence of airway compromise, since this will guide the diagnostic approach and therapy. The chest radiograph is usually although not invariably abnormal. [170] CT and MRI scanning provide valuable anatomic detail and staging information as well as vital detail for treatment planning. The majority of patients with SVCS present prior to an established tissue diagnosis. [169] Some tissue diagnoses may be obtained by sputum cytology, thoracentesis, and bone marrow and lymph node biopsy, with positivity rates of 23% to 67%. [163] However, bronchoscopy, mediastinoscopy, and even thoracotomy may be required. Recent series point to acceptable complication rates where these tests have been employed. [171,172 and 173] Although radiation is frequently employed in the management of this syndrome, other therapeutic options are often appropriate. Chemotherapy may be the preferred initial option in patients with SCLC (see below), and has been used successfully in patients with recurrent disease. [174] Stenting has been used successfully in selected cases. [175,176,177 and 178] Even long-standing lesions can be successfully recanalized. [179] Extended surgical resections in cases of NSCLC with direct invasion on the SVC can also be effective. [180]

The optimal initial management for the patient with small cell lung cancer and SVCS is generally combination chemotherapy, although radiation has been used in selected series. There is no difference in outcome or time to resolution between the two, [163,167] but chemotherapy offers the advantage of simultaneous management of systemic disease and avoidance of large-field irradiation to the heart and lung. Resolution of the syndrome is prompt (seven to 10 days) and is achieved in 43% to 100% of cases. [181,182] One randomized study in small cell patients with SVCS assessed the value of radiation versus chemotherapy in patients initially managed with chemotherapy and found no benefit to the radiation in this circumstance. [183]

Radiation Management of SVCS in Lung Cancer

Radiation is generally central to the management of the patient with NSCLC and SVCS. Initial treatment with 2 to 4 fractions of 300 to 400 cGy has been advocated, [163] based on limited evidence suggesting a more prompt response with this schedule. [166] The choice of higher initial radiation fractions has also been advocated in patients with poor performance status. [184] However, the optimal TDF schedule in SVCS has not been established, and there is no clinical data to suggest a dose response in terms of the final dose required. Where possible, all locoregional disease, including involved hilar and supraclavicular regions, with appropriate margins should be treated. Failure of resolution of SVCS despite optimal management should prompt the search for ancillary problems such as intravascular coagulation within the SVC itself. Refractory or recurrent SVCS, especially in the patient who has received prior radiation, may require the placement of an expandable or rigid stent to reestablish patency. [175,176,177 and 178,185] Sharp recanalization might also be effective in these circumstances. [179] Neoadjuvant chemotherapy is of uncertain and untested value in this circumstance; however, it is not without potential merit.

Locoregional Problems in Lung Cancer

Up to 70% of patients with lung cancer present with problems related to locoregional disease. Both at presentation and relapse, locoregional symptoms are of major importance in this tumor. Radiation represents the most active agent available in the management of these problems. The use of brachytherapy techniques, both low- and high-dose rate, are increasingly popular in this context. A detailed discussion of these is seen in Chapter 49. As with other palliative issues, radiation response rates are available from a variety of studies (mostly retrospective) within a heterogeneous patient population. Therefore individualization is required, and the results

quoted should be used as a rough guide only. The major symptoms and response rates are presented in Table 58.19. Randomized studies of a variety of TDF schedules in the palliative management of locally advanced NSCLC have shown equivalent survivals on the whole, irrespective of the technique used. [186],[187] and [188] Typically, approximately 25% of patients experience complete relief of symptoms, while almost 50% obtain partial but measurable improvements. The duration of this palliation is generally meaningful, and persists for more than half of the expected life of the patient. [188],[189] Selected retrospective reviews have shown symptom response rates equivalent to those quoted from these larger randomized studies. [189],[190] As discussed in above, the final choice of TDF schedules in the palliatve care of the patient with lung cancer varies significantly from physician to physician and country to country. [15] Since these patients have limited median survivals (generally six months) and there is no evidence of improvement in survival, response rates, time to, and duration of response, shorter TDF schedules are generally preferred. Doses of 30 to 35 Gy at 250 to 300 cGy per fraction are generally considered standard in the United States, while 17 Gy in two fractions (one week apart) is gaining favor in Britain. The significant rates of local relapse have made the issue of retreatment of locoregional disease a recently addressed issue. In general, 20 to 30 Gy using 200 cGy fractions may be safely administered to mediastinal and lung fields, with selected patient benefit.

Symptom	Frequency	Improved	Complete Relief
• Cough	61%–93%	56%–65%	30%–54%
• Hemoptysis	31%–47%	81%–86%	74%–82%
• Dyspnoea	54%	—	37%
• Pain	42%–57%	74%	50%–52%
• Atelectasis infection	26%	—	62%
• Hoarseness/TVC	25%	—	49%
• Dysphagia	11%	—	—

MALIGNANT PLEURAL EFFUSION

FRANK A. BACIEWICZ, JR

The discovery of a pleural effusion is a common clinical problem. The most frequent cause for a pleural effusion is an underlying malignancy. [1] Lung cancer is the most common cause of malignant effusion, followed by breast cancer and lymphoma.[2] Pleural effusions have been reported to occur in up to 50% of patients with breast cancer,[2] in about 25% of patients with lung cancer[3] and a third of patients with lymphoma.[4] These tumors are responsible for nearly 75% of all malignant pleural effusions. The remaining malignancies include the gastrointestinal tract, genitourinary tract, melanoma, mesothelioma, sarcoma, thyroid, and leukemia. Adenocarcinoma of the lung is the most frequent pulmonary malignancy-causing effusion. The primary tumor is unknown in 15% of patients.

Pleural effusions may be the presenting sign or symptom of the carcinoma or they may occur near the terminal period of the illness. Survival following presentation is related to the primary tumor. Survival is usually limited to months with lung carcinoma but in patients with breast cancer, survival can be much longer.

Since the patient presents with dyspnea and pleuritic pain, treatment of malignant pleural effusion is an important component of therapy. In addition, the respiratory distress may compound the anxiety the patient has due to the malignancy. Even if the patient's disease process cannot be cured, treatment of malignant pleural effusion will not only improve his or her symptoms but alter his or her emotional state. Prompt and efficacious treatment of malignant pleural effusion will not only contribute to patient well-being but decrease time of hospitalization and cost to the health care system.

PATHOPHYSIOLOGY OF MALIGNANT PLEURAL FLUID FORMATION

Anatomy of the Pleura

The parietal pleural receives its blood supply from the intercostal arteries and is drained by systemic intercostal and bronchial veins. The visceral pleural receives its blood supply from the bronchial (systemic) circulation.[5] Its venous drainage is via the subvisceral pleural capillaries into the pulmonary veins.

Lymphatic drainage[6] of the parietal pleura drains into both internal mammary nodes anteriorly and intercostal nodes posteriorly. The anterior and posterior mediastinal nodes also receive drainage from the diaphragmatic pleural lymphatics. The lymph from the visceral pleura flows centripetally toward the hilum. The lymph eventually reaches the right lymphatic trunk or the thoracic duct, which empties into the junction of the left internal jugular and subclavian veins.

Mesothelial cells form the lining of the parietal and visceral pleura. In addition stomata, 2 to 12 mm, form openings between the mesothelial cells. They are centered over the lymphatic channels. Stomata are the entry point of pleural fluid, particulate matter and protein from the parietal pleural space. Through the stomata there is a direct communication to the lymphatic channels. No communication exists between the lymphatics and the visceral pleura and the pleural space.

Normal Pleural Fluid Formation

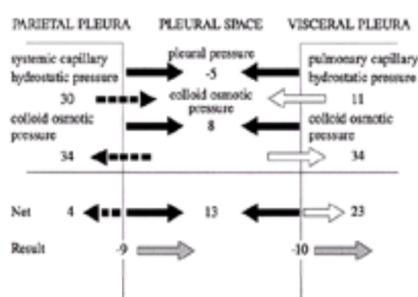
Pleural fluid formation had been thought to be dependent on the visceral and parietal pleural hydrostatic and colloid oncotic pressures. Following Starling's law, [7] the pleural fluid formation was the result of the mean capillary hydrostatic pressure minus the capillary colloid oncotic pressure which favored the movement of fluid from the parietal pleura into the pleural space (Figure 59.1). These forces also favored the reabsorption of fluid from the pleural space to the visceral pleura. Based on these calculations, there was a net movement of pleural fluid from the parietal pleura to the visceral pleura. The protein within the pleural space was cleared by the lymphatic system. Given this application of Starling's law, the rate of pleural fluid and protein production was thought to be as high as 7 L per day. [8]


FIGURE 59.1. Net flow of protein-free fluid in accordance with Starling's law and assuming that the visceral pleura is supplied by pulmonary circulation. Pressures are provided in cm H_2O.

These concepts have been updated recently.[6,9] The parietal pleura has assumed the major role in movement of pleural fluid. The parietal pleura, which is only 10 to 20 microns from the visceral pleura, produces 100 to 200 mL of fluid per 24 hours. Since the visceral pleural microcapillaries are removed from the visceral surface, they play only a minimal role in reabsorption of pleural fluid. Conceptually the pleural fluid can be thought of as being in continuity with the parietal pleura interstitium.

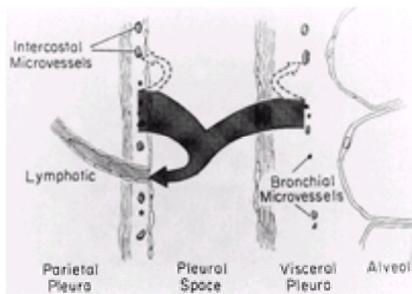
The current concept is that the parietal systemic capillaries produce a low-protein filtrate which enters the parietal pleura interstitium and then passes through the mesothelial cells into the pleural space. The protein content of the fluid in the pleural space is about 1.5 grams per dl.[10] The stomata lining of the parietal pleura allow the exit of pleura fluid, particulate matter, and protein from the pleural space. This passes into the lymphatic channels. Lymphatic fluid in the pleural space has a large reserve of up to 500 mL. With the equal entry and exit of fluid from the pleural space there is no accumulation of fluid (Figure 59.2).


FIGURE 59.2. The parietal pleura is the primary site of entry and exit of fluid and protein. (From Broaddus C, Staub NC. Pleura liquid and protein turnover in health and disease. *Semin Respir Med* 1987;9:7, with permission.)

Mechanisms of Abnormal Pleural Fluid Formation

Abnormal pleural fluid formation can be due to single or multiple etiologies. Changes in the hydrostatic or colloid oncotic pressure can result in transudative effusions.[11,12] Clinical scenarios including hypoalbuminemia, atelectasis, or congestive heart failure produce transudative effusions.

The usual cause of malignant pleural effusion is changes in the lymphatic drainage from the pleural space.[3,13] The etiology may be tumor obstruction of the parietal pleura stomata, mediastinal node involvement with impaired lymphatic drainage, or increased parietal capillary permeability due to lymphangitic tumor spread. The extent of metastatic pleural involvement does not correlate with the development of pleural effusion.[14] Pleural implants can alter capillary permeability by their production of vasoactive peptides.

Malignant pleural effusions are usually secondary to pulmonary artery invasion[12] by lung cancer and embolization of tumor cells to the visceral pleura with subsequent seeding of the pleural space. More peripheral lesions may have direct involvement of the pleural space. Direct extension from breast carcinoma involving the chest wall can cause malignant pleural effusion.

Pleural effusions can also be caused by factors that do not directly involve the pleural space.[15] Changes in the hydrostatic pressure from cardiac or pericardial disease or superior vena cava syndrome can be the underlying reason for pleural effusion. Mediastinal and chest radiation can impair lymphatic drainage and be the cause of pleural effusion. Pneumonic processes such as lung atelectasis can alter the pleural pressure. Communication from malignant ascites through diaphragmatic lymphatic channels can also cause secondary malignant pleural effusion. Conditions such as cirrhosis, connective tissue diseases, and hypoalbuminemia may also affect the rate of pleural fluid production and need to be considered when therapeutic interventions are made.

CLINICAL MANIFESTATIONS

Characteristics of Malignant Pleural Effusions

At the time of presentation, 77% of patients with malignant pleural effusions have symptoms. A malignant pleural effusion is the initial presentation in up to 90% of patients with primary or metastatic pleural malignancy.[16,17]

The most common respiratory symptom is shortness of breath. Dry cough and pleuritic chest pain are other commonly voiced complaints. The cough is a result of the underlying lung atelectasis and chest pain is due to the inflammation of the parietal pleura. Ipisilateral shoulder discomfort may be present when there is diaphragmatic parietal pleura involvement.

On physical examination there is dullness to percussion in the lower aspect of the thorax and with a larger pleural effusion there is dullness over the entire thorax. Breath sounds in the area of the effusion will be decreased. The effusion may also elicit a change in the character of the transmitted sound. Atelectasis of the compressed lung may result in hyperresonance above the fluid level due to distended alveolar air space. Below the fluid there may be loud bronchial breathing.

With significant tumor involvement of the chest wall there may be restricted expansion or intercostal fullness. The trachea may deviate to or away from the side of the effusion. The trachea is shifted away from the side of the pleural fluid when the malignant effusion is secondary to breast or ovarian carcinoma. When the trachea shifts toward the pleural effusion, the most likely etiology is carcinoma of the lung with either complete or partial bronchial obstruction.

The patients with an advanced stage of the malignant disease will have weight loss, appear cachetic, and feel chronically tired.

DIAGNOSIS

Radiologic Assessment

A chest radiograph is usually the initial test in a patient who presents with respiratory symptoms or physical examination suggestive of pleural effusion. The chest x-ray can demonstrate a varied appearance, with blunting of the costophrenic angle, a concave meniscus, disappearance of the diaphragmatic shadow, an apical cap, or fluid in the intralobar fissure. An upright chest film can demonstrate blunting of the costophrenic angle with as little as 175 mL of fluid.[18] A lateral chest x-ray can detect as little as 100 mL of fluid, and decubitus films can demonstrate free from loculated fluid collection. Decubitus films can also assist in diagnosis of some pulmonic effusions. Subpulmonic effusions are suggested when there is increased space between the inferior surface of the left lower lobe and the gastric air bubble on an upright chest film.[19]

Pulmonic effusion can sometimes be confused with atelectasis. Pulmonic effusion can cause mediastinal shift to the contralateral side, while atelectasis produces a shift in the mediastinum toward the same side. When the mediastinum is fixed in the case of a mesothelium or a patient with significant mediastinal adenopathy, this radiologic finding may not be helpful.

Computerized tomography (CT) can help distinguish between effusion, atelectasis, or pleural-based tumor. The Housefield units may distinguish between pleural effusions which have a density of 20 units compared with tumors or solid lesions which have higher Housefield units.[20] The Housefield units cannot differentiate between different causes of the pleural fluid. CT can distinguish or actively define loculated fluid collections and assess mediastinal adenopathy, which is important in determining treatment.

Characteristics of Malignant Pleural Effusion

A typical malignant pleural effusion is grossly bloody and exudative in nature. However, only 30% to 60% of bloody effusions are malignant. [21] Other possible diagnoses include infection (tuberculosis) and pulmonary infarction. The effusions are bloody because of tumor involvement of blood vessels, tumor occlusion of systemic or pulmonary veins, or parietal pleural capillary dilation secondary to the release of vasoactive substances from the primary tumor.

The effusion usually has a leukocyte count of 1,000 to 10,000. The cells are usually lymphocytes. [22] If neutrophils are the dominant cells, the pleural effusion is most likely inflammatory.

Eight-five percent of malignant effusions are exudates. Exudates characteristically have a pleural-to-serum-protein ratio greater than 0.5, pleural lactic dehydrogenase (LDH)-to-serum LDH ratio greater than 0.6, and a pleural fluid LDH level of greater than 200 international units. [23,24] Exudative effusions can also have a low pH (less than 7.30) and a pleural glucose serum glucose ratio less than 0.5. Patients who are found to have a malignant effusion with a pH of less than 7.3 and a low pleural-to-serum-glucose ratio (less than 0.5) usually have a shortened survival and do not respond well to therapeutic intervention for the malignant effusion. [25]

Adenocarcinoma of the lung or ovary may have an elevated amylase detected in the pleural fluid. [26] If the malignant pleural effusion is a transudate, it is usually early in the course of the malignant process. The transudates are usually related to mediastinal lymphatic involvement with impaired lymphatic drainage.

If thoracic duct flow is decreased either due to direct tumor invasion, obstruction, or from tumor emboli, chylothorax can occur. The malignancies most frequently associated with a chylothorax include lymphoma, lymphosarcoma, and bronchogenic carcinoma.

The pleural fluid has a characteristic milky appearance. The chylothorax has specific gravity between 1.012 and 1.025, lymphocytes of 400 to 7,000 per mL, fat of 4 to 5 grams per dL, cholesterol/triglyceride ratio of less than 1, a total protein of 2 to 6 grams per dL, albumin of 1 to 4 grams per dL, glucose of 50 to 100 mg per dL, and electrolytes identical to that in serum.

Cytology

The most straightforward way of making a diagnosis of a malignant pleural effusion is with thoracentesis. The procedure is usually done at the bedside after placing 1% lidocaine in the skin and intercostal space through which the thoracentesis will be performed. If the effusion is loculated or the patient has had a previous thoracotomy requiring precise localization of the fluid, the thoracentesis may be performed under CT scan or echographic direction. The patient's prothrombin, coagulation studies, and platelet count should be normal prior to doing thoracentesis.

A minimal sample of 250 mL should be removed and sent to the laboratory for examination. The samples may be cytocentrifuged and air dried or prepared as wet mounts with toluidine blue or 95% alcohol. Any cell blocks should undergo paraffin imbedding and sectioning. Malignant cells are recognized by clusters or single malignant cells. These cells will characteristically be pleomorphic, large, have a prominent nucleus with large nucleolus, and have a high nuclear-to-cytoplasmic ratio. [27] Adenocarcinoma of the lung is most commonly responsible for a positive malignant pleural effusion. [13,28]

The thoracentesis fluid may also be subjected to immunochemical testing using monoclonal antibodies, polyclonal antisera to epithelial membrane antigen, carcinoembryonic antigen (CEA), and IGG 1 antibody B72–3. There is a positive reaction to the CEA antisera in 50% and to the polyclonal antisera in 54% of malignant effusions. [29] Adenocarcinoma of the lung, breast, and ovary have a positive reaction to the IGG 1 antibody B72–3 in 100% of malignant effusions. [30,31] Other monoclonal antibodies that demonstrate a positive reaction with malignant cells include HMFG-2, AUA-1, Mbr, and Mov 2.

The laboratory is able to establish a diagnosis from 50% of patients with malignant effusion on initial thoracentesis. With a second thoracentesis, diagnosis is obtained in up to 65% of patients, and with a third thoracentesis, diagnosis is made in slightly more than 70% of patients. [32,33] Thoracentesis carries a 3% false-positive diagnosis rate. A pleural biopsy in conjunction with thoracentesis can raise the expected diagnosis of malignant pleural effusion to 80%. By itself, a pleural biopsy has only a 45% successful diagnosis which may be explained by localized pleural involvement with the malignant process. [34]

When thoracentesis or closed pleural biopsy have not established a diagnosis, thoracoscopy is the next diagnostic alternative. Thoracoscopy allows the direct biopsy of involved areas of the pleura or lung and is nearly 100% sensitive. This procedure requires that the patient have a good performance status, as a general anesthetic is usually administered. Video-assisted thoracoscopy (VATS) will be necessary in only 15% to 20% of patients for diagnosis. [35,36] Thoracoscopy may also allow insertion of a chest tube and sclerosis at the conclusion of the procedure. Localized pleurectomy may also be done at the time of diagnosis. Thoracoscopy is not indicated in patients who have had previous thoracic operations or previous chest radiation or may have loculated fluid collection due to previous thoracentesis or pleural biopsy. These patients may require an open biopsy for diagnosis.

Evaluation of tumor markers in the pleural fluid may became another adjunct to diagnosing malignant pleural effusion. Pleural fluid levels of CEA, creatinine kinase BB, galactosyl transferase, and adenosine deaminase [21,37,38] have been investigated in the pleural fluid. Markers have been neither sensitive or specific enough to establish a diagnosis. [39,40] When thoracentesis is not able to establish a diagnosis, cytogenic testing and chromosome analysis may be useful. Pleural effusion diagnosis using cytogenics has been reported in the range of 65% to 90%. [41,42 and 43] These changes have been most frequently abnormal in patients with lymphoma or leukemia.

TREATMENT

Approach

If pleural effusion is noted in a patient with a non–small cell lung cancer, the prognosis is poor. A complete diagnostic evaluation will usually demonstrate that the patient has advanced stage III B to stage IV lung carcinoma. All patients should undergo diagnostic evaluation, as the pleural effusions may be the result of lung atelectasis, congestive heart failure, cirrhosis, hypoalbuminemia, or pulmonary embolus. If even one of these etiologies is present, only 5.5% of patients with lung malignancy and negative pleural effusion are candidates for surgical resection. [44]

Malignant pleural effusion related to lymphoma, small cell carcinoma, or breast carcinoma and treated with systemic therapy may result in resolution of the effusion. [45] If the patient should be symptomatic with one of these diseases that are amenable to systemic therapy, thoracentesis can be performed for relief of symptoms while awaiting the effect of the systemic therapy.

Asymptomatic patients with a malignant effusion (25% to 30% of the patient population) do not need immediate treatment. Seventy-five percent of patients who will be symptomatic need treatment. The treatment must be effective in a short period, not lead to other complications, and have a low recurrence rate, as patients with malignant pleural effusions secondary to lung cancer have an average survival of only 2.2 months. [16] Since the patient's expected overall survival time is low, minimizing hospitalization or avoiding it by keeping the patient mobile and causing minimal distress are important factors when determining treatment.

Thoracentesis

Thoracentesis, in addition to being diagnostic, can also provide the patient with significant therapeutic improvement. Usually no more than 1,000 mL is removed with thoracentesis. Reexpansion pulmonary edema may occur with removal of a greater volume. Thoracentesis may cause vaso vagal reaction from irritating the parietal pleura. The physician must have atropine and volume infusion available. [46,47]

After thoracentesis, the effusion will usually recur in 4.2 days [48] and consequently this treatment option is recommended only if the patient has a very short expected life span or is waiting the effect of systemic therapy.

Repeated thoracentesis can result in loculated fluid accumulation, empyema, or pneumothorax. Chemical pleurodesis can be performed through thoracentesis needle

but is less effective than pleurodesis via a tube thoracostomy, as there is residual pleural fluid and the lung is not completely reexpanded.

Tube Thoracostomy Alone

The placement of a 28–32 French chest tube will be effective in relieving respiratory symptoms. As with thoracentesis, no more than 1,000 mL should be drained initially and then the tube clamped to avoid pulmonary reexpansion edema. Recurrence rates of 60% to 100% have been reported with tube thoracostomy alone. [49,50]

Tube Thoracostomy and Pleurodesis

Tube thoracostomy with subsequent pleurodesis is the most successful strategy to prevent the recurrence of malignant effusion. The chest tube, a 28–32 French, is inserted through the fifth intercostal space anterior axillary line and directed posteriorly and toward the diaphragm. If the pleural effusion is large, 1,000 mL of fluid is removed and then 500 mL amounts every four hours to prevent reexpansion pulmonary edema. The chest tube is placed to water seal and 20 cm of water suction. This allows for the lung to reexpand completely and the visceral and parietal pleura to come into contact. If the pleura are apposed, adhesion formation can begin.

For the pleurodesis to be successful, the lung needs to be completely reexpanded with visceral and parietal pleural in contact. There should be no loculated fluid collection in the pleural space which would prevent the sclerosing agent from bathing the pleural space. The sclerosing agent is introduced when there is less than 150 mL of drainage for 24 hours. [22] In addition, the chest x-ray must show absence of the pleural effusion and reexpansion of the lung. In addition to the mechanical pleuritis induced by reexpansion of the lung and the chest tube irritating the pleura, pleurodesis is thought to be successful because of cytoreduction and chemical pleuritis from the sclerosing agent.

When the drainage has met criteria, the sclerosing agent is delivered after premedicating the patient with a narcotic analgesic; 20 mL of 1% lidocaine should be added to the sclerosant for local anesthetic effect. The sclerosing agent is usually instilled in 50 mL of 0.9% normal saline. After instilling the sclerosing agent, the chest tube is clamped and the patient is rotated in the supine position, prone, left and right decubitis positions every fifteen minutes to improve distribution of the sclerosing agent. A publication studying the movement of radiolabeled tetracycline demonstrated that the rotation of the patient did not influence distribution of the sclerosing agent. [51] After the chest tube has been clamped for four hours, the clamp on the chest tube is removed. It is important to leave the chest tube in place for several days after instilling sclerosing agent to further adhesion formation. Usually the chest tube is discontinued when there is less than 150 cc of drainage for 24 hours. [52]

Recently a small pigtail catheter (up to 24 French) has been inserted under CT or echo guidance. [53,54 and 55] The catheters have been placed to a drainage bag and the patient's pleural effusion has been drained on an outpatient basis. Prior to removing the pigtail catheter, the sclerosing agent has been inserted. This approach allows the patient to be managed on an outpatient basis with a smaller tube which is more comfortable. In a preliminary trial from Duke University Medical Center, 19 consecutive patients with symptomatic malignant pleural effusions were enrolled. A fluoroscopically placed 10.3 French catheter was connected to a closed gravity drainage bag system. Sclerotherapy was performed when daily drainage was less than 100 mL. The tubes remained in place for two to 11 days (mean, 5.1 days). At 30 days, 10 (53%) patients had a complete response, five (26%) had a partial response, and four (21%) had progressive disease. Problems with this approach have included pneumothoraces requiring regular-sized chest tube insertion, inadequate drainage, and inability to use talc, which is the most effective sclerosing agent, through the small-bore catheter. When the chest tube has been discontinued, a suture is usually placed in the wound to prevent drainage of pleural contents through the chest tube site.

A unique but small, prospective, randomized study has compared pleurodesis using a small percutaneous catheter (10 French) inserted at bedside in patients with recurrent malignant pleural effusion with a conventional large-bore chest tube (24 French) placed in connection with diagnostic thoracoscopy. After drainage, pleurodesis was performed, with tetracycline as sclerosing agent. Of 18 evaluable consecutive patients (mean age 67.8 years), nine were randomized for pleurodesis with the small, and nine with the large catheter. The authors concluded that pleurodesis in patients with recurrent malignant pleural effusion using a small percutaneous catheter had similar efficacy to that obtained with a large-bore chest tube and with less discomfort for the patient. Trials with larger numbers of patients will certainly be necessary to evaluate whether small-bore catheters are as effective and cheaper for the patient during his or her care than the more standard techniques of drainage and sclerosis. [56]

Talc Pleurodesis

A highly effective treatment for recurrent malignant pleural effusions is thoracoscopic talc poudrage. Using either local anesthetic technique with intravenous sedation in a nonintubated patient or general anesthesia with a double lumen endotracheal tube, the 5 gm of talc is instilled over the entire pleural space and lung surface, usually with a simple bulb aspirating syringe. The response rate to thoracoscopic talc insertion is 90% to 96%. [35,57,58 and 59] Since this technique has such a high success rate, some physicians recommend it as an initial treatment.

A talc slurry of 5 grams in 250 mL of saline with lidocaine added has been successful in 93% of patients. [60] Complications including pneumonitis and respiratory distress syndrome have been reported. [59,60,61,62,63 and 64]

Other Sclerosing Agents

Many agents besides talc have been used as sclerosing agents. Successful response is defined as no reaccumulation on chest x-ray for at least one month after the removal of the chest tube and no need for additional thoracentesis. One of the initial agents, nitrogen mustard, was administered at a dose of 0.4 mg per kg. The response rate was 52% with this agent. [2] The side effects included pain, fever, nausea, vomiting, and bone marrow depression. [65]

Tetracycline had been the agent of choice until 1991 when it was withdrawn from the market as it did not meet the U.S. Food and Drug Administration purity standards. Tetracycline was instilled in a dose of 500 to 1,000 mg, usually diluted in 50 mL of NaCl 0.9% solution with 20 mL of 1% lidocaine. Significant complications included pain in 20% to 70% and fever in up to 33% of the patients. [66,67,68,69,70,71 and 72] Since tetracycline has been withdrawn, doxycycline has been used as a replacement agent in doses of 500 to 1,000 mg. When doxycycline has been instilled, there is a 90% success rate. Doxycycline is a relatively inexpensive sclerosing agent. [73,74,75 and 76]

Bleomycin 60 units dissolved in 100 mL of normal saline has given a response rate of 84%. [2,77,78] Bleomycin was responsible for two deaths and has not been used extensively since it is an expensive sclerosing agent.

Quinacrine has had multiple toxicities including hallucinations, hypotension, and fever. [79] Pain is not a complication with this drug. The usual dose was 800 mg, and instillation through thoracostomy tube gave a 70% to 90% response rate. [80,81]

Other agents include *Corynebacterium parvum,* which elicits an inflammatory response when used as a sclerosing agent. Four mg of *C. parvum* has been used after thoracentesis, as the agent usually requires multiple injections, with 30% of patients needing two injections, 60% three injections, and 10% four injections. [82,83,84,85 and 86]

Other agents that have been used for pleurodesis include methylprednisolone, doxorubicin, [87,88] cisplatin, cytarabine, [89] etoposide, [90] mitomycin-C, [91] radioisotopes including gold and phosphorus, [49] interferon, [92,93 and 94] and interleukin-2. [95,96 and 97]

Randomized Trials Comparing the Most Frequently Used Agents

There are few randomized trials comparing treatment for pleural malignancies for a number of reasons. Because life expectancy is limited, a large number of patients must be entered into a trial to have statistically meaningful numbers to analyze response rates. Pleurodesis is seldom an isolated variable, because many patients are simultaneously undergoing chemotherapy or radiotherapy. Moreover, there is no standard method of measuring response, and interpretation of radiologic response may be hindered by underlying lung disease. Because the goal of pleurodesis is palliation, quality-of-life issues, cost, and toxicity must be uniformly assessed.

A review of randomized trials reveals that most consist of small numbers of patients, dosages and administration vary, long-term follow-up is often lacking, and there is no central review of radiologic response. These trials are summarized in Table 59.1.

Investigators	Agents	Total Number of Patients	Result
Bayly[98]	TCN Quinacrine	20	Equal
Gupta[99]	Bleo TCN	25	Equal
Fentiman[119]	Nitrogen mustard Talc	46	Talc superior
Leahy[83]	CP TCN	32	Equal
Fentiman[101]	TCN Talc	41	Talc superior
Kessinger[100]	Bleo TCN	34	Equal
Hamed[102]	Bleo Talc	29	Talc superior
Masuno[106]	Doxorubicin and LC 9018	95	Doxorubicin and LC 9018 superior
Ruckdeschel[72]	Bleo	85	Bleo superior
Hartman[103]	TCN Bleo TCN	99	Talc superior
Pata[171]	Talc DCR	106	Equal

Bleo, bleomycin; CP, Corynebacterium parvum; TCN, tetracycline; DCR, doxycycline; from Keller SM. Current and future therapy for malignant pleural effusion. Chest 1993;103:63S, with permission.

TABLE 59.1. RANDOMIZED TRIALS COMPARING SCLEROSING AGENTS

In the trial by Bayly and colleagues comparing tetracycline (500 mg) to quinacrine (100 mg initially, followed by four daily doses of 200 mg), the agents were equally effective in controlling the pleural effusions (complete response equaled 66%).[98] However, the toxicity of quinacrine was higher.

Gupta and colleagues[99] and Kessinger and Wigton[100] reported that there was no difference between patient responses to bleomycin or tetracycline. Small numbers of patients were evaluable in these studies. However, in the multiinstitutional trial reported by Ruckdeschel and colleagues,[72] 30-day recurrences were significantly less for bleomycin versus tetracycline (36% versus 67%; p = 0.023) and remained less at 90 days (30% versus 53%; p = 0.047). The median time to recurrence was significantly longer for the bleomycin group than for tetracycline. The toxicities were low and equal between the two agents. Lung cancer accounted for 34% of the effusions in each group.

The trials reported by Fentiman and associates[101] and Hamed and colleagues[102] are instructive but included only patients with pleural effusions secondary to breast cancer. Leahy and colleagues[83] randomized patients to tetracycline (500 mg) versus *C. parvum* (7 mg) and found no significant difference between prevention of recurrence at one month. However, pain and pyrexia were significantly greater in patients receiving *C. parvum.*

Hartman and colleagues[103] reported a prospective phase II study that evaluated 39 patients undergoing talc insufflation under thoracoscopic guidance, as compared to patients enrolled in a multicenter study evaluating tube drainage followed by administration of either tetracycline (41 patients) or bleomycin (44 patients). Mean time of chest tube drainage was significantly less for the talc group than for patients randomized to bleomycin or tetracycline. Thirty-day success rates were 97% for the talc, 64% for bleomycin, and 32% for tetracycline. The 90-day success rates were 95% for talc, 70% for bleomycin, and 47% for tetracycline.

One of the more recent randomized trials compared the efficacy of bleomycin with doxycycline sclerotherapy using small-bore catheters. In this study, a 14 F self-retaining catheter was inserted into the pleural space and connected to continuous wall suction. When drainage fell below 200 mL per day, patients were randomized to 60 U of bleomycin or 500 mg of doxycycline sclerotherapy. Response at 30 days was determined. Of 106 patients enrolled in the study, 15 men (29%) and 37 women (71%) with a mean age of 57 years received bleomycin sclerotherapy; 21 of the 29 patients (72%) alive and evaluable at 30 days had successful sclerotherapy. Twenty-three men (43%) and 31 women (57%) with a mean age of 61 years received doxycycline sclerotherapy. Twenty-three of the 29 patients (79%) alive and evaluable at 30 days had successful sclerotherapy. There was no significant difference in response rates between doxycycline and bleomycin (p = 0.760).

Other Treatment Modalities

Biologic Response Modifiers

Use of standard treatment for malignant pleural effusions is occasionally not successful, necessiatating novel approaches. Other avenues have been tried, such as intrapleural installation of recombinant interleukin-2 (rIL-2). A response has been recorded in 22% to 50% of the patients.[95,97] Installation of beta-interferon was responsible for a 28% complete response rate in patients with non–small cell malignant effusion.[104] OK-432,[91,105] which is prepared from a substrain of *Streptococcus pyogenes* A3, and LC 9018, prepared from the *Lactobacillus casei* YIT9018,[106] have been able to effect complete responses in up to 70% of patients with protocols requiring more than one injection spaced over several weeks.

Management of the Recurrent or Refractory Malignant Pleural Effusion

When faced with the failure to control a malignant pleural effusion or reaccumulation of fluid after initial success, the need for retreatment should first be reassessed. If life expectancy is short (i.e., a few weeks or less), thoracentesis alone may be appropriate. The clinician must also decide whether the patient's predominant symptoms relate to the presence of pleural fluid and therefore whether expectation of relief warrants reintervention.

Failure of pleurodesis may result from a lung encased in scar or tumor (i.e., trapped lung), loculation of the pleural space by fibrin or adhesions, loss of pulmonary elasticity, high liquid output, or extensive pleural metastases. If the lung is fully expandable, the clinician's first inclination is to repeat the pleurodesis with the same or a different agent. For patients with lungs that do not expand completely, pleural peritoneal shunting or thoracoscopy could be considered.

Pleural Peritoneal Shunting

The first option to consider for patients with recurrent or newly diagnosed pleural effusions *with lung nonexpansion* is pleuroperitoneal shunting.[107,108,109 and 110] The shunt can be placed under general or local anesthetic. It is a unidirectional pumping chamber with connected arms, usually inserted with the pleural arm being in the most inferior aspect of the pleural space. The pumping chamber is placed over a rib or costal margin, and then the peritoneal arm placed through a pursestring suture through a muscle-splitting incision in the abdomen. The Denver or pleuroperitoneal shunt requires a cooperative patient to press the pump consecutively for 10 minutes on four to six occasions during the day. Each compression will propel 1.5 mL of fluid. A cooperative patient is required for its successful use.

There are a number of studies which document the utility of pleuroperitoneal shunting in recurrent effusions.[111,112 and 113] Tsang and colleagues[114] achieved good palliation without recurrence of symptoms in 15 of 16 patients. Mean duration of shunt function was 8.6 months. Ponn and colleagues[115] achieved similar results in a group of patients who did not benefit from chemical pleurodesis or who had a trapped lung. This group constituted 4% of patients undergoing treatment for pleural effusion.

Contraindications for placing the Denver pleuroperitoneal shunt include lack of patient cooperation, loculated pleural effusion, peritoneal space which is not free secondary to previous surgery, peritoneal dialysis, pleural infection, or a short life expectancy for the patient. The shunt can become occluded in 10% to 15% of patients with fibrinous material. Shunt occlusion requires revision, usually in the form of total replacement.[116]

Thoracoscopy

When pleurodesis has not been successful or a malignant effusion recurs, thoracoscopy under local or general anesthesia can be used to install talc under direct vision, but only after there is release of a trapped lung from adhesions, or loculated pockets have been obliterated which caused the pleurodesis failure. Since the procedure usually requires general anesthesia, the patient will need to have a high performance status and an acceptable expected long-term survival.[117]

Pleurectomy

Stripping of the parietal pleura has close to a 100% success rate in obliterating malignant effusions. This is a procedure which requires general anesthetic, and consequently the patients must have a high performance status and good prognosis. Few patients with malignant pleural effusion will have a survival rate which rate justifies the 30-day mortality of over 10% and a significant morbidity. [17,48]

Malignant Effusion Discovered at Thoracotomy

When new effusions are recognized at thoracotomy, chest tube placement effectively obliterates the pleural space. Thoracic surgeons have performed localized pleural resection to aid in the obliteration of the pleural space. A study of the infusion of hyperthermic cisplatinum in this setting with an extra corporeal circuit has 100% control of malignant pleural effusions, with patients having a mean survival time of 20 months. [118]

SUMMARY

Treatment of patients with malignant pleural effusions depends on the etiology of the malignancy and the patient's expected survival. Patients with non–small cell lung cancer have an expected survival of only several months, whereas patients with breast cancer have a much longer survival.

The first step is to perform a thoracentesis to establish the diagnosis, if not already known. In patients with short expected survival, thoracentesis alone can provide significant relief. In patients with a better prognosis, drainage of the pleural space with a CT-guided drainage catheter or a standard chest tube is the preferred treatment. After the chest tube drainage is less than 150 mL per day and the lung is in contact with the pleural surface, a sclerosing agent, most often talc 5 grams, can be instilled through a chest tube or drainage catheter. It can be repeated on several occasions if necessary.

If chest tube drainage and pleurodesis are not successful, other treatment options are available. Thoracoscopy can be used to free a trapped lung and break up loculated effusions prior to installation of talc. This treatment modality would require the patient to have an expected lengthy survival. If thoracoscopy is not an option, a pleuroperitoneal shunt can be considered, although our experience has been that these often become occluded.

Under special circumstances pleurectomy can be considered to obliterate the pleural space.

In patients with breast cancer or lymphoma, treatment of the malignancy with chemotherapy and radiation itself may result in resolution of the malignant effusion.

The treatment protocols outlined above are dedicated to improving the patient's symptoms and making them comfortable. The length of the treatment and the time the patient is in the hospital for that treatment figure prominently in the prescribed therapy. For this reason the experience of the clinician is important.

Future trials using small-bore catheters for treatment of malignant effusions, new biological modifiers, and new sclerosing agents may well affect the treatment of malignant effusions. The clinician must keep up to date with these trials and advances in the therapeutic management of the malignant pleural effusion.

MALIGNANT PERICARDIAL EFFUSION

JOSEPH B. ZWISCHENBERGER
ARAVIND B. SANKAR
RAYMAN LEE

Pericardial effusion is the most common manifestation of malignant pericardial involvement. In a series of 3,327 autopsies for cancer-related deaths, cardiac-related malignancy was detected in 5.1%.[1] Of these, the pericardium alone was involved in 45% of cases, the myocardium in 32%, and both in 22%. [2,3 and 4] Primary malignancies with a propensity for cardiac involvement, in decreasing order of frequency, include lung, breast, lymphoma (including Hodgkin's), leukemia, melanoma, gastrointestinal malignancies, and sarcomas. Malignant pericardial effusion (MPE) presents a clinical spectrum that ranges from totally asymptomatic to acute cardiac tamponade. Fortunately, clinically significant MPE is uncommon. Neoplastic cardiac tamponade is a clinical oncologic emergency, which may appear suddenly and precipitate death in a patient who would otherwise have a good short-term life expectancy. Patients presenting with cardiac tamponade usually have a known pulmonary primary.[5,6 and 7]

PATHOGENESIS

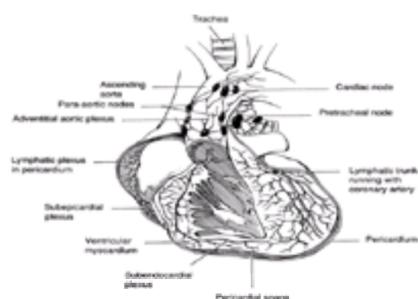
The pericardium is a strong, inelastic sac composed of two layers surrounding the heart. The outer fibrous parietal pericardium is commonly referred to as the pericardium. The thin, inner, serosal layer is the visceral pericardium, also known as the epicardium. These two layers form a thin, lubricated space which usually contains between 15 and 50 mL of fluid. Pericardial fluid is a clear ultrafiltrate of blood with a protein concentration one third that of plasma. Microscopically the pericardium has microvilli that decrease friction and increase the surface area of reabsorption. A fundamental knowledge of the lymphatic drainage patterns of the heart and pericardium is important in understanding the pathogenesis of MPE (Figure 60.1). The parietal lymphatics drain preferentially to the anterior and posterior mediastinal nodes, while the visceral lymphatics drain to the tracheal and bronchial mediastinal lymph nodes. [8] The pericardium itself is deficient in lymphatics, so most of the drainage occurs through the cardiac lymphatics. Flow begins in the extensive subendocardial plexus, which drains through an interconnecting system of myocardial channels into a subepicardial plexus. Efferent branches of the subepicardial plexus give rise to the cardiac lymphatic trunk, which runs with the coronary arteries to the root of the aorta. The cardiac lymphatic trunk then travels between the innominate artery and the superior vena cava directly to the cardiac node. The cardiac node then drains into the mediastinal nodes. [5] Tamura and colleagues reviewed 74 autopsies of primary lung cancer patients. [9] Metastases to the heart, or pericardium, were documented in 23 cases. MPE was present in 15 of the 23 cases. The metastatic pathway was lymphatic in 14 of 15 cases, utilizing hilar lymphatics in 10, and mediastinal lymphatics in four. Early development of MPE in lung cancer is primarily by hilar lymphatic spread. [9]


FIGURE 60.1. Lymphatic drainage of the heart and pericardium.

Venous and lymphatic drainage obstructed by neoplastic invasion leads to a disruption in the usual osmotic and hydrostatic forces, causing an accumulation of pericardial fluid. If the fluid accumulation is slow, the pericardial volume can expand to remarkable amounts (up to 3 to 4 L) and be clinically silent. The onset of tamponade can be rapid if the pericardium is fibrosed or thickened from previous radiation or inflammation or the fluid accumulation is rapid.

CLINICAL PRESENTATION

The clinical presentation of MPE varies dramatically from a complete lack of symptoms to acute cardiogenic shock. Fluid accumulation from lymphatic obstruction with a noncompliant pericardium results in acute restriction of atrial and ventricular filling, an increase in systemic venous pressure, and then an acute decrease in cardiac output. Since decreased cardiac filling decreases stroke volume, the initial cardiovascular response is increased sympathetic tone with compensatory vasoconstriction and tachycardia. Patients presenting with acute cardiac tamponade are typically in extremis with marked agitation or confusion, tachycardia, and tachypnea. In this setting, the classic clinical syndrome of Beck's triad can be seen with elevation of systemic venous pressures, systemic arterial hypotension, and a small quiet heart. When tamponade develops slowly, symptoms resemble heart failure, with orthopnea, tachycardia, and hepatic engorgement. The main complaint is usually dyspnea on exertion, accompanied by anorexia, lethargy, edema, or weight loss. In these patients there is almost always jugular venous distention and a parodoxical pulse. Table 60.1 describes the relative frequency of symptoms, signs, and laboratory findings in MPE. [10]

TABLE 60.1. RELATIVE FREQUENCY OF SYMPTOMS, SIGNS, AND LABORATORY FINDINGS IN MALIGNANT PERICARDIAL EFFUSION

DIAGNOSTIC EVALUATION

Physical Examination

Acute cardiac tamponade associated with MPE often requires immediate diagnosis and treatment. Pulsus paradoxus, an important finding in cardiac tamponade, was first described as the disappearance of the radial pulse despite a palpable heartbeat. Pulsus is not really parodoxical, but an exaggeration of the normal inspiratory drop in systolic pressure. It can be measured with a sphygmomanometer by inflating the cuff above the arterial pressure and very slowly deflating the cuff until the first Korotokoff sound is heard. At this point, the Korotokoff sound will disappear with inspiration. With further slow deflation of the cuff, a continuous pulsation will be heard. The difference in the systolic pressure of these two points is the amount of pulsus. A greater than 10 mm Hg fall in the systolic pressure with inspiration signifies a pulsus parodoxus.[10] In tachypneic patients, pulsus may be difficult to measure, but with invasive arterial monitoring, the inspiratory blood pressure drop can be visualized graphically. Upon palpation of the precordium the cardiac impulse is diminished or absent. Percussion of the anterior thorax may reveal dullness in the left lung base secondary to compression from a large effusion, called Ewert's sign. On auscultation, heart sounds may be distant and weak, with tachycardia or supraventricular arrhythmias. Surprising, only occasionally will a pericardial rub or splash be heard.

Radiographs

Chest radiographs show nonspecific but often supportive evidence for the diagnosis of MPE. Enlargement of the cardiac silhouette on chest radiograph does not occur until approximately 250 cc of fluid is present in the pericardial space. The classic "water bottle" cardiac silhouette may be seen on PA chest x-ray with long-standing MPE. In one third of cases a coexisting pleural effusion is seen. Press and Livingston showed that 90% of patients had abnormal radiographs and about 45% had signs of pericardial disease.[11] Unfortunately, an enlarged cardiac silhouette is suggestive, but not specific for pericardial fluid, and other conditions, especially congestive heart failure, have a similar appearance.[12] Computed tomography (CT) defines the size of the effusion, location of intracardiac or extracardiac masses, and often the origin of the primary cancer (usually of pulmonary origin). Johnson and colleagues have proposed several CT criteria for the diagnosis of MPE: (a) pericardial effusion of high CT density, (b) localized or irregular pericardial thickening, (c) masses arising from or continuous with the pericardium, and (d) obliteration of normal tissue planes between a paracardiac mass and the heart or pericardium.[13] Once the diagnosis of MPE is established, CT or echocardiography can be used to guide insertion of drainage catheters for diagnosis or treatment.

Electrocardiograms

About 90% of patients with symptomatic MPE have abnormal EKG findings, including nonspecific ST segment changes (63%), low voltage (59%), sinus tachycardia (25%), atrial flutter or fibrillation (21%), premature ventricular beats, and heart block.[11] With large effusions, the heart may develop a swinging motion within the pericardial sac, which is thought to cause electrical alternans seen in 5% of patients. Usually electrical alternans involve only the QRS complex in a two-to-one or three-to-one pattern, but when the P, QRS, and T wave are all involved, it is pathognomonic for a severe tamponade. [14],15 and 16

Echocardiography

Echocardiography is the most specific and sensitive noninvasive test for the evaluation of MPE. Transthoracic echocardiography is initially used to evaluate the anatomy and physiologic consequences of the pericardial fluid. Transesophageal and Doppler ultrasonography are complementary in patients who do not manifest characteristic transthoracic echocardiographic findings.[17] By using parasternal, subxiphoid, and transesophageal views, the entire pericardium can be inspected. Echocardiographic changes are best seen in the posterior cardiac wall, where normally a single echo is seen moving synchronously with the heartbeat. When a pericardial effusion is present separating the pericardium and epicardium, two distinct echoes are seen: one from the pericardium and one from the epicardium.[18] The quality of the pericardial fluid (homogenous versus heterogeneous), pericardial masses, or loculations, right and left ventricular function, and right and left ventricular diastolic collapse are imaged by echocardiography. Equalization of diastolic pressures across all cardiac chambers is the hallmark of symptomatic cardiac tamponade. Diastolic collapse of the right ventricle and atrium has been proposed as an echocardiographic indicator of cardiac tamponade.[19] Patients with this finding should undergo immediate drainage of the pericardium. If the echo is indeterminate, CT and MRI may be helpful, especially with loculated effusions, pericardial thickening, calcifications, blood, fat, or chyle.

TREATMENT

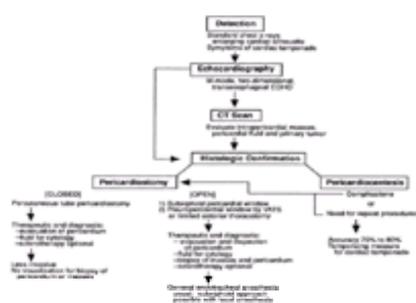
Management decisions in the treatment of MPE should include consideration of age, symptoms, general condition, origin, and prognosis of the tumor (Figure 60.2). The risks versus benefits of intervention for MPE may not be favorable in patients with end-stage metastatic cancer. The median survival for all malignant pericardial effusions is two to four months, with a 25% one-year survival.[20] In patients with known metastatic cancer, MPE and tamponade should always be considered when signs and symptoms of hemodynamic compromise present. Acute pericardial tamponade with cyanosis, dyspnea, impaired consciousness, shock, pulsus paradoxus greater than 50% of pulse pressure, or a decrease of more than 20 mm Hg in pulse pressure are indications for emergent drainage. If the patient is hemodynamically stable then a more definite procedure can be performed, including percutaneous insertion of a pericardial drain by Seldinger technique under radiographic guidance, open pericardiostomy by the subxiphoid approach, video-assisted thoracoscopic surgery (VATS), or limited anterior thoracotomy (see Table 60.2).[21],22,23,24,25,26,27,28 and [29] In a review of different malignant pericardial effusion treatments, no modality was clearly superior to another (Figure 60.3).


FIGURE 60.2. Algorithm for the diagnosis and treatment of malignant pericardial effusion.

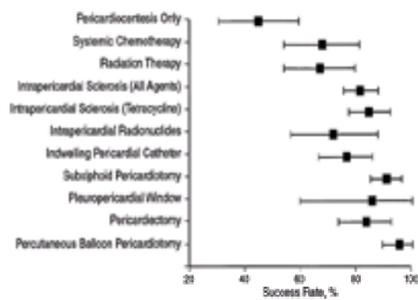
TABLE 60.2. COMPARISON OF PERICARDIAL PROCEDURES


FIGURE 60.3. Success rates for treatment of malignant pericardial effusion.

Needle- or catheter-based procedures are best image-directed by transthoracic or transesophageal echocardiography or by computed tomography. In all instances the basic technique is the same and has been well described. [23,27,29,30] Imaging by any of the mentioned modalities is used to identify the largest collection of pericardial fluid in close proximity to the skin, to identify the safest needle entry site. After local infiltration with 1% lidocaine, a sheathed needle (16 to 18 gauge) is used for the initial pericardial entry. Upon aspirating pericardial fluid, the needle is removed, leaving only the sheath in the pericardial space. A small amount of saline can be used for echocardiographic confirmation of the sheath position. If prolonged drainage is desired, a guide wire is introduced through the sheath, the sheath withdrawn, and a dilator (6–7 F) advanced over the guide wire. A multisidehole pigtail angiographic catheter (6–7 F) is placed in the pericardial space. The catheter typically remains in place until the fluid return is less than 50 cc every 24 hours and follow-up imaging shows insignificant residual effusion.

General endotracheal anesthesia in the setting of acute tamponade increases the risk of any intervention and should be avoided if possible. Patients in cardiac tamponade have markedly increased endogenous catecholamines for circulatory support. Induction of anesthesia inhibits these compensatory autonomic responses and may lead to circulatory collapse before drainage can be effected. Positive pressure ventilation can further impede venous return in these compromised patients. Inotropes and intravenous fluids to improve contractility and maintain preload to the heart may be temporarily necessary to allow the induction of anesthesia. Because of the risk of anesthesia, percutaneous drainage of MPE using local anesthesia only has become the procedure of choice.

Pericardiocentesis

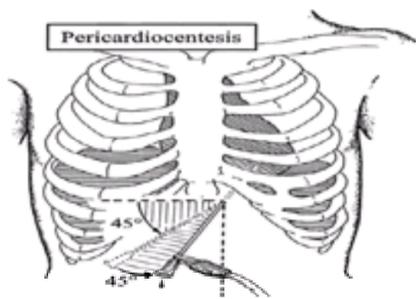
Controversy exists regarding the roles of pericardiocentesis, pigtail catheter drainage, and pericardiotomy. Pericardiocentesis is both a diagnostic and therapeutic tool in the management of MPE. In the setting of acute hemodynamic compromise, the procedure of choice is urgent pericardiocentesis (see Figure 60.4). An 18-gauge spinal needle with an ECG lead is inserted into the pericardial sac by aiming the needle toward the patient's left shoulder at a 45 degree angle, while constantly maintaining negative pressure. If an ECG injury pattern or arrhythmia is seen, the needle is repositioned. Occasionally the pressure is so great that the plunger is pushed out. Two thirds of these patients will develop recurrence and require repeat drainage. [26]


FIGURE 60.4. Pericardiocentesis.

The use of M-mode echocardiography to guide pericardiocentesis was first reported by Goldberg and Pollack in 1973 and quickly replaced ECG for directing needle placement.[31] Two-dimensional echocardiography has currently replaced M-mode. The transducer is placed at the cardiac apex while pericardiocentesis is performed from the subcostal position. The interpericardial position of the needle is confirmed by the appearance of microbubbles in the pericardial sac. If the needle has penetrated the cardiac chamber then intracardiac bubbles may be seen. [30] Once the needle is in the pericardial space, the fluid can be evacuated and a guidewire inserted for pigtail catheter drainage. Wiener and colleagues reviewed 95 cases of pericardial effusion treated initially with pericardiocentesis. [32] Pericardial fluid collected from known cancer patients revealed neoplastic cells in 66% of these patients. When the pericardial fluid was correlated with the known primary, it was 100% specific. Similar results by Press and Livingston confirm that cytology of pericardial fluid remains valuable in the diagnosis of MPE. [11] The fluid is generally hemorrhagic with a high LDH level. Pericardial fluid analysis includes cell count, glucose, protein, lactate dehydrogenase, bacterial culture, and cytology. [33]

With drainage, the crisis of acute cardiac tamponade is averted. A single pericardiocentesis is unlikely to prevent recurrence of the tamponade unless the underlying malignancy is addressed. Recurrence rates as high as 90% within 90 days are reported. [7] MPE indicates advanced systemic disease; therefore a multidisciplinary approach with oncology, radiation therapy, and thoracic surgery is necessary for appropriate palliative management.

Complications of pericardiocentesis are uncommon but can be catastrophic. In a review of medical patients requiring pericardiocentesis, 40 of 46 (87%) experienced symptomatic relief after therapeutic pericardiocentesis, but 3 (7%) had major complications including right ventricular laceration, cardiac arrest with hypoxic brain damage, and emergency ventricular repair.[34] Other potential complications include laceration of the coronary arteries, internal mammary artery, or lung, contamination of the pericardial or pleural space, and injuries to intra-abdominal organs.

Open Pericardiotomy

Open pericardiotomy, or "pericardial window," is usually performed in the operating room under general endotracheal anesthesia, although it can also be performed with local anesthesia. The procedure can be performed quickly (15 to 20 minutes), especially if hemodynamic compromise develops. The subxiphoid approach requires a midline incision from the xiphoid/sternal junction extending caudad 6 cm (Figure 60.5). The xiphoid is resected and the linea alba is divided without entering the peritoneum or diaphragm. The sternum is firmly retracted anteriorly, and the fatty tissue overlying the pericardium is incised and retracted laterally to allow the pericardium to be identified. The pericardium is elevated and incised. One should be ready for a sudden gush of blood under pressure if any tamponade is present. An immediate improvement of pulse pressure should be noted. The serosanguinous pericardial fluid is then sent for a cell count, cytology, gram stain, and culture if the diagnosis is uncertain. The pericardium is then digitally explored, and loculations, nodules, and masses are noted. A generous anterior portion of the pericardium is excised and sent for pathology. One should strive to excise the largest extent of pericardium possible. Large drainage tubes are placed anteriorly and posteriorly, and placed to -20 cm H_2O suction. The drains are removed when the drainage is less than 50 cc per day. Some evidence indicates that the pericardiotomy remains

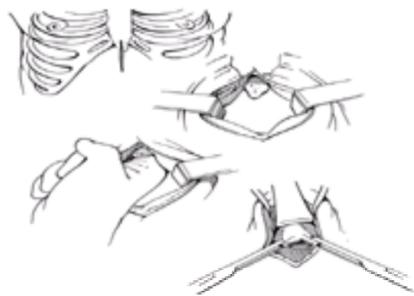
open long after the effusive process ends. Sugimoto and colleagues believe that obliteration of the space is the goal, and maintain drainage for as long as four weeks.[35] These observations have prompted the use of sclerosing agents similar to those used to treat malignant pleural effusions.


FIGURE 60.5. Subxiphoid pericardiotomy.

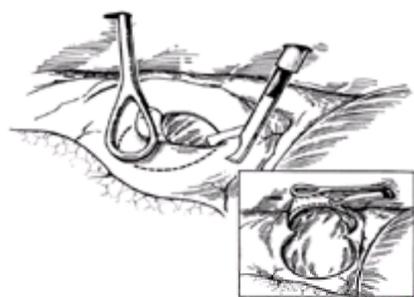
VATS is a minimally invasive technique that provides excellent visualization of the pericardium (Figure 60.6) and perhaps decreased morbidity when compared with a thoracotomy.[40] VATS allows complete visualization of the hemithorax, during which the pericardium hemithorax can be inspected and drained. [36] One disadvantage is that VATS requires a double lumen endotracheal tube with lung collapse for visualization of the pericardium, therefore the subxiphiod approach is still preferred by most.


FIGURE 60.6. Video-assisted thoracoscopic surgery (VATS) pericardiotomy.

Pericardial Biopsy

Pericardial biopsy can be obtained by several approaches, including subxiphoid or subcostal pericardiostomy, limited anterior thoracotomy, or VATS. [20,37] A new technique of pericardioscopy with guided biopsies increased the diagnostic yield an additional 20% in patients with malignancy when cytology and conventional biopsy were negative.[38]

Pharmacologic Agents

The recurrence rate of catheter-drained pericardial effusions has been reported at 3% to 20%. If the effusion recurs, the pericardium is again drained, followed by sclerotherapy. We initially use bleomycin, 30 to 120 mg in 30 cc of 1% lidocaine for sclerotherapy. For refractory MPE we use sterile talc, 10 g in 50 cc of normal saline. Shepherd recommends the instillation of tetracycline for persistent effusions. [6] They report 74% success in control of effusions longer than 30 days with a median survival of 168 days. Recommended agents include oxytetracycline, OK-432, a penicillin-treated and heat-treated lyophilized powder of the substrain of *Streptococcus pyogenes* A3, cisplatin, bleomycin, vinblastine, interferon, and sterile talc. [39,40,41,42,43,44 and 45] Piehler and colleagues have reported that the amount of pericardium left in the patient is directly related to the rate of recurrence, postoperative pericardial constriction, and the need for repeated therapy. [46] Since most patients with MPE have an end-stage malignancy, long-term survival is rarely affected, emphasizing the desirability of a quick, less-invasive, and short-term effective treatment approach. Complications of sclerotherapy include transient atrial arrhythmia, pain after injection, and fever. When constrictive pericarditis or extensive involvement of tumor exists, pericardiectomy is a rare option. Although this is a highly morbid procedure, it has been reported in carefully considered circumstances. [47]

Radiotherapy is generally reserved for pericardial effusions associated with lymphoma. The recommended dosage is 2 to 3 Gy, which is given over a two to three week course. Pericardial inflammation is a complication of radiotherapy. Stewart and colleagues describe giving 40 Gy for fractionated radiotherapy of the heart and adjacent structures.[48] Acute pericarditis is a complication of radiation but is usually self-limited.

SUMMARY

The treatment of MPE should proceed in a stepwise fashion. We use CT- or echocardiography-guided percutaneous tube pericardiostomy to accomplish both diagnosis and therapy. Once the pericardium is drained, we use bleomycin or talc for sclerotherapy. If sclerotherapy fails, we proceed with subxiphoid pericardiotomy for evacuation of effusion, resection of pericardium, biopsy, and placement of drains. If the effusion recurs, this is again followed by sclerotherapy. Patients responding to treatment should have a mean life expectancy of nine to 13 months if tamponade does not recur. Even with cardiac tamponade, short-term palliation is possible.

MANAGEMENT OF MALIGNANT AIRWAY OBSTRUCTION

RALPH DE LA TORRE

DOUGLAS MATHISEN

BACKGROUND INFORMATION/INTRODUCTION

Lung cancer, with more than 150,000 cases every year, represents a major oncologic challenge.[1] There are more than 120,000 deaths annually, and most therapeutic approaches result in a high incidence of local failure that frequently manifests as malignant airway occlusion.[2,3] According to one estimate, 20% to 30% of newly diagnosed malignant neoplasms will present with atelectasis and pneumonia due to endobronchial disease.[3] Death from airway occlusion is often a painful process of slow asphyxiation, frequently complicated by obstructive pneumonia and hemoptysis. The management of patients with malignant airway obstruction represents a therapeutic challenge for physicians engaged in their care. With either unresectable disease at presentation, recurrence after attempted curative resection, or metastatic disease, the surgical alternatives are limited, and chemotherapy is, for most patients, ineffective or response is brief.

The ability to manage acute airway obstruction can be lifesaving. Airway relief should be expeditious and immediate, with low morbidity and mortality. It should not interfere with future definitive therapy. In patients with terminal malignancy, it should be economical in costs and should minimize hospitalization.

Acute respiratory distress, stridor, and obstructive pneumonia may be the presenting signs of advanced airway neoplasms.[4] Reduction of the tracheal lumen by 80% (3 to 5 mm) may occur before symptoms become severe. However, inflammatory swelling or poststenotic retention of mucus or blood may lead to acute obstruction and severe hypoxia.[5]

Symptoms depend on location and extent of the tumor. Neoplasms of the trachea and carina may cause obstructive airway symptoms, as opposed to neoplasms of the distal airway, which are more likely to show initial symptoms of postobstructive pneumonia. Dyspnea may initially be present only with exertion, but may progress as the tumor enlarges to dyspnea at rest, stridor, and acute respiratory distress. In patients with pedunculated tumors, symptoms may vary with body position.

Management of patients with malignant airway obstruction depends on the urgency of presentation, etiology, localization, extent of obstruction, and prognosis of the disease. Complications from the obstruction, therapeutic measures available, and the experience of the physician influence the management of such patients.[5] Many methods of relieving airway obstruction are available. Palliation of symptoms and establishment of an airway in an expeditious manner are the goal.[4]

When patients present with respiratory distress, efforts are aimed at relief of symptoms rather than extensive evaluation of the patient. Functional assessment of the patient and evaluation of the extent of disease can be performed after the airway obstruction has been relieved. For those patients who present in a less acute fashion, functional assessment of the patient and radiologic evaluation of the extent of disease are appropriate. Above all else, one should consider the possibility of curative resection even in patients with obstructing airway neoplasms. Bronchoplastic techniques are available to allow resection and reconstruction of the trachea, carina, main bronchi, and lobar orifices.[6] Opening an obstructed airway in patients who have acute respiratory distress with potentially resectable tumors will allow time for a thorough workup, correction of underlying medical problems, or tapering of steroid administration if the patients have been incorrectly treated for "asthma."[4]

RADIOLOGIC EVALUATION

If time permits, careful radiologic evaluation is a valuable asset to operative management. Frequently the site of tracheal obstruction may be seen on chest x-ray in two planes. Tomography of the trachea and carina provides information about the extent of involvement, configuration, axis of the airway, and patency of the distal airway.[7] A lateral neck with oblique tracheal views along with AP views of the larynx and trachea may show stenoses, intraluminal densities, or luminal narrowing and displacement. Computerized tomography with axial 4 mm. sections may be used to assess intraluminal and extraluminal malignant tumors, including lymph node metastases. Magnetic resonance imaging with axial coronal and sagittal T1 and T2-CW images delineates tumors in the coronal, axial, and lateral projections; it is helpful in the evaluation of extraluminal tumor extension, vascular invasion, and lymph node metastases.[8,9,10]

ANESTHESIA

When there is a significant degree of airway obstruction, it is desirable to induce anesthesia with a controlled inhalation technique, as described by Wilson.[11] Ethrane is our agent of choice. When adequate alveolar ventilation exists and there is no need for an extremely high (99%) inspired oxygen concentration, nitrous oxide is often used to hasten and smooth induction of anesthesia. Muscle relaxants should not be used, because ventilation provided with mask and positive pressure through an obstructed airway is generally less satisfactory than the degree of gas exchange produced with spontaneous ventilation using assisted positive-pressure breathing. Anesthesia administration is continued until the patient is at a suitable depth to withstand bronchoscopy. This technique allows a patient to maintain spontaneous ventilation throughout the procedure. It can be time-consuming and requires patience on the part of the anesthesiologist and surgeon, but the disadvantage this imposes is greatly outweighed by the tremendous advantage of having the patient spontaneously ventilating throughout the procedure. This is especially important because the exact nature of the obstruction may not be known. During the course of tumor removal, maintaining the airway may be difficult and the patient's ability to breath is often the only thing that sustains him or her through this period.[4] When spontaneous ventilation is preserved, the surgeon will have more time to establish an airway than in the paralyzed, apneic patient. For this reason, we have avoided the use of narcotics, barbiturates, and paralyzing agents.

TECHNIQUES

Coring Out

The combination of biopsy forceps and the tip of the rigid bronchoscope to "core out" the tumor is very effective and satisfies many of the requirements for opening an obstructed airway. The authors find this to be the procedure of choice for management of malignant airway obstruction. This technique demands that the surgeon and assistants be in attendance during induction of anesthesia and have all necessary instruments available to establish an emergency airway. Rigid bronchoscopes of graded sizes should be available (3.59 mm). The small pediatric bronchoscope may be the only bronchoscope that can be inserted through a very proximal, tight stricture. This allows immediate control of the airway subsequent to further manipulations. The bronchoscope is introduced and insinuated with gentle pressure past the malignant stricture. It is almost always possible to pass a rigid bronchoscope beyond an obstructing tumor. If the tumor is not based circumferentially, the rigid bronchoscope may be insinuated along the wall of the trachea that is not involved. Once the patient has an airway and is well ventilated, the bronchoscope may be withdrawn above the tumor and the bulk of the tumor removed. The tumor is first biopsied to determine its consistency and vascularity. The tip of the bronchoscope is

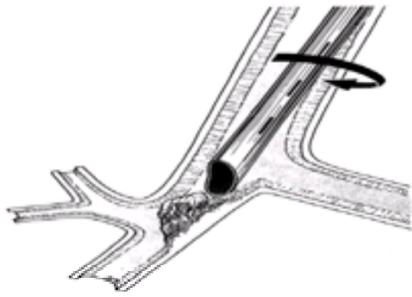
then used as a coring device to shave larger pieces of tumor. Once a piece is dislodged, suction or biopsy forceps are used to extract it. This is repeated until an adequate airway is achieved. It is vitally important to perform this in the axis of the airway to avoid penetration through the wall and injury to vascular structures or creation of a pneumothorax. The procedure usually takes 15 to 30 minutes [12] (Figure 61.1).


FIGURE 61.1. Technique of "coring out" utilizing the rigid bronchoscope.

For more distal tumors, insertion of a larger bronchoscope in the proximal airway allows careful inspection and suctioning of any secretions. The distal airway can be evaluated by inserting a flexible bronchoscope through the rigid bronchoscope. It is important to establish an airway, clear retained secretions, and stabilize the patient before proceeding with tumor removal. Using standard rigid bronchoscopy techniques, even lobar obstructions can often be managed with this technique.

Mathisen and Grillo reported our results of treating malignant obstruction with this technique in 1989. [4] The location of the obstruction was trachea in 16 patients, carina in 24, main bronchi in eight and distal airway in eight. Improvement in the airway was accomplished in 90% of patients. A single bronchoscopy was sufficient in 96%. There were numerous histologic types of tumors amenable to this approach (Table 61.1). An improved airway was achieved in 51 of the 56 patients after endoscopic removal of tumor, with no intraoperative deaths in the series. Only two patients required repeat bronchoscopy within two months of initial successful core-out. Nineteen complications occurred in 11 patients, including pneumonia, bleeding, pneumothorax, hypoxia, hypocarbia, arrhythmias, and laryngeal edema. Four patients died within two weeks of endoscopy of causes unrelated to the procedure. All patients had received no benefit from previous radiation therapy and were in desperate condition with postobstructive pneumonia.

Histology	Location of Tumor*		
	Trachea	Carina	Bronchus
Squamous carcinoma	8	11	6
Adenoidcystic	2	7	0
Adenocarcinoma	0	3	4
Thyroid	3	0	0

TABLE 61.1. HISTOLOGY OF OBSTRUCTING NEOPLASMS

Major hemorrhage rarely occurs with this technique and did not occur in this series of patients. Only three out of 56 patients had more than minor bleeding (500 mL). [4] Minor bleeding is easily controlled with simple measures such as irrigation with saline or tamponade with epinephrine (0.1 mg per mL) soaked pledgets on long applicators. Use of the rigid bronchoscope to tamponade the raw surface of the tumor is also effective. Tamponade with Fogarty venous occlusion catheters or an inflated endotracheal tube balloon against the raw surface is also effective for persistent oozing from a raw surface.

Short-term survival depends on the success of the endoscopic core-out of the tumor and long-term survival depends on the effectiveness of proposed treatments. The survival of inoperable patients after radiation or chemotherapy in the series presented by Mathisen ranged from two months to 82 months, with a median of six months. Histology, location, and extent of disease determine success of treatment. For patients with failed previous therapies, endoscopic removal of the tumor is a temporary measure that allows a patent airway. Use of tracheotomy tubes, T-tubes, or other stents may be effective in maintaining an airway in this group of patients who have no other options.

Cryotherapy

Cryotherapy is of limited usefulness, especially in the acute setting. Treatment requires application of probes that are cooled to -60° C to -80° C with liquid nitrogen. Tumors may be frozen and removed mechanically. The stated advantage of endoscopic cryosurgery is the capacity to extend it to extramural parts of tumors up to 1.5 to 2 cm. With this technique, only tumors of 1 to 2 cm. on half the circumference of the trachea can be removed in one session. Reepithelization after removal is reportedly very good. [5] The obvious disadvantages in its application for severe tracheal obstruction are in the actual mechanics of its application. The probes are clumsy and make exact endoscopic placement difficult. Acute manipulation of the airway is limited, because the probe cannot be removed immediately but remains stuck to the tissues for about one minute. If the diameter of the probe is reduced, then the speed of cooling may be diminished. With a slower rate of cooling, tumor cells are preserved rather than destroyed. Coring out and laser surgery, along with endobronchial brachytherapy, have supplanted the role of cryotherapy in malignant airway obstruction.

Expandable Metallic Stents

The last several years have seen a substantial growth in the availability and use of endolumenal stents. Available expandable stents basically break down into covered and uncovered metallic stents. The first stent commonly used, the Gianturco stent, is a self-expandable, stainless steel stent made of a thin-diameter stainless steel wire laced into a zigzag cylinder that expands on placement. Use of the Gianturco self-expandable stent was initially intended for treatment of stenoses within the vascular system and biliary tree. [13,14,15] Similarly, the covered Wallstent was first used in the vascular tree and has recently gained popularity within the tracheobronchial tree.

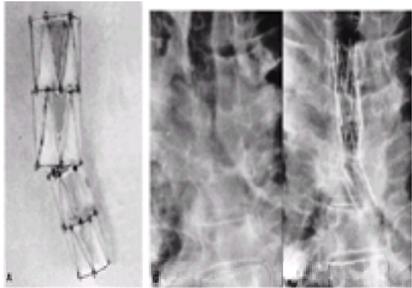
Different lengths and widths are available, and commonly, two Gianturco stents are joined together with lateral barbs affixed to the stent to minimize migration (Figure 61.2). Varela and colleagues, Wilson and colleagues, and others have described a technique for stent placement. [16,17] A guidewire is passed through a flexible bronchoscope through the obstruction. The bronchoscope is then reinserted so that the deployment of the stent can be observed. The stents are inserted in a compressed form, loaded in a 12 French Teflon sheath over the guidewire. The stent is advanced through the Teflon sheath until it reaches the distal aspect of the sheath. The pusher is held with one hand while the Teflon sheath is removed, allowing the distal aspect of the stent to expand. Two or more stents may be required, and the stents should always be longer than the obstructing lesion. Correct placement is confirmed with the fiber-optic bronchoscope. [15,16,17,18,19]


FIGURE 61.2. A: Gianturco stent for endobronchial stenting. (Photo, courtesy of Dr. Rosch, Professor of Radiology, Oregon Health Sciences University.) **B:** Chest x-ray of endobronchial stent in place. (Photo, courtesy of Dr. Rosch, Professor of Radiology, Oregon Health Sciences University.)

The deployment of the covered Wallstent was well described by Monnier and associates in a prospective multicenter study. Two methods for deployment currently exist. The Rigistep device consists of a rigid bronchoscope through which the stent is deployed after the lesion has been crossed. If the lesion cannot be crossed with a rigid bronchoscope or the resources for rigid bronchoscopy do not exist, the telestep device can be used to deploy the stent while observing with a flexible bronchoscope or under fluoroscopy. This proceeds in a manner similar to that described above. [20]

Multiple studies have now looked at the efficacy of expandable stents. Wilson and colleagues looked at 56 patients with inoperable malignancy and significant airway compromise. These patients underwent stenting with the Gianturco expandable stent. Of the patients treated, 77% showed significant symptomatic improvement and 67% showed improvement in pulmonary function tests. Four patients died perioperatively, two of respiratory causes and two of myocardial infarction. One patient suffered a pneumothorax and one suffered a hemopneumothorax. Mean survival of all patients was 77 days (1 to 477 days). [17] Another study by Monnier and associates looked at the efficacy of covered Wallstents in 40 patients presenting with inoperable tracheobronchial cancer. Except in cases of pure extrinsic compression, an initial lumen was created using the Neodymium-Ytrium-Garnet (Nd:YAG) laser. The tumor was situated in the trachea in 11 patients, in the carina in six, right main or intermediate in 12, and the left main in 11. Following stent deployment, the lumen was returned to within 92% of normal (plus or minus 6.3%). Patients were evaluated post procedure and at 30 and 90 days. At 30 days, 22 patients were alive and 19 underwent bronchoscopy. Eleven showed partial obstruction and three showed minor stent migration. There was no significant progression of dyspnea. At 90 days, 13 were still alive and 10 underwent bronchoscopy. All patients showed incomplete tumor coverage but once again, there was no significant difference in dyspnea. [20] Tojo and associates sought to compare these stents. They used Gianturco stents to treat 11 patients with extrinsic compression; the airway remained open in 10 of these patients. Sixteen patients with intraluminal tumor were treated as follows: Nine with bare metal stents, four with covered metal stents, three with Dumon stents. Four of the patients treated with a covered stent suffered tumor ingrowth necessitating laser therapy. None of the covered stent or Dumon stent patients needed further therapy. [21] None of the patients treated with bare stents for extrinsic compression required further therapy.

In conclusion, expandable stents represent a viable option in the treatment of obstructing malignant airway disease. While hard data are lacking, several inferences can be made. It appears that bare metal stents are more secure and tend to migrate less. On the other hand, tumor ingrowth through the metal lattice appears a real phenomena. At present these properties suggest that bare metal stents are more suitable for extrinsic airway compression and covered stents are more suitable for intraluminal tumor growth. Both stents become intensely incorporated after about two weeks. It also appears that deployable metallic stents induce a granulation response at their anchoring points. These properties make them contraindicated in the treatment of benign disease. [20,22] As with all devices, innovations and revisions are surely underway.

Silastic Stents

The T-tube that is presently in clinical use was developed in 1965 by Montgomery [23] and has been most widely used by otolaryngologists and thoracic surgeons [24,25] as a stent in subglottic and tracheal obstructions.

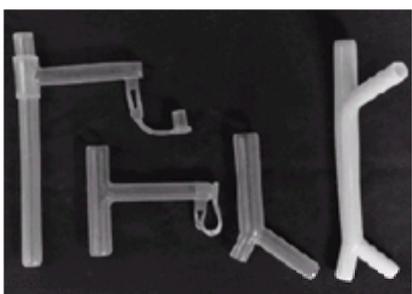
The T-tube is made of a light and pliable silicone rubber and comes with a silicone plug secured in place by friction from a slight twisting motion. The intratracheal edges of the tube are trimmed and smoothed to avoid trauma to the tracheal mucosa. Tissue reaction to silicone is usually minimal, and the stent can remain in place for extended periods of time. The flexibility of the cannula allows easy insertion and removal via tracheostomy. If the laryngeal airway is adequate, normal phonation and humidification through the nasopharynx are preserved. The Montgomery T-tube endoprosthesis comes in a variety of sizes and shapes (Figure 61.3). Sizes range from 4 to 16 mm in outside diameter. A variety of tubes are available with long inferior limbs for intrathoracic tracheal obstructions. There are also available either single-armed or Y-shaped cannulas with the lower ends acting as stents for the carina and main bronchi when the lesion involves that area. [26,27]


FIGURE 61.3. Variety of available Montgomery T-tubes with modifications shown.

In cases where malignant obstruction of the airway cannot be operated on because of extent of disease, the T-tube can be inserted to relieve asphyxia and allow a relatively good quality of life. Insertion of the T-tube requires careful preoperative assessment of the airway. Measurements are obtained with a rigid bronchoscope to determine proximal and distal extent of the tumor, carina, stoma, and vocal cords. The T-tube is inserted through a preexisting tracheal stoma or a newly created stoma. [28] After the proper diameter T-tube is selected and the ends trimmed to the desired length, the upper limb of the intratracheal tube is grasped with a Kelley clamp and the lower end is introduced into the stoma. With the tube inserted, the lower limb is advanced toward the distal trachea until the entire endotracheal portion is within the lumen. A second Kelley grasps the outside horizontal branch, pulling it to seat the cannula in the proper position. This is all done with the aid of the rigid bronchoscope under direct vision to minimize any iatrogenic injury to the trachea and provide an airway. The upper limb of the tube should be positioned, unless contraindicated by involvement of the subglottic and glottic region, about 1 cm below the vocal cords. If the upper limb is too long, irritation of the subglottic region and vocal cords will lead to laryngeal edema or predispose to aspiration. In rare cases, however, the proximal extent of the T-tube has been placed through the vocal cords, with some patients even developing pharyngeal speech. The side arm should be plugged as soon as possible to allow speech and natural humidification. Failure to plug the side arm will quickly lead to crusting and obstruction of the tube. Humidification should be provided and the tube suctioned frequently. Acetylcysteine can be instilled with normal saline to prevent formation of mucous plugs. The skin around the stoma should be cleaned regularly to minimize contamination. Patients can be easily trained to perform routine care of the tube at home.

Similar to the T-tube, the Dumon tube is a silastic stent placed directly into the airway. Unlike the T-tube, there is no stomal connection. Instead, the tube is held in place by a series of silastic studs that line the outside of the stent (see Fig. 61.3). The Dumon tube requires rigid bronchoscopy for placement and comes in a Y shape for stenting of the mainstems or carina. The Dumon tube has both advantages and disadvantages compared to the T-tube. Its advantages include cosmesis and placement without the need for a stoma. Its disadvantages include the lack of a stoma through which suctioning of secretions is facilitated and, despite the silastic

studs, a greater tendency to migrate.

In general, the authors favor the use of a T-tube over the Dumon tube. We find dealing with inspisated secretions considerably easier with a stomal component in place. Patients with an end tracheal stoma who develop an intratracheal recurrence, however, pose a specific problem. In these patients, a Dumon tube is preferable to an amputated T-tube, primarily due to its anchoring capabilities. A special situation that requires close monitoring is the patient with a Y stent in place and a severe forceful cough. On occasion these patients have dislodged an arm of the Y stent causing the stent to buckle and occlude the airway.

Lasers

Laser is an acronym for light amplification by the stimulated emission of radiation. The principle upon which lasers are based was expounded by Einstein in 1917 [29] but was not put into practical use until 1958, when groups at Bell Laboratories and Hughes began using a doped ruby crystal. [30] Endoscopic application of laser technology began in 1973 with the use of carbon dioxide CO_2 laser therapy to ablate benign neoplasms such as papillomas and later to palliate malignant obstruction of the major airways.[31] Laser mediated ablation of tissue proceeds from the rapid deposition of energy into a small area. Following absorption of this energy, a primarily thermal process ensues, culminating in a phase change and vaporization of tissue. The absolute quantity of energy deposited, the wavelength of light used, and the pulse duration all significantly impact the process. The wavelength of the emitted light determines the molecule within the tissue that will act as the absorber. The pulse duration affects thermal dissipation and hence lateral thermal injury.

The carbon dioxide laser emits an invisible beam of light with a wavelength of 10,600 nm. The beam has a very high water-absorption coefficient and is absorbed by all tissues with little or no scatter or penetration. This produces a precisely localized vaporizing instrument with very little surrounding edema or trauma adjacent to the focal point of the beam. CO_2 laser light cannot at present be transmitted through fiber-optic bundles but must be reflected in transit off prisms and articulation, and therefore requires a cumbersome delivery system of articulated arms. Because of these mechanics of delivery, only tracheal and proximal bronchial lesions are accessible. The CO_2 laser is a precise cutting instrument and affords hemostasis only to the microcirculation. Vessels greater than 0.5 mm. are ineffectively coagulated. However, because of minimal edema next to the focal point of the beam, there is excellent healing ability in the adjacent tissues. With the advent of the Nd: YAG laser for similar lesions, the CO_2 laser has become less important. Ablation and resection of tumor mass in major airways is much more effectively and safely performed with the Nd:YAG laser.[32]

The Nd:YAG laser can be delivered through an optical fiber and produces excellent vaporization. The high thermal energy can produce vaporization, coagulative necrosis, and coagulative hemostasis. The energy output of this laser far exceeds that of the CO_2 laser. This laser system can be used through flexible optical fibers and allows for resection of tumor by vaporization and for effective coagulation and hemostasis of larger vessels (1 mm). [33,34 and 35]

Contraindications to Nd:YAG laser therapy include the following: obstruction due to extrinsic compression; obstruction due to lack of cartilaginous support; tracheoesophageal fistula; lobar or more distal occlusion; total obstruction over 4 to 6 cm with no probable distal airway, and bleeding diathesis. [32]

Use of a No. 9 Wolf ventilating bronchoscope with a Sanders injector for ventilation is recommended. The FI02 should be less than 40% to prevent combustion and/or fire. The tumor is assessed through the rigid scope, and any large bulky portions are dislodged by manipulations of the tip of the bronchoscope as previously described in the coring-out technique. Hemorrhage from the tumor is usually only mild to moderate. Indeed, most of the tumor bulk can be removed through this simple method of debridement. A flexible bronchoscope can then be passed through an occluding grommet at the open end of the scope, and a laser fiber can be passed through the channel of the fiberoptic scope and positioned under direct vision of the operator. Smoke is aspirated with the use of a vinyl suction catheter in the rigid scope. The power output is between 45 and 55 watts in half-second pulses.

If during laser therapy there is need for suctioning of secretions, purulent material, or blood, or removal of large portions of necrotic debris, the flexible scope can be removed, the ventilation converted to a jet system with the Sanders injector, and a large-bore suction catheter and biopsy forceps inserted directly into the open end of the bronchoscope. This particular technique allows for simple and rapid conversion from one delivery system to another. Repetitive treatments may be necessary to obtain an adequate airway. A dilute solution of epinephrine is occasionally injected into the scope to arrest bleeding from the raw tumor bed. The patient can either be extubated in the operating room, or reintubated with an endotracheal tube after the rigid bronchoscope has been removed and extubated in the recovery room.

The major advantages of the Nd:YAG laser over other lasers are the superior vaporization, excellent coagulative necrosis, and deeper penetration achieved. Safe and effective ablation can be performed much more quickly with this laser. The procedure may be done either through a flexible bronchoscope, as described, or through a rigid bronchoscope exclusively, as described by Dumon. [34] Complications include hypoxemia, hemorrhage, perforation, fire, pneumothorax, and endobronchial spillage of distal obstructive purulent material.

McDougall and Cortese[33] defined the selection criteria for laser therapy. They stated that these patients should have malignant airway obstruction which has failed all other reasonable therapy, and the lesion should be protruding into the bronchial wall without obvious extension beyond the cartilage. They further stated that the actual length of the endobronchial component of the tumor should be less than 4 cm, and that the bronchoscopist should be able to see the bronchial lumen at all times. There should be functioning lung tissue beyond the obstruction. Their initial series included 22 patients who received 28 treatments during a five-month period. After the initial treatment, immediate improvement in airway diameter and symptomatic relief was achieved in 20 of 22 patients.

The efficacy of the Nd:YAG laser in endobronchial tracheal obstructive lesions has been shown by several series. [35,36,37 and 38] Perhaps the largest is from France, where Dumon and colleagues reported 1,503 endoscopic YAG laser treatments on 839 patients.[34] Brutinel and associates, from the Mayo Clinic,[38] reported that airway caliber improvement was achieved in up to 83.4% of treatments. Obstructions at the level of the trachea, mainstem bronchi, and bronchus intermedius were improved more often than those at the lobar bronchi. At follow-up, 36% of patients in his series were alive at one year. The median time to retreatment or death was 130 days. In Parr's and colleagues' series of 40 patients, [36] patients had primary lung malignancies. Of those treated with the Nd:YAG laser, results were reported as excellent in 22 patients. Kvale and associates at Henry Ford Hospital reported a series of 55 patients treated a total of 82 times. Satisfactory results (doubling of airway size with relief of dyspnea or drainage of obstructive pneumonitis) were obtained in 12 of 13 patients with bronchogenic carcinoma initially managed with laser and in 22 of 32 patients with recurrent malignancies. [37]

The major cause of death during or after laser resection is hypoxemia and perforation (less than 40%). [32] Hemorrhage is rare in the series listed (1% to 3%).[31,33,34,35,36,37 and 38] Dumon and colleagues[34] state that experimental data suggests a continuous radiation at a power setting of 40 watts or more creates massive tissue coagulation and uncontrolled penetration. Consequently, to preclude perforation and exsanguinating hemorrhage, the endoscopists must use the laser sparingly over intermittent exposures (0.5 to 1 second) at power settings not higher than 45 watts. For coagulation, long low-powered shots are used; for resection, short high-powered shots are needed. Another rule of safety consists in firing parallel to the airway wall and strictly avoiding perpendicular shots. Further economy in laser firing can be had by photocoagulation and mechanical removal of the tumor mass using the tip of the bronchoscope to shave off fragments and the suction tubing to evacuate them. Oxygen concentration should not exceed 50% during laser resection to avoid fire at the fiber-optic tip. Kvale and associates [37] utilized computer axial tomography (CAT) with contrast infusion and rapid sequence imaging to display the relationships between the involved bronchus and the surrounding structures, particularly the large intrathoracic blood vessels. The image provided by the CAT scan may be useful, particularly when the lesion is obstructing the distal trachea or more peripherally.

In summary, exophytic lesions of the trachea and mainstem bronchi are most amenable to therapy by laser, and improvement in symptoms correlate best with improved patency of large airways. In most patients the major portion of the endobronchial debulking procedure can be performed quickly and safely by physically coring out the exophytic tumor mass with the rigid end of the bronchoscope. The laser can then be used to remove any remaining tumor and produce hemostasis by coagulation of the tumor bed.[32]

Bronchoscopic Balloon Dilatation

Bronchoscopic balloon dilatation is a well-known technique in the management of children and infants with tracheobronchial stenosis. Its usefulness, however, in the management of malignant airway obstruction has been quite limited. For now, its use is primarily as an adjunct to laser photoresection or stenting. It serves to create an adequate lumen for the deployment of more definitive modalities. [39]

Intratumoral Injections

When other modalities have been unavailable, some physicians have turned to direct intratumoral injection of chemotherapeutic agents. Celikoglu and associates recently looked at 93 patients who presented with over 50% obstruction of at least one major airway. All patients were treated with 5-fluorouracil, mitomycin, methotrexate, bleomycin, and mitoxantrone, injected directly into the tumor. Thirty-five patients presented with complete obstruction of one lung; of these, 18 saw complete reexpansion, six had partial reexpansion, and 11 had no effect. Overall, 39 of the 93 patients showed an increase in the lumenal diameter to over 50%, and 42 showed a 25% to 50% increase.[40]

While direct intratumoral injection does not appear as efficacious as other modalities, it clearly holds promise. Its role as an adjunct to other techniques, for example, has not been investigated. Furthermore, the development of other chemotherapeutic regimens and/or selective activation (as with esophageal PDT) may greatly extend its efficacy.

CONCLUSION

Short-term survival is directly dependent on the ability to open the obstructed airway; long-term survival depends on the effectiveness of proposed treatments of the underlying cancer. For patients who have failed previous therapy, endoscopic removal of tumor is a temporary measure to relieve airway obstruction. Use of tracheotomy tubes and T-tubes may ultimately be effective in maintaining an airway in this group of patients who have no other options. The use of the Nd:YAG laser is an acceptable alternative to core-out, but more costly. Endoluminal stenting, although more costly than silastic stents or core-out, has the advantage of not requiring rigid bronchoscopy or general anesthesia. Endobronchial brachytherapy, although very labor-intensive, has also shown good success. It is important to note that all these modalities are acute therapy for airway occlusion and do not treat the underlying problem. Since no modality has proven clearly superior, the choice of therapy should depend on the expertise and resources of the staff and institution. Also, these therapies should not deter definitive therapy—tracheal resections, carinal resections, and sleeve resections of the tracheobronchial tree are accepted methods of treatment and can be curative.[6] These should always be considered on patients with obstructed airways so as not to deny patients the opportunity for cure.

SUPERIOR VENA CAVA SYNDROME: SURGERY AND STENTS

JONATHAN C. NESBITT

INTRODUCTION AND HISTORY

Obstruction of the superior vena cava (SVC) is well recognized as a complication of lung cancer. The degree of clinical manifestation varies among patients, but recognition and prompt management are essential. Although the usual treatment is nonsurgical, selected patients can benefit significantly from operative or interventional measures.

Superior vena cava syndrome (SVCS) was originally described by William Hunter in 1757 in a patient with a saccular aneurysm of the ascending aorta. [1] At autopsy, he noted that the SVC and innominate vein were "both so much compressed by the dilated artery, as hardly to have any thing left of their natural capacity and appearance." William Stokes in 1837 reported SVCS secondary to a right-lung malignancy, noting that the progressive physical findings were a consequence of the compressive effects of tumors on the SVC and the development of collateral circulation. [2] He described a patient whose "face was bloated, pale, and slightly edematous, which, with an appearance of the eyes as if the balls were protruded from the sockets, and a marked dilatation of the nostrils during breathing, gave his countenance an expression of distress and suffering. . .. The right jugular vein was much distended, as were the veins in the right axilla; but this symptom was chiefly remarkable on the surface of the belly, where two veins . . . pursued a remarkably tortuous course . . . being turgid and dilated to the size of swan quills." In his comprehensive review of lung cancer in the nineteenth century, Rosenblatt refers to several reports from Ireland and Germany that describe SVCS secondary to bronchogenic carcinoma. [3]

Prior to the mid twentieth century, malignancy accounted for roughly one-third of all cases of SVCS. Most cases occurred secondary to infectious conditions such as luetic aortic aneurysms, tuberculosis, and fibrotic mediastinitis. [4] Today, however, intrathoracic malignancy has far surpassed benign disease as the primary cause of SVC obstruction. The increased incidence of bronchogenic carcinoma over the past several decades and improved treatment for granulomatous and infectious diseases have accounted for these etiologic changes.

ANATOMY AND PATHOGENESIS

The normal SVC measures 6 to 8 cm in length and 1 to 2 cm in diameter. It is formed by a union of the left and right innominate veins and is positioned in the middle mediastinum to the right of the aorta and anterior to the trachea. The inferior aspect of the SVC resides within the pericardial cavity for a length of 2 to 3 cm. For most of its length, the azygos vein is located posteriorly and adjacent to the vertebral column. As it approaches the SVC, it courses anteriorly over the right mainstem bronchus and enters the posterior wall of the SVC above the level of the pericardial reflection, several centimeters cephalad to the right atrium.

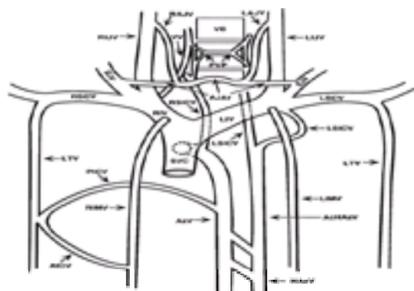
There are eight principal collateral pathways for drainage of the venous system in the chest: the paravertebral, azygos-hemiazygos, internal mammary, lateral thoracic, anterior jugular, thyroidal, thymic, and pericardiophrenic veins. The five major venous collateral networks are depicted in Figure 62.1. Each system is elaborately interconnected to provide innumerable possibilities for variations and directions in flow, depending on the situation. The presence of SVCS depends on individual anatomic patterns and compensatory changes during the evolution of the pathologic process. The location of the obstruction, the extent of the process, the presence of access pathways, and the capability of the pathways to adapt to excess blood flow determine the severity of the syndrome.


FIGURE 62.1. The five major collateral venous networks of the thorax. The thyroidal, thymic, and pericardiophrenic veins are not depicted. AcHAzV, accessory hemiazygos vein; AICV, anterior intercostal vein; AJAr, anterior jugular arch; AzV, azygos vein; EJV, external jugular vein; HAzV, hemiazygos vein; LAJV, left anterior jugular vein; LIJV, left internal jugular vein; LIMV, left internal mammary vein; LIV, left innominate vein; LSCV, left subclavian vein; LSICV, left superior intercostal vein; LSCV, left subclavian vein; LTV, lateral thoracic vein; PICV, posterior intercostal vein; PVP, paravertebral plexus; RAJV, right anterior jugular vein; RIJV, right internal jugular vein; RIMV, right internal mammary vein; RIV, right innominate vein; RSCV, right subclavian vein; RSICV, right superior intercostal vein; SVC, superior vena cava; VB, vertebral body; VV, vertebral vein. (From Chasen MH, Charnsangavej C. Venous chest anatomy: clinical implications. In: Greene R, Muhm JR, eds. *Syllabus: a categorical course in diagnostic radiology.* Presented at the 78th Scientific Assembly and Annual Meeting of the Radiological Society of North America. 1992:121, with permission.)

By using contrast venography, Stanford and Doty have described four patterns of associated venous flow determined by the degree of SVC obstruction [5] (Figure 62.2, Figure 62.3, Figure 62.4 and Figure 62.5). Obstruction of the SVC below the insertion of the azygos vein may result in use of the azygos arch as the major collateral pathway, with reversal of flow and drainage into the inferior vena cava. Obstruction of the SVC above the level of insertion of the azygos vein results in flow through alternative pathways, primarily the cervical and paravertebral plexuses. The collateral vessels, in turn, drain into the azygos system, which flows retrograde into the inferior vena cava. A sparse number of central venous collaterals appear when the SVC and the major venous channels undergo extensive thrombosis. In such

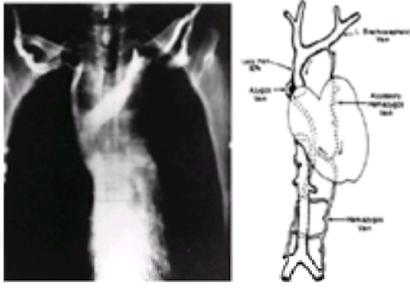
circumstances, collateralization occurs through a network of extrathoracic pathways within the chest wall musculature and skin.


FIGURE 62.2. Partial obstruction of the superior vena cava with patency of the azygos; right atrial pathway. (From Stanford W, Doty DB. The role of venography and surgery in the management of patients with superior vena cava obstruction. *Ann Thorac Surg* 1986;41:158, with permission.)
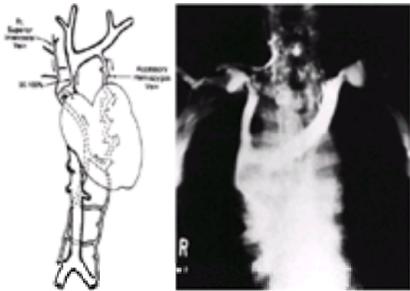

FIGURE 62.3. Near-complete to complete obstruction of the superior vena cava with pathway and antegrade flow in the azygos; right atrial pathway. (From Stanford W, Doty DB. The role of venography and surgery in the management of patients with superior vena cava obstruction. *Ann Thorac Surg* 1986;41:158, with permission.)
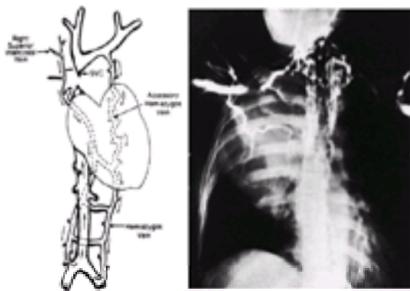

FIGURE 62.4. Near-complete to complete obstruction of the superior vena cava with reversal of azygos blood flow to the inferior vena cava. (From Stanford W, Doty DB. The role of venography and surgery in the management of patients with superior vena cava obstruction. *Ann Thorac Surg* 1986;41:158, with permission.)
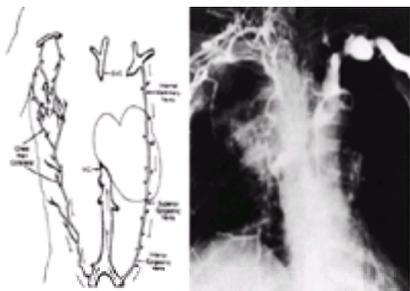

FIGURE 62.5. Complete obstruction of the superior vena cava and one or more of the major vena caval accessory pathways, including the azygos systems. (From Stanford W, Doty DB. The role of venography and surgery in the management of patients with superior vena cava obstruction. *Ann Thorac Surg* 1986;41:158, with permission.)

The progress of the vena caval obstructive process determines the severity of the syndrome and the changes associated with alterations of venous flow. Gradual strangulation of a major venous pathway (i.e., vena cava, innominate vein, or azygos vein) induces compensatory rerouting of flow into smaller systems. The process usually evolves as a subacute or chronic phenomenon which develops more quickly than the body's ability to create collateral vessels to circumvent the resulting congestion. The high venous circulatory pressure above the obstruction causes shunting into the adjacent lower pressure plexuses and venules. As time passes over weeks or months, the sustained pressure imposed upon the collateral pathways invokes their gradual distension and dilation. Eventually, small veins become major channels for flow.

When cutaneous veins are recruited to unload back pressure, increased venous blood in the skin is manifested clinically by a ruborous hue which gives the impression of cyanosis. Swelling and edema from the increase in capillary hydrostatic pressure are common; the extent of these conditions is determined primarily by the degree of collateral flow to reduce venous hypertension. If obstruction is insidious, the circulatory system has the ability to adapt to flow changes, often with only subtle clinical signs. In a few instances no clinical signs are expressed. Typical anatomic and physiologic changes which reflect congestion of flow include facial plethora, mild edema and rubor of the face and upper extremities, and dilated cutaneous veins. When the obstructive process is acute or subacute, physiologic changes of venous collateralization cannot occur quickly enough to compensate: compensatory collaterals for pressure unloading are nonexistent and pronounced venous hypertension results. In this situation, clinical signs and symptoms are more evident and are manifested more overtly by more severe facial, neck, and arm edema; headache; dyspnea; periorbital swelling; and facial erythema.

ETIOLOGY

Obstruction of the vena cava is due to extrinsic pressure, tumor invasion, thrombosis, or impedance of venous return from intra-atrial or intraluminal pathology.

Approximately 73% to 97% of cases of SVCS occur secondary to malignancy.[6,7,8,9,10 and 11] Malignant encroachment on the SVC occurs either by direct extension or compression by the primary tumor or by invasion of superior mediastinal lymph nodes that contain malignancy. In addition, progressive tumor growth may violate the vascular intima and serve as a nidus for thrombus formation, which can evolve to extensive thrombosis of the SVC, branch vessels, and collateral tributaries. The malignancy that most frequently causes SVCS is lung cancer. Approximately 3% to 5% of patients with lung cancer develop the syndrome,[11,12,13,14 and 15] and approximately 10% to 15% of patients with right-sided chest malignancies will develop SVCS.[6,14] Of 337 patients with malignancies and SVCS registered at the University of Texas M.D. Anderson Cancer Center Department of Patient Studies through 1992, 218 (64.7%) had lung cancer. The histologic type varied: 77 (35%) had small cell carcinoma, 46 (21%) adenocarcinoma, 44 (20%) squamous cell, 8 (4%) large cell, and 63 (29%) nonspecified carcinomas. Other reviews have noted that lung cancer constituted 65% to 95% of all malignant causes of SVCS.[8,11,16,17,18,19 and 20]

CLINICAL PRESENTATION

The signs and symptoms of mature SVCS are usually easily recognized. Common symptoms and physical findings are noted in Table 62.1 and Table 62.2. Early in the course, the presenting changes are subtle with minimal physical changes and no symptoms. On rare occasions, the SVC can be completely occluded without the development of physiologic or anatomic changes. At the other extreme, acute SVCS can result in the abrupt onset of symptoms with pronounced clinical manifestations reflective of the rapidly obstructive process. The average duration of symptoms is approximately 45 days,[21] with 90% of patients noting the duration of symptoms as less than eight weeks.[17]

TABLE 62.2. COMMON PHYSICAL SIGNS OF SUPERIOR VENA CAVA SYNDROME

The typical presentation reflects venous hypertension above the level of the obstruction. At a certain point in the process, venous collaterals will develop, including small, tortuous, vertically oriented cutaneous tributaries above the level of the rib cage margin. Features include upper body venous engorgement with dilated primary venous tributaries of the trunk, upper extremities, and neck. Facial plethora is most common, and unrecognized facial swelling is a frequent manifestation. The skin may appear ruddy or with a slight violet hue, giving the impression of cyanosis or flushing. Mild edema of the neck, face, and periorbital region with proptosis and conjunctival suffusion may be present. Assuming a recumbent position, bending over, and coughing exacerbate symptoms from transient elevations in venous pressure that is already hypertensive. Headache, nausea, dizziness, and visual disturbances are not uncommon. Lethargy, obtundation, syncope, stupor and/or coma occur in fewer than 2% of cases and appear more commonly in patients with rapidly progressive and severe SVCS. Such neurologic symptoms may be secondary to metastatic disease, not cerebral edema from venous occlusion. Laryngeal edema and glottic swelling can occur, but it is unusual for respiratory decompensation to occur from laryngeal edema alone. Significant compromise of the airway is uncommon, but when it does occur, it may be caused by the SVCS or by other factors that include glottic swelling, vocal cord paralysis, and extrinsic tracheal compression.

EVALUATION AND DIAGNOSIS

The superior vena cava syndrome is a clinical diagnosis; the signs and symptoms usually permit easy recognition. Confirmation by radiologic studies is not necessary, but histologic diagnosis is essential prior to the initiation of treatment.

Ultrasonography

Ultrasonography is valuable in evaluating the patency of the jugular, subclavian, and axillary veins. It is a safe, quick, and noninvasive bedside procedure. As a screening study to evaluate the presence of obstructive pathology, Doppler flow measurements are easy and accurate but are limited by their inability to view the intrathoracic veins adequately.[22,23] Further assessment of the intrathoracic venous system can be accomplished by transesophageal echocardiography (TEE), which has been shown to be an excellent method for evaluating the SVC and surrounding structures.[24,25]

Radionuclide Venography

Nuclear scintigraphy is an accurate and relatively noninvasive method of imaging the venous system. The images are not as precise as contrast venography in clearly defining the venous anatomy, but technetium-99m DPTA studies can readily confirm the presence of SVCS, allow visualization of the site of obstruction, demonstrate regions of collateral flow, assess the general quantity of accessory circulatory patterns, and identify areas of pulmonary emboli.[26,27 and 28] When evaluation of the venous system is desired in anticipation of surgery, nuclear scintigraphy is not the study of choice; contrast venography should be performed.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) provides much information about SVCS. CT shows details of the thoracic anatomy, including tumor proximity to the SVC, heart, trachea, and other major structures; visualizes the extent of vena caval occlusion, including thrombi; permits visualization of collateral venous pathways, including the "collateral loop" of interconnecting intrathoracic veins[29]; and assists in directing diagnostic and therapeutic maneuvers. Using chest CT, Raptopoulos[30] has identified five categories of SVC compression that correspond to the severity of symptoms.

Type Ia is moderate narrowing of the SVC without collateral flow or increase in the size of the azygos vein.

Type Ib is severe narrowing of the SVC with retrograde flow into the azygos vein.

Type II is obstruction of the SVC above the azygos arch with retrograde flow into the thoracic, vertebral, and other peripheral veins.

Type III is obstruction of the SVC below the azygos arch with retrograde flow through the azygos arch into the inferior vena cava.

Type IV is obstruction of the SVC at the azygos arch with multiple peripheral collaterals and nonvisualization of the azygos vein.

Opacification of thoracic venous collaterals by CT often is suggestive of SVCS, but opacification of the anterior thoracic subcutaneous channels is the best indicator of SVC occlusion, with a specificity of 96%.[31] Moncada and colleagues noted the specific advantages of combining CT scans with CT digital phlebography for patients with SVCS to highlight detailed resolution of the thoracic and venous anatomy.[32] Magnetic resonance imaging (MRI) allows images in multiple planes and does not require iodinated contrast material. The ability of MRI to diagnose thoracic venous obstruction is high, with sensitivity and specificity rates of 94% and 100%, respectively.[33] Disadvantages of MRI include increased scanning time and cost.

Contrast Venography

Venacavography is an essential procedure when operative intervention is being considered and is a fundamental aspect of evaluation in anticipation of endovascular stent placement. The exact location and severity of caval obstruction, the sites of major vascular patency, the degree of associated thrombosis, and the extent of collateralization—key information in formulating an operative plan—can be precisely identified by contrast venography. Venography can be performed by bilateral antecubital venous injections or by conventional single-catheter injection, depending on the extent and location of the obstruction.

In a series of 36 patients, Stanford and Doty used venography to identify those patients whom they felt would most likely benefit from surgical bypass procedures [5] (Figure 62.2, Figure 62.3, Figure 62.4 and Figure 62.5). Each radiographic pattern appeared to have a uniquely similar clinical presentation. As expected, the worst obstructive patterns and most severe symptoms were seen in patients with complete or near-complete obstruction of the SVC along with reversal or occlusion of flow in the azygous vein. The severity of the symptoms was the basis for selecting patients for palliative bypass grafting. Their results suggested that the patients who benefitted the most from surgical bypass were those with severe symptoms and with the worst obstructive patterns on venography.

Sputum Cytology, Fine-Needle Aspiration, and Lymph Node Biopsy

The simplest method of obtaining a histologic diagnosis is sputum cytologic analysis, which can yield a diagnosis in two thirds of patients. [17] Fine-needle aspiration or lymph node biopsy are important diagnostic methods that also yield a diagnosis in most cases. For lesions that are amenable to these procedures, they should be employed before proceeding to other more invasive methods, because hemorrhage or hematoma formation at the biopsy site is a concern. Prudent attention to the potential for associated coagulopathy and the reduction in venous hypertension while maintaining head and shoulder elevation is important. In most cases these procedures can be performed readily without complications. [34]

Transluminal Radiographic Biopsy

Another method for obtaining a histologic diagnosis is transluminal biopsy under fluoroscopic guidance. This combined procedure allows evaluation of the venous system as well as pathologic diagnosis, [35,36] but only rarely is it indicated. It is best used in circumstances of diagnostic difficulty when surgical intervention is being considered. If contrast venography is performed and identifies an intraluminal tumor, fluoroscopic transluminal biopsy can be performed.

Mediastinoscopy

The safety of mediastinoscopy in patients with SVCS has been questioned; in fact, some clinicians feel that it is contraindicated. Fears of hemorrhage, hematoma formation, perioperative respiratory distress, and infection have served as the principle factors discouraging many physicians from recommending or performing the procedure, but such fears are unjustified. SVCS has been the direct cause of very few complications in patients who have undergone mediastinoscopy. Kirschner performed mediastinoscopy in 16 patients with SVCS without a complication.[37] Callejas and colleagues, noting that mediastinoscopy is useful and reliable in the diagnosis of tumors that cause SVCS, reported one wound infection and one carotid artery injury in eight such cases.[38] Little and colleagues had no complications in eight patients who underwent cervical mediastinoscopy.[34] Jahangiri and colleagues performed mediastinoscopy in 14 patients with SVCS and had only one complication, an innominate artery injury.[39] They concluded that the procedure is safe and effective for establishing a diagnosis when other less invasive techniques have been unsuccessful. In two series of 53 patients with SVCS who underwent mediastinoscopy, one patient had excessive bleeding [40] and another had respiratory compromise requiring intubation for three days.[41]

When considering mediastinoscopy in patients with SVCS, the surgeon should be cognizant of SVCS physiology and take appropriate measures to reduce the potential for bleeding. Assuring adequate coagulation parameters is fundamental. Placing the patient in the reverse Trendelenburg position will help to reduce some of the upper-body venous hypertension, which in turn alleviates capillary oozing during the procedure. Enlarged subcutaneous venous collaterals should be avoided and pushed to the side. Heightened attention to hemostasis is key to the prevention of postoperative hemorrhage. When these usual precautionary measures are taken, mediastinoscopy is a safe procedure to perform in patients with SVCS.

MANAGEMENT

SVCS is an alarming phenomenon with seemingly dire consequences. Although it is often characterized as a medical emergency, [42,43 and 44] this is rarely the case. In a review of 90 publications that described 1986 cases of SVCS, there was only one death, of aspiration of epistaxis, that was directly attributable to SVC obstruction. [10] Frequently mentioned severe complications of SVCS include cerebral edema and laryngeal edema with associated respiratory distress, [5,12,42] but actual experiences of these types have been reported infrequently. [7,11,45] In fact, cerebral edema and seizures may be secondary to associated metastatic disease, and respiratory compromise may be caused by tracheal compression from a tumor that is also causing SVC compression. Therefore, by recognizing that SVCS is very rarely a true oncologic emergency, clinicians should be able to identify the etiology prior to embarking on a therapeutic course. Treatment can be and should be delayed until appropriate evaluation is undertaken to determine the cause.

The management of SVCS depends on the severity of the patient's symptoms, the cause of the obstruction, and the histologic type of the tumor. Conservative measures such as head elevation, rest, judicious administration of fluids, and supplemental oxygen are important primary maneuvers until a diagnosis is made and more definitive treatment can begin. The roles of diuretics and corticosteroids in the treatment of SVCS are unclear. After a diagnosis is made, therapy should be initiated promptly. Treatment should not be initiated until a diagnosis is made.

Most patients with SVCS secondary to malignancy have traditionally been treated nonoperatively, with radiotherapy, chemotherapy, or both. More recently, endovascular stents have been successfully used to alleviate symptoms; a prompt and durable resolution of symptoms is achieved in 75% to 95% of patients.[46,47,48,49,50,51,52,53,54,55 and 56] Such success occurs from direct thrombolysis of SVC clot and mechanical enlargement of the SVC to reestablish normal flow. With radiotherapy, diminished venous distension and subjective improvement usually do not occur until three to seven days after beginning therapy. Approximately 46% to 70% of patients with bronchogenic carcinoma will demonstrate a symptomatic response to radiotherapy or combined radiotherapy and chemotherapy within the first two weeks.[17,41] This improvement reflects either reestablishment of vena caval patency through recanalization or the further development of venous collaterals. Imaging studies performed after improvement of SVCS often show persistent SVC occlusion by stenosis, thrombosis, or residual tumor; the improvement in the syndrome in such instances is usually due to the recruitment of collateral flow.

Surgery has a very limited role in the management of SVCS. Some authors believe that surgery with bypass grafting has no role in the treatment of patients with SVCS secondary to malignant disease because of the morbidity associated with a major operation,[7,57] but others believe that surgery has a role in treating selected patients such as those with acute SVC occlusion and severe symptoms or those with complete occlusion of the SVC, severe refractory symptoms, and thrombosis of venous collaterals (Table 62.3). An operation can provide almost immediate, sustained relief of symptoms in most patients. The decision for any invasive procedure

must be made with regard to the acuity of the syndrome, severity of the underlying disease, the patient's overall health, the risk of surgical intervention, the patient's life expectancy, and the anatomy of the receptive vein. In the current setting of improved anesthesia and perioperative monitoring, surgical procedures can be performed safely and effectively in selected patients.

Chronic occlusion with moderate to severe refractory symptoms
Acute occlusion with severe symptoms
Recurrent occlusion with severe symptoms

Venography shows superior vena cava occlusion with absence or thrombosis of collaterals.

TABLE 62.3. RELATIVE INDICATIONS FOR OPERATIVE INTERVENTION IN SUPERIOR VENA CAVA SYNDROME

Surgical Procedures

A number of surgical procedures have been described for the treatment of SVCS secondary to both benign and malignant conditions (Table 62.4). The objective is to decompress safely the venous system above the level of the obstruction. Two techniques of operative management exist: bypass and resection. Bypass procedures reroute the venous blood of the upper compartment around the obstructed segment to the right atrium. The tumor itself is not handled. A single major vein (i.e., jugular, innominate, or subclavian) is used for the bypass; unilateral decompression relies on the normal venous flow patterns that readily cross the midline within the head and neck to decompress the contralateral side. The other operative technique, surgical resection (Figure 62.6), involves *en bloc* removal of the SVC and the tumor, followed by reconstruction of the SVC with an interposition graft.

SVC to right atrial appendage[58,60]
Innominate vein to right atrium[20,58–60,72,103,104,118]
Jugular vein to intrapericardial SVC[72]
Jugular vein to right atrium[59,60,72]
Right subclavian vein to SVC[105]
Left subclavian vein to right atrium[105]
Azygos vein to right atrium[59–61]
Azygos vein to intrapericardial SVC[62]
Azygos vein to inferior vena cava[63]
Extra-anatomic bypass to femoral vein[59,60,64–67]
Resection with interposition graft[69,93,94,106–114]
Endarterectomy with patch[115,116]

TABLE 62.4. SURGICAL PROCEDURES FOR SUPERIOR VENA CAVA SYNDROME

FIGURE 62.6. Superior vena cava resection and reconstruction with a synthetic graft.

As previously mentioned, venacavography is essential prior to operative intervention for SVCS. Contrast venography accurately delineates the major venous structures to be used for the bypass procedure. The degree of collateralization, the proximity of SVC occlusion, and the presence of intraluminal thrombosis should be noted for operative planning. Some thrombus exists in approximately 20% of cases[20]; thrombectomy can be accomplished at the time of surgery in most circumstances. Extensive thrombotic occlusion of the innominate, subclavian, or jugular veins may preclude bypass.

Surgical Bypass

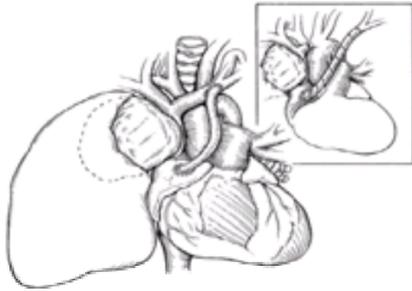
Median sternotomy provides the best exposure to the heart and innominate vein for bypass procedures. If no diagnosis has been obtained, biopsy should be performed to confirm the histology prior to proceeding with surgical treatment of the SVCS. In a few patients, tissue diagnosis requires an open procedure when other methods have failed. In such circumstances, simultaneous biopsy and bypass grafting have been performed with satisfactory results. [58] The innominate vein is the vein most amenable for bypass, though other major veins can be used. The innominate vein is usually easily identified and can be encircled with tapes proximally and distally to expose an adequate length that is free from thrombosis or tumor involvement. With tourniquet pressure to the tapes, a 1 cm incision is made along the inferior aspect to permit a Fogarty catheter. The catheter should be passed proximally and distally to remove potential thrombi. A side-biting vascular clamp is applied, and the venotomy is extended for 2.5 to 3 cm. Autologous vein or synthetic graft is used for the bypass; both are discussed in the following section. If a synthetic graft is used, a 10 to 14 mm graft is most favorable. The graft is sutured to the vein in an end-to-side fashion using 5–0 monofilament suture. Alternatively, an end-to-end anastomosis can be performed after ligation and division of the innominate vein (Figure 62.7). After the anastomosis is complete, the graft should be flushed with heparinized saline, clamped, and measured for length to the right atrium. A comfortable length should be determined with the graft coursing to the side of the aorta. The graft may be sutured to the atrial appendage or the atrium proper, taking care to divide intra-atrial bands before performing the anastomosis.


FIGURE 62.7. Innominate vein to right atrial bypass can be performed using autologous vein, synthetic graft, or spiral vein.

Other types of bypass procedures have been described for the treatment of SVCS. Several reports have noted use of the azygos vein for bypass.[59,60,61,62 and 63] Such approaches can be performed through a right thoracotomy, which provides satisfactory exposure to both the vein and the right atrium. Extra-anatomic bypasses have been successfully used and are appealing because they are less invasive,[59,60,64,65,66 and 67] but they have suffered from poor patency rates caused by inherent low flow rates.

Grafts

Bypass procedures use a variety of conduits to reroute the venous return to the right atrium (Table 62.5). The autogenous vein has the obvious advantage of providing a conduit of native tissue, which historically has allowed the highest patency rates of all conduits. One disadvantage, however, is the easy compressibility of the conduit, which can lead to occlusion. With connection of a bypass graft from peripheral to central veins, surrounding mediastinal tissues have the propensity to apply pressure along the course of the conduit. Lack of rigidity of the graft may lead to compression with consequent restrictive flow and graft occlusion. Another disadvantage of autogenous veins exists with the size discrepancy: a larger vein is more desirable. Doty[23] has championed the use of the composite spiral, autogenous vein graft that was originally described by Chiu in 1974.[68] Other authors also prefer the spiral vein to other graft types.[69,70] In several articles, Doty describes his technique for preparation of the vein and for bypass procedures from the jugular or innominate veins to the right atrium for both benign and malignant disease.[23,71] In 1990 he reported his experience with nine patients with benign disease and noted success in seven of 10 grafts placed.[72] In a separate report, he noted 100% success in six patients with lung malignancies.[5] Certainly the advantages of a spiral vein are its autogenicity and its larger size, which theoretically permits greater volumes of flow. The disadvantage is its compressibility which subjects it to occlusion. Alimi and colleagues have noted success with the placement of endovascular stents in grafts that develop stenoses or occlusions.[70]

Polytetrafluoroethylene (PTFE)[58,64,69,93-95,103,106,107,109-113,117]

Spiral vein[69,72,93,108]

Saphenous vein[95,104]

Femoral vein[118]

Dacron[20,94,109]

Pericardial tube[54,95,119]

Umbilical vein[95]

TABLE 62.5. GRAFTS

Expanded or ringed polytetrafluoroethylene (PTFE) seems to be the most popular synthetic graft for bypass and for interposition. It is preferred for several reasons, including its excellent immediate and long-term patency rates, and noncompressibility.[73] With its inherent skeleton, ringed PTFE prevents the problem of extrinsic compression leading to occlusion.

Other conduits have been used with less uniform success, although only scattered reports exist. Dacron, pericardial tubes, and umbilical vein are not considered desirable options because of their marginal patency rates; these conduits are not recommended unless others are unavailable.

Endovascular Stents

Over the past 15 years, expanding (self-expanding and balloon-expandable) endovascular stents have been effectively used for treatment of stenoses of the arterial system[74] venous system,[56,75,76] esophagus,[77,78] biliary tree,[79,80,81 and 82] urologic tract,[83,84] and airway.[85,86,87,88 and 89] Stents mechanically expand and support structures that are obstructed by either an intrinsic or extrinsic process. They provide immediate palliation of symptoms and often render a long-term effect.

The advantages of expanding stents include the simplicity of insertion, dynamic expansiveness, and low profile. While stents open the stenoses and obstructions, their thin meshwork slowly sinks into the inner lining of the adjacent tissue, where it is incorporated. The stent, in essence, becomes a part of the wall of the structure into which it is inserted. Several types of expanding stents are available. Each has a different fundamental design, though they were developed with the same goal of low-profile expandability.

Self-Expanding Stents

Symphony Stent

The Symphony stent (Medi-Tech, Boston Scientific Corporation, Quincy, Massachusetts) is made of a nickel-titanium alloy called nitinol and is constructed from a single strand using an open knitted loop mesh design. The ends of the stent are looped and atraumatic, and the unique design allows the stent to bend easily to conform to angled lumen and to maintain a uniformly fixed open radius in all twisting positions. It can be deployed through a 7–10 French vascular introducer. Its low-profile release mechanism allows controlled incremental deployment to permit proximal readjustment of the position during deployment. Whereas most other deployment systems require protective introducer sheaths, this stent requires only an exchange guidewire over which the delivery catheter is placed.

Wallstent

The Wallstent (Medi-Tech, Boston Scientific Corporation, Quincy, Massachusetts) is composed of stainless steel monofilaments braided into a cylindrical tube. The stent is longitudinally stretched to fit within a delivery catheter that can be compressed into a 7–9 French introducer. The Wallstent has a larger surface area in contact with the wall of the vessel to provide position stability and to reduce the potential for erosion. A quality of the Wallstent is its excellent flexibility and conformance, which allows it to adapt particularly well to angulated, tortuous lesions. It requires a protective sheath for insertion and deployment.

Gianturco Stent

The Gianturco stent (William Cook Inc.) is constructed from 0.018 inch (460 μm in diameter) stainless steel monofilament wire fashioned in a zigzag pattern with five to ten bends. The two ends are joined to create a cylinder. Compressed, a stent will fit within an 8 French introducer sheath. Several modifications have been made since the stent was first designed to reduce migration and to facilitate precision in placement. The current stent is a tandem stent of two individual stents connected in multiple locations with monofilament sutures, which allows much better control of positioning, insertion, and deployment. The stent has very little longitudinal elasticity, which makes it less effective in a tortuous or highly angulated vascular stenosis. But it tends to have a slightly greater dynamic pressure of outward expandability than the other self-expanding stents.

Balloon-Expandable Stents

Palmaz Stent and Strecker Stent

In 1985, Palmaz and associates introduced the balloon-expandable stent (Johnson & Johnson Interventional Systems, Warren, NJ) that has been used extensively as an intravascular stent.[90] The stent consists of a slotted, seamless, stainless steel tube with a wall thickness of 0.15 mm. An angioplasty balloon catheter is used to inflate the malleable framework into staggered rows of diamond-shaped slots which are resistant to collapse. The Strecker stent (Medi-Tech, Boston Scientific Corporation, Quincy, Massachusetts) is comprised of a knitted meshwork of tantalum wire 0.1 mm in diameter. The design provides greater flexibility when inserted into narrow, tortuous vessels. As opposed to the Palmaz stent, the Strecker stent is compressible in a longitudinal and radial fashion. Both types of stents are crimp-mounted on a folded angioplasty balloon catheter. The Palmaz stent is inserted through a protective introducer sheath. The Strecker stent requires no protective sheath and is inserted into the vascular system with a slightly smaller introducer.

Covered Expanding Stents

The meshwork of metal alloy is a fundamental design of all expanding stents. Unfortunately, this property has a downside because tissue, or tumor, can grow through the interstices of the stent and lumenal occlusion can subsequently recur. In recognition of this potential problem for patients who have disease within the vascular lumen, covered stents have been developed using a thin membrane of silastic or dacron to surround the stent cylinder.[91] Each type of expanding stent has a covered version, most of which remain in developmental stages and are not commercially available.

Insertion of Expanding Prostheses

Endovascular stents are inserted with fluoroscopic guidance. Initially, the anatomy of the SVC system is evaluated with venography. The extent of endovascular thrombus, the degree of SVC narrowing, and the length of lumenal stricture are ascertained. Thrombolytic agents are often locally delivered to enhance visualization of the anatomy and to provide access to the target site. Balloon dilation of the SVC is performed as an initial step, depending on the degree of obstruction. The size and length of stent are determined, as well as type, covered or uncovered. Standard sizes range from 10 to 14 mm in diameter and 4 to 10 cm in length. Following insertion of the stent, confirmation of SVC patency is established by repeat venography. A second stent is inserted if residual stenosis is present proximal or distal to the initial stent.

RESULTS

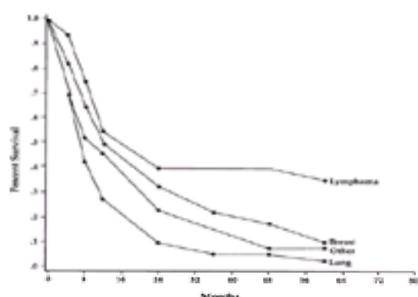
For patients with SVCS secondary to malignancy, survival varies significantly depending on the tumor histologic type. The prognosis correlates with that implied by the natural history of the underlying disease. Patients with SVCS from lung cancer have a very poor prognosis, as shown by the five-year survival rates of 337 patients registered at M.D. Anderson Cancer Center with the diagnosis of SVC obstruction (Figure 62.8): lung 2%, breast 10%, lymphoma 40%, and all other 7%. None of these patients underwent surgical bypass. The response to therapy in patients with lung cancer and SVCS may have an impact on survival. In one series, those who did not respond to nonoperative therapy within 30 days had a significantly lower rate of one-year survival (7%) than those who did respond to therapy (17% to 24%).[17] Patients who receive no therapy or who develop mentation changes and airway compromise have a median survival of only six weeks. [5,92]


FIGURE 62.8. Survival by histology of 337 patients with malignancy and superior vena cava syndrome at the M.D. Anderson Cancer Center.

Surgery

Because of the infrequency of bypass procedures, large collections of patients from single centers do not exist. Moghissi and colleagues reported a series of 43 patients with bronchogenic carcinoma who underwent bypass procedures for malignant SVCS.[26] This group experienced an operative mortality rate of 4.4% and an average survival of 32 weeks. Stanford and Doty, reviewing their series of six patients with SVCS from lung cancer, noted no operative mortality and a mean survival of 10.8 months.[5] The mean survival for those who did not undergo bypass was 8.2 months. In each of the series, immediate graft occlusion rates were low and long-term patency rates were unknown. In the few patients with lung carcinoma who have undergone SVC resection, one, from the six-patient series of Dartevelle and colleagues[106 and 107], died of pneumonia after surgery, whereas no operative mortality was noted in three other small series. [93,94 and 95] In none of these series did surgery have a significant impact on long term survival rates.

The purpose of bypass procedures is to provide immediate relief of the SVCS prior to the patient's undergoing more definitive treatment for the underlying disorder. The objective is not to provide sustained rechanneling for blood flow but to palliate the patient by promptly alleviating symptoms before administering more definitive therapy directed at the tumor. It is believed that most bypass grafts placed in patients with malignant obstructions become occluded within five to six months. Usually, by the time the graft becomes occluded, the vena caval obstruction has been adequately relieved by the development of collateral vessels, recanalization of the SVC, or reduction of the tumor compressive effects. In most patients the SVCS will not return, and if it does, it usually will do so without significant symptoms.

Endovascular Stents

The Wallstent and Gianturco stent have been the most common endovascular devices used for treatment of SVCS (Figure 62.9 and Figure 62.10), though the Palmaz stent has also been used with success.[51] Clinical experiences are limited, because this technique for management of SVCS has truly evolved during this decade, but the uniformly successful results suggest that stent placement should be considered the optimal form of management. Several clinical groups comprising the largest experiences have established that the procedure for insertion is straightforward and can be performed with a low complication rate. Kee and colleagues [54] performed catheter-directed thrombolysis and/or endovascular stent placement to treat SVCS. They achieved technical success in 56 of 59 patients (95%) with mortality and morbidity rates of 3% and 10%, respectively. Mathias and colleagues [96] had a success rate of 96% using Gianturco and Wallstents in 176 patients with SVCS. Overall success rates have ranged from 85% to 96%.[54,55 and 56,96,97 and 98] Mortality has ranged from 0% to 4%.[47,55,56] The most common complication is early stent thrombosis 8% to 20%.[100] Late thrombosis (more than a month postprocedure) is manifested by recurrence of symptoms (5% to 45%) and has been successfully treated with further thrombolysis or further stent insertion. [47,53,54,55 and 56,97,99,100] It is significantly reduced when chronic anticoagulants (warfarin, platelet inhibitors) are administered

following the procedure.[101]

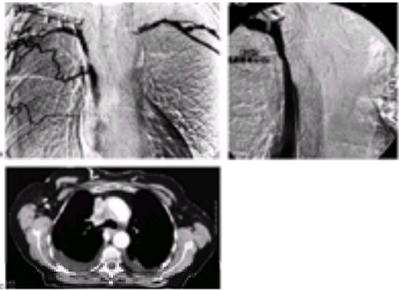
FIGURE 62.9. A: A right-arm venogram shows occlusion of the SVC with adjacent collateral vessels. **B:** Two Wallstents have been placed after transluminal dilation. A repeat venogram shows excellent patency of the SVC.


FIGURE 62.10. A: Bilateral upper extremity venography shows significant stenosis of the upper SVC with collateral flow and reconstitution of the lower SVC. **B:** Repeat venography following SVC dilation and placement of two Wallstents demonstrates near-normal flow into the right atrium. **C:** Computed tomography of the same patient shows tumor surrounding the SVC that contains the stent.

Stent placement for SVCS provides rapid relief of symptoms within six to 48 hours in most patients, as opposed to the relief associated with radiotherapy, which gradually evolves, beginning three to seven days after the initiation of treatment. Nicholson and colleagues [98] prospectively compared radiation therapy to stent placement for patients with SVCS. They concluded that stent placement was a more effective palliative therapy and recommended that stent placement should be the procedure of choice.

CONCLUSIONS

SVCS is commonly caused by lung cancer and requires prompt recognition and management. In the absence of tracheal compression and airway compromise, however, the syndrome is rarely an oncologic emergency. Management depends on the etiology of the obstructive process and should not be undertaken until a diagnosis is obtained. Traditionally, patients with SVCS secondary to lung cancer have been treated with nonsurgical methods, which include appropriately directed chemotherapy and radiotherapy. Operative decompressive measures are rarely necessary, though they can be accomplished with good palliation and low morbidity. Over this decade, percutaneous implantation of endovascular stents has proven to be an excellent and safe palliative measure for the relief of SVCS. It provides prompt and sustained resolution of symptoms with minimal morbidity. In the setting of SVCS secondary to lung cancer, endovascular stent placement not only should be considered the optimal method of treatment but also should be considered early in the course of management.

TREATMENT OF NON-SMALL CELL LUNG CANCER IN THE ELDERLY PATIENT

SUSAN BLACKWELL
JEFFREY CRAWFORD

EPIDEMIOLOGY OF LUNG CANCER IN THE ELDERLY

Cancer is a major concern for people age 65 and older, with 58% of all cancers occurring in this segment of the population. Incidence data from the National Cancer Institute's (NCI) surveillance epidemiology and results (SEER) have shown that older persons have a 10 times greater risk of developing cancer than those individuals under age 65. In the United States, the leading cause of cancer deaths in men and women is lung cancer. When incidence rates are calculated for age specificity, lung cancer rates escalate to more than 500 per 100,000 persons for those 70 to 84 years of age, with a peak of 567 per 100,000 in the 80–84-year-old group. In women, lung cancer incidence rates peak in the 70–79-year-old group, with more than 200 per 100,000. The number of older people who will develop lung cancer is expected to increase as the smoking exposure time effects on birth cohorts become more apparent.[1]

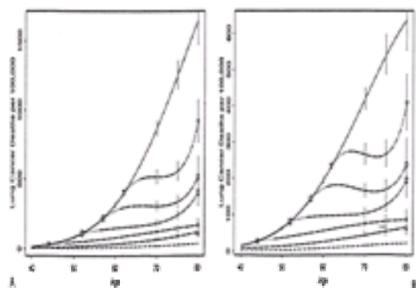
An American Cancer Society study provides further insight into the risk of lung cancer mortality as a function of age and smoking history. [2] In a prospective cohort study of more than 900,000 people, with 6 years of follow-up, the absolute risk of lung cancer mortality was compared in individuals who had never smoked, those currently smoking, and former smokers. As expected, those individuals who quit smoking early in life had a lower lung cancer death risk, and the risk for those who were former smokers was significantly lower than those who continued to smoke. However, the influence of age was remarkable (Figure 63.1). The lung cancer death risk for those who stopped smoking between the ages of 30 and 49 rose gradually with age at a rate slightly greater than for those persons who had never smoked. For a person who quit smoking between the age of 50 and 64, the lung cancer death risk leveled off at the risk attained at the time of quitting until around the age of 75 when it significantly increased. The annual lung cancer mortality for current smokers at age 75 was estimated at 1 per 100 for men and 1 per 200 for women (Table 63.1). Nonsmokers have a relative risk of lung cancer death of 0.05 or less compared to current smokers. However, former smokers had a relative risk of lung cancer death of approximately .45 if they quit smoking in their early 60s, 0.20 if they stopped smoking in their early 50s, and 0.10 for those who had stopped smoking in their 30s.


FIGURE 63.1. A: Model estimates of lung cancer death rates by age for male current, former, and never smokers, based on smokers who started at age 17.5 and smoked 26 cigarettes per day. Estimates are plotted for current smokers (*solid line*), never smokers (*dotted line*), and former smokers (*dashed lines*). The five age-at-quitting cohorts are distinguished by the following symbols on the graph at the age of quitting and also at age 80: D 30–39, à 40–49, ¨ 50–54, ¡ 55–59, Ñ 60–64. **B:** Model estimates of lung cancer death rates by age for female current, former, and never smokers, based on smokers who started at age 18.5 and smoked 22 cigarettes per day. Estimates are plotted for current smokers (*solid line*), never smokers (*dotted line*), and former smokers (*dashed lines*). The five age-at-quitting cohorts are distinguished by the following symbols on the graph at the age of quitting and also at age 80: D 30–39, à 40–49, ¨ 50–54, ¡ 55–59, Ñ 60–64.

	RR		
	Age 55	Age 65	Age 75

Current smokers	1.0	1.0	1.0

TABLE 63.1. ESTIMATED RR OF LUNG CANCER DEATH FOLLOWING SMOKING CESSATION: NEVER AND FORMER SMOKERS COMPARED WITH CURRENT SMOKERS

In terms of reducing risk of lung cancer mortality, stopping smoking at any age is beneficial, but it is much more beneficial for those quitting at a younger age. It was also shown that even though absolute lung cancer risks can plateau following smoking cessation, the lung cancer risk for former smokers is still consistently greater than for those who have never smoked.[2]

In addition to age effects, a dose-response relationship exists for smoking and lung cancer. The risk for lung cancer increases with longer smoking duration and greater number of cigarettes smoked, early age of onset of smoking, greater use of unfiltered cigarettes, high tar and nicotine content, and greater degree of inhalation.[3,4] A survey of tobacco use found that older smokers smoked cigarettes with a higher nicotine content than younger smokers, although the number of cigarettes smoked per day was similar.[5] In this analysis, it was estimated that 50% of Americans age 21 to 49 years were ever smokers, including 31% current smokers and 22% former smokers. In the older population, age 50 to 74, 58% were ever smokers, including 23% current smokers and 35% former smokers. Even though the older smokers had smoked for more than twice as many years as the younger group, the AUTS survey showed very little difference between older and younger smokers, either in smoking habits or quitting history. Although the older smokers had smoked longer, they did not report an increased number of quitting attempts.[6]

CLINICAL PRESENTATION AND EARLY DETECTION

Most patients with lung cancer are symptomatic at the time of diagnosis. Unfortunately, the symptoms they present with are often caused by locally advanced or distant disease. Depending on the location of the tumor, patients can present with a variety of signs or symptoms. Unfortunately, many of the symptoms of lung cancer are nonspecific, and in elderly patients these symptoms may be attributed to comorbid disease. This often can result in a delay in diagnostic testing for the older patient. In a study by DeMaria and Cohen, it was shown that patients of all ages had similar presentation of cough, hoarseness, dysphagia, and weight loss. However, patients greater than 70 years of age presented more often with dyspnea but less often with chest pain than did younger patients. [7]

Although routine screening for lung cancer has not been recommended, this is currently being reevaluated. High-risk patients (smokers/former smokers) over age 65 might benefit from screening because of the high incidence of lung cancer in this population. The prospective randomized studies using serial chest x-rays complemented by sputum cytology did not demonstrate that intensive screening led to a lower death rate, but these studies focused on a younger population, largely 45–55, where the incidence is substantially lower. In addition to the high frequency of lung cancer in the elderly, data suggest that lung cancer may present at a less advanced stage with increasing age. [8] Twenty-two thousand, eight hundred seventy-four cases from the centralized cancer patient data system information were analyzed. The percentage of lung cancer patients with local disease increased from 15.3% for patients age 54 years of younger to 25.4% for those 75 years or older. In addition, 6,332 cases were analyzed after undergoing surgical staging, and there was a greater likelihood of local stage disease as age increased. Screening trials targeted at the elderly with current techniques are warranted. In the interim, the clinician should now have a high index of suspicion for lung cancer in the older smoker or former smoker and have a low threshold for obtaining a chest x-ray in this population when symptoms arise.

TREATMENT APPROACHES IN THE ELDERLY

Even though cancer is a disease of the elderly, older patients are often treated less aggressively. This may be due, in some cases, to the presence of comorbid conditions in the elderly. Whether young or old, the patient's ability to tolerate treatment is of great importance, whether the planned treatment is surgery, radiation therapy, chemotherapy, or multimodality. Older patients have the same right as younger patients to take part in the decision-making process about their treatment. Cancer is no less a devastating illness to an elderly person than to a younger person. For most older patients, quality of life is equally important, and they often prefer improved quality over quantity of life. [9]

Non–small cell lung cancer (NSCLC) represents 80% of all lung cancers. Treatment recommendations for patients with NSCLC have clearly been affected by the age of the patient at presentation. Younger patients, despite presenting with more advanced disease, are more likely to be offered surgical resection than older patients. In older populations, the option of surgery may be more limited because of associated comorbidity or because of beliefs within the medical community that chronological age automatically excludes an aggressive surgical approach. [10] By contrast, age seems to have less influence on whether patients are offered radiation therapy. [11] Lung cancer is one of the most common tumors treated with primary radiation therapy in the over 65 age group. Despite this, studies evaluating the benefits and toxicities in the elderly are limited.

The therapeutic nihilism that has surrounded the role of chemotherapy in NSCLC is even more pronounced in treatment decisions regarding the elderly. Many physicians are hesitant to subject older patients to aggressive chemotherapy. However, studies over the last decade have shown that elderly patients may be able to cope with the impact of chemotherapy as well as younger patients. [12] Older patients do not report any greater frequency of toxic side effects, and when compared to younger patients, often experience lower levels of emotional distress and life disruption.

Lastly, the "quantity of life" available to the elderly is often underappreciated by health care providers and needs to be factored into any treatment decision. An 80-year-old American man has a current life expectancy of 6.7 years and an 80-year-old woman has a life expectancy of 8.8 years. At age 85 a man can expect to live 5.3 years and a woman 6.7 years. [13] In addition, a 75-year-old can expect 75% of his or her remaining years to be spent active as opposed to dependent. At age 85, about 50% of one's life is independent. [14] With this in mind, the degree of potential for quality longevity far exceeds the expected survival of untreated or treated lung cancer patients at any stage. [15]

As the population ages, the number of older patients presenting with lung cancer will indeed increase. In the past, this older age group has been under-represented in clinical studies, resulting in a general decreased knowledge and, therefore, uncertainty about the best management of the older lung cancer patient. Fortunately, recently studies have begun to clarify the treatment options for this population and are reviewed here.

SURGERY IN THE ELDERLY LUNG CANCER PATIENT

Surgical treatment of lung cancer in the elderly patient is still a controversial area because of concern about the increased morbidity and mortality from pulmonary resection in the older patient. However, as the life expectancy rises and numbers of elderly people increase, surgeons and oncologists will be faced with increasing numbers of patients in their 70s and 80s who present at a resectable stage. The observation from cancer center databases that the older patient may actually present with an earlier stage lung cancer, [8] is supported in surgical series. [16] In the report by Gebitekan from the *European Journal of Cardiothoracic Surgery*, 58% of patients above the age of 70 presented with stage I disease versus 40% in younger patients, whereas 13% of older patients had stage III disease versus 22% in the younger population.

In the 1970s, Thompson-Evans reported the outcomes of surgical treatment in the elderly. [17] He showed that patients aged 65 years or more were resectable in a range comparable to that of younger patients. Twenty-three percent were operable and 15% were suitable for curative resection. However, the operative mortality exceeded 15%, making the benefits debatable. Over the last two decades with refined staging approaches and improved surgical techniques and postoperative support, considerably lower mortality rates have been reported.

Massard et al. reviewed 1,616 patients who underwent thoracotomy for lung cancer from January 1983 to December 1992 with 233 patients age 70 years or more, at the University Hospital in Strasbourg, France. [18] Twenty-nine percent of these patients had no medical history, 26% had a history of cardiovascular disease, and 19% had a previous history of malignancy that was in complete remission; 48% of patients were stage I, 17% stage II, and 30% stage III. Two hundred ten patients were able to undergo resection, with 60 receiving pneumonectomies and 150 lobectomies. A total of 16 patients died postoperatively—7.2% for the whole series, 10% after pneumonectomy, and 6.6% after lobectomy. The mortality was similar below and above 75 years. The five-year survival for stage I was 45%, 36.3% for stage II, and 13.8% for stage III, with an overall five-year survival of 39.9%. Survival was not influenced by age.

In a series from St. Rafael and Yale New Haven Hospital, Pagni et al. reviewed the short-term and long-term results of pulmonary resection with the intention of cure from lung cancer in patients 80 years and older. [19] There were 54 octogenarians, which represented 4% of 1,328 operations for lung cancer between 1980–1995. There were 28 men and 26 women, with the mean age of 82 years in the range of 80 to 88 years. Thirty-one percent of these patients had chronic obstructive pulmonary disease, 24% had a history of angina pectoris, myocardial infarction, or cardiac arrhythmia requiring treatment, and 19% had previous treatment for malignant disease or were free of evidence of recurrence at the time of their lung cancer operation. None of these patients received induction chemotherapy or chemotherapy/radiotherapy with the exception of two patients who were treated with preoperative radiation for clinical nodal stage III-A disease. The types of surgery performed were 43 standard lobectomies, 2 extended lobectomies, 2 bilobectomies, 3 lower lobe superior segmentectomies, 3 wedge resections, and 1 left pneumonectomy. There were two perioperative deaths for a 3.7% operative mortality rate. Twenty-three patients had nonlethal complications, with cardiac problems making up the majority of these complications. There were six nonfatal problems, which were considered major complications because they extended the hospital stay and required unusual intervention. These problems were air leaks, congestive heart failure, pneumonia, recurrent laryngeal nerve injury, and reoperation for evacuation of hemothorax. Minor complications occurred in 17 patients, including atrial arrhythmia, urinary retention, depression, or confusion. Forty-nine of the 52 patients were discharged to home after their operation; however, three patients required temporary care at a convalescent facility. The actuarial survival of the 52 discharged patients was 86% at 1 year, 62% at 3 years, and 43% at 5 years. For stage I patients, survival was 97% at 1 year, 78% at 3 years, and 57% at 5 years. Those patients with more advanced lung cancer did poorly. There were 13 patients in this group and only two were alive at 8 and 27 months after the operation. The remainder died between 4 and 40 months postoperatively. The median survival for the combined stage II and III cohort was only 15 months. The authors concluded that age in the 80s was neither a contraindication to operative treatment nor routine indication for lesser resection.

In a second study evaluating the surgical treatment of lung cancer in octogenarians, Hanagiri et al. reviewed 20 patients aged 80 or older who underwent surgery for lung cancer in Japan. [20] In this review, the authors found that the postoperative complication rate was 50% in patients over 80; however, there were no fatal complications. The most common postoperative complication seen in these patients was transient cardiorespiratory complications such as difficulty in expectoration

and arrhythmia. A five-year survival rate was 42.6%, which was similar to that obtained in younger patients.

From the University of Milan, Italy, Santambrogio et al. compared the short- and long-term results of treatment of patients age 70 and older with a group of younger patients undergoing surgical treatment for lung cancer.[21] From March 1986 to March 1997, 424 consecutive patients were evaluated. These patients had documented NSCLC stage I or II. Of 519 evaluable cases, 54 were age 70 or over and 465 were between the ages of 40 and 69 with a mean age of 58. Although the composition of the two groups was homogeneous, for the most part, there was noted a reduced forced vital capacity and FEV1 in the patients over 70 as well as significantly higher incidence of risk factors, including heart disease, hypertension, diabetes, chronic obstructive pulmonary disease (COPD), and peripheral vascular disease. For both groups, the most frequent operation undertaken was lobectomy; however, pneumonectomy was performed significantly less in the older patient group. The operative mortality as occurring within 30 days of surgery was 5.5% in the older group and 1.3% in the younger group. The total complications were 7.4% and 6.9%, respectively. At 5 years, patients with stage I disease, the older group had a 52% survival and the younger patients had a 57.8% survival. In stage II disease, five-year survival was 50% and 30.6% in the older and younger groups, respectively. In another study from Milan, Italy, Cicraco et al. determined that the postoperative outcome and survival at 12 months in patients 70 years or older, who underwent surgical resection for stage I, II, or III-A disease, was determined not by stage or histology but by the postoperative complications and concomitant cardiopulmonary disease.[22] Seventy-six patients underwent surgical resection between January 1992 and June 1996. There were 15 cases of postoperative complications and a 30-day operative mortality of 1.3%. Overall actual survival at 54 months was 53%. Mortality at 12 months was found not to relate to the stage of disease, histology, or whether patients underwent lobectomy versus wedge resection. Specifically, compromised preoperative pulmonary function and spirometry and concomitant cardiac disease were predictive of postoperative complications.

From these series of lung cancer patients undergoing surgery,[18,19,20,21 and 22] it appears clear that the operative mortality and postoperative complication rate has substantially decreased in the 1990s compared to the 1970s. In addition to better preoperative staging of these patients, significant improvements have been made in pre- and postoperative care. Furthermore, because all of these studies are retrospective, patient selection continues to be a critical factor in achieving comparable surgical outcomes in the elderly compared to younger patients. Even in this setting, it is clear that the comorbid cardiac and pulmonary disease does lead to a somewhat higher, although fortunately manageable, complication rate in these series of patients. Thus age alone should not be a factor in determining the best operative procedure for lung cancer patients with adequate physiologic status and functional reserve.

For patients who do have significant pulmonary compromise that might otherwise preclude standard surgical approaches, newer minimally invasive techniques have been developed that may be particularly useful in the elderly population. Preliminary reports have suggested that video-assisted lobectomy can be performed in the elderly[23] with less morbidity. Secondly, thoroscopic surgery[24] is a useful diagnostic and potential therapeutic tool in this population. One report of video-assisted thoroscopic surgery for partial pulmonary resection for lung cancer in elderly patients with severe emphysema demonstrated not only successful removal of the tumor but actual improvement in the pulmonary function.[25] Thus in appropriate candidates such pulmonary resection may not only remove the cancer but also improve underlying pulmonary function. These small series of patients require larger prospective surgical trials to better define both the short-term complications of this procedure as well as long-term benefits compared to more standard surgical approaches. In the interim, however, the standard surgical staging of mediastinoscopy takes on an even more important role in the elderly lung cancer patients to be as certain as possible about the nodal status of the patient before undertaking definitive surgical resection.

RADIATION

Radiation is an important treatment modality in the management of lung cancer. The acute side effects of radiation may result in physicians altering or interrupting a course of treatment in elderly patients. This action may compromise the efficacy of treatment even though most of these side effects are reversible. In contrast, the late side effects of radiation therapy may be neglected in older patients but can significantly impact on quality of life. Pignon et al. reviewed radiation data from patients treated on European Research Organization for Treatment of Cancer, (EORTC) trials to determine the influence of age on the frequency and severity of acute and late side effects of radiation therapy and if the prognosis of tumors sufficiently differed between patients of six age groups.[26] One-thousand three-hundred seventy-seven patients with lung cancer or esophageal cancer enrolled from 1976 to 1987 in six trials initiated by the lung cooperative group or by the gastrointestinal cooperative group of the EORTC were examined. Survival and toxicities according to age were analyzed in six age groups: less than 50, 50–54, 55–59, 60–64, 65–70 and more than 70 years. Data regarding age and acute toxicity were available for 1,208 patients who experienced 640 greater than 1 World Health Organization (WHO) toxicities. Of the patients evaluated for nausea, 30% had toxicity. The difference in distribution of the occurrence of nausea between age groups was not significant, but there was a trend toward more nausea in the younger age groups. Only two cases of grade IV nausea were seen in the 55–59 and 60–64-year-old age groups. Weight loss during the treatment affected 228 of 470 patients evaluated. By contrast to nausea, there was a statistical difference in the distribution of weight loss with regard to age with a trend toward more weight loss in the older patients (p = .0002). Common symptoms included 16% of patients experiencing dyspnea, 30% esophagitis, and 23% weakness. There was no difference in the distribution of these complications according to age.

There was also no significant difference in the distribution of WHO performance status in relation to age; change in performance status was evaluated in 112 patients during radiation therapy, and they did not show an age effect. Regarding late side effects, 1,082 grade more than 1 late toxicities were recorded in 935 of 1,106 patients available for analysis, after 90 days. Approximately 40% of patients were free of late toxicity at 4 years in each age group. The comparison of late toxicity for all complications and all grades in each age group showed no significant difference in the actuarial incidence of late effects among age groups. When the analysis was restricted to grade more than 2 toxicities, there was a trend for more severe complications in older groups. However, only esophagitis demonstrated a significant difference with a higher frequency in the older patient (p = .01). Importantly, overall survival was related to stage and no differences were reported between the various age groups. These results, similar to the surgical data, suggest that age alone is not a reason to withhold another standard radiation treatment in the elderly patient with adequate physiologic reserve. Lastly, the addition of chemotherapy to radiation therapy had no influence on late complications as a function of age. Specifically, posttreatment weakness was noted to be equally distributed in all age groups. This finding is important because a common reason for applying a shortened course of radiation, or less aggressive treatment, in older patients is to reduce the duration to decrease the risk of fatigue.

In a study from Japan conducted between 1976 and 1992, 32 patients age 75 and older with a mean age of 79 years and 11 patients over 80 years with stage I and II NSCLC were given definitive radiation therapy.[27] Four patients were T_1N_0, 9 patients were T_2N_0, and 19 patients were T_2N_1. Twenty-six patients had a performance status of 0 to 1 and six patients had a ³ 2 performance status. A total dose more than 60 Gy radiation was given to each patient, and all 32 patients completed treatment without treatment-related complications. The two-year survival rate was 40% and the five-year overall survival rate was 16%. There were 11 intercurrent deaths with 7 patients dying with heart disease. The two- and five-year cause-specific survival rates were 57% and 36%, respectively. In Japan most patients receive radiation treatment as inpatients, and all but three patients on this study were treated on an inpatient basis. None of the patients developed pneumonitis requiring hospitalization.

Another retrospective study of radiotherapy for lung cancer patients age 75 years and over by Patterson et al. from the United Kingdom concluded that radiation therapy for elderly patients with lung cancer is well tolerated with similar responses as seen in younger patients;[26] however, patient selection was deemed important. There were 149 patients over 75 years of age referred for radiation therapy. Eighty-three percent of these patients were ambulatory and independent in self-care but 12% were dependent. These patients had non–small cell and small cell carcinoma of the lung, 24% had known metastatic disease, and 91% had received previous treatment either with surgery or chemotherapy. No patients received chemotherapy during radiation. One hundred forty-two patients received radiation therapy, 8 received aggressive treatment with curative intent because they were either unfit or refused surgery, and 134 patients received palliative radiotherapy, 25 receiving a single fraction, 104 receiving two to five fractions over 1 week, and 5 patients were treated 9 to 14 days. One patient died before completing the treatment. The most common pretreatment symptoms reported by about 50% of the patients were cough and breathlessness. Hemoptysis and chest pain were seen in one-third of the patients and one-quarter of patients experienced weight loss. A complete or moderate response was reported in 80% of patients with hemoptysis (34/44), 56% with chest pain (25/45), 44% with dyspnea (32/73), 25% with cough (14/57), and 18% with dysphagia (2/11). Twenty-five patients reported side effects, 12 with dysphagia, 7 with lethargy, and 5 with pain. These reported side effects were for the most part graded as mild (61%), 50% (4/8) patients who received aggressive radiotherapy were alive after 21 to 25 months, the mean survival being 12 months. Only 4 (3%) of the 133 patients who completed palliative radiotherapy were alive 15 to 24 months later with the mean survival being 5 months. Thus these institutional experiences suggest that radiation treatment can be delivered in the lung cancer patient over 75 years of age with curative[27] or palliative[28] intent, with results comparable to younger patients.

Combined modality treatment with radiation therapy and chemotherapy in patients with unresectable stage III NSCLC is becoming standard of care in good performance status patients, as discussed elsewhere in this book. Older patients have been included in many of these trials, but studies evaluating combined modality aproaches in NSCLC as a function of age are limited. By contrast, radiation therapy and chemotherapy as a combined modality has been a standard of care for limited-stage small cell lung cancer (SCLC) for many years, and trials evaluating this approach in the elderly have been reported. A treatment regimen consisting of carboplatin and etoposide with accelerated hypertractionated radiation therapy achieved encouraging results in elderly patients with limited-stage SCLC.[29] Seventy-five patients who were 70 years of age or older with Karnofsky performance status greater than or equal to 60 and no other major medical problems were treated on this protocol. The patients received carboplatin at 400 mg/m^2 on days 1 and 29, oral etoposide 50 mg/m^2 on days 1 through 21 and days 29 through 49,

with accelerated hyperfractionated radiation at a dose of 1.5 Gy twice daily for a total dose of 45 Gy beginning on day 1 of treatment. There was a median follow-up of 61 months with a response rate of 75% complete response in 57% of patients and a median survival time of 15 months. The two-year survival rate was 32% and the five-year survival rate 13%. Grade III toxicities included leukopenia in 8.3% of patients, thrombocytopenia in 11% of patients, and esophagitis in 2.8% of patients. Only one patient experienced grade IV thrombocytopenia. There was no grade III or higher late toxicity seen. Fifty-two of the 61 patients who began treatment with a Karnofsky performance status of less than or equal to 90% had an improvement in their performance status.

In a retrospective review of two studies from the NCI Canada in which patients with limited-stage SCLC were randomized to received combined modality therapy, 88 of 608 patients were 70 years or older.[30],[31] The conclusion of this study was that potentially curative combined modality therapy for limited-stage SCLC should not be withheld from patients because of their age. In this trial there were two arms: patients could, on arm A, receive CAV chemotherapy for three cycles alternating with etoposide/platinum chemotherapy for three cycles or CAV chemotherapy followed by etoposide/platinum chemotherapy for three cycles. In this arm, patients received radiation at week 18 for 25 Gy in 10 fractions or 37.5 Gy in 15 fractions. In the second arm, patients received CAV for three cycles alternating with etoposide/platinum for three cycles and then were randomized to receive either early thoracic radiation beginning at week 4 for 40 Gy at 15 fractions or late thoracic radiation beginning at week 16 for 40 Gy at 15 fractions. There was no significant difference in the tolerance between the two age groups; however, there was a trend toward a greater number of days required to complete treatment in patients receiving the late thoracic radiation with a greater variation seen in the older population. There were similar incidence of both acute and late grade III or IV toxicities between the two age groups. Incidence of esophagitis was not noted to be increased for the elderly group, although it was increased for all patients with increasing doses of radiation. There was no significant difference in response rates, local relapse rate, or overall survival in the two groups. The authors concluded that it is possible to administer combined modality therapy with chemotherapy and thoracic radiation safely in older patients presenting with limited-stage SCLC.

Although these results may differ in NSCLC patients, at a minimum it suggests that combined modality approaches should be evaluated in physiologically fit elderly patients with inoperable stage III NSCLC in an attempt to offer curative therapy.

Chemotherapy In the Elderly Patient

Of all the treatment modalities, the use of chemotherapy in the elderly has remained the most controversial. This relates to a variety of factors, including the perception of limited benefit of chemotherapy in NSCLC in general, as well as the potential for increased toxicity in the elderly. Over the last decade (as discussed elsewhere in this book), the benefit of chemotherapy has been well recognized in patients with advanced-stage cancer, as well as in patients with locally advanced disease in combination with either radiation treatment, surgery, or both. Unfortunately, most of the clinical trials that have documented this benefit have focused on patients in general younger than 70. In addition, most of the trials that have documented the benefit of chemotherapy have been combination chemotherapy regimens including cisplatin. Therefore, because of the relatively small database with regard to the benefit of combination chemotherapy in the elderly as well as the presumed increased toxicity in this population, there has been a reluctance to treat elderly patients with advanced NSCLC in the same way that younger patients have been treated. Fortunately, in the last few years several trials specific to the elderly have been conducted that clarify the benefits of treatment in this population.

In treatment of patients with advanced NSCLC, the most consistent factor predicting for survival has been performance status.[32] Of interest in this review published by Dr. Albain from the Southwest Oncology Group (SWOG) experience, increasing age in fact had a positive influence on survival. This may reflect a somewhat different biology of lung cancer in the elderly or simply that physician selection of elderly patients might be even more rigorous than in younger patients enrolling on chemotherapy trials. A more recent report reviewed the outcome of chemotherapy in patients with advanced NSCLC treated at the Royal Marsden Hospital from 1990–1995.[33] Of the 290 patients enrolled, 44% were over the age of 60 and 12% were over the age of 70. A variety of combination chemotherapy regimens were administered. In a multivaried analysis of the overall population, poor performance status elevated alkaline phosphatase more than 2 times normal, extensive-stage disease, and hypoalbumenia were all predictors of poor survival. However, in this study, age had no influence either positive or negative on survival or symptom relief because equivalent benefit was seen across all populations.

Although these trials suggest that elderly patients with comparable performance status to younger patients may receive the same benefit of chemotherapy without added toxicity, preselection remains a major problem in interpreting the data of such retrospective reviews. Fortunately, several prospective trials targeting elderly patients have now been performed and reported. It is instructive to review the work of Gridelli[34] as an initial attempt to develop a less toxic regimen. Carboplatin at a dose of 300 mg/m^2 intravenously on day 1 was combined with oral etoposide 100 mg per day for 7 days, with the treatment to be cycled every 4 weeks. Of the first 14 patients treated, no objective response was observed and remarkable hematologic toxicity was recorded.[34] This regimen was developed to be "kinder and gentler" treatment, but declining renal function in the elderly was likely a significant factor in the toxicity of carboplatin dosed on body surface area. By contrast, Dr. Frasci performed another trial with carboplatin and oral etoposide, but in this study initiated carboplatin and an area under the curve (AUC) of 4, which allows correction for the decreased renal function in the elderly, and combined this with etoposide 50 mg twice daily orally for 14 days.[35] If no excess toxicity was noted, then the carboplatin dose was increased to an AUC of 5 on the second course and the etoposide course was extended to 21 days of administration on the third course. A total of 38 NSCLC patients over the age of 70 were enrolled in this trial. The overall response to treatment was 22%, with a median survival time of 11 months in the elderly patients. Of significance was that the quality of life improved in 41% of patients. Thus these phase II trials not nicely document that by adjusting chemotherapy for differences in organ function in the elderly, both improvement in clinical benefit and reduction in toxicity may be seen.

The new agents have had a major impact in the treatment of NSCLC with a potential to have an even greater impact in the elderly. The new agents (discussed elsewhere in this textbook) have significant advantages in terms of less fatigue and less effect on appetite and weight loss, which may be particularly important to the elderly. Also, because these agents have been largely tested with contemporary populations, more detailed toxicity data is available. Lastly, in order to establish the activity of these agents, single-agent studies have been conducted, and it appears that monotherapy may be a very appropriate alternative for elderly patients with advanced NSCLC.

Vinorelbine was the first new agent approved for treatment for NSCLC.[36],[37] In the U.S. trial,[36] single-agent vinorelbine at 30 mg/m^2 intravenously weekly was compared to a five-day 5FU leucovorin regimen administered monthly. This trial documented a survival advantage for a single-agent vinorelbine compared to 5FU leucovorin with 25% of patients with stage IV NSCLC alive at 1 year compared to 16% on the control arm. Similar results were seen in the European trial.[37] In this study, both stage IIIb and IV patients were included, and the one-year survival for vinorelbine was 30% with a combination of vinorelbine and cisplatin superior at 35%. In both of these trials, elderly patients were included, but the median age of the patients was 61. Therefore, limited conclusions can be made from these two trials about the absolute benefit of either single-agent vinorelbine or vinorelbine and cisplatin in elderly patients over 70. Of interest, in a subsequent analysis of the European trials,[36] the benefit of cisplatin/vinorelbine in combination over single-agent vinorelbine was limited to patients with a performance status of 0 and 1. No additional benefit of the combination chemotherapy was seen in the performance status 2 patients.

In light of these data, it is interesting that Vernisi evaluated the role of single-agent vinorelbine in an elderly population of patients felt to be "unfit" for cisplatin-based chemotherapy. There were 23 patients over the age of 70 out of 83 patients treated.[39] In this study, the overall response was 30% and toxicities were mild with a median survival of 9 months. No effect of age on outcome was detected, and it was suggested that single-agent vinorelbine was a reasonable option for patients with advanced NSCLC, particularly in the elderly.

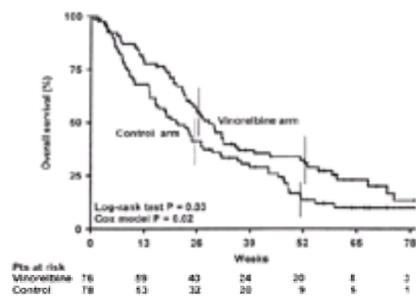
With this background, the most significant trial of chemotherapy in the elderly to date is the study performed by Dr. Gridelli and the Elderly Lung Cancer Vinorelbine Italian Study Group, also known as the ELVIS trial.[40] Elderly patients over the age of 70 with stage IIIb or IV NSCLC ineligible for radiotherapy with a performance status of 0 to 2 were enrolled in a trial that compared vinorelbine to supportive care alone. The vinorelbine dose was 30 mg/m^2 intravenously on days 1 and 8 with no planned dose on day 15. This three-week cycle was repeated for a maximum of 6 cycles of treatment. In addition to standard follow-up studies, a quality-of-life assessment was performed using the EORTC core questionnaire as well as the lung cancer specific module. A statistically significant survival advantage was seen in patients receiving vinorelbine (p = .03). The median survival was 28 weeks in the vinorelbine arm versus 21 weeks in the control arm, and survival of 1 year was 32% in the vinorelbine group and 14% in the control arm (Figure 63.2). These survival outcomes are similar to, if not superior to, the U.S. trials of single-agent vinorelbine versus 5FU leucovorin in younger patients. Of the 71 patients assessed for toxicity of vinorelbine, treatment was stopped in five patients because of severe toxic events. Four of the five patients developed constipation after multiple cycles of treatment. Other milder toxicities, as the vinorelbine were seen, but despite the treatment-related side effects, there was an overall improvement in quality-of-life scores for patients receiving vinorelbine versus supportive care alone. This trial clearly establishes the potential benefit of single-agent therapy in the elderly population across the range of performance status categories. These results confirm the earlier work of Dr. Gridelli and colleagues in the phase II study that preceded the ELVIS trial.[41] This large phase II and phase III experience with vinorelbine in the elderly provides an excellent database against which other new agents or combinations may be tested.


FIGURE 63.2. Estimated survival according to treatment arm as calculated by the Kaplan-Meier method. Number of patients at risk by treatment arm is shown at the bottom. Pts, patients; vertical bars, representative of 955 confidence intervals.

A second agent that also has a favorable side effect profile has been gemcitabine. [42] Like vinorelbine, extensive studies have been performed with gemcitabine as a single agent in advanced NSCLC across a range of ages. Specific review of gemcitabine experience in patients over age 65 enrolled in phase II trials has also been reported.[43] In these trials, gemcitabine dose ranged from 800 to 1,250 mg/m^2 weekly for 3 weeks out of 4 with repeated monthly cycles of treatment. In these studies 255 patients were under the age of 65 and 105 patients were over the age of 65. Of interest was the fact that the group under 65 had a median survival of 8.1 months and a one-year survival of 27%. By contrast, the older population had a median survival of 9.1 months and a 36% one-year survival. Several cycles associated with dose reduction or dose omissions in the mean number of treatment cycles administered were similar between the two groups. Although this trial has the same limitations as other retrospective reviews with regard to patient selection, it supports the conclusion that gemcitabine is active and well tolerated in elderly patients with NSCLC and may also be a potential consideration for monotherapy in the elderly. To help explore the relative benefits of vinorelbine versus gemcitabine, the Multiagent Italian Lung Cancer Elderly Trial (MILES) is ongoing, which is randomizing patients to single-agent vinorelbine versus single-agent gemcitabine versus the combination of the two agents. These trials will be invaluable in determining the relative benefits of chemotherapy in general and the new agents specifically in elderly patients with NSCLC.

Although monotherapy is certainly an appropriate alternative to combination chemotherapy in the elderly patients and those with lower performance status, for the higher performance status, physiologically fit, elderly lung cancer patients with potential curable NSCLC, a much larger prospective database is needed to establish the benefits of combination chemotherapy in stage III patients and in the adjuvant setting. Until such trials are performed, we must look to ongoing cooperative group trials that cross the age groups to determine relative benefits of combination chemotherapy in this population. Specifically, the taxanes, paclitaxel and docetaxel, have demonstrated substantial clinical activity as single agents and in combination treatment. Because of the increased toxicities associated with cisplatin in association with paclitaxel and docetaxel, there has also been a shift from cisplatin use to carboplatin use in combination with these agents. The relative benefits of these newer combinations are the subject of ongoing trials.

The initial report by the SWOG has suggested that cisplatin and vinorelbine and carboplatin and paclitaxel have a similar impact on survival in advanced NSCLC patients across the range of ages.[44] Although detailed quality-of-life data and economic analyses are pending, there was a higher dropout rate noted for patients on the cisplatin arm of the study, supporting the better tolerability of carboplatin-based therapy. A second trial of major importance in this area is an ongoing trial performed by the Eastern Cooperative Oncology Group (ECOG) also comparing carboplatin and paclitaxel to three cisplatin-based regimens, including cisplatin and paclitaxel, cisplatin and docetaxel, and cisplatin and gemcitabine. Full analysis of this study awaits completion of the trial, but a preliminary analysis has suggested that the carboplatin arm of the trial had an improved toxicity profile compared to all three of the cisplatin-based therapies. [45] Because of the increased toxicity in the performance status to patients compared to historical controls in the ECOG database, the trial was closed to performance 2 patients. Analysis of the data, however, reflected statistical differences favoring carboplatin and paclitaxel over the other three arms of the study in terms of grade 3–5 toxicities. Survival data and other outcomes await completion of the trial and its subsequent analysis, but it appears from the safety data that carboplatin is the preferred platinum agent.

Lastly, a third trial of importance by the Cancer and Leukemia Group B (CALGB) is evaluating the role of single-agent paclitaxel versus carboplatin and paclitaxel. This trial is open to enrollment of performance status 0 to 2 patients, and a monitoring committee is in place to review potential toxicities seen in the performance 2 patients. However, in view of the lower toxicity profile of this combination regimen in the ECOG trial, it is hoped that this trial will reach its completion. Because elderly patients are eligible for this trial and are being actively enrolled, it is hoped that this study will help address the relative benefit of monotherapy versus combination chemotherapy in elderly patients with NSCLC.

SUMMARY

Because of the demographics of lung cancer, the elderly population has become an increasingly important group for evaluation of the relative benefits of both curative and palliative approaches to this disease. In addition to the specific trials of surgery, radiation therapy, and chemotherapy that have recently been performed in this population, increasing experience is being gained in the supportive care of all cancer patients, and the elderly may particularly benefit from the improvements in pain management, reduction in hematologic toxicity, and in improving our understanding of fatigue as well as other supportive care approaches. The growing database and number of clinical trials specifically targeted to the elderly is encouraging and should be useful to the clinician and the patient in making informed decisions about treatment options in this disease.

TREATMENT OF SMALL CELL LUNG CANCER IN THE ELDERLY PATIENT

FRANCES A. SHEPHERD
ANDREA BEZJAK

The global incidence of lung cancer is increasing at a rate of 0.5% per year, and is the leading cause of cancer mortality for both men and women in most countries. [1] Although in North America the age-adjusted incidence rates for men began to decline in the 1980s, they continued to increase for women and are still increasing to this day. The average age of patients with lung cancer is also rising such that the age-specific incidence for men peaks at 75–79 years and for women at age 70–74. Incidence rates decline thereafter in both genders, likely due to the lower prevalence of smoking in the population at the beginning of the century. In some areas of the world, all-cancer mortality rates in the elderly have increased substantially over the past two decades, due almost exclusively to an increase in lung cancer and other tobacco-related cancers in both men and women.[2,3]

Small cell lung cancer (SCLC) accounts for approximately 20% of all pulmonary neoplsms, and unlike squamous cell lung cancer, which tends to increase in incidence with increasing age, SCLC appears to be equally distributed over all age groups.[4,5] Some investigators have shown an inverse relationship between age and stage of disease.[5,6] This trend has been shown most clearly for patients with non–small cell lung cancer (NSCLC), but has also been reported in several series of small cell patients.[5,6 and 7]

It is clear that large numbers of elderly patients have lung cancer, including SCLC, for whom treatment decisions must be made. However, there are few data on how treatment for this group of patients differs or should differ from that of younger patients. Until recently, elderly patients were often excluded from clinical research trials, and few studies have been designed specifically for the elderly population. Goodwin et al. reported that although 31% of all adult patients with cancer were over 70 years of age, only 7% of patients enrolled in the Southwest Oncology Group (SWOG) trials were in that age group. [8] Specifically, in the SWOG lung cancer trials, only 18% of the patients were over age 65, and 9% were over age 70. Dajczman et al. reported that only 1 of 81 elderly patients was enrolled on an experimental protocol for SCLC compared to 19% of patients age 60–69 and 28% of patients less than 60 years of age. [9] Furthermore, several investigators have shown that treatment *of any kind* may be withheld from elderly patients with SCLC despite a high expectation of benefit and even a chance of cure for patients with limited-stage disease.[7,8,9 and 10] The University of Toronto group reported that over the 12-year period 1976–1988, only 78 of 123 patients (63%) age 70 years or greater were treated with chemotherapy (only one-third over age 80), and 25 patients received no treatment at all. [7] The most important determinant in the decision to treat or not to treat was performance status: only 38% of patients with performance status 3 or 4 received treatment, compared to 66% of patients with performance status 0, 1, or 2. Similar statistics were reported by de Rijke et al. from the Netherlands, where 52% of patients over age 70 were offered no treatment at all compared to 14% and 22% for patients age 50–59 and 60–69, respectively. [10]

It would appear that the reasons for not referring older patients for investigation and treatment of SCLC are based on widely held beliefs and perceptions rather than on well-documented scientific data. It is possible that many primary care physicians assume that elderly patients have a limited life expectancy and, therefore, do not warrant treatment of malignant disease in general and lung cancer in particular. In fact, the life expectancy of a woman who reaches age 70 is 15 years, and 8–10 years for a man that age.[11] It is also a commonly held belief that elderly patients have a poorer prognosis and tolerate therapy less well than younger patients, perhaps due to the presence of other comorbid illnesses that commonly occur in this population. These issues will be addressed in the sections that follow. Finally, some physicians view the elderly as emotionally as well as physically frail, which may lead to the extreme of withholding not just treatment but even the diagnosis from older patients. However, this view does not seem to be justified, as shown by Nerenz et al. [12] and Ginsburg et al.[13]

In view of these attitudes, it is clear that the treatment of elderly patients with SCLC requires critical evaluation. Should all elderly patients be offered the same therapy as younger patients, and if not, what guidelines are available to help determine which patients are most likely to benefit from treatment? Should treatment be attenuated in dose or duration, and is combined modality therapy appropriate in the older population? Should specific protocols be designed to meet the needs of the elderly patient? Because elderly patients were excluded from most clinical research trials until recently, it is difficult to address these questions with data that are not heavily influenced by referral bias and physician treatment bias. Furthermore, even in the overviews of large cooperative group databases, the extremely elderly population of over 75 or over 80 years of age is under-represented. Clearly, clinical trials for older patients are desperately needed. [14]

AGE AS A PROGNOSTIC FACTOR

Several of the cooperative groups have analyzed their databases to determine the relative prognostic importance of various baseline clinical and laboratory factors in SCLC.[15,16,17 and 18] There is universal agreement that stage is the most important determinant of prognosis, with median survival times of 12 to 16 months reported for limited-stage compared to only 7 to 11 months for extensive-disease patients. Other important clinical parameters include performance status, gender, and baseline level of lactate dehydrogenase (LDH). [15,16]

A summary of the findings related specifically to age is shown in Table 64.1. The largest study was that of the SWOG database reported by Albain et al. [15] They found that age under 70 years was significantly favorable in both limited- and extensive-stage patients. Furthermore, age was significant even when entered into the Cox regression model of multiple prognostic indices. In a retrospective review of 1,521 patients, the Cancer and Leukemia Group B (CALGB) identified female gender and performance status as important predictors of survival in both limited- and extensive-stage disease. [17] Limited-stage patients older than 60 years had a higher mortality rate than younger patients (p < 0.008), but age was not predictive of survival duration among patients with extensive disease.

	Age Break	Limited Stage		Extensive Stage	
Author		Univariate	Multivariate	Univariate	Multivariate
Albain et al.[15] n = 2,580	70	Hazards ratio 1.4 (p < 0.0001)	Hazards ratio 1.5 (p < 0.00002)	Hazards ratio 1.3 (p < 0.002)	Hazards ratio 1.3 (p < 0.001)
Sagman et al.[16] n = 614	70	Relative risk 1.22 (p = 0.023)*	Not significant	—	Not significant
Spiegelman et al.[17] n = 1,521	60	—	Relative hazard 1.23 (p = 0.008)	—	Relative hazard 1.03 (p = 0.74)
Siu et al.[18] n = 608	70	Age as a continuous variable p = 0.02 Age 0–69 vs. ≥70, p = 0.14	Not significant	—	—

*The effect of age was examined together for limited and extensive disease

TABLE 64.1. THE IMPORTANCE OF AGE AS A PROGNOSTIC FACTOR IN SMALL CELL LUNG CANCER

Sagman et al. analyzed 614 patients from the University of Toronto database and reported a modest survival advantage for patients less than 70 years (RR 1.32, p = 0.023);[16] however, using recursive partitioning and amalgamation modeling (RECPAM) techniques, age was not significant and did not appear in any of the terminal pods of the four prognostic groups identified by the model. Albain et al.[15] also applied the RECPAM technique to the SWOG data set and identified four separate prognostic groups. Age was of importance only in the two limited-stage subgroups. This observation is similar to that reported by Spiegelman et al. for the CALGB.[17]

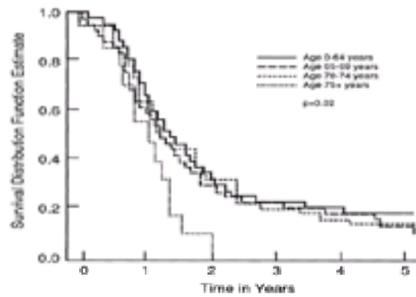
Siu et al. analyzed the National Cancer Institute of Canada, Clinical Trials Group (NCIC-CTG) BR.3 and BR.6 trials in limited-stage SCLC to determine the influence of age on both outcome and chemotherapy delivery.[18] This analysis is particularly important because all 618 patients received the same chemotherapy. They showed that, when analyzed as a continuous variable, age was of modest prognostic significance (p = 0.02), but when the survival of patients less than 70 years was compared to that of the older patients, there was no significant difference (p = 0.14). In fact, survival was similar for patients of all age groups, with the exception of the 13 patients age 75–80 who had significantly poorer survival than the rest of the group (Figure 64.1).


FIGURE 64.1. Comparison of survival by age group: 0–64, 65–69, 70–74, and 75+. (From Siu L, Shepherd FA, Murray N, et al. Influence of age on the treatment of limited-stage small-cell lung cancer. *J Clin Oncol* 1996;14:821, with permission.)

Pignon et al. reported the results of a metaanalysis of 2,140 patients who participated in 13 randomized trials designed to assess the importance of thoracic radiotherapy in limited-stage SCLC.[19] The relative risk of death in the combined therapy group compared to the chemotherapy-alone group was 0.86 (CI 0.78–0.94, p = 0.001), and the benefit in terms of overall survival at 3 years was 5.4%. There was a trend toward a larger reduction in mortality in younger patients, with a relative risk of death in the radiation group being 0.72 for patients less than 55 years of age. In contrast, the relative risk of death was actually *increased* at 1.07 (CI 0.70–1.64) with radiotherapy in patients over 70. Three-year survival rates estimated using the Kaplan-Meier method were 9.2% for chemotherapy alone compared to 17.4% for chemotherapy and radiotherapy in patients less than 55 years. For patients over 70, the rates were 10.2% and 8.75%, respectively.

CHEMOTHERAPY

With the exception of two studies that included elderly patients among other poor-prognosis populations,[20,21] there have been no randomized clinical trials of chemotherapy for SCLC in the elderly. For that reason, it is necessary to rely on retrospective reviews of large data sets that have compared the results achieved by elderly patients to those of younger patients in the same cohort, or to small prospective trials designed specifically for the elderly population. The definition of elderly has not been standard in these studies and has even been as low as 55 years or greater.[23] Most reports dealing with SCLC, however, have used age 70 years or greater to distinguish between the young and the elderly.

Retrospective Reviews

The results of nine retrospective reviews have been summarized in Table 64.2.[7,9,18,22,23,24,25,26 and 27] Several authors reported that many patients with SCLC were not offered treatment of any kind.[7,9,22,24] In the Toronto Hospital review,[7] 25 of 123 patients received no therapy and 20 were offered palliative radiation only. Survival correlated significantly with treatment received, ranging from 1.1 months for those not treated to 10.7 months for those who completed four to six cycles of combination chemotherapy (p = 0.0001). Dajczman et al.[9] also reported that suboptimal treatment was given to 57% of patients age 60–69 and 77% of patients over 70. Furthermore, the administration of suboptimal treatment was associated with significantly poorer survival, although this was true across all age groups studied. Shepherd et al.[7] and Dajczman et al.[9] examined the possible reasons for withholding or delivering less than standard treatment to elderly patients, and both investigators reported that performance status was the most important determinant in decision making. In the Toronto study,[7] only 38% of patients with Eastern Cooperative Oncology Group (ECOG) performance status 3 or 4 were treated with chemotherapy. In fact, performance status played a greater role than age itself, stage of the tumor, or the presence of other comorbid diseases. Several investigators have reported that the elderly population have more comorbid illnesses than their younger counterparts;[7,9,22] however, even serious illnesses such as chronic obstructive pulmonary disease, atherosclerotic heart disease, hypertension, diabetes, and so on do not seem to influence the decision to treat the elderly patient, nor do they affect the ability to deliver therapy.

TABLE 64.2. RETROSPECTIVE ANALYSES OF CHEMOTHERAPY IN ELDERLY PATIENTS WITH SMALL CELL LUNG CANCER*

Once a decision has been made to treat with chemotherapy, elderly patients often receive lower doses than younger patients. Shepherd et al.[9] showed, once again, that the decision to reduce initial doses was based most often on performance status. Physician decision to reduce doses for the elderly is based largely on the perception of poorer bone marrow reserve in the elderly and poorer tolerance for other toxicities. Although there are theoretical reasons why physiological changes in the elderly might lead to higher area under the curve (AUC) drug concentrations, and hence increased toxicity, this does not always seem to be the case in clinical practice.[28] Begg et al.[25,30] reported that with the exception of methyl-CCNU and methotrexate, agents that are seldom used in the treatment of SCLC any longer, neither the frequency nor the severity of toxicity was increased in the elderly.

More recent studies have also shown that elderly patients, if they meet the criteria for entry into SCLC clinical trials, do not experience increased rates of toxicity.[18,31] Siu et al. reported that grade 3 and 4 toxicity was not increased in elderly patients treated in two NCIC-CTG trials of limited SCLC in which patients received three cycles of cyclophosphamide, doxorubicin, and vincristine, and three cycles of etoposide and cisplatin. However, in an older study that used the more myelosuppressive regimen doxorubicin, cyclophosphamide, and etoposide, Poplin et al.[23] found that the incidence of fever and infection increased with age. Nou et al.[26] also reported that although nadir blood counts were similar in patients less than or greater than 70 years of age, the rates of septicemia per course and lethal septicemia were significantly higher in the older patients. However, this group also used highly myelosuppressive combinations that included both methotrexate and

CCNU. With the possible exception of peripheral neuropathy, [24] significantly increased nonhematologic toxicity has not been reported in any series to date. It would appear, therefore, that elderly patients of good performance status tolerate chemotherapy well, and that when regimens associated with modest degrees of myelosuppression are used, the risk of severe or fatal infectious complications is not increased.

Even though toxicity rates in elderly patients do not appear to be higher than those seen in younger patients, several authors have reported that elderly patients receive significantly fewer chemotherapy cycles than younger patients, and this situation appears to occur even in the stricter setting of a clinical research trial. [7,9,8,27] Siu et al. [18] reported that only 69% of elderly patients completed six chemotherapy cycles compared to 82% of younger patients (p = 0.01) in two NCIC-CTG trials. They did not find that the elderly patients had higher rates of dose reduction, although this finding has been reported by other authors. [9,27] When initial dose reductions, subsequent dose reductions for toxicity, and dose omissions are considered, the elderly population may actually received only one-half to two-thirds the treatment given to younger patients.

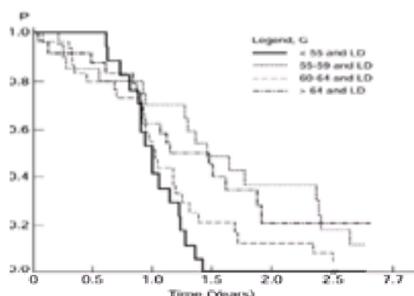
Clearly, the most important question to be asked is whether this attenuation of treatment in the elderly has a significant effect on survival. The results for the patients who received chemotherapy in several reported series are summarized in Table 64.2. All studies were retrospective reviews and some looked only at an elderly population, whereas others compared the results in elderly and young patients using variable age cutoffs. Siu et al. [18] showed that for patients with limited disease, response rates and median and five-year survival rates were similar for elderly and young patients. These observations are important because all patients were treated on a clinical trial and received the same chemotherapy. Poplin et al. [23] showed wider variations among four age subgroups of patients with limited disease (Figure 64.2), but it is interesting to note that the patients with the poorest survival were those in the *youngest* age group less than 55 years. Less difference was seen for patients with extensive-stage tumors (Figure 64.3). Other investigators who treated the elderly and the young with relatively uniform chemotherapy combinations reported similar response rates in both age groups, particularly for limited-stage disease patients, [9,26,27] and the Montreal group showed that median and two-year survival rates were similar for patients in three age groups if they were of good performance staus and received chemotherapy. [9] However, both Nou [26] and Tebbutt et al. [27] reported shorter survival for elderly patients, although the difference was statistically significant only in the Nou study [26] when examined in a multivariate analysis.


FIGURE 64.2. Kaplan-Meier survival plots for different ages; all patients had LD. (From Poplin E, Thompson B, Whitacre M, et al. Small cell carcinoma of the lung; influence of age on treatment outcome. *Cancer Treat Rep* 1987;71:291, with permission.)
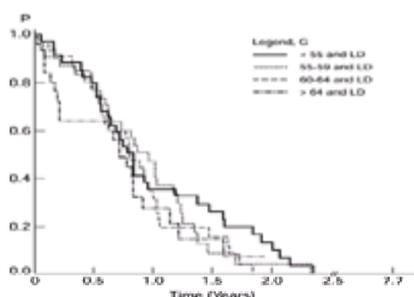

FIGURE 64.3. Kaplan-Meier survival plots for different ages; all patients had ED. (From Poplin E, Thompson B, Whitacre M, et al. Small cell carcinoma of the lung; influence of age on treatment outcome. *Cancer Treat Rep* 1987;71:291, with permission.)

A closer examination of Table 64.2 shows that for each report that compares young to elderly patients, survival in the older group is less. Frequently, the differences were not statistically different in the individual studies, and further deductions should probably not be drawn in view of the variability in treatment delivered and the differing definitions of elderly. However, these data suggest that the true impact of age on treatment outcome still requires further examination. Furthermore, little can be said about chemotherapy for the extremely elderly. Siu et al. [18] reported that the patients with the worst survival in the NCIC trials were those in the 75–80 age group. Only 46% of patients completed all six courses of chemotherapy, and no patient survived beyond 2 years (Figure 64.1). Patients over age 80 were excluded from all research trials until recently, and some authors have reported that patients in this age group are seldom offered chemotherapy of any kind, even that which is considered to be "gentle." [7] As the likelihood of surviving past 80 years of age increases, more attention will have to be paid to determining appropriate treatment for this group.

Prospective Trials for the Elderly

It is clear that some elderly patients can derive significant benefit from combination chemotherapy for SCLC. However, many investigators continue to question whether such treatment is appropriate for the elderly, and some have suggested that less aggressive treatment might be more appropriate even if this results in some compromise in overall response or survival rates. [25] Findlay et al. [25] reviewed their results for 72 elderly patients treated with either intensive combination chemotherapy or less rigorous treatment using either single agents or reduced doses of combination chemotherapy. In the intensive group, there were three treatment-related deaths, but despite this, median survival was longer (36 weeks versus 16 weeks), particularly for patients with limited disease (43 versus 26 weeks). Although other investigators might have reached a different conclusion from these results, these authors summarized by saying that intensive chemotherapy for elderly patients results in higher response rates and higher toxicity but not a major survival benefit.

In an attempt to avoid the toxicity of combination chemotherapy without compromising efficacy, several groups have developed treatment strategies specifically for elderly patients with SCLC. The results of several prospective trials are summarized in Table 64.3. [32,33,34,35,36,37,38,39,40] and [41] The epipydophyllotoxins, etoposide and teniposide, are among the most active agents for the treatment of SCLC, and as single agents produce response rates of 70% or more. Three trials of single-agent teniposide in the elderly produced conflicting results. Borke et al. [35] treated 33 patients (27 over age 70) and reported 90% response, median survival exceeding 8 months, and virtually no toxicity. In contrast, Cerny et al. [36] reported only 48% response and an unacceptably high toxic death rate of five patients in the first cycle despite using the same dose and schedule of teniposide. This may have been due to the inclusion of seven patients of poor ECOG performance status 3. However, Cascinu et al. [40] also reported a low response rate of only 23% without toxic deaths.

TABLE 64.3. PROSPECTIVE SINGLE-ARM TRIALS OF CHEMOTHERAPY FOR ELDERLY PATIENTS WITH SMALL CELL LUNG CANCER

Etoposide may be administered orally and is associated with only modest toxicity when used this way.[42] The Dublin group were among the first to use single-agent oral etoposide in the treatment of elderly SCLC patients.[32] Keane et al.[34] treated 63 elderly patients with etoposide, 200 mg orally daily for 5 days, and reported an overall response rate of 76% and median survival of 38 weeks. Using slightly different doses and schedules of etoposide, other investigators have also found similar response and survival rates as shown in Table 64.3.

These favorable results led to two randomized trials of single-agent oral etoposide in the United Kingdom, one by the Medical Research Council (MRC) Lung Cancer Working Party,[21] and the other by the London Lung Cancer Group.[20] The schemata and results of these two studies are summarized in Table 64.4. The MRC compared oral etoposide, 50 mg twice daily for 10 days to two standard combinations of chemotherapy. The survival of the patients treated with single-agent etoposide was significantly shorter than that of patients treated with combination chemotherapy (130 versus 183 days, p = 0.03). Furthermore, quite unexpectedly, the etoposide group experienced more life-threatening side effects (19% versus 10%, p = 0.05). The London group compared etoposide, 100 mg twice daily for 5 days to alternating combination chemotherapy. It should be noted that this trial was limited to the extremely elderly over age 75, or to younger patients with extensive disease and poor performance status. Overall response rates (39% versus 61%, p = 0.01), median survival (146 days versus 189 dates), and one-year survival rates (6.5% versus 17%) all favored the combination chemotherapy arm. Although toxicity was greater in the combination arm, severe grade 3 and 4 toxicities were uncommon in either arm.

TABLE 64.4. PROSPECTIVE-RANDOMIZED TRIALS FOR ELDERLY PATIENTS WITH SMALL CELL LUNG CANCER

Although the aforementioned studies have shown that elderly patients of good performance status may tolerate combination chemotherapy, several investigators have attempted to modify current regimens to improve the therapeutic index for this patient population. The most common maneuver has been to substitute carboplatin for cisplatin and to combine it with either etoposide or teniposide. The results of three trials are shown in Table 64.3.[37,38, and 39] All investigators reported response rates that ranged from 60%[39] to 89%,[37] and median survival that ranged from 33 weeks[38] to 40 weeks.[39] In general, the regimens were well tolerated, although Evans et al. reported that 4 of 40 patients suffered toxic deaths due to treatment.[39]

Westeel et al.[41] elected to use the standard chemotherapy agents cisplatin, doxorubicin, vincristine, and etoposide given in smaller doses in their PAVE regimen. For patients with limited-stage tumors, thoracic irradiation was administered concurrently with chemotherapy in cycle 2, but only cisplatin and etoposide were administered during that cycle. They reported a favorable overall response rate of 895, and median survival times of 70 and 46 weeks for limited and extensive stages, respectively.

RADIOTHERAPY

Radiation therapy plays several important roles in the treatment of patients with SCLC. Thoracic irradiation has been shown to improve response rates, and two large metaanalyses found significant improvements in two- and three-year survival rates in patients with limited-stage tumors.[19,43] All studies of prophylactic cranial irradiation reported a decreased risk of isolated cranial metastases for treated patients, and a metaanalysis has shown that this treatment is accompanied by a modest survival benefit in patients achieving a complete clinical response.[44] Radiation also has an important role in symptom palliation in patients who have relapsed or who are not candidates for aggressive treatment.

Given the essential role of thoracic irradiation in the treatment of limited-stage SCLC and the relatively modest side effects seen with conventional doses and fractionation schemes, many studies of combined modality chemotherapy and radiotherapy have included elderly patients. Despite the limitations of lack of uniformity in the dose and timing of radiation among studies, some conclusions may be drawn from analyses of the small populations of elderly patients in these trials.

Retrospective Reviews

There have been only a few analyses of the efficacy and tolerability of thoracic radiation in older patients with SCLC. Quon et al.[45] undertook a retrospective review of two NCIC-CTG studies of combined modality treatment for limited-stage SCLC, BR.3 and BR.6. Of 608 patients, 520 were less than age 70 and 88 were older (254 younger and 46 older patients in BR.3, and 266 younger and 42 older patients in BR.6). In the BR.3 study, patients were randomized to receive thoracic irradiation with either 25 Gy in 10 fractions or 37.5 Gy in 15 fractions, after completing six courses of chemotherapy consisting of cyclophosphamide, doxorubicin, vincristine (CAV), and etoposide and cisplatin (EP) administered in either sequential or alternating fashion. In BR.6, all patients received CAV alternating with EP, and randomization was to early (with cycle 2) or late (with cycle 6) thoracic irradiation (40 Gy in 15 fractions), administered concurrently with EP. In BR.3, 179 patients (60%) participated in radiotherapy randomization (61% of the young, 52% of the elderly), and 176 actually received radiation. In BR.6, randomization occurred at study entry for all patients, and 282 patients (91.6%) received radiation (92% young, 88% elderly). More patients of both age groups randomized to late radiation did not receive treatment, but this did not differ by age. The authors could identify no tendency to reduce field size in the elderly, even at the higher radiation doses. Once radiation started, there was no significant difference between the age groups with respect to the proportion of patients who completed treatment, and no differences were seen in time to complete radiation therapy dose delivered, or incidence of acute and late radiation toxicity. Some trends were noted, with elderly patients being somewhat less likely to complete late radiation in the BR.6 study. Elderly patients also tended to have lower rates of complete response in the BR.3 trial, although this was not the case in the BR.6 trial in which chemotherapy and radiotherapy were delivered concurrently. Local control rates were similar for both age groups in both trials.

Pignon et al.[46] analyzed the effect of age on acute and late toxicity of curative thoracic irradiation given to 1,208 patients who participated in six randomized trials of lung and esophageal cancer conducted by the European Organization Research for the Treatment of Cancer (EORTC). The largest of these trials compared sequential to alternating radiochemotherapy in 389 patients with limited-stage SCLC.[46] Patients received either 50 Gy in 20 fractions after chemotherapy (sequential

design), or four courses of 12.5 Gy in 5 fractions (alternating with chemotherapy). Of 389 patients, 95 (24%) were 65–70 years of age, and 29 (7%) were older than 70. This study contributed to the analysis of the effect of age on the pulmonary and esophageal toxicity, although results were reported collectively for all of the six EORTC trials. There was no difference in the distribution of either acute or late pneumonitis or esophagitis with increasing age. The analysis of other toxicities revealed no difference with age in the severity or incidence of nausea, weakness, or late side effects. The only difference related to age was significantly greater weight loss seen in older patients, which suggests that the clinical impact of esophagitis may have been greater in this population. This outcome however, was not accompanied by a greater decline in performance status in the elderly compared to the younger patients. The authors concluded that good general condition and performance status, rather than age alone, are the best predictors of tolerance of curative thoracic radiotherapy.

Other reports of radiation side effects in older patients treated for a variety of tumors document that radiation is well tolerated by patients 80 and older [47] and even patients over 90.[49] The high degree of tolerability of radiation in the elderly population with SCLC may be due to the relatively modest doses of radiation traditionally employed to treat this type of cancer. The standard dose is 40–50 Gy delivered in 15–25 fractions, although an increasing number of studies of dose escalation and hyperfractionation have been conducted,[50,51 and 52] which may affect future practice.

Despite the good overall tolerance of thoracic irradiation, one cannot ignore the physiological decline in organ function, including a decline in pulmonary reserve, that occurs with increasing age. Studies of radiologic changes of radiation pneumonitis have documented a lower tissue density of lung with increasing age,[53] which would lead to a greater dose transmission through the lung in an older patient. This response is even more pronounced in patients with emphysema or other lung disease. The impact of radiation damage is also clinically more apparent in patients whose lung reserve is reduced due to chronic obstructive pulmonary emphysema (COPD) or other factors. The radiation portals for SCLC that traditionally include the initial tumor volume (prior to any treatment), although whether or not uninvolved nodes need to be included is controversial. If a large volume needs to be irradiated, then the potential for radiation toxicity is greater. For this reason, some investigators have suggested that there might be merit in giving a higher radiation dose to a smaller volume by treating areas of residual disease only. [54] However, the review by Quon et al.[45] did not suggest that practicing radiation oncologists felt that it was necessary to reduce field size in the elderly, and there was no evidence of increased pulmonary toxicity in the older patients, even when radiation was administered concurrently with chemotherapy.

Side effects may also be influenced by the type of chemotherapy used. This is especially true when doxorubicin is employed because the incidence of esophagitis increases greatly when it is administered concurrently or soon after radiation. In the NCIC-CTG trials reviewed by Quon et al, [45] all patients received chemotherapy with a doxorubicin-containing regimen, and no differences in the rates of esophagitis were seen.

Prospective Trials of Combined Modality Treatment for the in Elderly

Several studies described in the chemotherapy section of this chapter included radiation; however, these studies, although they included elderly patients, were not designed specifically for this population. Recently, though, some investigators have undertaken combined modality therapy trials of abbreviated chemotherapy and radiation for elderly patients, and their results are summarized in Table 64.5.[41,55,56]

Author	Treatment	Number of Patients	Response	Median Survival	Toxic Deaths
Westeel et al.[41]	PAVE + S	25	ORR 92%, CR 76%	70 weeks, 25% 5 yr	0
	Thoracic XRT (variable doses and fractionation)				
Murray et al.[56]	CAV × 1	55	ORR 89%, CR 51%	12.5 months, 28% 2 yr, 18% 5 yr	3
	EP × 1				
	Thoracic XRT 20–30 Gy with EP				
Jeremic et al.[55]	BC × 1	75	ORR 75%, CR 57%	11 months, 32% 2 yr, 19% 3 yr	0
	Accelerated hyperfractionated XRT 1.5 Gy BID × 15 days starting day 1				

ORR, overall response rate; CR, complete response; CAV, cyclophosphamide 1,000 mg/m², doxorubicin 50 mg/m², vincristine 2 mg; EP, etoposide 100 mg/m² IV days 1–3, cisplatin 25 mg/m² IV days 1–3; BC, etoposide 50 mg/m² PO days 1–21 and 29–49 and carboplatin 400 mg/m² IV day 1 and 29; PAVE, cisplatin 30 mg/m² day 1, doxorubicin 40 mg/m² day 1, vincristine 1 mg/m² day 1, etoposide 100 mg/m² intravenously day 1 and orally days 3 and 5.

TABLE 64.5. PROSPECTIVE TRIALS OF COMBINED MODALITY THERAPY FOR ELDERLY PATIENTS WITH LIMITED SMALL CELL LUNG CANCER

Westeel et al.[41] treated 66 elderly patients with PAVE chemotherapy given every 3 weeks for five cycles. The 25 patients with limited-stage tumors also received concurrent thoracic irradiation (dose and schedule was variable) administered with etoposide and cisplatin in cycle 2. The overall response rate for the limited patients was 92%, and 76% achieved complete remission. Their median survival was 70 weeks, and 25% remained alive at 5 years. There were no toxic deaths in this group, although one patient with extensive disease died from neutropenic sepsis, and the febrile neutropenia rate for patients treated with combined modality therapy was 18%.

Jeremic et al.[55] administered accelerated hyperfractioned radiotherapy, giving 1.5 Gy twice a day to a total dose of 45 Gy over 3 weeks administered concurrently with carboplatin intravenously days 1 and 29, and oral etoposide days 1–21 and 29–49. No further chemotherapy was given. They treated 77 patients aged 70–77 years. All patients had limited-stage disease, but 12 patients had a Karnofsky performance status of only 60% or 70%, and 18 patients had weight loss of more than 5% of body weight. The patients tolerated treatment remarkably well with only 2.8% grade 3 esophagitis, 8.3% grade 3 leukopenia, and 4.2% grade 3 infection. Despite the abbreviated chemotherapy treatment, the overall response rate was 75%, and survival rates were promising (74% 1-year, 32% 2-year, 19% 3-year).

In a trial of similar design, Murray et al.[55] gave only two cycles of chemotherapy (CAV followed by EP) and radiation consisting of either 20 Gy in 5 fractions or 30 Gy in 10 fractions concurrently with EP to the frail elderly (more than 70 years) as well as to younger patients who had significant comorbidity or who refused standard chemotherapy. Although 14 of the 55 patients were less than 70 years of age, the remainder were elderly, with 22 older than 75, and four were above age 80. Three patients died of treatment-related complications, although two of these deaths were acute cardiac events that may have had other causes in this elderly or infirm patient cohort. Other toxicities were no different than expected. The overall response rate was 89%, and median survival was 12.5 months with 28% and 18% of patients alive at 2 and 5 years, respectively.

The results of these phase II studies are compelling, and they raise interesting questions for the treatment of both elderly and younger patients. As shown from the analyses in the chemotherapy section, elderly patients complete fewer cycles of chemotherapy than younger patients even when participating in clinical research protocols. However, their overall outcome does not seem to be significantly worse because of this regimen. The results of the Murray and Jeremic pilot studies suggest that when combined with early concurrent thoracic irradiation, chemotherapy may be further abbreviated to as few as two cycles without compromising efficacy. This approach deserves further study in a randomized clinical trial of elderly or infirm patients.

Radiation Alone

If a patient is not only elderly but also frail and not suitable or interested in standard chemotherapy or combined modality treatment, radiation alone may be considered with the intent of improving symptoms and palliating the disease. Given the radiosensitive nature of SCLC, symptom improvement is likely, especially in patients with thoracic symptoms, painful bone lesion, or symptomatic soft tissue, nodal, or brain metastases.

In this clinical setting, shorter fractionation courses are appropriate because symptom improvement does not necessarily depend on complete eradication of the local tumor. This is especially true for patients with extensive-stage disease, who may require and benefit from palliative radiotherapy to several symptomatic disease sites.

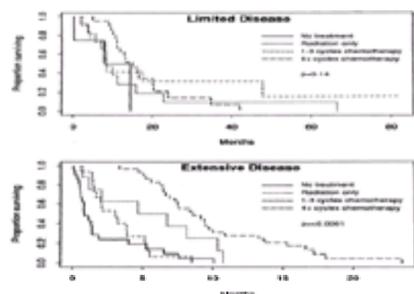
Although the intent of such treatment is largely palliative, some patients with localized thoracic disease may achieve prolonged symptom-free survival with radiation alone. In the Toronto Hospital review,[7] 20 of 123 patients over the age of 70 received radiation only. Their median survival was 7.8 months, which was superior to the 1.1 month survival of the 25 patients who had no treatment, and 3.9 month survival of the 27 patients who had fewer than three courses of chemotherapy without radiation. This is shown graphically in Figure 64.4.


FIGURE 64.4. A comparison of survival by treatment modality for patients with limited (*above*) or extensive disease (*below*). (From Shepherd FA, Amdemichael E, Evans WK, et al. Treatment of small cell lung cancer in the elderly. *J Am Geriatr Soc* 1994;42:64, with permission.)

This degree of potential benefit from radiation alone, especially given its high degree of tolerance by most elderly patients, emphasizes the need for informing patients of this therapeutic option should they decline to have chemotherapy. However, that is not to say that it should be recommended as an equal alternative to all elderly patients. Yellen et al.[57] in a survey of cancer patients given hypothetical vignettes of different disease stage and treatment toxicity showed that older patients are as likely as younger ones to accept both curative and palliative chemotherapy. They were, however, less willing to accept higher degrees of treatment toxicity for a given treatment benefit. Thus all treatment options need to be presented to elderly patients and discussed in the framework of their values and goals of therapy to determine the optimal treatment plan for each patient.

SUMMARY

To summarize, it appears that elderly patients can derive benefit from treatment for SCLC that is similar to that achieved by younger patients. However, this can only be stated with a word of caution because of the limitations of the studies of elderly patients performed to date. To tolerate therapy, older patients must be of good performance status, and this should be the major determinant in reaching a decision to treat and how to treat. Firm recommendations cannot be made for the extremely elderly population of 75 years or more, and further studies of this subgroup and all elderly patients must be encouraged in the future.

COST EFFECTIVENESS AND LUNG CANCER

CRAIG C. EARLE
DOUGLAS COYLE
WILLIAM K. EVANS

There have been many recent advances in lung cancer treatment, particularly for patients with locally advanced or metastatic tumors; however, lung cancer is a common disease, and these interventions can be costly. Health care systems around the world are feeling economic pressures from multiple sources. Western countries have an aging population that is developing age-related infirmities such as cancer and heart disease. At the same time, new technologies have increased the complexity and expense of medical care. Patients are also generally more informed about treatment options and often demand access to the latest interventions. As a result, the health economic literature is growing rapidly. In this chapter, we present an overview of the methodological components of an economic analysis, review the current literature of economic studies in lung cancer, and discuss how these result relate to policy issues.

METHODOLOGICAL COMPONENTS OF AN ECONOMIC STUDY

Research Question

The first step in doing an economic study is to clearly identify the research question. The essential elements of the question are (a) the alternatives being compared, (b) the perspective of the analysis, and (c) the analytic technique. The analytic technique is largely determined by the outcome being measured. From an assessment of these components, readers should quickly be able to determine whether a particular study is relevant to their practice.

Treatment Alternatives

A full economic evaluation is a systematic comparison of at least two alternative healthcare strategies. The reader should be able to easily identify the alternatives being compared and find them fully described; however, there can be different comparators in different situations. If appropriate, a "do nothing" alternative should be included to determine whether there should be any intervention at all for the condition. In addition, guidelines have proposed that the cheapest [1] and the most commonly used options [2] should be considered. The reader must decide whether any appropriate alternative has been excluded.

Perspective

The perspective of an analysis affects the range of costs and benefits considered, and ultimately the conclusions of the evaluation. Ideally, a full economic evaluation should include the costs and benefits to all sectors of society affected by the interventions. However, evaluations often are carried out from one relevant perspective, such as that of the providers or purchasers of health care. The most economic management strategy from the perspective of a hospital may not be the same as that from the perspective of the entire healthcare system. For example, a program of early discharge after a lung resection might save a hospital money, but increased costs for home care services may offset these savings. On the other hand, the perspective of healthcare institutions or the healthcare system may ignore important costs to social service agencies or to family members who may lose wages staying home to provide care. [3] One solution to this problem is to take a broader perspective and to present the costs and benefits broken down into the component parts of that broader perspective. [4] In this way, various stakeholders can examine the results from their own perspective.

Analytic Technique

There are four types of commonly used economic evaluations (Table 65.1). Each involves a comparison of both the costs and consequences of alternative interventions. The main differences among them are the methods used to measure the consequences.

Cost-minimization analysis	Compares strategies of equal effectiveness to determine which is least expensive.
Cost-effectiveness analysis	Compares ratios of the incremental cost over the incremental effectiveness of alternative strategies.
Cost-utility analysis	Compares ratios of the incremental cost over the incremental utility. The utility is a measure of the value attributed to a health state, usually measured in quality-adjusted life-years (QALY).
Cost-benefit analysis	Assigns monetary value to the health benefits of an intervention. If the cost/benefit ratio is <1, then the intervention is attractive.

TABLE 65.1. TYPES OF ECONOMIC ANALYSES

Cost-Minimization Analysis

Also called a "cost-analysis," cost-minimization analysis is the simplest form of economic evaluation. This type of study assumes that the outcomes or effectiveness of the interventions are equal. Resource utilization is the only significant difference between the options. The direct costs associated with each intervention are compared, and the least costly strategy is the preferred choice. No assessment of the consequences of treatment is required. Although some examples in the oncology literature address staging procedures, [5,6] radiotherapy techniques, [7,8 and 9] and systemic therapy, [10] cost-minimization studies are not common because cancer treatments rarely produce equivalent survival or quality of life.

Cost-Effectiveness Analysis

If the interventions being assessed are not of equal effectiveness, thus a more sophisticated analysis is required. Cost-effectiveness analysis includes a comparison of outcomes as well as costs. In this form of analysis, the effectiveness of alternatives is measured in natural units, such as life-years gained, cases successfully treated, or cases averted. These outcomes are then related to the direct costs of the procedure by calculating ratios of cost per unit of effectiveness, such as cost per life-year gained.

Cost-effectiveness analysis has the advantage of being easily understandable. As a result, it is the most common approach to economic evaluation in healthcare. [11] However, only one measure of effectiveness can be related to the cost of the interventions. A cost per life-year gained looks only at survival, but not at toxicity, inconvenience, or effects on quality of life, which are also important considerations in cancer treatment. For example, surgery versus radiation for the primary treatment of a specific cancer can be compared in terms of their costs per life-year gained, but this comparison may lead to an invalid conclusion if the treatments effects on quality of life are different. Therefore, cost-effectiveness analysis can help choose between similar treatments for a specific disease but not for choices across dissimilar treatments and conditions.

Cost-Utility Analysis

A cost-utility analysis is similar to a cost-effectiveness analysis. The main difference is that cost utility combines mortality and morbidity data into a single multidimensional measure, usually a quality-adjusted life-year (QALY). [12] The QALY is a measure of the *quantity* of life gained by a treatment, weighted by the *quality* of that life. This measure is relevant in oncology because many anticancer treatments are inconvenient and have substantial toxicities that impair quality of life. Because the QALY is not disease-specific, it allows comparison of the relative efficiency of healthcare interventions for different conditions.

Quality of life is approximated by a *utility,* which is a measure of preference for a given health state rated on a scale where 0 equals death and 1 equals perfect health. Theoretically, a utility is most accurately determined using a "standard gamble" exercise, where a subject in a particular health state finds the balance between a chance of returning to perfect health and a risk of possibly dying in the process. Other techniques such as time trade off and direct rating on visual analogue scales have also been employed. [13] Alternatively, instruments such as the Health Utilities Index [14] and the EuroQoL [15] have been administered alongside standard gamble exercises in order to relate their scores to utilities; however, most quality-of-life instruments have not undergone such testing. An approach often used to integrate quality and quantity of life calculates the quality-adjusted time with and without symptoms or toxicity (Q-TWiST). [16] It is particularly useful when looking at interventions that have health effects persisting beyond the duration of treatment (e.g., adjuvant chemotherapy).

Controversy exists regarding whether utilities should be derived from patients, their families, healthcare workers, or lay societal "jurors" given detailed scenarios describing the health state. Recent guidelines favor the latter approach as being most consistent with a societal perspective. [17] However, there is concern that people without relevant disease experience may not properly understand the health (disease) state. Any of these approaches to defining utilities is defensible, as long as it is stated clearly in the methods section of the publication.

Cost-Benefit Analysis

Cost-benefit analysis takes cost-utility analysis one step further. It tries to determine whether the benefits of an intervention outweigh its cost. As a result, cost-benefit analysis is in theory the gold standard of the different forms of economic evaluation. The quality-adjusted life-years in the denominator are valued in monetary terms to arrive at the absolute benefit of the intervention. An intervention is "cost-beneficial" if the benefits (measured in currency) are greater than the costs. Because these analyses always produce a monetary outcome, it is relatively easy to compare different potential uses of resources. However, placing a monetary value on the often intangible outcomes of health care, in particular the value of a life, is problematic. As a result, true cost-benefit analyses are rare.

Each of these analytic techniques has its place. Cost-utility analysis is ideal for comparing toxic treatment options, whereas a cost-effectiveness analysis may be adequate when deciding between two diagnostic strategies.

Assessing Costs

Identification and Assessment of Costs and Benefits

Depending on the perspective taken, the resource costs (inputs) in an economic analysis can include:

- *Direct treatment costs:* the resources used by the health sector to provide treatment (e.g., healthcare provider time, drugs, equipment, diagnostic tests, overhead).
- *Direct nontreatment costs:* the resources used by patients and family to gain access to and participate in treatment, such as travel, parking, and accommodations near a cancer treatment center. These costs are often measured by having patients complete diaries of their out-of-pocket expenses.
- *Indirect costs:* costs such as lost work time for the patient or caregiver, or the time of volunteers assisting with treatment. In accounting practice, the term "indirect cost" refers to overhead, but in health economics, overhead is considered a direct cost.
- *Intangible costs:* the costs of anxiety, uncertainty, or pain caused by the treatment itself. These costs have proved difficult to measure. Techniques, such as "willingness to pay" have been developed, but can be affected by each subject's own economic circumstance.

The choice of *time horizon* is important to ensure that the analysis has considered all relevant resources. If a new treatment intervention has an impact on the natural history of a disease, it could affect "downstream" costs. For example, when analyzing the cost of treating lung cancer, upfront costs include the costs of physician visits, diagnostic tests and procedures, hospitalization, as well as drugs and dispensing fees. Downstream costs include those for treatment of long-term complications and terminal care. One of these downstream costs, hospitalization for terminal care, has been found in the Canadian health care system to be the largest single component of management over the entire course of illness. [18] Interventions that affect terminal care can have large impacts on the lifetime costs of the disease [19,20] that might be missed if the time horizon only included the active phase of disease treatment.

If satisfied that all relevant resources have been considered, then it is important to assess whether they have been quantified accurately and valued credibly. It is important to consider whether the analysis is based on costs or charges. Charges for health care are influenced by market forces, government regulations, and taxation laws [21] and often bear little resemblance to actual incremental resource costs. [22] Medicare providers are required to provide cost-to-charge ratios that can be used to estimate costs; however, the accuracy of these ratios is undetermined.

Another issue is whether resource consumption data have been collected prospectively or retrospectively. Prospectively collected data, such as those gathered as part of a clinical trial, are more likely to be complete. This process also allows for the timely availability of economic data to help decision-makers after an important clinical result is found; however, prospective data is more expensive to collect. Furthermore, care in clinical trials is often more resource intensive than routine practice. For example, trials usually take place in expensive tertiary care teaching hospital settings and involve more frequent monitoring with blood tests and imaging studies. As a result, retrospective data or prospective data collected outside a clinical trial can each be effectively used in many circumstances.

It is often necessary to determine costs in several steps and to use a combination of empirical data and modeling in the analysis. Resource consumption data such as hospital days could first be gathered from a clinical trial. Then, this data could be adjusted to reflect anticipated usual care. For example, the frequency of imaging studies might be greater in a study situation than in routine practice. Lastly, the costs can be allocated to the resources consumed to calculate the cost of delivering the intervention. By separating resource consumption from cost, local variations in costs or charges can be assessed.

Discounting

Costs and benefits that occur in the future should be adjusted, or discounted, to their present value because of "time preference." We generally prefer to incur benefits sooner rather than later and costs later rather than sooner. Thus future costs and benefits have less weight than current costs and benefits, and are usually accounted for by multiplying them by a constant discount rate with the formula:

$$\frac{1}{(1 \; + \; r)^n}$$

where *r* is the discount rate, and *n* is the number of years.[23] Such adjustment favors therapeutic procedures that provide immediate benefit, while rendering preventive and screening programs, which require immediate expenditure for future benefits, less attractive.

There is a lack of consensus over what the appropriate discount rate should be. Recent American guidelines suggest 3%, [12] whereas Canadian guidelines have recommended 5%[24] and British recommendations have been 6%.[25] The choice of discount rate can seriously affect the results of evaluations [26] and should be subject to sensitivity analysis. Also of debate is whether benefits and costs should be discounted at the same rate because empirical studies have demonstrated that people do not have the same preferences for future health benefits as for future costs. [27,28,29 and 30]

Assessing Effectiveness

Healthcare benefits (outputs) can be measured as:

- *Direct benefits:* monetary savings in treatment-related resource consumption
- *Indirect benefits:* from increased productivity
- *Intangible benefits:* such as prolonged survival, or alleviation of pain and suffering associated with health improvements

As described previously, the type of study (cost-effectiveness, cost-utility, etc.) determines the type of benefit considered.

Large, randomized controlled trials or metaanalyses provide good measures of clinical effectiveness; however, extrapolation of economic and clinical data to routine practice is not always straightforward. Controlled clinical trials usually test the *efficacy* of a procedure under strictly defined "ideal world" conditions. Differences in the demographic characteristics of the population, variations in clinical practice, and availability of resources may mean that the procedure is less *effective* in routine clinical management.[31] For example, we might expect an elderly patient with multiple comorbidities to have a different experience with chemotherapy for advanced lung cancer than the highly selected patients studied in a clinical trial. Clinicians must decide whether patients are likely to derive the same benefits as the patients included in the study.

Similarly, toxicity of therapy may differ between the experimental and normal practice settings. The complication rate reported in a trial of complex therapy given to highly selected patients in a tertiary care setting might not be the same as that seen when the treatment is moved into general practice. As a result of the costs associated with these complications, the treatment might prove to be more expensive than predicted by the economic model.

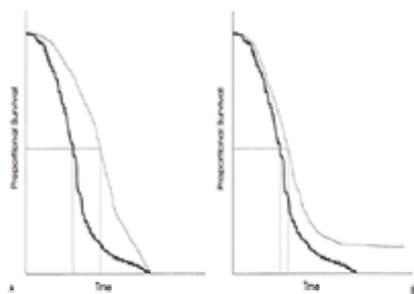
When survival is the outcome of interest, it is important to accurately quantify the benefit. Because survival distributions are skewed, the median survival is most often reported in cancer trials; however, this measure may disregard important information when trying to determine the average benefit a patient can expect from a therapy. For example, an intervention that results in some cures creates a long tail on the survival curve that contributes to the number of life-years gained. Such an intervention can be highly cost-effective, even if there is little or no increase in the median survival time (Figure 65.1). As a result, economic evaluations should use the area between two survival curves to determine the average benefit from treatment.


FIGURE 65.1. The effect of the shape of survival curves on life years gained from an intervention. **A:** This treatment results in a relatively large increase in medium survival time, but there are no cures. **B:** This treatment causes a small increase in median survival time; however, because some patients are cured, there is a plateau on the tail of the curve that may eventually produce a larger increase in the area between the two.

Assessing cost-effectiveness

The cost-effectiveness ratio (CE) is the *incremental* cost of an intervention divided by its *incremental* benefits, as given by the formula:

$$CE \; = \; \frac{C_1 \; - \; C_2}{E_1 \; - \; E_2} \frac{(\$)}{(e.g., \; time)}$$

where *C* represents the cost of each intervention and *E* represents their effectiveness.

Many people use thresholds to decide whether an intervention is cost-effective. Canadian authors have proposed that interventions costing less than $20,000 per QALY be considered cost-effective.[32] Americans tend to set the threshold at approximately $50,000 per QALY.[21] However, these cutoff points are arbitrary.

Another type of decision rule is a "league table." Economic evaluations assume that resources are limited and have alternative uses if not applied to the intervention in question. Policymakers must make decisions that will maximize health by getting the highest value for the resources consumed. Their decisions often reflect a utilitarian philosophy of doing the greatest good for the greatest number of people. In order to achieve this goal, a technology must be assessed for its efficiency relative to all other potential uses of the same resources. Cost-effectiveness league tables such as Table 65.2 rank interventions by cost per life-year or cost per QALY gained.

Medical Intervention	Cost Per Life-Year Gained*
Liver transplantation	251,000
Screening mammography, <50 years old	245,000
Zidovudine for HIV infection	87,000
Renal dialysis, in-center benefit, men	53,000
Screening mammography, >50 years old	37,000
Smoking cessation counselling, men	1,400

TABLE 65.2. AN EXAMPLE OF A LEAGUE TABLE

There are two major attractions to league tables: (a) they place results in the context of the cost-effectiveness of other technologies, and (b) they offer an easy mechanism to inform or justify resource allocation decisions. Resources can then be spent on the most cost-effective programs until the resources are exhausted. Numerous examples of league tables have been published across specialties, [33],[34] and [35] and in oncology in particular. [36]

There are many methodological difficulties in creating league tables, necessitating caution when using them for resource allocation. [37] One major problem is that they often group studies that were undertaken at different points in time. Cost-effectiveness figures can be adjusted to a base year, but this method requires assumptions of constancy of relative costs, resource use, disease management, and treatment efficacy over time.

There may also be differences in study methodology, including the choice of treatment comparisons, the length of follow-up of patients, the quality-of-life or utility instrument adopted, the assumptions made, and the range and sources of costs included. [37] Such differences may affect the ranking of various technologies within a league table, leading to erroneous conclusions.

Both the threshold and league table approaches assume that QALYs have the same value in all situations; however, empirical evidence tells us otherwise. Society generally adheres to the "rule of rescue": we value interventions that actually save a patient from dying from a disease more than one that may make many patients live a little longer. We are also more willing to pay for an intervention that saves an identifiable life, such as an individual who requires a heart transplant, than one for which a "statistical" life may be saved, as in preventive programs.

Because of these problems, neither league tables nor thresholds should be seen as providing accurate answers to difficult resource allocation decision; rather, they should be seen only as an aid to inform decision-makers.

Deciding Whether to Believe the Results

Knowledge of the key methodological principles that well-conducted studies should follow [23],[38],[39] is important in order to avoid inappropriately applying the results of a poor study or using data that are not applicable in a certain setting. Because of this need, American guidelines have recently been published for reporting economic studies,[17] and useful strategies have been proposed for critically appraising economic analyses. [40],[41] Table 65.3 summarizes some important considerations when appraising economic studies.

1. The study question, perspective, and design must be clearly stated. Are they relevant and appropriate?
2. The study should involve a comparison of at least two alternative interventions. Are they the most relevant ones? The "do nothing," the least costly, and the most used options should be considered. Are any other important alternatives missing?
3. All relevant costs and benefits of the alternatives should be identified. Were they measured accurately and valued credibly? Are they likely to be transferable to your setting?
4. Future costs and benefits should be discounted. Is the discount rate appropriate?
5. The setting and type of patients analyzed should be clear to allow inference about the likelihood of similar costs, benefits, and toxicity in your particular patient or practice.
6. Detailed sensitivity analyses should be conducted. Did they include all relevant parameters across an adequate range of values?
7. Data should be presented in a transparent fashion.

TABLE 65.3. KEY CONSIDERATIONS IN THE EVALUATION OF ECONOMIC STUDIES

Sensitivity Analysis

Sensitivity analyses assess the effect of varying the estimates of resource use (such as the number of treatments of a new drug, the number of hospital days for treatment administration or for palliative care), and effectiveness (e.g., the amount of survival gained, utility estimates) over a range of plausible possibilities. No matter how accurately costs and benefits have been quantified and valued, it is likely that certain assumptions have been required. Skeptics often attack these assumptions to dismiss a study. If altering the value of key parameters significantly changes the outcome of the study, then the analysis is said to be "sensitive" to that variable. If not, it is "robust." The question becomes not whether all estimates of resource use and survival were accurate, but whether any errors would have a meaningful impact on the results.

Setting

Economic evaluations are relatively specific to the healthcare system in which they are performed. Countries such as Canada have single-payer universal healthcare systems in which the government funds virtually the entire system. In contrast, health care in the United States is funded by multiple payers, primarily private insurers, and providers compete for contracts to manage the care of groups of individuals. A third type of system, common in European countries, provides universal health care with patients responsible for a copayment.

Extrapolating the results of a study from one healthcare environment to another involves more than simply adjusting the figures by the exchange rate. Costs for a health care intervention may be affected by differences in (a) demographics and disease incidence, (b) clinical practice patterns, and (c) relative prices. Practice patterns may be influenced by the availability of alternative treatments and diagnostic tests, as well as incentives to professionals and institutions (e.g., salary versus fee for service).[42] There have been few studies reported to date addressing this issue. Drummond et al. assessed misoprostal for the prevention of nonsteroidal antiinflammatory drug (NSAID) induced ulcers simultaneously in four countries (i.e., Belgium, France, United Kingdom, and the United States) using identical methodology. They found misoprostol to be more cost-effective in the United States despite the drug being 36% more expensive because it averted surgical procedures that were relatively more costly in America. [43] Recently, Copley-Merriman et al.[44] made similar observations when they found that gemcitabine monotherapy in advance non–small cell, cancer (NSCLC) compared to standard etoposide/cisplatin (excluding chemotherapy drug costs) saved more money in the United States than in Germany or Spain because it averted more costly hospitalization and antiemetic use.

Transparency

A concern with many economic papers is a lack of *transparency* in the description of methods and assumptions. Transparency refers to how easy it is to see exactly what the authors of a study have done. After reading the results of an economic analysis, the reader should not be left with the impression that the study was done in a "black box." It is best to report disaggregated data on costs, resource use, and quality of life. [4] Ideally, the numerator and denominator of cost-effectiveness ratios should be reported separately. Costs should be shown in the format:

$$\text{quantity} \times \text{unit price} = \text{cost}$$

while effectiveness measures should be separated from their utility weightings. Obviously, it is important to know the currency and year of the costs; however, reports should also identify instances of price adjustment, such as use of the consumer price index to inflate prices from another time period, or the date and exchange rate used to translate costs from other countries.

PUBLISHED ECONOMIC STUDIES RELATED TO LUNG CANCER

Prevention

Smokers accrue significant lifetime medical costs[45] as well as costs due to passive smoking, accidental fires, and lost productivity due to illness. [46] However, studies have generally found that smoking is not an economic burden on society. Savings in other medical costs due to early mortality offset the treatment of smoking-related diseases.[47,48 and 49] Furthermore, costs to society are offset by tobacco taxation and unclaimed pensions. [50] These conclusions tend to be sensitive to the discount rate used because the costs from smoking occur in the present, whereas the savings occur in the future.

Smoking cessation is the main form of lung cancer prevention. Intervention studies focus on restrictions on smoking and smoking advertisement, [45] and taxation,[51] which are modestly effective and appear to be cost-effective. [52] For example, a mass media campaign costing $759,436 over 4 years was estimated to cost $754 per smoker averted, with a cost per life-year gained of $696. [53] Although the effectiveness of screening programs for lung cancer has not been established, an economic model has indicated that screening programs involving detection of genetic aberrations in the sputum would likely be cost-effective if shown to be clinically effective. [54]

Diagnosis and Staging

Economic studies have also tried to define an optimal diagnostic strategy for NSCLC. For example, Govert et al. determined that the addition of either brushings or washings to bronchoscopic biopsy increased the sensitivity of the test at relatively low cost; however, addition of both procedures was unnecessary and not cost-effective.[55] Several groups have shown that computed tomography (CT) chest with selective mediastinoscopy is more cost-effective than routine mediastinoscopy.[56,57] Furthermore, positron emission tomography (PET) scanning may eventually be a cost-effective addition to CT scanning in this setting. [58] However, routine CT of the head in patients without clinical evidence of metastases has been shown not to be a cost-effective staging procedure. [59]

Similar techniques allowed Richardson et al. to develop an optimal protocol for staging small cell lung cancer (SCLC) patients. [60] Clinical exam and biochemistry followed by bone scan, abdominal CT, head CT, bone marrow aspirate and biopsy, CT chest, and finally pulmonary function testing were able to avert one-third of the overall cost of staging as long as the workup was discontinued as soon as a metastasis was identified.

Cost of NSCLC

It has been estimated that lung cancer management accounts for approximately 20% of cancer care costs and 2% of all healthcare costs in the United States. [61] Several studies have examined the costs associated with lung cancer. [62] Evans et al. calculated the average direct care costs for diagnosis and treatment of NSCLC in Canada to be $19,778 in 1988 Canadian dollars over 5 years. The first-year costs ranged from $6,333 for supportive care for stage IV disease, to $17,889 for surgery and radiotherapy in earlier stage lung cancer (Table 65.4). Hospital costs were found to dominate, accounting for 36.8% of all costs (Figure 65.2). About one-third of the total cost is for hospitalization during the initial diagnostic workup. Terminal care accounts for about one-half of the total cost whether a patient receives chemotherapy or not. The five-year costs ranged from $16,501 to $23,881.

Stage	Primary Treatment	Lifetime
I	$14,110	$21,400
II	$14,110	$23,881
IIIa	$12,474	$22,131
IIIb	$11,714	$19,366
IV	$6,333	$16,501

* 1988 Canadian dollars.

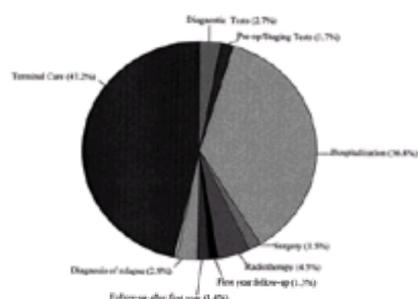
TABLE 65.4. SUMMARY OF DIRECT CARE COSTS PER CASE FOR NSCLC IN CANADA BY STAGE*


FIGURE 65.2. The cost component of lung cancer management.

In the United States, Riley et al. compared the Medicare payments for patients aged 65 and over with common cancers. [63] They found that lung cancer was the most expensive cancer site for initial treatment at $17,518 (1990 US$) due to high costs for hospitalization ($10,782, or 62%); however, because of the relatively short survival of lung cancer patients, it was among the least expensive in terms of total payments from diagnosis to death at $29,184.

Recently, Hillner et al. looked at the cost of lung cancer for a commercially insured cohort in Virginia. [64] These patients were younger and fees generally were higher than those for the Medicare population studied by Riley et al. They found that the total cost of treatment from diagnosis to death was $47,941 (in 1992 US$), with inpatient hospital facility costs accounting for up to 65% of the total cost. Patients receiving no active treatment still incurred significant costs ($26,597 in the first year after diagnosis). On average, patients spent 27.6 days in the hospital in the last 6 months of life.

Methodological differences and different time frames make these studies not completely comparable; however, hospitalization consistently stands out as the dominant cost in all of them. Similar findings have been seen in other tumor sites. [65,66 and 67] This sort of research has led to the shift in recent years of treatment in the ambulatory setting, development of care maps and algorithms to expedite diagnosis, [68] and increased use of hospices for terminal care.[69]

Cost of SCLC

Less work has been published on the costs associated with SCLC treatment. Evans et al. found that direct care costs for the diagnosis and initial treatment of SCLC ranged from $18,691 (1988 Canadian dollars) for management of limited-stage disease, to $4,739 for the supportive care of patients with extensive disease who were not candidates for chemotherapy. The average total cost for treating SCLC was $25,988. [18,70] This figure is comparable to the $18,234 (1990 Australian dollars) for limited and $13,177 for extensive disease calculated by Rosenthal. [71] Again, hospitalization was the dominant cost.

Cost-Effectiveness of Treatment

Through a MEDLINE search to identify studies whose principal objective was to examine the cost-effectiveness of lung cancer treatment options, and by searching the references of relevant articles, we identified 15 economic evaluations [20,44,72,73,74,75,76,77,78,79,80,81,82,83 and 84] (Table 65.5). All but one study included an evaluation of the cost-effectiveness of chemotherapeutic alternatives in lung cancer treatment. [72] The one exception involved a comparison of two different radiotherapy regimens for NSCLC: conventional radiotherapy treatment *versus* continuous hyperfractionated accelerated radiotherapy. Despite the recognition of the importance of quality-of-life effects on treatment choice, only two studies incorporated estimates of patient's quality of life into QALYs. [82,84]

TABLE 65.5. ECONOMIC EVALUATIONS OF TREATMENT ALTERNATIVES IN LUNG CANCER

All studies used effectiveness data derived from clinical trials, although not all were based on randomized evidence. Several studies examined resource consumption from those same trials,[20,72,78,82,83 and 84] whereas others adopted an approach whereby resource use estimates were obtained from other sources (e.g., institutional databases) and were combined with effectiveness data within a modeling framework.[44,73,74 and 75,77,79,80 and 81]

In most cases, costly but effective treatment options were found to be cost-effective due to savings in the consumption of other resources. For example, a cost analysis performed by the National Cancer Institute of Canada (NCIC) on a multicenter randomized trial comparing chemotherapy with best supportive care (BSC) found chemotherapy to be not only cost-effective but also cost-saving by reducing the need for palliative radiotherapy and the length of terminal care hospitalization. [20] A record linkage study of more than 600 patients in the province of Manitoba recently corroborated this finding (Statistics Canada, personal communication, 1999). Although another analysis of the same trial failed to confirm this result, [82] in general, effective interventions tend to be cost-effective.

Supportive interventions have also been evaluated. Ondansetron has been shown to be cost-effective for prophylaxis against cisplatin-induced emesis. [85] On the other hand, granulocyte colony-stimulating factor (G-CSF) was not found to be a cost-effective adjunct to SCLC treatment. [86]

LUNG CANCER ECONOMICS AND HEALTH CARE POLICY

The expenditures associated with medical practice are coming under increased scrutiny. Both public and private payers are demanding increased efficiency and "value for money" in the provision of healthcare services. As a result, policymakers in both Australia and the province of Ontario (Canada) have developed formal guidelines for economic analyses that are to be part of drug reimbursement submissions. [1,2]

Recent practice guidelines[87,88] have recommended that it is "reasonable to offer cisplatin-based chemotherapy to medically suitable patients as a treatment option" for survival, symptom control, and quality-of-life outcomes in metastatic NSCLC patients. [87] As Evans et al. reported,[89] the average cost (all stages) of managing a lung cancer patient from diagnosis to death without palliative chemotherapy is just under $20,000. Therefore, for all 17,128 cases diagnosed in Canada in 1992, the total cost was approximately $350 million (and about 10 times as much in the United States). Even though palliative chemotherapy is considered cost-effective, [90] by virtue of lung cancer's high incidence, the cost of treating all advanced-stage patients with chemotherapy would add significantly to healthcare budgets and labor requirements.

Oncologists are still fairly conservative in their management of advanced lung cancer. [91] Additionally, many patients are not candidates for systemic therapy because of biologic age, performance status, or comorbid conditions; therefore, the actual impact of a new treatment for lung cancer on national health budgets is likely to be less than projected.

CONCLUSION

Because of its high incidence, lung cancer is a significant burden on healthcare systems. Studies indicate that strategies to minimize hospitalization are likely to have the greatest impact on these expenditures. [74] Despite common perceptions to the contrary, supportive care for advanced lung cancer is associated with significant cost, and many chemotherapeutic treatments are cost-effective relative to other commonly accepted medical interventions; however, decision-makers sometimes have trouble seeing past the price of these interventions. Therefore, it is important to understand how to assess these technologies in the broader context of the costs and consequences associated with their use. Providing decision-makers with useful information from methodologically sound studies will help optimize use of health care resources and ensure continuing access to care for lung cancer patients in the future.

STATISTICS AND TRIAL DESIGN

SETH M. STEINBERG

The purpose of this chapter is to provide a brief description of the types of clinical trials that are currently used to evaluate treatments for cancer and to discuss statistical techniques involved in analyzing such trials. These techniques include such methods as Kaplan-Meier survival curves, Cox proportional hazards models, and metaanalysis, all of which are common in the literature today. Before beginning any discussion of specific types of clinical trials, it is useful to define a clinical trial: a clinical trial is a carefully planned study used to determine the effect and value of interventions in human subjects. In order to conduct a trial, there must be a primary question of interest, a detailed study protocol, and availability of resources. These needed resources include patients for the study, clinicians, any study drugs, and any other types of equipment or supplies that would be needed for the trial.

In oncology, three types of clinical trials are generally conducted, known as phase I, phase II, and phase III. A phase I trial is typically the first trial that is conducted in humans. It is used to determine the maximum tolerated dose of therapy and may indicate whether or not there is some degree of benefit from the drug or drugs. A phase II trial usually measures the disease response to a single therapy or combination of therapies, whereas a phase III trial compares the effectiveness of two or more therapies in a randomized, prospective fashion. In addition to these three main types, other variations exist such as phase I/II trials, phase II/III trials, and trials that are known as *pilot,* or *feasibility,* studies. A pilot, or feasibility, study is a trial of limited numbers of patients intended to determine whether a new procedure may be safely carried out using human subjects. Such trials rarely have efficacy end points and are typically limited to no more than 10 patients. The next few sections discuss some of the statistical issues in each type of trial.

PHASE I TRIALS

The objective of a phase I trial is to determine dose levels of a single agent or combination of agents that balance toxicity with efficacy. Patients enrolled in a phase I trial may come from a wide variety of disease types. In general, the starting dose of drug for a phase I trial is one-tenth of the mouse LD_{10}, which has been determined previously in preclinical studies. A common procedure that can be used for determining the rate of dose escalation for a phase I trial is called a *modified Fibonacci approach.* Table 66.1 provides a hypothetical example of a modified Fibonacci procedure for selecting dose levels for a Phase I clinical trial. As can be seen in this table, the initial dose would be one-tenth of the mouse LD_{10}. In step 2 this amount would be doubled. The third step would be 67% above step 2; the fourth step would be 50% above that of step 3; and finally the smallest increment that is normally used for escalating doses is 33%. As shown in this table, with a hypothetical starting dose of some drug of 100 mg/m², by the sixth step the dose is approximately nine times the initial starting dose.

Step Number	Relative Dose	Example
1	1:10 Mouse LD_{10}	100 mg/m²
2	Double Step 1	200 mg/m²
3	67% Above Step 2	333 mg/m²
4	50% Above Step 3	500 mg/m²
5	33% Greater Than Step 4	667 mg/m²
6	33% Greater Than Step 5	890 mg/m²

TABLE 66.1. EXAMPLE OF MODIFIED FIBONACCI PROCEDURE FOR SELECTING DOSE LEVELS FOR A PHASE I CLINICAL TRIAL

The standard procedure for enrolling patients in a phase I trial is as follows: at the lowest starting dose, three patients are entered. Those three patients would be treated and followed for toxicity. If none of those three patients have unacceptable toxicity as defined by the protocol, then the next dose to be evaluated would be that of the second dose level. However; if one patient of the three experiences dose-limiting toxicity, then up to three additional patients would be treated on that same dose level. If none of those additional three patients experiences dose-limiting toxicity, then the next three patients would be entered at the next higher dose level. If, however, a dose level is identified at which two or more patients have dose-limiting toxicity, then that dose would be the highest dose level examined. The next patients to enter the study would be placed at the preceding dose; that is, the dose below the one in which toxicity was noted, in order to verify safety at that level. This dose, if found to be acceptable, would be called the *maximum tolerated dose* (MTD). Escalation continues in this fashion until the MTD is reached.

Because of the nature of the standard accrual scheme of phase I clinical trials, three times the number of dose levels, plus six, would be an estimate of the maximum number of patients that would be needed to evaluate an agent during phase I using a standard accrual approach. For example, if a clinical trial were to be conducted with six dose levels, then it would be expected that up to 24 patients might be required on this trial. This information can be useful for planning accrual to the study.

Recently, Simon and co-workers developed an alternative design approach, based on rapidly escalating doses treating one patient per dose level until evidence of any toxicity is encountered, followed by a standard dose-escalation until an MTD is reached. [1] Under appropriate assumptions, this design can attain the identical MTD as a conventional escalation scheme but may require far fewer patients. In another report, Ahn compares a variety of novel phase I escalation methods and makes recommendations for selecting one of these newer designs. [2]

It is commonly believed that a phase I trial is not designed for evaluating efficacy of a therapy. That is generally true, especially with conventional phase I trials, because most patients are treated at doses that are below the one that would most likely produce a response; however, it may be possible to see responses in patients, even at the lowest doses of therapy. In general, no more than 5% of patients would be expected to respond to a phase I study; thus, although phase I studies are conducted with therapeutic intent, clear efficacy from phase I trials is believed to not be readily determinable.

Data from phase I trials are typically analyzed using descriptive methods. A wide range of toxicity results by dose level are often tabulated to demonstrate the degree to which patients treated at the various doses are effected adversely by the treatment. Any responses identified may also be noted.

A specific type of phase I trial, known as a *biologic response modifier trial,* is often conducted in two phases. In phase IA, the objective is to find the maximum tolerated dose much as one would do customarily in a standard phase I trial. In phase IB, one would try to find the optimal biologic response modifying dose. This dose may not be the same as the maximum tolerated dose. The MTD is used to define the upper limit of therapy that is safe to evaluate in patients, whereas the OBRMB is the dose that is believed to have the most potential benefit for patients. For additional, more detailed discussion on phase I clinical trials, consult a reference book on this

topic.[3]

PHASE II TRIALS

The objectives of a phase II trial are to screen the drug or drugs evaluated for any antitumor activity in a specific disease, and to try to increase knowledge of pharmacology and toxicology of drugs that are being evaluated. In general, success or failure from a phase II study is determined according to whether or not an observed response proportion in patients with measurable disease (i.e., the fraction of patients who successfully receive treatment and are able to experience a well-defined clinical response) is consistent with, greater than, or less than a hypothesized response proportion. One needs to have strictly stated objective criteria for response prior to initiation of the study to ensure correct evaluation of efficacy.

Phase II trials normally treat patients using approximately 75% to 90% of the MTD as found in a phase I trial. This dosage ensures that the study can be conducted safely. It should be noted that in the absence of severe toxicity found in a phase I trial, there are no scientific grounds for terminating a drug's clinical development without conducting a phase II trial because only a phase II trial has sufficient patients enrolled at potentially therapeutic doses in order to make an evaluation of whether the drug has benefit.

Phase II trials are not generally comparative. They are used to indicate whether a new treatment should be pursued further, and to determine its priority relative to other agents being evaluated for treatment of the same disease. A randomized phase II trial provides a means of making a comparison between two or more agents. In this type of trial, two or more agents are randomized against one another so that patient characteristics are similar for each of the agents being evaluated; no formal statistical comparison is undertaken between the groups. It is expected, though, that the agent that produces the greatest response rate from among those compared is the one that is most likely to be useful for advancement into the larger phase III trials.

Several factors should be considered when designing a phase II trial. First, it is important to plan to accrue a homogeneous group of patients with respect to disease type and estimated prognosis. Homogeneity enhances the interpretability and meaningfulness of the findings from this study. It is also important to try to estimate the potential response rate to this agent or combination of agents. This estimation can be determined to some extent from literature results of trials in patients treated for this disease. Careful consideration of the possible differences in prognosis between the historical group and the present group of patients should be taken into consideration. Furthermore, with tumor shrinkage as the end point in most phase II trials, it is important that potentially measurable changes in size of tumor be used. Also, if a trial is to evaluate efficacy in subgroups of patients, it is important to allow adequate numbers of patients in each subgroup.

Determination of sample size for a phase II trial can range from being simple to somewhat complex depending on the assumptions one is willing to make. One of the earliest types of designs commonly used was developed by Gehan[4] and is a straightforward two-stage design. In the first stage, 14 patients are accrued, treated, and evaluated. If no responses occur in the first stage, then accrual is terminated because there is less than a 5% probability that the true response rate is at least 20%. If at least one of the initial 14 patients has an objective response to therapy, then a second stage would be conducted with accrual of at least 11 additional patients. The more patients entered on the second stage, the more precise the estimate of the response. However, with this particular example, if the true response probability was 5%, then there is a 51% chance of observing one or more responses in 14 patients. Thus if an agent had a true response probability that was very low, this design would not likely result in an appropriate early termination with high probability.

Lee and Wesley[5] describe another relatively simple approach to determining the number of patients to enter as a function of acceptable or unacceptable response proportions. With their method, if one was interested in stopping a study if the results are inconsistent with 30% response, then accruing nine patients and observing no responses would allow accrual to end. Or, to quickly rule out consistency with a 50% response proportion, entering five patients and observing no responses could result in termination at this point.

An improved design was developed by Simon.[6] His design is called an *optimal two-stage design* for a phase II clinical trial and is optimal in the sense that the expected sample size required for evaluation is minimized if the agent has a low activity level. Potentially, one could stop accrual to a study evaluating a poor agent with fewer patients on average than with a standard two-stage design because many poor agents would end up being evaluated in both stages using the standard Gehan approach. To design a study of this type, one first needs to decide on two error probabilities (the probability of accepting an uninteresting drug and the probability of rejecting a desirable drug), the response probability which is uninterestingly low, P_0, and that worthy of further exploration, P_1. After deciding on these parameters, one can determine a two-stage design that specifies the number of patients to accrue and corresponding maximum number of responses consistent with an insufficiently active agent. Table 66.2 provides a few examples (with 10% as each error probability) of numbers of patients to be accrued at an interim point and the highest number of responses observed that would cause termination of the study at that point. This table also indicates the highest final response proportion that is inconsistent with a desirable drug. For example, if it were considered uninteresting in a particular disease to have a response proportion of 20% and of more interest to have a response proportion of 40%, if 17 patients were initially entered into the trial, and if no more than 3 experienced objective clinical responses, then accrual would be terminated and the drug would be declared unsatisfactory. However, if in the initial 17 patients there were 4 or more responses, then accrual would continue until 37 patients were entered into the trial. In that event, if there were 10 or fewer total responses, the agent would be considered unsatisfactory. Otherwise, with 11 or more responses, the agent would be considered worthy of further investigation. Other examples are presented in this table as well as in the original article.

Reject Drug if Observed Response Rate is Below:			
P_0*	P_1**	Interim Point	Final Evaluation
0.20	0.40	3/17	10/37
0.30	0.50	7/22	17/46
0.40	0.60	7/18	22/46
0.20	0.35	5/22	19/72
0.30	0.45	9/30	29/82

* Response probability if drug is uninteresting.
** Response probability if drug is desirable.
From Simon RM. Optimal two-stage designs for Phase II Clinical Trials. *Controlled Clinical Trials* 1989;10:1, with permission.

TABLE 66.2. EXAMPLES OF RESPONSE PROPORTIONS CAUSING REJECTION OF DRUG, USING OPTIMAL TWO-STAGE DESIGN

Analysis of the main results of the phase II study typically includes a summary of the demographic and clinical characteristics of the patients accrued, the toxicities observed, and categorization of the responses observed according to how complete the responses are. In addition, confidence intervals about the observed response proportions are often presented to assess the precision of the results obtained and to indicate the approximate degree of consistency with other studies. Confidence intervals that are appropriate to the two-stage nature of many designs may be employed.

Finally, it is important to realize that in a Phase II study there are many sources of variability that can affect the responses observed and the interpretation of study results.[3] First, the doses and schedules of drugs administered can vary, and the eligibility criteria for patients to be entered into the studies may also vary considerably. Such things to consider in assessing comparability of studies include the extent of disease, performance status, and any prior treatments the patients may have received. The response criteria may also differ. It is important that these criteria be consistently defined. There could be inter-observer variability because individuals do not necessarily agree on every aspect of evaluation of a patient's response. Dosage modifications and protocol compliance issues could also vary from institution to institution. Differences in reporting procedures, primarily regarding which patients are to be included in the analyses, may be identified. For example, every patient who has entered into the study that was initially found eligible or only those who successfully completed the treatment may ultimately be included in analysis. Finally, the sample size of an individual study can effect the interpretation. Tighter confidence limits are obtained with more patients, and results based on larger numbers of patients could therefore be more likely to be better estimates of the responses that would be observed in a population of similar patients. These considerations may suggest that, in phase II trials designed to test agents or combinations in diseases for which active agents already exist, an appropriate randomized concurrent active control group may be useful to help estimate the clinical importance of the new agent or combination prior to attempting to evaluate a phase II agent or combination in a larger, more definitive trial.

PHASE III TRIALS

Phase III clinical trials require the largest number of patients. These trials are designed to compare the ability of two or more therapies, or combinations of therapies, to treat patients with a particular disease. Three or more treatments can be randomized against one another; however, the remainder of this section focuses on studies comparing two treatments. Although these studies can be accomplished at single institutions, randomized phase III trials often involve groups of institutions that combine their resources to accrue larger numbers of patients in order to answer study questions within a reasonable period.

Phase III trials are randomized to ensure unbiased placement of patients into the study arms and to allow probability to provide approximately equivalent patients on the arms. Ideally, differences noted between two arms of a randomized study should be due to the treatment, not to imbalances in patient characteristics. In order to randomize, a computer program that creates random sequences of treatment group identifiers is typically employed. A procedure known as *blocking* is often employed to ensure even numbers of patients on each arm throughout the trial. For every fixed number of patients (e.g., 4, 6, 8), equal numbers of patients receive both treatments by the end of the block. For example, with a block size of six, three patients would each receive treatment A and three would receive treatment B in some random order in the first block. In the next block, three patients would each receive treatment A and treatment B but in a (probably) different random order from the prior block. The objective is to provide balance in the study after fixed periods and to create a pattern of treatment assignment that is difficult to discern by investigators in order to prevent bias in entering patients in the study.

Conducting randomized studies is sometimes difficult when the treatments administered might have different long-term physical effects or changes in patients being entered into the trial. For example, in early-stage breast cancer, it can be difficult to enroll patients into a study randomizing between lumpectomy plus radiation versus mastectomy. Other designs can be used if randomization is overly problematic to accomplish; however, these other approaches have potentially serious drawbacks. Consultation with a statistician about alternatives to standard randomization schemes may be worthwhile in those situations.

Patients are typically randomized in equal proportions between the two arms; that is, in a 1:1 ratio. However, a 2:1 randomization is sometimes employed. In such cases, typically two patients would receive the newer treatment to every one patient who receives the more conventional therapy. The best rationale for this method would be to gain more information about the new treatment. For example, in some studies it may be considered more of an inducement for investigators to put patients in a trial if they believed that their patients will have a better than 50% chance of receiving the new or experimental therapy. On the other hand, 50% allocation is more consistent with the belief of equipoise, or genuine unbiased indifference toward the placement of patients in trials, which in theory is required for physicians before entering patients into randomized studies. In a 2:1 randomization trial, only 10% to 15% additional patients would be required than a corresponding 1:1 allocation, so the numbers of additional patients needed are small. On the other hand, by using this design, it may be a clue to the subject and to the physician that one intervention is preferred over the other. Thus potential for unintended bias may result.

Stratification

In order to balance prognostic characteristics among patients on the two or more treatment arms in a randomized phase III trial, stratification is often employed. Stratification refers to placing patients into relatively homogeneous groups before performing the randomization. With this approach, patients are randomized within one stratum independently of patients who have characteristics of another stratum. Stratification is more helpful in trials with relatively few patients where probability might not permit patients to balance out with respect to important characteristics over the course of accrual. Stratification at time of randomization is not necessary to perform stratified or subgroup analysis at the end of the trial. One should try to limit the number of strata. Overstratification, defined as placing patients into an excessive number of strata, is not useful and may result in situations in which there will be so few patients in any given stratum that the final trial may end up with a greatly imbalanced number of patients between the two arms.

As an example of stratification in a phase III trial, consider the following: the two treatment arms are designated as A and B, and it is assumed that there were two important prognostic factors for patients with the particular disease: (a) size of tumor and (b) nodal involvement, each with two categories. Size may be classified as being less than 2 cm or more than 2 cm and patients may either have or not have nodal involvement. Thus four possible categories result from these two factors: (a) less than 2 cm with nodal involvement, less than 2 cm without nodal involvement, more than 2 cm with nodal involvements, and more than 2 cm without nodal involvement. Patients are randomized separately to treatment A or B within each of these four categories to ensure an approximately equal number of patients receiving both treatments within each category.

Sample Size Determination

Determination of sample size for a phase III trial is a multi-step process. The first step is to decide the primary end point of interest. For example, a simple end point would be a comparison of the proportions of patients responding to therapy; for example, does the proportion responding to one therapy equal the proportion responding to the other therapy or do the response proportions differ? Another end point could be disease-free survival; for example, for patients who have their disease eliminated at or before the start of therapy, how long does it take for the disease to return with either therapy, and are these intervals different? Survival is a common end point that is measured from date of randomization until the date of death or last follow up. Progression-free survival can also be determined from the date of randomization until the date progression is first noted.

The next step is to decide whether a one-tailed or two-tailed hypothesis test should be used. A one-tailed test would indicate that the difference between the two groups is of interest in only one direction; for example, to test whether therapy A would be better than therapy B. A two-tailed test is used to determine whether the two therapies are different and allows for the possibility that either one could be better. The reason for making this decision is that the significance level, known as *alpha (a),* is affected by it. A two-tailed test would require somewhat greater numbers of patients than a one-tailed test, all else being equal. A two-tailed test is generally preferred unless there is strong justification for expecting a difference in only one direction. [7]

Once the decision has been made about whether to use a one-tailed or two-tailed test, the next step is to estimate the magnitude of results to be obtained and the minimum difference of interest between study arms. In order to do so, it is best to use estimates based on the literature in the same patient population, if such data exist. It is most important to try not to assume that the two arms would result in extreme differences in outcome because the study will end up with too few patients to identify a significant difference if an effect is noted. Therefore, it is useful to be conservative.

The next step is to estimate the approximate accrual rate of the particular types of patients to be treated. Again, it is useful to be conservative. If the trial is unable to accrue patients at the expected rate, this deficiency could lead to termination of the trial without useful results. The fifth step is to decide the magnitude of errors that would be acceptable to make. Table 66.3 presents definitions of alpha and beta, known as the type I and type II error in the context of a comparative trial. As shown in this table, type I and type II errors are made when clinical trial results differ from the real relationship between the two arms.

		Decision	
		Two Treatments Equal	One Treatment Better Than the Other
Actual Relationship	Two Treatments are Equal	OK	α-Type I Error
	One Treatment Better	β-Type II Error	OK
		Power (1-β) × 100%	

TABLE 66.3. DEFINITIONS OF TYPE I AND TYPE II ERRORS IN CONTEXT OF COMPARATIVE CLINICAL TRIAL

Based on the preceding steps, a preliminary sample size estimate can be made. In order to do so, a variety of methods are possible depending on the outcome of

interest. In Table 66.4, an example of the number of patients required to detect a difference between two proportions is presented for a two-tailed alpha level of 0.05. Based on hypothetical values of response proportions in two arms on a trial, the number of patients required per arm is tabled according to the specified power, where power is defined as (1 - beta × 100%. As can be seen by examining Table 66.4, the number of patients required per arm for this type of study varies greatly depending on the anticipated or clinically meaningful difference between the two arms. For a study with 80% power, a comparison of 20% versus 50% responses requires only 45 patients per arm, whereas a trial seeking a difference between 20% and 30% would require 313 patients per arm.

Hypothetical Values		Patients Per Arm According to Power		
		70%	80%	90%
P_1	P_2			
0.2	0.25	900	1,134	1,504
0.2	0.30	250	313	412
0.2	0.35	122	151	197
0.2	0.40	74	91	118
0.2	0.45	50	62	79
0.2	0.50	37	45	57

TABLE 66.4. NUMBER OF PATIENTS REQUIRED TO DETECT DIFFERENCE BETWEEN TWO PROPORTIONS (TWO-TAILED a = 0.05)

This method of determining the sample size is simple. Other more complex methods are available for determining sample size with survival-type end points, such as overall survival, disease-free survival, or progression-free survival. These techniques consider factors such as the relative ratios of median survival, disease-free survival, or progression-free survival between the two groups, the amount of follow-up time per patient, and the accrual rate. These methods can be more complex to implement, but they can result in a requirement for fewer patients than using the method based on comparing proportions of patients alive or disease-free by a fixed point in time. It is important to realize that the sample size estimate is just a guess of the number of patients needed to find a significant difference. The final end point results may be different from those projected. Thus it may be sufficient to use a sample size estimate based on something as simple as a proportion alive at a given point in time because the assumptions that were employed with the more complex approaches may not turn out to be correct.

Once this preliminary sample size estimate has been determined, the length of the accrual period required can be calculated. If this accrual period is likely to be too lengthy, then it may be necessary to reevaluate the parameters used for calculating the sample size. For example, if there is willingness to tolerate greater errors in the study, or there are ways to increase the accrual by including additional institutions in the study, or a difference of a larger magnitude would be acceptable to try to detect with the trial, then these decisions can be used to address the feasibility of conducting the trial. It is important to realize that, for a specific number of patients accrued, only a difference of a given magnitude can be detected. Thus if not enough patients can be accrued for the study in order to detect a difference of a reasonable magnitude, then whether the study can be conducted in the framework that has been selected must be evaluated. For example, it is not a good practice to reevaluate study design parameters and then decide that it is acceptable to detect only an unrealistically large difference. Failure to conclude that an observed difference is statistically significant may be due to either a correct finding of no (or little) difference or a type II error; that is, the lack of power to correctly identify the difference. Freiman et al.[8] determined that of 71 randomized studies with conclusions of no difference between therapies, 50 of these studies were too small to have 90% power to identify a 50% difference in outcome. Thus trials with insufficient patients were found to be prevalent but should be avoided because of the lack of certainty about the interpretations of results.

Analysis

The type of analysis used in phase III trials largely depends on the type of end point being considered in the trial. When the proportions of patients responding to treatment are the primary end point, a test for differences of binomial proportions is sufficient. For example, depending on the numbers of patients being evaluated in these trials, a Chi-squared statistic or Fisher's exact test might be appropriate.

Many trials in oncology focus on end points such as survival, disease-free survival, or progression-free survival. When the main end point in a trial is time to an event, in order to describe the data, the most common approach used is the Kaplan-Meier method.[9] An example of a pair of Kaplan-Meier curves is presented in Figure 66.1. As can be seen, the curves have the following characteristics: initially, all of the patients were alive or in remission and thus the proportion surviving, or remaining disease-free, was 100%. As time progressed, events were noted by drops in the curve at the times at which the events took place. Patients who did not have the event in question occur during the period of observation were considered to have censored observations and had their follow-up times denoted by small, vertical tick marks on the curves. Thus Kaplan-Meier curves incorporate all follow-up data on all patients. They only reach 0% if the patient with the longest follow-up has the event in question. In the example in Figure 66.1, the patient with the longest follow-up in the arm (denoted by open squares) dies shortly after 36 months, whereas in the other arm, a patient with approximately 39 months of follow-up remains alive. These curves are constructed such that the magnitude of the drop is proportional to the number of patients who remain at risk for the event at the time at which the event occurs. Thus, early in time, any drops are small because a large number of patients are potentially at risk, whereas at later time points, few patients are at risk and the drops are larger. As would be expected, because the drops in the curve are larger later on, greater variability is introduced at this point in the curve. In studies with large numbers of patients, it may be difficult to graphically display the follow-up time of every patient entered into the study, whether a failure or a censored observation. In those cases, it is useful to provide a count of the number of patients remaining at risk along the time axis.

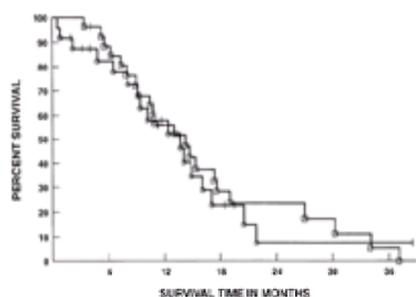

FIGURE 66.1. Example of Kaplan-Meier survival curves. Treatment A denoted by circles (¡) and treatment B denoted by squares (¨). The two curves are not statistically significantly different from one another ($P_6 = 0.73$).

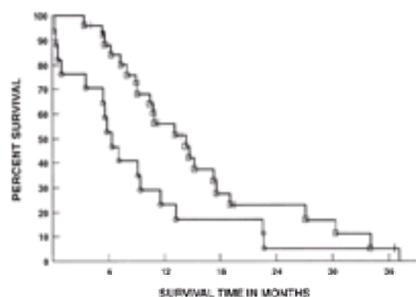
Evaluation of the difference between two survival curves, such as those shown in Figure 66.1, may be done through a variety of methods. The most commonly used technique is known as the Mantel-Haenszel method[10] which considers the actual times of events and provides a generally accepted test for the difference between two curves. This type of test is not always the most appropriate, especially if curves cross one another. In those cases, other methods of analysis can be used. However, in general, it is important to decide in advance of seeing the results of the study which method to use in order to avoid selecting the test that results in the most significant result. For example, in Figure 66.1, the two treatments have approximately the same results. Using a Mantel-Haenszel statistic, the p-value is 0.73. Thus it is easy to see that neither treatment is preferred. In Figure 66.2, however, a difference could be interpreted as being of borderline statistical significance, $p_2 = 0.06$, between the two groups.


FIGURE 66.2. Example of two Kaplan-Meier survival curves in which two treatments have virtually significantly different effects on outcome ($p_2 = 0.060$).

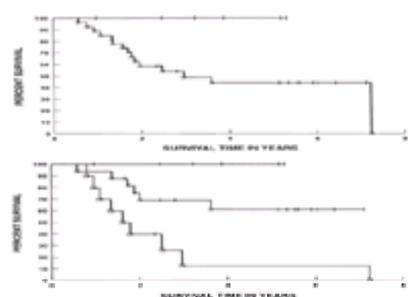
Kaplan-Meier survival curves and Mantel-Haenszel statistics can be useful to help identify potential prognostic factors in patients on randomized studies. In Figure 66.3A, all six patients with a low value of a potential prognostic marker survive, whereas the 27 patients with a higher value of the prognostic marker experience significantly greater mortality ($p_2 = .05$). In Figure 66.3B, the patients are further divided according to whether they have metastatic or localized disease. All patients with a low value of the marker had localized disease. As shown in this figure, when one divides the patients according to whether the disease is metastatic or localized, it becomes less clear whether the marker has the beneficial effect or whether the effect is more an attribute of having localized or metastatic disease. The top and middle curves present a comparison of patients with localized disease according to low versus high values of the marker, and in this group of patients, the p-value for the difference between the two curves is 0.14. Patients with metastatic disease all had high marker values, and their survival curve drops rapidly. The comparison between patients with a high marker value for the localized versus metastatic disease is significant ($p_2 = 0.012$). This example illustrates how Kaplan-Meier curves can help explain the effects of more than one prognostic factor on a time-to-event (e.g., survival) end point.


FIGURE 66.3. A: Use of Kaplan-Meier curves to help elucidate prognostic effects. In the top curve (no symbols), all six patients with a low value of a potential prognostic marker survive, whereas those with a higher value experience significantly greater mortality ($p_2 = 0.05$). **B:** Same data as Figure 66.3A, but now examining effect of metastatic disease as well. Top curve (no symbols): localized disease with low levels of the marker; middle curve (¡), localized disease with high levels of the marker; bottom curve (¨), metastatic disease with high levels of the marker. Statistical comparisons are as follows: local/low vs. local/high: $p_2 = 0.14$; local/high vs. metastatic/high: $p_2 = 0.012$.

COX PROPORTIONAL HAZARDS REGRESSION MODELS

In 1972, Professor D. R. Cox published a method for analyzing multiple prognostic factors from clinical trials with time-to-event end points.[11] The method, known as the *Cox proportional hazards model,* is widely used today and is generally considered an acceptable method for determining the relative importance of potentially prognostic factors in a group of patients under investigation in a clinical trial with a time-to-event end point. An excellent discussion of the Cox proportional hazards model can be found in a book intended to be read by clinicians.[12]

The Cox proportional hazards model assumes that the risks of failure on two or more Kaplan-Meier survival curves are proportional. That is, the death rates for individuals with nonbaseline values of some factor under evaluation are constant multiples of the death rates of patients who have baseline values of the factors. Specifically, this assumption means that the Cox proportional hazards model is not suitable when the Kaplan-Meier survival curves crossed at some point in time. Because this is a regression technique, some of the general guidelines that apply to linear regression analysis apply to proportional hazards regression analysis as well. For example, it is not good practice to include more parameters in a model than the square root of the number of failures in the data set. For example, in a study of 100 patients with a total of 30 patients dying, it might be reasonable to develop a model with up to five parameters, provided that such a large number of factors could be suitably interpreted.

An important outcome measure from the Cox proportional hazards model is an estimate of the relative risk of death for patients having one level of a potentially prognostic variable compared to patients who have the baseline level of the potentially prognostic variable. For example, Table 66.5 shows that three parameters (i.e., stage, gender, and metastases) were simultaneously identified to be associated with survival in a group of patients. According to the results shown in the table, each of these parameters is statistically significant in the presence of one another. Stage, which has a p-value of .031, is shown to have a relative risk of 3.74. If only patients with either stage 3 or stage 4 disease are entered into the study, then patients with stage 4 disease have approximately 3.74 times the risk of dying at any given point than patients who have stage 3 disease. Similarly with gender, if the baseline group were males, then females would have approximately 50% more risk (e.g., 1.5 times the relative risk) of dying during any small interval of time. Patients with metastatic disease would have 15 times the relative risk of dying compared to patients with localized disease only. These statistics are the results of all three of these characteristics taken simultaneously. In the Kaplan-Meier survival curve, typically only one factor is portrayed at a time. In the Cox proportional hazards model results, the effects can be identified simultaneously and are adjusted for the effects of the other parameters. Because patients have a constellation of traits that could be important in prognosis, the Cox proportional hazards model results, if based on appropriate factors, are considered preferable to results obtained only in a univariate fashion. The univariate results, however, are useful for illustrative purposes and for leading one to identify factors for consideration in proportional hazards models. Also shown in Table 66.5 is the 95% confidence interval for the relative risk for each of the three factors in the model. This figure is important because it provides an indication of the preciseness of the estimated relative risk. For example, although stage has a relative risk of 3.74, the 95% confidence interval ranges from 1.26 to 11.1, meaning that it is likely that the true relative risk is between 1.25 and 11.00. For gender, there is a tighter interval from approximately 1 to approximately 2, whereas the interval for metastases ranges from 4 roughly to 53.

Variable	Parameter Estimate	p-Value	Relative Risk (RR)	95% Confidence Interval for RR
Stage	1.32	0.031	3.74	(1.26, 11.10)
Gender	0.74	0.027	1.49	(1.07, 2.08)
Metastases	2.71	0.0037	15.03	(4.25, 53.15)

TABLE 66.5. EXAMPLE OF COX PROPORTIONAL HAZARDS MODEL RESULTS

GROUP SEQUENTIAL DESIGNS

Some small clinical trials are designed to accrue the total number of patients originally intended without any interim evaluations for efficacy; however, in many phase III studies, particularly those of moderate to large size, the design must allow for the possibility of early termination of the trial if results appear to be statistically significant early on. Trials that allow for formal evaluations that could result in termination after fixed prespecified points are called *group sequential designs.* A whole body of literature exists on these designs. Two specific, easily described designs permit examination of the data at prespecified time points and adjust the p-values required for termination so that highly significant findings may lead to termination of the trial depending on proximity to the planned end of the trial. These two methods were developed in the late 1970s. The first, by Pocock, [13] allows one to terminate the trial when a p-value of less than some small fixed value, which remains constant for each potential evaluation, is reached. For example, in a study with plans for up to five equally spaced looks at the data prior to termination of accrual, if at any of the five looks the significance of the difference between the two groups was such that p_2 was less than 0.008, then accrual to the study could be terminated because this result could be shown to be consistent with a final p-value of less than 0.05. Another approach, developed by O'Brien and Fleming, [14] allows for decreasingly stringent p-values to be used in the evaluation at successive interim looks. For example, in this same example with five interim evaluations, if at the first evaluation the p-value were less than approximately 3×10^{-6}, then accrual would terminate. The p-value required for termination would increase gradually, so that at the second evaluation the required p-value would be 7×10^{-4}; 4×10^{-3} would be the threshold for the third evaluation, .011 for the fourth, and .021 for the fifth interim evaluation. Many other possible designs have been studied and can be considered for use in clinical trials. The important point is that stopping a trial early because of an interim significant finding requires great care. It is insufficient to stop accrual with an early p-value of .05 because it can be shown that it is likely, if the study were to progress to the intended accrual target, that the ultimate p-value could be much greater than .05 and thus one would have erred in making this early decision.

METAANALYSIS

Conducting a randomized clinical trial can be a time-consuming and expensive process, and sometimes the answer to a major clinical question might be obtained by examining and synthesizing the results of other research that has been previously conducted. *Metaanalysis* is a term that was first used in the mid 1970s by an educational researcher, and is a discipline that critically reviews and systematically statistically combines the results of previously conducted research studies. An article by Sacks et al.[15] provides a description of the subject. The purposes of metaanalysis are to increase the statistical power of primary end points and within subgroups, to resolve uncertainty when reports disagree, to understand interstudy differences and results, to improve estimates of effect size, and to answer questions not posed at the start of individual trials. [15] When studies that are pooled are similar with respect to the treatment, the patient population, and data quality, then averaging results makes sense.[16] However, in practice, the doses of drugs actually delivered differ, the patient population may differ, and there may be different degrees of protocol compliance, adequacy of follow-up, and reliability of data. Perhaps well-designed and well-conducted clinical trials are still the best means of answering questions concerning what treatments are effective and how effective they are.

Sacks et al. published a careful evaluation of metaanalyses in the English language medical literature. [15] In order to be included in their report, data from more than one study had to be combined, and at least one of the studies pooled had to be a randomized controlled trial. This study determined that the number of articles that can be included in their metaanalysis increased rapidly through the mid-1980s, from a starting point in the 1950s, when few such articles existed. These authors identified six major areas for determining the quality of a metaanalysis: study design, combinability, control and measurement of potential bias, statistical analysis and methodology used, sensitivity analysis, and the application of the results. These six major areas were further subdivided into 23 individual items. Their study determined that 28% of the metaanalyses addressed all six of these major areas, 36% addressed five, 29% addressed four, and 7% addressed either two or three of these areas. When the individual items, and thus the quality of the metaanalyses, were examined, out of 23 possible items, not a single paper received more than 14 adequate ratings, and in most articles, 5 to 8 of the 23 points were addressed. Thus it was believed that many metaanalyses that were reported were not adequate on several grounds.

A properly performed metaanalysis can be useful in a setting where one wants to obtain a global answer to an important question incorporating the results from a large number of properly done and reported studies. Metaanalyses should be reported with sufficient information in order for the readers to draw conclusions about the validity of the results reported. A metaanalysis should be conducted like a scientific experiment with a clear study design, evaluation methods, and results presented. Because metaanalyses typically use results of published clinical trials, there is a potential bias in the articles that can be included in a metaanalysis. It is well known that clinical trials with positive results are more likely to be published than ones with negative results. Unpublished trials might be less reliable and might not be conducted with the same care as published studies. Nonetheless, this is a bias because not all studies may be included in the metaanalysis.

There are instances, however, of metaanalyses that are conducted on large numbers of trials that can produce interesting results, which could not necessarily have been found from the examination of any single trial. As an example, the Early Breast Cancer Trialist's Collaborative Group performed a metaanalysis based on 133 randomized trials from around the world involving 24,000 deaths among 75,000 women. [17] This metaanalysis was able to demonstrate highly significant reductions in the annual rates of recurrence and of death by use of Tamoxifen, although the results varied. Because this metaanalysis was performed on an extensive group of randomized clinical trials run by centers and consortiums from around the world and conducted with great care by the organizing committee in Oxford, England, this metaanalysis may be valuable because complex questions were able to be answered without the need to resort to additional randomized clinical trials.

As a second example, the Non-small Cell Lung Cancer Collaborative Group performed a metaanalysis based on 52 randomized clinical trials from around the world, which included 9,387 patients, of whom 7,151 died. [18] The objective of the metaanalysis was to determine the impact of cytotoxic chemotherapy on survival in patients with non–small cell lung cancer. This study demonstrated that modern chemotherapy regimens containing cisplatin were favored in all comparisons performed, and that the benefit attained conventional levels of statistical significance when combined with radical radiotherapy and supportive care. This metaanalysis was carefully performed, involved a large worldwide set of all available trials, including unpublished studies, and was done under the auspices of a group with substantial expertise in conducting such studies. Thus the conclusions of this metaanalysis are likely to be reliable and would obviate the need for additional randomized trials to address the specific questions being posed in this study, which had remained controversial and uncertain until this metaanalysis was performed.

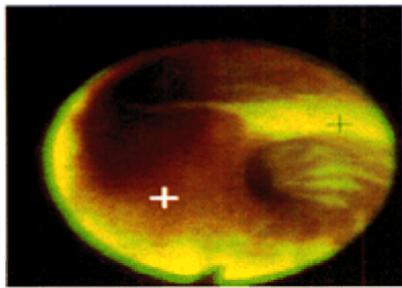
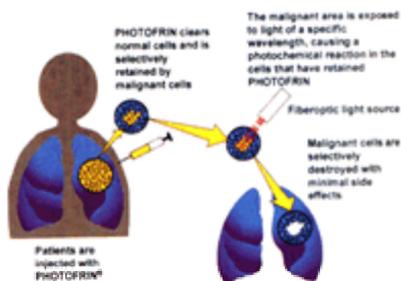
COLOR FIGURE 8.6. Tobacco smoking causes loss of function of the *FHIT* gene. Carcinogens present in tobacco smoke cause deletion in a *FHIT* allele. Continued exposure causes deletion in the second allele, leading to loss of Fhit expression. *FHIT* alterations and then mutations in p16, *p53,* and other loci cause precancerous lesions (bronchial dysplasia), some of which will later evolve into frank carcinomas. (From Huebrev K, Sozzi G, Brenner C, et al. *FHIT* loss in lung cancer: diagnostic and therapeutic implication. *Adv Oncology* 1999;15:3, with permission.) (See also black and white Figure 8.6.)

COLOR FIGURE 24.1. Energy states and interaction of photosensitizing agents. Before exposure to light, a molecule of sensitizer is in the ground state. When a photon of the appropriate wavelength is absorbed, an electron is raised to a higher energy level. The molecule then rearranges to a stable excited state. At this point,

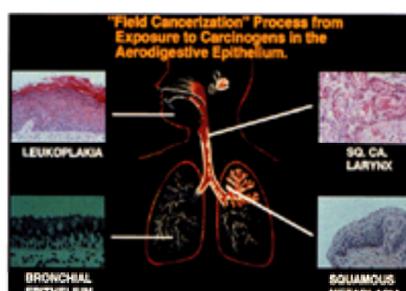
there are two possibilities. The excited molecule can fluoresce, emitting a photon and dropping back to the ground state, or an intersystem crossing can change the spin of an electron. During the lifetime of the resulting triplet state, absorbed energy can be passed along to molecular oxygen in tissue, activating the oxygen molecule to the singlet state. Singlet oxygen can oxidize any oxidizable biologic molecule with which it is in contact. (From Kessel D. Photodynamic therapy. *Sci Med* 1998;5:46, with permission.) (See also black and white Figure 24.1.)

COLOR FIGURE 24.2. The relative phototoxic effect of a sensitizer is a function of irradiation wavelength. Longer wavelengths penetrate tissue to a greater depth. (From Kessel D. Photodynamic therapy. *Sci Med* 1998;5:46, with permission.) (See also black and white Figure 24.2.)


COLOR FIGURE 24.3. A: Autofluorescence spectra of normal bronchial mucosa and squamous cell carcinoma *in situ.* **B:** Reddish brown fluorescence of carcinoma *in situ* distinguished from the green fluorescence of normal bronchial mucosa. (Courtesy of XILLIX Technologies Corporation, British Columbia, Canada.) (See also black and white Figure 24.3.)


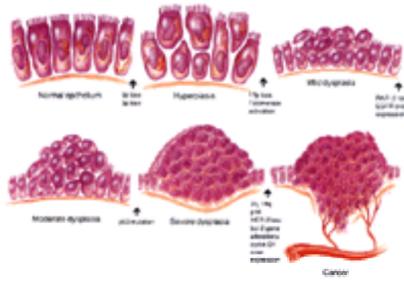
COLOR FIGURE 24.4. Schema of photodynamic therapy for bronchial lesions. See text for details. (Courtesy of Dr. Jeffrey Wiemann, Louisville, Kentucky.) (See also black and white Figure 24.4.)

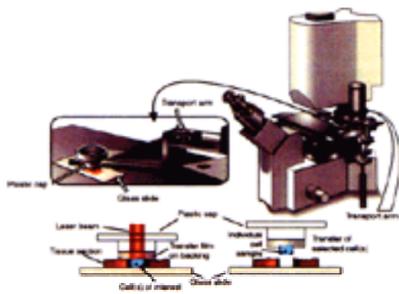
COLOR FIGURE 24.5. Photodynamic therapy for a patient with partial obstruction of the right mainstem bronchus. **A:** 90% obstructive non–small cell lung cancer 0.5 cm from the main carina. **B:** Laser fiber is positioned for interstitial treatment 48 hours after the patient received Photofrin II. **C:** Appearance of the lesion 48 hours after treatment before any debridement of the avascular base. **D:** Appearance of the lesion base after bronchoscopic debridement revealing the right upper lobe orifice to the right and the bronchus intermedius straight ahead. **E:** Appearance of the airway 2 months later. Only a superficial ulcer is present at the site of the original lesion **F:** Appearance of the airway 3 months after treatment. A histological complete response was documented. (See also black and white Figure 24.5.)

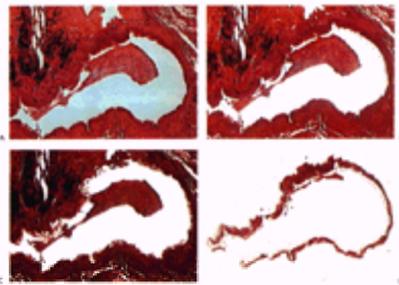


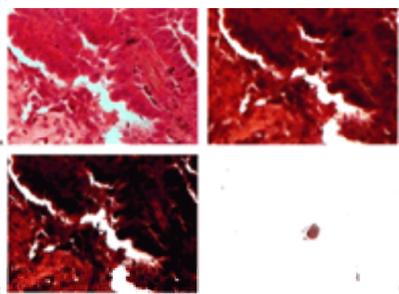
COLOR FIGURE 25.1. A schematic and pathologic representation of the Concept of Field Cancerization: Epithelium throughout the respiratory tract is affected by

similar toxins, hence the concern about second primary cancer prevention. (See also black and white Figure 25.1.)

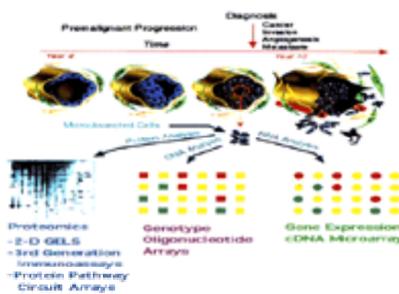


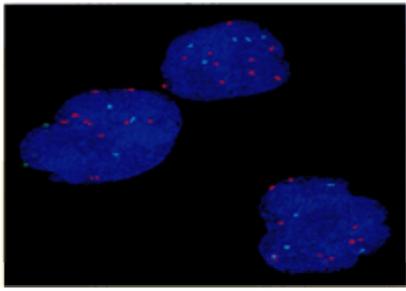
COLOR FIGURE 25.2. Multi-step process of lung carcinogenesis: A schema of molecular changes that have been reported to occur during the multi-step lung carcinogenic process. While representing potential points for intervention (i.e., chemoprevention), these events could potentially (once available) serve as biomarkers of cancer risk and intermediate end points for clinical studies. (From Papadimitrakopoulou VA. New developments in the chemoprevention of lung cancer. *Prim Care Cancer* 1998;18[Suppl. 1]:52, with permission.) (See also black and white Figure 25.2.)


COLOR FIGURE 27.1. Laser capture microdissection (LCM) system showing the process of microdissection of cells from tissue. The laser beam activates the thermoplastic film embedding the underlying cells, which can then be separated from the tissue. (See also black and white Figure 27.1.)


COLOR FIGURE 27.2. Microdissection of normal bronchiolar epithelium. **A:** roadmap, **(B)** before microdissection, **(C)** after microdissection, and **(D)** cap with dissected tissue (200 X magnification). (See also black and white Figure 27.2.)


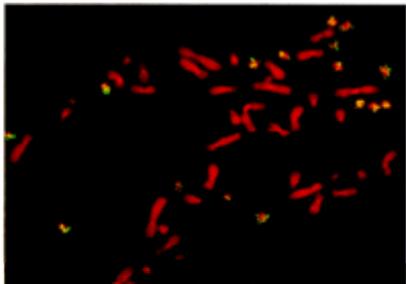
COLOR FIGURE 27.3. Microdissection of a single cell from bronchioloalveolar carcinoma *(arrow).* **A:** roadmap, **(B)** before microdissection, **(C)** after microdissection, and **(D)** cap demonstrating microdissected cell (1000 X magnification). (See also black and white Figure 27.3.)



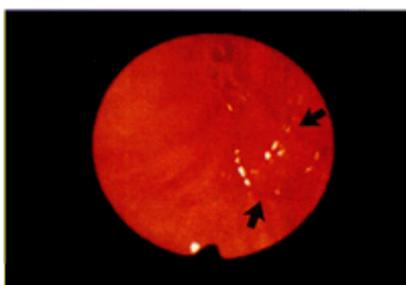
COLOR FIGURE 27.4. Application of LCM to study the molecular events associated with cancer progression. The expression pattern of proteins (two-dimensional gel electrophoresis or immunoassays), RNA (differential display, microarray hybridization, or cDNA libraries), and DNA genotype (mutational analysis, loss of heterozygosity, comparative genomic hybridization) can be compared within the same patient. In the tissue section, normal precursor epithelium, premalignant lesions, and invasive cancer foci can be microdissected and compared. (See also black and white Figure 27.4.)


COLOR FIGURE 28.4. Fluorescence *in situ* hybridization of two chromosome-specific centromere repeat probes to interphase cell nuclei, counterstained blue with diamidino-2-phenylindole, from a human non-small cell lung cancer specimen. DNA probes labeled with biotin or digoxigenin hybridizing to complementary centromere sequences within the nuclei were detected by immunofluorescence using fluorophores emitting green (fluorescein isothiocyanate) or red (rhodamine). The nuclei exhibit abnormally high numbers of chromosome 7 (red spots) and chromosome 18 (green) fluorescent signals, indicative of gains of these chromosomes. (See also black and white Figure 28.4.)

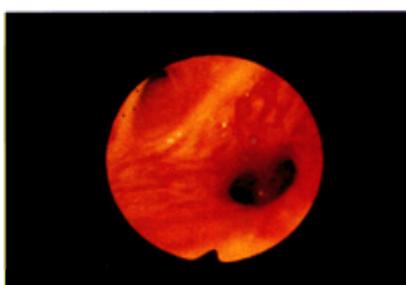
COLOR FIGURE 28.5. A: Computer-generated fluorescence ratio image of a normal human metaphase spread after comparative genome hybridization with biotin-labeled DNA, detected by fluorescein isothiocyanate (FITC), from a lung cancer cell line, and digoxigenin-labeled DNA, detected by rhodamine, from normal placenta. Yellow-green indicates balance between the FITC and rhodamine values. Bright green indicates overrepresentation of DNA in the tumor, and red represents underrepresentation of tumor DNA. Intense green fluorescence on chromosome 8q24 (*arrows*) suggests that the MYC protooncogene located in this band may be amplified in the lung cancer cells. **B:** The same metaphase spread, stained with diamidino-2-phenylindole, which permits the identification of each chromosome. The two copies of chromosome 8 are indicated by numbers. (See also black and white Figure 28.5.)

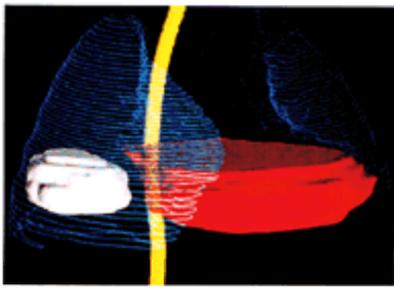


COLOR FIGURE 28.6. Fluorescence *in situ* hybridization of a MYCN probe to a partial metaphase spread from the small cell lung cancer cell line. Multiple fluorescent signals are observed on each of the double minutes, indicating that the amplified *MYCN* oncogene resides within these small chromatin bodies. (See also black and white Figure 28.6.)



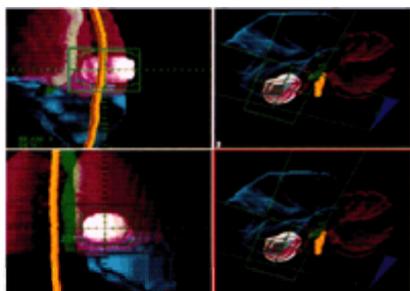
COLOR FIGURE 31.1. Endobronchial mass occluding a segmental bronchus. (See also black and white Figure 31.1.)

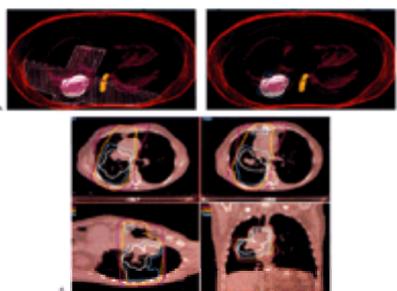


COLOR FIGURE 31.2. Submucosal infiltration of bronchogenic carcinoma. Normal bronchial markings are lost and engorged bronchial collateral vessels are prominent. (See also black and white Figure 31.2.)


COLOR FIGURE 48.5. A: Lung cancer tumor target and normal organs displayed in "room view." **B:** Multiple images of anteropostero (AP) beam for lung cancer treatment. Note in the upper-right image that the green contour CTV does not have an adequate margin around the red GTV contour. This is because a 3D margin tool to generate the CTV was not used, thus only 2D margins were generated. (See also black and white Figure 48.5.)

**COLOR FIGURE 48.6.** Beam's eye view of tumor with port defined by multileaf colimation. (See also black and white Figure 48.6.)

COLOR FIGURE 48.7. A: Multiple images used in 3D plan evaluation, including "room view," beam's eye view, axial, and saggital views. (See also black and white Figure 48.7.)


COLOR FIGURE 48.7. B: Multiple images used in 3D plan evaluation, including "room view," beam's eye view, axial, and saggital views. (See also black and white Figure 48.7.)


COLOR FIGURE 48.8. A,B,C: Various images depicting isodose coverage and various dose levels in 3D. (See also black and white Figure 48.8.)
