Most recently, the results of the Anti-Lung Cancer Association screening program were presented. From 1975 to 1993, 26,338 examinations with chest x-rays and sputum cytology were performed, with a detection rate of lung cancer at 0.16%. When low-dose spiral CT examinations were added from 1993 to 1998, 35 lung cancer cases were found in 9,452 (0.37%) examinations. Moreover, this translated to a 3-year survival of 83% from 1993 to 1998 compared to 56% in the former

period.[39]

The results of the Early Lung Cancer Action Project (ELCAP) have been reported [40] and are complementary at the Japanese data. ELCAP was designed to evaluate baseline and annual repeat screening by low-radiation-dose computed tomography (low-dose CT) in people at high risk of lung cancer. One thousand symptom-free volunteers, 60 years or older, with at least 10 pack-years of cigarette smoking and no previous cancer, who were medically fit to undergo thoracic surgery were enrolled. Chest radiographs and low-dose CT were done for each participant, and noncalcified pulmonary nodules were investigated using short-term high-resolution CT follow-up for the smallest noncalcified nodules. Noncalcified nodules were detected in 23% of the participants by low-dose CT at baseline, compared to 7% by chest radiography. Malignant disease was detected in 2.7% by CT and 0.7% by chest radiography. Of the 27 CT-detected cancers, 26 were resectable. Biopsies were done on 28 of the 233 participants with noncalcified nodules; 27 had malignant noncalcified nodules and one had a benign nodule. No participant had thoracotomy for a benign nodule. These data point to the utility of low-dose CT in detecting small noncalcified nodules, which could prove to be lung cancer at an earlier and potentially more curable stage. Plans are under way for a multicenter national trial to verify these results.

DEVELOPMENT OF MOLECULAR APPROACHES TO EARLY LUNG CANCER DETECTION

Development of new approaches to identify lung cancer in sputum is being pursued. Sputum, bronchial washings, and bronchoalveolar lavage fluid are complex specimens containing a wide variety of soluble and cellular components, only a portion of which are epithelial derived. Novel techniques to derive epithelial cell–enriched specimens from sputum are being developed.[41] Computerized image analysis of Feulgen-stained exfoliated cells has shown significant promise in improving diagnostic capabilities.[41] Encouraging reports of increased sensitivity of monoclonal antibodies for detecting malignant cells in sputum have not been duplicated by additional groups, but further development of this assay is underway. [41,43] Several additional novel markers are under evaluation (see also Chapter 23), including mutation detection targeted at p53 and *ras* genes. In addition, DNA methylation is often aberrant in lung tumors, [43] and a polymerase chain reaction–based method of methylation detection has recently been applied to sputum. Although considerable excitement, has been generated regarding the application of molecular markers to the early detection of lung cancer, none of the tests developed to date are currently ready for large-scale application. Prior to applying any molecular marker to early detection of lung cancer, test characteristics, such as reproducibility (both within a laboratory and between laboratories) sensitivity, and specificity when tested in appropriate disease and control groups, need to be determined.

In addition to early detection, molecular markers have a high potential to achieve clinical application to identify high-risk individuals in whom other screening techniques might be applied for surveillance. [45] Several genetic aberrations have been described in the respiratory epithelial cells of lung cancer patients and current or ex-smokers without lung cancer,[46,47] p53 mutations affecting nonmalignant respiratory epithelial cells have only rarely been described in individuals without lung cancer and might define a group of smokers at extremely high risk for the development of cancer. [48] (see also Chapter 6) Loss of heterozygosity of chromosomes 3p and 9p can be found in most smokers studied to date and might therefore be a less attractive risk marker (see also Chapter 23, Chapter 28).[46,47] Either specific combinations or the total number of mutations detectable in respiratory epithelium may be prognostic.

A panel of biomarkers instead of a single marker will likely be required to identify occult lung cancer. The cancer gene marker may be present in exfoliated cells, which appear morphologically normal. This marker is an important new area of outcomes research, which could lead to algorithms that may increase the efficiency and reduce the cost of case finding or screening. [49,50]

ADVANCED IMAGING TECHNIQUES

Recently, F-fluorodeoxyglucose PET scanning has revealed a high degree of sensitivity and specificity in lung cancer identification, [51,52,53 and 54] with positive predictive values greater than 90% and negative predictive values approaching 100%. The finding of a metabolically active nodule is highly indicative of malignancy. [51] Whole-body PET scanning can be used in the staging of non–small cell cancer [54] (see also Chapter 30).

ENHANCED BRONCHOSCOPY TECHNIQUES

The best outcome in lung cancer management is treatment when the lesion is discovered in preinvasive stages. However, the intraepithelial neoplastic lesions are somewhat difficult to localize by conventional white light bronchoscopy, particularly if the bronchoscopist is not highly experienced in searching for subtle changes that may indicate lung cancer, as was the case in the Grand Junction Study. [31]

Autofluorescence bronchoscopy was introduced to detect high degrees of dysplasia or in carcinoma *in situ*[55,56] (see also Chapter 23, Chapter 24). Conventional white light bronchoscopy uses illuminated light that is reflected backscattered absorbed, but it does not induce tissue fluorescence, a process known as *reflectance imaging*. The tissue autofluorescence is not visible to the unaided eye because the intensity is low and obscured by the backscattered light. With suitable instruments, however, the autofluorescence reflected to create an image, which indicates a high likelihood of malignancy. [56] In a recent study, autofluorescence bronchoscopy, when used as an adjunct to standard white light bronchoscopy, enhanced the bronchoscopist's ability to localize small, subtle lesions, which were often malignancies, that were confined to the epithelium (i.e., *in situ* or preinvasive).[57] It is virtually certain that a cure of these lesions with surgery, radiation, and/or laser therapy will be likely. In addition, a novel new therapeutic approach, photodynamic therapy, may also achieve a cure for *in situ* and stage I carcinoma.[58,59] Fluorescent bronchoscopy can be used in surveillance of subsequent carcinomas and sputum markers, either molecular or cytomorphologically, which suggest a second or recurrent lung cancer. Surveillance employing malignancy-associated changes (MACs) is also under study as a method of detecting small peripheral adenocarcinomas and as an indication of lung cancer recurrence. [60,61]

A NEW, EXCITING APPROACH TO THE EARLY IDENTIFICATION OF LUNG CANCER

Individual cases of lung cancer must be diagnosed on the basis of clinical suspicion, bolstered by the necessary technology to prove presence and location and to determine the histologic type of malignancy. Suspicion must be based on smoking histories, family histories, occupational exposures, and symptoms. When a high-risk individual is identified (i.e., heavy smoking with any of the following: airflow obstruction, positive family history, additional carcinogenic exposures, or symptoms), systematic studies to identify the presence or absence of lung cancer seem reasonable, given the lack of currently available scientific information that attempts at early identification are not useful in this patient group. The algorithms shown in Figure 22.6 and Figure 22.7, although overly simplistic, may be useful in this regard. Either sputum markers of malignancy using cytomorphology or standard chest x-rays or CT scans will identify the presence of a premalignant or malignant lesion (sputum), or an airway or peripheral abnormality (CT imaging). The next step is to identify the site through white light bronchoscopy or if that modality is unrevealing, with fluorescent endoscopy. When the tumor is located, a biopsy should be performed, and staging should proceed thereafter.

The phenomena of MACs may add still another surveillance tool (see also Chapter 23).[60,61] MACs are subtle alterations in the size, shape, or texture of the cell nucleus of nonmalignant exfoliated calls that appear to be a result of growth factors produced by nearby lung cancer cells. Their presence may be used in early identification or for surveillance of recurrent lung cancer. [60,61]

Today, the main diagnostic focus should be on early lesions that are amenable to cure. It is distinctly possible that early intraepithelial lesions can be dealt with by photodynamic therapy,[58,59] or other methods such as electrocautery, cryotherapy, or thermoablation, with a YAG laser or brachytherapy. Indeed, the identification of premalignant lesions would expand the possibility of controlled clinical trials in chemoprevention, using the premalignant lesions as endpoints [62,63] (see also Chapter 25).

Thus far, the growing problem of lung cancer, caused primarily by smoking, has eluded prevention, in part because of persistence of transformed epithelial cells lining the airways of aging former smokers. Recent studies have reported that similar numbers of new lung cancer cases arise from former smokers compared to current smokers.[64]

The continued seduction of 3,000 teenagers daily into the bondage of tobacco addiction with advertising financed by a tobacco industry bent on sustaining its economic success unfortunately ensures that lung cancer will remain a major clinical problem for many years, even if all recruitment of new smokers were to stop immediately. The growing tobacco epidemic has created the most vexing and recalcitrant cancer of our time. With tobacco smoking out of control in large countries such as China, we face a true global disaster. These frightening realities pose an immense challenge to clinicians and scientists who aim to reduce the socioeconomic

impact of lung cancer as we approach the new millennium.

MOLECULAR AND CYTOLOGIC TECHNIQUES OF EARLY DETECTION

ADI F. GAZDAR
STEPHEN LAM
IGNACIO I. WISTUBA

Lung cancer is the most frequent cause of cancer deaths in both men and women in the United States,[1] and tobacco smoking is accepted as the number one cause of this devastating disease.[2] Lung cancer is classified into two major clinic-pathological groups, namely small cell lung carcinoma (SCLC) and non–small cell lung carcinoma (NSCLC).[3] Squamous cell carcinoma, adenocarcinoma, and large cell carcinoma are the major histologic types of NSCLC.[3] Large cell carcinoma probably represents poorly differentiated variants of the other NSCLC types.[3]

As with other epithelial malignancies, lung cancers are believed to arise after a series of progressive pathological changes (preneoplastic lesions).[4] Many of these preneoplastic changes are frequently detected accompanying lung cancers[5] and in the respiratory mucosa of smokers.[6] Although many molecular abnormalities have been described in clinically evident lung cancers,[7] relatively little is known about the molecular events preceding the development of lung carcinomas and the underlying genetic basis of tobacco-related lung carcinogenesis. The risk population for targeting early detection and chemoprevention efforts to has been defined as current and heavy smokers, and patients who have survived one cancer of the upper aerodigestive tract. However, conventional morphologic methods for the identification of premalignant cell populations in the airways have limitations. This has led to a search for other biological properties of respiratory mucosa that may provide new methods for assessing the risk of developing invasive lung cancer in smokers, for early detection, and for monitoring their response to chemopreventive regimens. These markers (also referred as "intermediate markers") include genetic abnormalities in bronchial epithelial cells.

Less than 15% of patients with lung cancer today will survive their disease.[8] Survival of patients with advanced disease has not improved significantly over the last three decades.[9] Essentially, the only patients who achieve long-term survival are those with stage 0 or stage I disease. The five-year survival for patients with stage 0 disease is more than 90%.[9] Unfortunately, patients with stage 0 disease constitute only a minority of the lung cancer population;[10] less than 0.6% of patients with lung cancer are currently diagnosed at this stage because these small cancers do not usually produce any symptoms.

Examination of the age-standardized mortality rate for all cancers shows an interesting difference between men and women.[11] While the overall cancer mortality rate, has remained relatively unchanged among men in the last two decades, there has been a gradual decline in the mortality rate among women. This is thought to be due to improvements in the detection of preinvasive lesions by means of the Papanicolaou (Pap) smear for cervical cancer[12] and screening mammography for breast cancer,[13] followed by the subsequent removal of these lesions. The success of screening in these tumor sites offers hope that a similar strategy may also lead to a reduction in lung cancer mortality.

Sputum cytology examination is currently the only noninvasive method that can detect early lung cancer and premalignant lesions. Preinvasive and microinvasive cancers that are found by sputum cytology examination are very amenable to curative treatment such as surgery,[14,15] laser hyperthermia with the Nd:YAG laser,[16] cryotherapy,[17] electrocautery,[18] or photodynamic therapy with porfimer sodium (Photofrin).[19] Unfortunately, enthusiasm for the use of sputum cytology as a technique for early detection of lung cancer has been dampened by the negative screening studies in the 1970s, which failed to show a survival benefit.[20,21,22,23 and 24] However, the reasons why sputum cytology as practiced two decades ago fails to be the equivalent of the Pap cervical smear need to be examined critically in order to understand how modern methods can improve the usefulness of exfoliated sputum cells as an early detection tool.

SPUTUM CYTOLOGY EXAMINATION

Since the 1930s, sputum cytology examination has been used for the diagnosis of advanced and early lung cancer.[20,21,22,23,24,25,26 and 27] The range of sensitivity varies from 20% to nearly 100%. In screening studies, the sensitivities are usually in the 20% to 30% range, while the higher numbers are from studies in patients with invasive lung cancer. The average sensitivity and specificity from a review of the literature was 64.5% and 97.9% respectively.[28] There is no obvious trend of improvement in the sensitivity of sputum cytology between 1940 to 1990, as one might expect with better experience and training. One possible obstacle to improving the sensitivity of sputum is the present classification system. The present system is based upon years of careful observation of patients who developed lung cancer and is derived partially from similar observations in uterine cervix. Individuals are trained to recognize abnormal cells and place them into discrete categories. These categories are often based upon subjects who developed lung cancer and are divided into seven categories: (a) normal, (b) squamous cell metaplasia, (c) squamous cell metaplasia with mild atypia, (d) squamous cell metaplasia with moderate atypia, (e) squamous cell metaplasia with marked atypia, (f) carcinoma *in situ,* and (g) invasive carcinoma.[4] Although based upon extensive observation and with reasonable correlation to histology, there is considerable interobserver variation in the diagnosis. The agreement is good for the normal and invasive carcinoma categories but poor for the intervening categories.[4,29] Among the reasons for the interobserver variability in classifying specimens is that observers place emphasis on different cellular features. This may also account for the difference in the reported spontaneous regression rate of preinvasive lesions, which vary from 20% to 80% for marked atypia.[30,31]

Another reason for the low sensitivity of sputum cytology in previous screening studies may lie in the selection of loose enrollment criteria. For example, in the NCI Early Lung Cancer Cooperative Group study, the inclusion criteria were 45 years of age and smoking at least one package of cigarettes daily at the time of enrollment or within the previous year.[26] Using a stricter smoking history (greater than or equal to 40 pack-years) and the addition of airflow obstruction (FEV_1 per FVC less than 70%) as another enrollment criteria, Kennedy and coworkers recently reported that 0.9% of their patients with chronic obstructive pulmonary disease were found to have carcinoma *in situ,* invasive cancer was found in another 0.9%.[32] This detection rate is much higher than the 0.2% to 0.3% in the NCI prevalence screening study.

Other factors were found to influence the sensitivity of sputum cytology examination. The yield is highest in those with squamous cell carcinoma and lowest in adenocarcinoma.[31] The location of the tumor and the size of the lesion are also important. The yield is higher for tumors that are located centrally or in a lower lobe and with lesions that are greater than 2 cm in diameter.[33,34] The yield is lower for peripheral tumors and for lesions in the upper lobe or those that are smaller than 2 cm. For example, in a screening setting in subjects with predominantly small peripheral cancers detected by spiral CT, only 11% of the lung cancers were detected by sputum cytology examination alone, with another 15% detected by both methods.[35]

NEWER DETECTION METHODS USING SPUTUM CELLS

To improve the sensitivity of sputum test as a population screening tool for the detection of early lung cancer, three approaches are currently under development: immunostaining of transformed epithelial cells, polymerase chain reaction (PCR)-based assays to detect oncogene mutations, and computer-assisted image analysis of exfoliated sputum cells.

A nuclear ribonucleoprotein—hnRNP A2/B1—was found to be overexpressed in most lung cancer cell types as well as transformed epithelial cells. [36,37] In a retrospective study using sputum specimens that were collected during the Johns Hopkins Lung Project, 64% of the subjects whose sputum samples showed moderate atypia and positive immunostaining for hnRNP A2/B1 developed lung cancer on follow-up while 88% of those with negative immunostaining did not. [38] The sensitivity increased to 91% with no change in the specificity if the sputum specimens were limited to those that preceded the clinical appearance of lung cancer by less than two years.

Two prospective studies were carried out to evaluate hnRNP A2/B1 overexpression for the detection of preclinical lung cancer: one in patients with completely resected stage I lung cancer and the second among tin miners in China. [37,39] At the end of the first year of follow-up, the positive predictive value of hnRNP overexpression in sputum cells was 67%. The sensitivity and specificity for predicting the development of second primary lung cancer were 77% and 82% respectively. For the development of primary lung cancer, the corresponding figures were 82% and 65% respectively among the tin miners.

PCR-based assays can detect one mutant-containing cell among an excess of 100,000 normal cells. [40,41 and 42] A retrospective study in ten patients with adenocarcinoma—eight with K-*ras* mutation and two with *p53* mutation, eight showed an identical mutation in the sputum cells one to 13 months prior to clinical diagnosis. [40] These mutations were absent in samples from control subjects without lung cancer and those that were collected more than 24 months prior to diagnosis. Another study using enriched PCR identified K-*ras* mutation in 47% of the sputum samples from patients with non–small cell lung cancer. [43,44 and 45] However, 12.5% of the control subjects without lung cancer also carried this mutation. Because a given mutation is found in only a proportion of the patients with lung cancer and because these genomic alterations may also be present in a significant number of smokers without lung cancer, [46,47] the use of PCR-based assays to detect genetic mutations needs to be evaluated in a prospective manner in a large population of smokers with and without lung cancer. There are as yet no long-term follow-up studies to determine the risk of lung cancer when one or more of these mutations are found. Furthermore, for some mutations such as K-*ras*, a very limited number of mutations occur in human cancers.[48] Such mutations can be readily detected by a wide variety of methods, including some highly sensitive ones. [49] In contrast, many different mutations have been described in the *p53* gene, and methods to detect the wide range of mutations need to be utilized. [50]

Immunostaining and PCR-based methods require the presence of premalignant or malignant cells (or DNA shed from these cells) for diagnosis. Preinvasive cancers, especially peripheral adenocarcinomas, typically do not exfoliate many cells into the bronchial lumen. The number of epithelial cells from the lower respiratory tract in an expectorated specimen is also influenced by the subject's performance and collection method. For example, a study by the Lung Cancer Early Detection Working Group showed that with sputum induction using hypertonic saline, 19.6% of the specimens from current smokers and 28.9% of the specimens from former smokers were unsatisfactory.[51]

The use of nongenetic changes in normal cells that are induced by the presence of malignant cells in the vicinity, such as malignancy associated changes (MACs), [52] may overcome the problems discussed above. MACs refer to subvisual or nonobvious changes in the distribution of DNA in the nuclei of normal cells due to the presence of preinvasive or invasive cancer in the vicinity. These changes can be quantitated by computer-assisted image analysis. [53] In a study using bronchial biopsies taken from the opposite lung or from a lobe different from the primary tumor, MACs were found to be present in 86% of the normal-appearing specimen. [54] A retrospective analysis of sputum cytology slides that were collected during the Mayo Lung Project [55] revealed that MACs alone correctly identified 74% of the subjects who later developed lung cancer. Furthermore, the presence of MACs was found to precede clinical diagnosis by 12 months or more. The advantage of this approach is that the method is not dependent on the presence of malignant cells in the sputum, although the presence of atypical or malignant cells can improve the sensitivity of detection to over 90%. [55]

DETECTION OF PERIPHERAL LUNG CANCER

On a spiral chest CT, lesions as small as 1 mm can be seen. Despite this sensitivity, preinvasive lung cancers in the central airways are usually not detectable because these early lesions are only a few cell layers thick. [56,57] Chest CT however, may be better for the detection of tumors in the *peripheral* airways. Although spiral CT is several times more sensitive than standard chest x-ray,[58] lesions smaller than 10 mm that are discovered by this means present a diagnostic challenge. In one of the largest studies using CT detection of early lesions, [35,59] 7% of patients found to have abnormal CTs required further investigations such as thin-section CT, and 13% required biannual follow-up examinations. Lung biopsy procedures such as bronchoscopy, CT-guided fine-needle aspiration biopsy, or video-assisted thoracoscopy was performed in only 3% of the subjects for tissue diagnosis. Of those that had a lung biopsy procedure, approximately 10% turned out to have a nonmalignant lesion. The use of molecular markers or MAC in exfoliated sputum cells to improve the diagnostic accuracy of chest CT needs to be investigated further. Newer studies incorporating helical CT are discussed in Chapter 22.

FLUORESCENCE BRONCHOSCOPY FOR LOCALIZATION OF EARLY LUNG CANCER

Only 30% to 40% of carcinoma *in situ* are visible to an experienced endoscopist on conventional white-light bronchoscopy. [57] A new development in bronchoscopic localization of intraepithelial neoplastic lesion is fluorescence bronchoscopy. [60] When the bronchial surface is illuminated by light, the light can be reflected, back-scattered, absorbed, or induce tissue fluorescence. Conventional white-light bronchoscopy makes use of the first three optical phenomena. The tissue autofluorescence is not visible because the intensity is very low and overwhelmed by the background illuminating light. However, with suitable instrumentation, the tissue autofluorescence can be made visible to enhance our ability to localize areas of intraepithelial neoplasia in the tracheal bronchial tree.

When the bronchial surface is illuminated by violet or blue light (400 to 440 nm) normal tissues have significantly higher fluorescence intensity compare to dysplastic lesions or carcinoma *in situ,* especially in the green region of the emission spectrum. [61] There are several reasons for the decrease in autofluorescence in precancerous and cancerous tissues. [62,63] The major portion of the fluorescence signal comes from the submucosa. A decrease in the extracellular matrix in the submucosa, such as from the secretion of cancerous tissues[64] will result in a decrease in the amount of fluorophores or the quantum yield of these molecules. Recently it was observed that the microvascular density is increased in dysplastic lesions and *in situ* carcinoma.[65] Due to the increased absorption of the blue light and the fluorescent light by blood, the fluorescence intensity of these lesions is decreased. A third reason for the decrease in autofluorescence in dysplastic tissues and carcinoma *in situ* is the increase in thickness of the epithelial layer. [63] This thickening impedes transmission of the blue light to the submucosa and the fluorescent light from the submucosa to the bronchial surface. These effects are particularly pertinent to the green region of the autofluorescence spectra because the absorption characteristics of bronchial tissue and blood favor the absorption of green light. These differences in the autofluorescence property of normal, preneoplastic, and neoplastic tissues were used in the development of the lung imaging fluorescence endoscopy (LIFE) device for the detection and localization of intraepithelial neoplasia.[66,67] The procedure is part of a standard fiber-optic bronchoscopy, except that the illuminating light is white, not blue, and a special camera is used. The fluorescence examination adds an average of ten minutes to the diagnostic bronchoscopic procedure under a local anesthetic.

Worldwide experience, including a recently completed multicenter trial in the United States and Canada, showed that the addition of the LIFE-Lung examination to conventional white-light bronchoscopy improved the sensitivity of detecting intraepithelial neoplastic lesions by severalfold. [68,69,70,71 and 72] (LIFE bronchoscopy is discussed further in Chapter 24).

NUCLEAR MORPHOMETRY OF BRONCHIAL BIOPSIES

A problem that is common to all early detection and chemoprevention programs is how to diagnose intraepithelial (preinvasive) neoplasia accurately and reproducibly. For example, a review of over 700 bronchial biopsies obtained in a multicenter early-detection clinical trial [72] by two experienced reference pathologists showed little disagreement in the interpretation of normal biopsies and invasive cancer but considerable disagreement about the preinvasive lesions. The classification by pathologists from different institutions agreed with those by the reference pathologists in only 34.8% of the biopsies. [73]

The morphological criteria for the histopathology of intraepithelial neoplasia of the bronchus developed several decades ago [4,74,75] have not been critically examined, particularly in terms of reproducibility of the diagnosis and, more important, as a grading system that would reflect the biological behavior of these lesions. Recently, the Armed Forces Institute of Pathology in the United States pioneered an effort to define preinvasive lesions to be included in the new World Health Organization

(WHO) classification.[76] However, the current histopathology classification does not lend itself to quantitative analysis readily.

In an attempt to overcome the problems of intra- and interobserver variation in the grading of intraepithelial neoplastic lesions, computer-assisted image analysis has been used to quantitate the morphometric changes in tissue sections.[77] Quantitative nuclear morphometry is performed in normal and invasive cancer biopsies in order to generate a morphometric index which separates these two groups. This index was tested on 377 bronchial biopsies (Figure 23.1). This test set confirms the wide variation in the diagnosis of preinvasive lesions using conventional histopathology criteria. However, using quantitative nuclear morphometry, a morphometric index of 7.5 was found to separate the dysplasia groups from the carcinoma *in situ* and the invasive cancer group. An index of 2.66 was found to separate the biopsies that were graded as normal, hyperplasia, or metaplasia from the dysplasia biopsies. This method is highly reproducible (Figure 23.1). A change in the absolute morphometric index of three or more represents a significant change. These results suggest that quantitative morphometric measurements may provide a better method to grade intraepithelial neoplastic lesions objectively.

OVERVIEW OF MOLECULAR ABNORMALITIES IN LUNG CANCER

Several cytogenetic, allelotyping, and comparative genomic hybridization (CGH) studies have revealed that multiple genetic changes (estimated to be between 10 and 20) are found in clinically evident lung cancers and involve known and putative recessive oncogenes as well as several dominant oncogenes. [7]

Dominant Oncogenes

Examples of abnormal dominant oncogenes in lung cancer are the *ras* family members (K-*ras,* H-*ras* and N-*ras*) (see also Chapter 4), the *myc* family members (C-*myc,* N-*myc,* and L-*myc*) (see also Chapter 5), and the *HER-2/neu* gene. *ras* mutations occur in approximately 20% of NSCLC, mainly in adenocarcinomas (90% involving K-*ras* gene at codon 12), while *ras* mutations have not been detected in any SCLC tumor or cell line.[7,78] Another example of a dominant oncogene in lung cancer would be overexpression of the *myc* family of genes, which occurs in nearly all SCLCs and in many NSCLCs.[79,80 and 81] Recent CGH studies have shown that lung cancer cell lines and tumor tissues demonstrate increased copy numbers consistent with amplification of underlying dominant oncogenes at several chromosomal regions, including 1p, 1q, 2p, 3q, 5q, 11q, 16p, 17q, 19q, and Xq.[82,83,84,85 and 86] Some of these regions, like 1p32 (L-*myc*), 2p25 (N-*myc*), and 8q24 (C-*myc*), contain known dominant oncogenes, while in others, the genes need to be identified.

Recessive Oncogenes

The list of recessive oncogenes that are involved in lung cancer is likely to include as many as ten to 15 known and putative genes. [7] These include changes in *TP53* (17p13), *RE* (13q14), *CDKN2* (9p21), and new candidate recessive oncogenes in the short arms of chromosome 3 (3p) at 3p12 (*DUTT1* gene),[87] 3p14.2 (*FHIT* gene),[88,89] 3p21 (*BAP-1* gene), and 3p25 regions. [7] Recessive oncogenes are believed to be inactivated via a two-step process involving both alleles. Knudson has proposed that the first "hit" is frequently a point mutation, while the second allele is subsequently inactivated via a chromosomal deletion, translocation, or other event such as methylation.[90] Two key examples in lung cancer are the *TP53* and the *RE* genes. Mutations of *TP53* gene are very common in lung cancer, occurring in over 90% of SCLCs and approximately 50% of NSCLCs.[7] There is evidence that *TP53* gene mutations occur in association with specific carcinogen exposure and that specific carcinogens predispose to specific mutations. Of interest, a coincidental mutational hotspot at the *TP53* gene has been found between invasive lung carcinomas and adduct hotspots caused by benzo(a)pyrene metabolites derived from cigarette smoke.[91] Another well-documented genetic change that occurs frequently in lung cancer is that of the *RE* gene. In more than 80% of SCLCs and some 20% to 30% of NSCLCs the protein has been mutated, so it cannot fulfill its normal cell cycle regulatory function.[92,93 and 94]

Many recessive oncogenes remain to be identified, although in most instances their chromosomal locations are known from cytogenetic and molecular analysis. Loss of heterozygosity analysis (LOH) using polymorphic microsatellite markers is frequently used to identify allelic losses at specific chromosomal regions, suggesting the involvement of other tumor-suppressor genes in lung cancer pathogenesis (see also Chapter 28).[95] The chromosomal regions include 1q, 2q, 5q, 6p, 6q, 8p, 8q, 9q, 10q, 11p, 11q, 14q, 17q, 18q, and 22q.[95,96,97,98,99,100,101,102 and 103] Although several of these chromosomal arms contain known or candidate tumor-suppressor genes (such as MCC and APC at 5q21, TSCI at 9q34, WT1 at 11q13, DCC at 18q221, and NF2 at 22q12), these genes are not known to be mutated in lung cancer. Recently, two new candidate tumor-suppressor genes called PTEN/MMAC1[104] and PPP2R1B,[105] located at 10q23 and 11q22–24 respectively, have demonstrated frequent somatic alterations in lung cancer.[105,106]

Tumor-Type-Specific Genetic Changes Are Found in Lung Cancers

Studies of large numbers of lung cancers have demonstrated different patterns of involvement between the two major groups of lung carcinomas (SCLC and NSCLC)[95] and between the three major histologic types of lung carcinomas (SCLC, squamous cell carcinomas, and adenocarcinomas) (Wistuba et al., unpublished data).[98,107] Thus genetic abnormalities in lung cancer can be classified into two groups; those that are common to all lung cancers and those that are associated with a specific histologic type of lung cancer. *RE* mutations are usually limited to SCLCs, *CDKN2* mutations to NSCLCs, and *RAS* mutations to adenocarcinomas. Our published[95,107] and unpublished results of allelotyping lung cancer cell lines and microdissected invasive primary tumors indicate that SCLCs demonstrate more frequent losses at 4p, 4q, 5q21 (APC-MCC region), 10q, and 13q14 (*RE*), while losses at 9p21 and 8p21–23 are more frequent in NSCLCs. Of interest, is that we have found different patterns of allelic loss involving the two major types of NSCLC (squamous cell and adenocarcinoma), with higher incidences of deletions at 17p13 (*TP53*), 13q14 (*RE*), 9p21 (*CDKN2*), 8p21–23, and several 3p regions in squamous cell carcinomas. These results suggest that more genetic changes accumulate during tumorigenesis in squamous cell carcinomas than in adenocarcinomas. These differences may be related to differences in tumorigenic mechanisms, such as etiologic factors (for instance, type and extent of smoking exposure), operating via separate pathways. In fact, different patterns of allelic losses [96] and *TP53* gene mutations have been reported in lung carcinomas arising in nonsmokers versus smokers. [108]

PRENEOPLASIA AND THE DEVELOPMENT OF LUNG CANCER

Lung cancers are believed to arise after a series of progressive pathological changes (preneoplastic or precursor lesions) in the respiratory mucosa. [4] While the sequential preneoplastic changes have been defined for centrally arising squamous carcinomas, [4] they have been poorly documented for large cell carcinomas, adenocarcinomas, and SCLCs.[3]

Mucosal changes in the large airways that may precede or accompany invasive squamous cell carcinoma include hyperplasia (basal cell hyperplasia and goblet cell hyperplasia), squamous metaplasia, squamous dysplasia, and carcinoma *in situ* (Figure 23.2).[4] Because all forms of lung cancers are strongly smoking-associated, the sequential preneoplastic changes associated with squamous carcinomas may also be present in adenocarcinomas and SCLCs. Hyperplasia of the bronchial

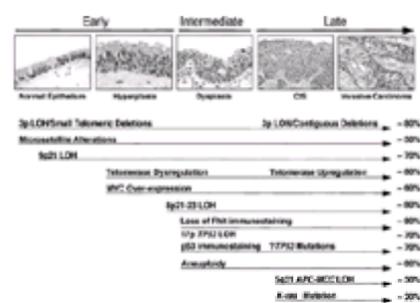
epithelium and squamous metaplasia are extremely common reactive findings and occur in response to cigarette smoking [6,109] as well with a variety of other stimuli, such as chronic infection, asthma, and so on. These changes are reversible and are not, in the strict sense, truly premalignant. Squamous dysplasia and carcinoma *in situ* are the changes most frequently associated with the development of squamous cell lung carcinomas. [5] Because dysplasia and carcinoma *in situ* are seldom visible to the naked eye, their reported frequencies may be underestimated.


FIGURE 23.2. Sequential histologic and molecular changes during the multistage pathogenesis of lung cancer. Molecular changes occurring during lung cancer pathogenesis may commence early (normal or slightly abnormal epithelium), at an intermediate (dysplasia) stage, or relatively late (carcinoma *in situ,* CIS, or invasive carcinoma).

Adenocarcinomas may be accompanied by changes, including atypical adenomatous hyperplasia (AAH), [110] in peripheral airway cells, although the malignant potential of these lesions has not been demonstrated. However, lesions with AAH features are frequently detected accompanying adenocarcinomas, especially when a bronchioloalveolar carcinomatous pattern is seen at the edge of less differentiated adenocarcinomas. [110,111] The concept of the adenoma-carcinoma sequence as it applies to AAH and adenocarcinoma of the lung suggests there is a continuum from AAH to peripherally arising adenocarcinomas.

Bronchiolar neuroendocrine cell hyperplasia represents a proliferation of neuroendocrine cells in and around small airways. [112] Because of their association with peripheral carcinoid tumors, it has been suggested that they are precursors to the carcinoid tumors. [112] While no specific preneoplastic changes have been described for SCLC, smoking-related changes, including squamous dysplasia and carcinoma *in situ,* may be found in association with these tumors.[113]

Currently available information suggests that lung preneoplastic lesions are frequently extensive and multifocal throughout the lung, indicating a field effect ("field cancerization") by which much of the respiratory epithelium has been mutagenized, presumably from exposure to carcinogens. [114] Thus lung carcinomas may occur anywhere in the vast and anatomically complicated respiratory tree, including the peripheral lung, and second tumors are relatively frequent after one upper aerodigestive tract carcinoma.[115]

GENETIC ABNORMALITIES DURING THE MULTISTAGE DEVELOPMENT OF LUNG CANCER

Although our knowledge of the molecular events in invasive lung cancer is relatively extensive, until recently we knew little about the sequence of events in preneoplastic lesions. A few studies have provided suggestions that molecular lesions can be identified at early stages of the pathogenesis of lung cancer.[40,116,117,118,119,120,121 and 122] *MYC* and *RAS* upregulation, cyclin D1 expression, *p53* immunostaining, and DNA aneuploidy have been detected in dysplastic epithelium adjacent to invasive lung carcinomas.[121,123,124,125,126,127,128 and 129] *KRAS* mutations have been also detected in atypical adenomatous hyperplasia,[130] which may be a potential precursor lesion of adenocarcinoma. *TP53* gene abnormalities (including mutations, deletions and overexpression) have been demonstrated in nonmalignant epithelium of lung specimens resected for lung cancer. [120,121] They also occur in the histologically normal and abnormal epithelium of smokers. [46,47] Recently, Franklin and colleagues described an identical *p53* gene mutation widely dispersed in normal and preneoplastic epithelium of a smoker without lung cancer.[131]

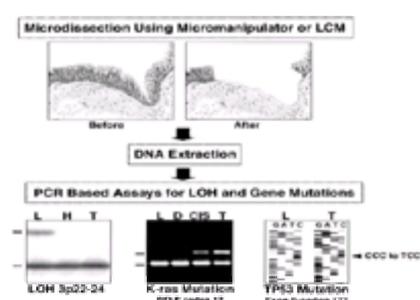
To further understand the sequential molecular changes involved in lung cancer pathogenesis, we have developed a scheme to search systematically for mutations in preneoplastic lesions and normal epithelium using archival paraffin-embedded materials (Figure 23.3).[132] Microsections from lung cancer resections and bronchoscopic biopsies containing preneoplastic lesions and normal respiratory epithelium are examined for the presence of genetic changes. Using a precise microdissection technique (micromanipulator or laser capture microdissection) [116,133] (see also Chapter 27) under direct microscopic observation, a variable number of cells from these areas are precisely isolated along with invasive primary tumor and stromal lymphocytes (as a source of normal constitutional DNA). Using PCR-based techniques, these different specimens are examined for point mutations and allelic losses at chromosomal regions frequently mutated or deleted in clinically evident lung carcinomas.


FIGURE 23.3. Schema outlining procedures for investigating molecular lesions in preinvasive lesions and invasive cancers of the respiratory tract. **Top:** representative example of microdissection of hyperplastic lesion. **Bottom:** molecular analyses of microdissected invasive carcinoma (T) and preneoplastic lesion (H). Normal lymphocytes (L) are used as source of constitutional DNA. Representatives examples of loss of heterozygosity (LOH) (**left**); designed restriction fragment length polymorphism for K-*ras* mutation analysis at codon 12 (**center**); and sequencing of *TP53* gene showing mutation at exon 5, codon 177 (**right**).

MUTATIONS FOLLOW A SEQUENCE

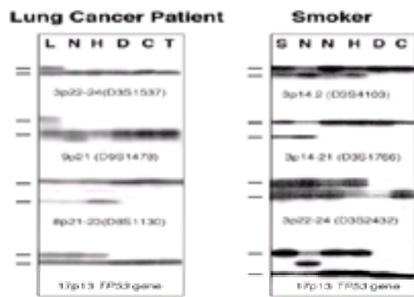
Our data have demonstrated that in lung cancer the developmental sequence of molecular changes is not random (Figure 23.2), with LOH at one or more 3p regions (especially telomeric regions 3p21, 3p22–24, and 3p25) and 9p21, and to a lesser extent at 8p21–23, 13q14 (*RE*), and 17p13 (*TP53*), being detected frequently very early in pathogenesis in histologically normal epithelium (Figure 23.4).[134] In contrast, LOH at 5q21 (APC-MCC region) and K-*ras* mutations were detected only at the carcinoma *in situ* stage, and *TP53* mutations appear at variable times. Detailed examination of all our material suggests that the order of events (allelic losses) is usually either 3p®9p®8p or 3p®8p®9p deletions followed by *TP53* deletions. In early lesions (normal epithelium to metaplasia), the 3p losses are small and multifocal, commencing at the distal half of the chromosomal arm. [134] In later lesions (carcinoma *in situ* and invasive cancers), all or almost the entire chromosome is lost.


FIGURE 23.4. Representative autoradiographs of microsatellite analyses for loss of heterozygosity (LOH) and microsatellite alterations (MAs) at four chromosomal regions of a lung squamous cell carcinoma case and its corresponding bronchial histologically normal epithelium and preneoplastic lesions (**left**), and biopsy specimens representing a constellation of normal and premalignant areas from four smoker subjects. *L* and *S,* lymphocytes (as source of constitutional DNA); *N,* histologically normal epithelium; *H,* hyperplasia; *D,* dysplasia; *C,* carcinoma *in situ;* and *T,* invasive carcinoma.

Recent attention has focused on the *FHIT* gene at 3p14.2, a candidate tumor-suppressor gene for lung and other cancers, which spans FRA3B, the most common of the aphidocolin-inducible fragile sites (see also Chapter 8).[89,135,136] We speculated that breaks at FRA3B destabilize the entire short arm of chromosome 3, leading to multiple deletions and loss of the entire arm. However, our data indicated that allelic losses at other more telomeric 3p regions (3p21, 3p22–24, and 3p25) appeared at earlier morphological stages than losses within and around the *FHIT* gene.[134] This is in agreement with the recently published findings of loss of the Fhit protein expression (as demonstrated by immunostaining) from the dysplasia stage.[137]

Our data also indicate that different patterns of sequential deletions are detected in the pathogenesis of the major histologic types of lung cancers. Overall, more cumulative and earlier allelic loss at 9p21, 17p (*TP53*), 13q14 (*RB*), and at different 3p regions are found in centrally arising SCLCs and squamous cell carcinomas than in peripheral adenocarcinomas (Wistuba et al., in preparation).

ACCUMULATION OF GENETIC CHANGES IN THE DEVELOPMENT OF LUNG CANCER

The development of epithelial cancers requires multiple mutations, [138] the stepwise accumulation of which may represent a mutator phenotype.[139,140] Thus it is possible that those preneoplastic lesions that have accumulated multiple mutations are at higher risk for progression to invasive cancer. Of interest is that using a panel of microsatellite markers targeting chromosomal regions frequently deleted in invasive lung carcinomas, we have detected similar incidences of LOH between histologically normal epithelium and slightly abnormal epithelial changes (hyperplasia and squamous metaplasia) accompanying lung carcinomas, [134] indicating that the latter foci may represent reactive foci and are not at higher risk for progression to invasive carcinomas. However, high-grade dysplasias and carcinoma *in situ* accompanying invasive squamous cell lung carcinomas demonstrated a significant increase of total number of allelic losses, [134] suggesting that the accumulation of mutations correlates with the morphologic changes and may lead to development of invasive carcinomas (sequential theory of lung cancer development). In particular, the allelic loss patterns of carcinoma *in situ* lesions were identical or nearly identical to those present in the corresponding invasive carcinomas. [134] As some specimens of histologically normal or mildly abnormal epithelia, especially accompanying SCLCs, have demonstrated a very high incidence of allelic loss, equal or greater than that present in some high-grade dysplasia and carcinoma *in situ* samples, we suggest that, in some cases, especially SCLC, carcinoma *in situ* and invasive carcinoma may arise directly from histologically normal or from mildly abnormal epithelium without passing through the entire histologic sequence (parallel theory of cancer development).

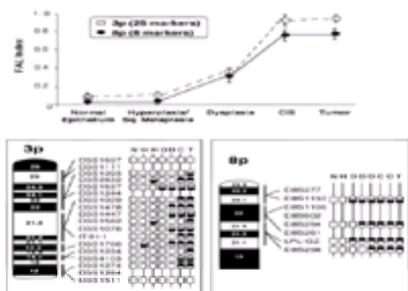
Of great interest is that our detailed allelotyping analyses of chromosome arms 3p [134] and 8p[141] during the multistage development of squamous cell carcinomas have demonstrated that the extent of the deletions increases with progressive histologic changes (Figure 23.5). Thus in all squamous cell invasive carcinomas and carcinoma *in situ* lesions, most of the 3p and 8p arms were deleted, and in all patients the extent of the losses in carcinoma *in situ* and invasive carcinomas was greater that the 3p and 8p allelic losses found in the corresponding normal and preneoplastic foci.


FIGURE 23.5. Top: loss of heterozygosity (LOH) expressed in terms of the means of Fractional Allelic Loss (FAL) Index (i.e., fraction of microsatellite loci showing LOH in each epithelial sample) of chromosome 3p and 8p21–23 regions. **Bottom:** examples of allelotyping analysis at the chromosome 3p and 8p21–23 regions of normal epithelium and precursor lesions accompanying resected squamous cell carcinomas using eighteen 3p (**left**) and eight 8p (**right**) microsatellite markers.   , No LOH; ▄, lower allele lost; ▆ upper allele lost. They demonstrate progression in the size of the chromosome 3p and 8p deletions in the invasive carcinomas and their accompanying normal epithelium and precursor lesions. Notice that the same allele is lost in preneoplastic, noninvasive, and invasive lesions. **N,** histologically normal epithelium; **H,** hyperplasia; **D,** dysplasia; **CIS,** carcinoma *in situ;* and **T,** invasive carcinoma.

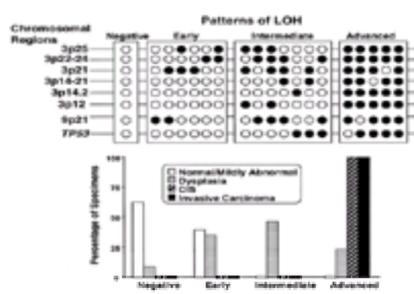
Analysis of our data indicated that four patterns of allelic loss could be identified (negative; early; intermediate; advanced) in histologically normal epithelium and precursor lesions accompanying squamous cell lung carcinomas (Figure 23.6).[134] Histologically normal or mildly abnormal foci had a negative pattern (no allelic loss) or early pattern of loss, while all foci of carcinoma *in situ* and invasive tumor had an advanced pattern. However, dysplasias demonstrated the entire spectrum of allelic loss patterns and were the only histologic category having the intermediate pattern. These findings suggest that dysplasias represent a heterogeneous group of lesions at a molecular level. As only a fraction (10% of moderate dysplasia, 40% to 80% of severe dysplasias) are believed to progress to cancer, [30,142,143] molecular studies may aid in the identification of the subgroups of smokers with dysplasia who are at the greater risk of progression to lung cancer.


FIGURE 23.6. **Top:** patterns of loss of heterozygosity (LOH) observed in 12 lung squamous cell carcinomas and their corresponding histologically normal epithelium, preneoplasias, and carcinoma *in situ* lesions. ¡, No LOH; I, LOH. **Bottom:** relationship between histologic categories and patterns of LOH. Only dysplasias demonstrated the entire spectrum of patterns and were the only histologic category having the intermediate patterns.

Our findings demonstrate that despite similar smoking exposures, different pathways and genotypic changes are involved in the pathogenesis of the three major histologic types of lung carcinoma, namely SCLC, squamous cell carcinoma and adenocarcinoma. It appears that more allelic deletions accumulate during the tumorigenesis in centrally arising SCLCs and squamous cell carcinomas than in peripherally located adenocarcinomas. The findings of different patterns of LOH in the three major types of lung cancers are consistent with their different clinical characteristics.

LUNG CANCER PRECURSOR LESIONS REPRESENT OUTGROWTH OF MULTIPLE CLONES

Molecular analyses suggested that precursor lesions represented outgrowths of multiple clones, a finding compatible with the field effect theory. [144] Our recent analysis of 58 normal and noninvasive foci accompanying 12 invasive squamous cell carcinomas having one or more molecular abnormalities, indicated that 30 (52%) probably arose as independent clonal events, while 28 (48%) were potentially of the same clonal origin as the corresponding tumor. If the potentially clonal lesions are truly clonal in origin, subclonal drift [145] must have occurred as an early and widespread event, as only four foci (6%) (from two subjects) of 62 lesions had identical patterns of mutations. However, we cannot exclude the possibility that some other earlier molecular event (for which we did not examine) occurred in a single cell whose progeny were dispersed widely throughout the bronchial epithelium and subsequently gave rise to all of the foci we examined. If this event occurred, then subclonal drift[145] must have occurred as an early and widespread event. In addition, our recent genetic analysis of the histologically normal or mildly abnormal (hyperplasia and squamous metaplasia) bronchial epithelium adjacent to invasive lung cancers indicated that multiple small clones of cells (up to 400) having identical pattern of LOH are frequently detected (Park et al., in preparation). These findings suggest that histologically normal bronchial epithelium and lung cancer precursor lesions having smoking-related genetic damage represent outgrowths of multiple small clones of genetically abnormal cells, a finding compatible with the field effect theory.

SIMILAR GENETIC CHANGES ARE DETECTED IN INVASIVE LUNG CANCERS AND THEIR PRECURSOR LESIONS

We and others have noted that the specific parental allelics lost in chromosomal deletions present in preneoplastic lesions and their accompanying cancers are similar (Figure 23.4 and Figure 23.5).[116,117,121,134] We have referred to this phenomenon as allele-specific mutations (ASM). Others have noted ASM in advanced bronchial (severe dysplasias) lesions, [121] which are believed to be the immediate precursors of invasive cancers and which were located adjacent to centrally arising squamous cell carcinomas. We have detected ASMs in preneoplastic lesions located in all regions of the respiratory epithelium (bronchi, bronchioles, and alveoli) involving several differentiated cell types (mucous cells, metaplastic squamous cells, Clara cells, and type II alveolar pneumocytes). [116,117,134] In addition, we have detected this phenomenon in a wide spectrum of preneoplastic lesions, including hyperplasia, squamous metaplasia, dysplasia, and carcinoma *in situ*.[116,117,134] Of great interest is that we have detected ASMs in smoking-related damaged epithelium, even in biopsy samples obtained from different lungs. [47]

What is the mechanism by which ASMs arise? We have proposed two possibilities. First, the lesions could be clonal in origin: a single cell or small clone of cells develops loss or point mutations at a specific allele at one or more loci, migrates widely throughout the respiratory epithelium of both lungs, and eventually gives rise to a tumor. For the reasons stated above, this is highly unlikely. This possibility would require an unexpected fluidity of the bronchial epithelial cells or at least of those cells in which initial genetic changes arise. The second possibility is that in individuals, one of any pair of alleles has a greater tendency to be lost, perhaps as a result of some form of genomic imprinting or the presence of fragile sites, resulting in an inherited propensity to lose one of the two alleles.

However, some studies support alternative theories by which ASMs may arise. Multicentric development of lesions is supported by a study by Sozzi and associates of five patients with multiple lesions in their bronchial tree. The authors detected losses of different alleles of chromosome 3p regions and different mutations in the *TP53* and K-*ras* genes between invasive lung tumors and accompanying preneoplastic lesions. [119] In addition, as previously mentioned, Franklin and colleagues studied the entire bronchial tree of a smoker dying without lung carcinoma. [131] A single, identical point mutation, G-to-T transversion in codon 245, was identified in the bronchial epithelium from seven of ten widely dispersed bilateral epithelial tissues. The morphology of the involved sites varied from normal to squamous metaplasia to moderate dysplasia. These findings support the alternative theory that a single clone of cells can become widely dispersed throughout the respiratory epithelium. Our recent findings of the ASM phenomenon in lung cancer precursor lesions that appeared to be of independent clonal origin suggests that ASM occurs via an alternative mechanism.[134] Whatever its mechanism, ASM is likely to be a phenomenon of major biological significance.

GENOMIC INSTABILITY IN THE PATHOGENESIS OF LUNG CANCER

In addition to the specific genetic changes discussed above, other evidence indicates that genomic instability occurs in lung cancer and its preneoplastic lesions. This evidence includes our finding of widespread aneuploidy throughout the respiratory epithelium of lung cancer patients. [126] Another molecular change frequently present in a wide variety of cancer types is microsatellite alterations (MAs) (also known as genomic alterations).

In hereditary nonpolyposis colon cancer (HNPCC), inherited defects in DNA mismatch repair enzymes result in large-scale genetic instability, with the formation of a ladderlike pattern replacing the normal allele pattern. [146] Another form of microsatellite change, where only a single band of altered size is found, has been described in many forms of sporadic cancers, including lung cancer at frequencies of 0% to 45%). [147,148,149 and 150] We and others refer to these changes as microsatellite alterations.[134,147,151,152 and 153] While the relationship of MAs to defects in the DNA repair mechanism has not been established, MAs probably represent evidence of some form of genomic instability.[154] Because they arise in noncoding regions of the genome, they are not in the direct pathway of tumorigenesis. MAs represent changes in the size of polymorphic microsatellite markers compared to the normal germ line in individual persons. Nevertheless, MAs are attractive candidates for the early molecular detection of lung and other cancers. [147,152,155] Our data demonstrated the presence of MAs in a subset (50%) of lung carcinomas,[134,153] as well as in their accompanying preneoplastic lesions and normal appearing epithelium. [134] Unlike allelic losses, the frequency of MAs did not increase with more advanced histologic changes. Of interest is that MAs, when present in nonmalignant foci, were always of a different size from those present in the corresponding invasive tumors. These findings indicate either that the preneoplastic lesions are not clonally related to the corresponding tumors or that the MAs arose during subclonal evolution. The finding of MAs in exfoliated cells present in sputum [152] from cancer patients suggest that they may be markers for lung cancer or for subjects at increased risk of developing lung cancer.

TELOMERASE DYSREGULATION IN THE PATHOGENESIS OF LUNG CANCER

Telomerase is currently recognized as a nearly ubiquitous tumor marker. Telomerase is a specialized ribonucleoprotein polymerase that adds TTAGGG repeats at the ends of vertebrate chromosomal DNA called telomeres. [156] Human telomeres undergo progressive shortening with cell division through replication-dependent sequence loss at DNA termini.[157] Telomerase is thought to compensate for the loss of telomeric repeats and is associated with the acquisition of the immortal phenotype. A variety of immortal cell lines, malignant tumors, and testicular cells have been found specifically to express telomerase activity, [158,159,160 and 161] whereas most normal somatic cells do not express this activity.[162,163] Most NSCLC and SCLC tumors are telomerase-positive (see also Chapter 9).[159]

Telomerase has been detected in preinvasive lesions in a number of tumor systems, including lung. [164] In the lung, low levels of telomerase activity have been detected in hyperplasia, dysplasia, and carcinoma *in situ,* compared to invasive cancer. While weak telomerase RNA expression is detected in basal layers of normal and hyperplastic epithelium from lung cancer patients, dysregulation of telomerase expression increases with tumor progression, with moderate to strong expression throughout the multilayered epithelium in metaplasia, dysplasia, and carcinoma *in situ*.[164] Of interest, foci of intense telomerase upregulation are seen in carcinoma *in situ* lesions in the vicinity of the invasive component of lung cancers. In addition, similar patterns of dysregulation of telomerase expression with increasing histologic grade have also been noted in bronchoscopic biopsies of smoking-damaged epithelium of current and former smokers, suggesting that telomerase could be also used as a potential marker for risk assessment (Rahti et al, in preparation).

MOLECULAR MARKERS FOR EARLY DETECTION OF LUNG CANCER

Mutant K-*ras* and *TP53* genes have been detected in the sputum some months prior to diagnosis of cancer,[40] and K-*ras* mutations have been detected in bronchoalveolar lavage fluids from patients with adenocarcinoma (56%) but not in patients with squamous cell carcinoma or with other diagnosis.[44] Recently, Ahrendt and co-workers[165] have reported that molecular assays could identify cancer cells in bronchoalveolar lavage fluid from patients with early-stage lung cancers. Using PCR-based assays for K-*ras* and *TP53* gene mutations, CpG-island methylation of the *CDKN2* gene, and microsatellite instability, they were able to detect identical molecular abnormalities in the bronchoalveolar fluid and corresponding tumors in 23 of 43 (53%) of the cases. These findings suggest that molecular strategies may detect the presence of neoplastic cells in the central and peripheral airways in patients with early-stage lung carcinomas.

SMOKING-DAMAGED BRONCHIAL EPITHELIUM

It has been established that advanced lung preneoplastic changes occur far more frequently in smokers than in nonsmokers and increase in frequency with amount of smoking, adjusted by age.[5,6] Although morphologic recovery occurs after smoking cessation,[5,166] elevated lung cancer risk persists.[167] Changes in bronchial epithelium, including metaplasia and dysplasia, have been utilized as surrogate end points for chemoprevention studies.[168,169] Risk factors that identify normal and premalignant bronchial tissue at risk for malignant progression need to be better defined. However, most of the molecular studies of lung preneoplastic lesions have been performed in material from small numbers of subjects with concurrent lung cancer, and only scant information is available about molecular changes in the respiratory epithelium of smokers without cancer.[46,47,121,122]

Two independent studies describing genetic changes in bronchial biopsy specimens from current and former smokers have been reported.[46,47] Mao and colleagues[46] described their analyses of the LOH and histologic abnormalities present in biopsies from 54 current and former smokers and nine nonsmokers. In each of the current and former smokers, bronchoscopy biopsies from six preselected sites demonstrated histologic changes, including squamous metaplasia and dysplasia. In addition, LOH using three microsatellite markers at chromosomal region 3p14, 9p21, and 17p13 (*TP53*) were used as surrogate markers of tumor-suppressor gene inactivation in the tissues. Although some differences were seen when the specimens of current smokers were compared with those of former smokers, allelic losses were surprisingly common in the nonmalignant lung epithelial tissue of both groups. Of the 76% of smokers who demonstrated allelic loss at one or more of the three chromosomal regions analyzed, deletions were detected in 75%, 57%, and 18% of the subjects at 3p14, 9p21, and 17p13 (*TP53*), respectively.

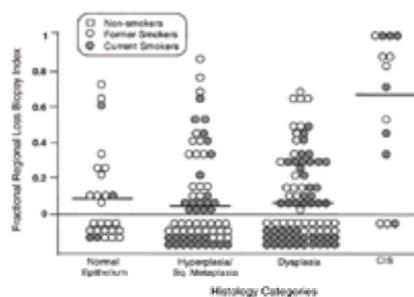
Our results,[47] which are in agreement with the above-described findings, also indicate that genetic changes similar to those found in lung cancers can be detected in nonmalignant bronchial epithelium from current and former smokers and may persist for many years after smoking cessation. In our study, multiple biopsy specimens were obtained from 18 current smokers, 24 former smokers, and 21 nonsmokers. PCR-based assays for fifteen polymorphic microsatellite DNA markers were used to examine eight chromosomal regions (3p14.2 at the *FHIT* gene, 3p14–21, 3p21, 3p22–24, 5q21 at the APC-MCC region, 9p21, 13q14 at *RB,* and 17p13 at *TP53*) for genetic changes (LOH and MAs). High frequencies of LOH and MAs were observed in biopsies from current and former smokers and no significant differences were observed between the two groups. Of great interest is that no molecular changes were detected in nonsmoking subjects. Among individuals who smoked, 86% demonstrated LOH in one or more biopsies and 24% showed LOH in all biopsies. Somewhat surprisingly, about half of the histologically normal epithelium showed LOH; however, the frequency of LOH and the severity of histologic changes did not correspond until the carcinoma *in situ* stage (Figure 23.7). A subset of the biopsies from smokers with either normal or preneoplastic histology showed LOH at multiple chromosomal sites, a phenomenon frequently observed in carcinoma *in situ* and invasive cancer. Our findings suggest that carcinoma *in situ* and other histologically normal and abnormal foci having multiple regions of allelic loss are at increased risk for progressing to invasive cancer. As has been observed in epithelial foci accompanying invasive lung carcinoma,[134] allelic losses on chromosome 3p and 9p were more frequent than deletions in chromosomes 5q21, 17p13 (*TP53* gene), and 13q14 (*RE* gene).


FIGURE 23.7. Loss of heterozygosity (LOH) in individual biopsy specimens obtained from current and former smokers according to smoking status and histologic categories. LOH is expressed in terms of the fractional regional loss index by biopsy specimen (i.e., the fraction of chromosome regions showing LOH in each biopsy specimen, range 0 to 1). Horizontal bars indicate the mean for each histologic category.

All these findings suggest the hypothesis that identifying biopsies with extensive or certain patterns of allelic loss may provide new methods for assessing the risk in smokers of developing invasive lung cancer and for monitoring response to chemoprevention. As with all diagnostic tests, this concept will need to be validated in clinical trials.

THE USE OF LIGHT FOR THE EARLY DETECTION AND TREATMENT OF LUNG CANCER

HARVEY I. PASS
DENIS A. CORTESE
ERIC S. EDELL
STEPHEN LAM
HARUBUMI KATO

Light has been the subject of medical treatments since the ancient Greeks.[1] Raab first described the phenomenon in 1900 by documenting the death of paramecia with acridine and light,[2] and Tappeiner coined the term "photodynamic therapy" (PDT).[3] Skin cancer was treated with eosin and light in 1903,[3] Hausman found in 1910 that *porphyrins,* naturally occurring iron-or magnesium-free respiratory pigments present in the protoplasm of plant and animal cells, promoted photochemically induced cell death.[4] In the late 1950s, hematoporphyrin derivative (HpD) was prepared by Lipson and Baldes[5] based on a personal recommendation by Dr. Samuel Schwartz that the tumor-localizing properties of crude hematoporphyrin may be improved by using the supernatant that results from the preparation of hematoporphyrin. HpD concentrated in squamous cell carcinomas and adenocarcinomas,[6] and Lipson was the first to report that endoscopic fluorescence could be observed in patients with endobronchial tumors using HPD as the sensitizer.[7] In 1966, Lipson and colleagues were also the first to report a therapeutic response in a patient with recurrent breast cancer using multiple sessions of PDT with HpD.[8] The tumor was not eradicated, but objective evidence indicated a cytotoxic effect.

Ensuing studies by Dougherty and others explored the use of PDT in the treatment of various animal and human malignancies,[9,10,11,12,13,14] and[15] and in 1982, Hayata was the first to use HpD to treat endobronchial tumors using a fiberoptic bronchoscope.[16]

PHOTODYNAMIC THERAPY: BASIC PRINCIPLES

PDT is based on the photochemical reaction that occurs when a sensitizing drug is exposed to light in the presence of oxygen. Absorbed light energy converts the sensitizer to an excited state, which in turn interacts with molecular oxygen to form singlet oxygen or oxygen-free radicals. Singlet oxygen is a powerful oxidizing agent that damages plasma membranes and other subcellular organelle (Figure 24.1). PDT is of no value unless all three components of a photochemical reaction—light, oxygen, and sensitizer—are simultaneously present when treating disease.

FIGURE 24.1. Energy states and interaction of photosensitizing agents. Before exposure to light, a molecule of sensitizer is in the ground state. When a photon of the appropriate wavelength is absorbed, an electron is raised to a higher energy level. The molecule then rearranges to a stable excited state. At this point, there are two possibilities. The excited molecule can fluoresce, emitting a photon and dropping back to the ground state, or an intersystem crossing can change the spin of an electron. During the lifetime of the resulting triplet state, absorbed energy can be passed along to molecular oxygen in tissue, activating the oxygen molecule to the singlet state. Singlet oxygen can oxidize any oxidizable biologic molecule with which it is in contact. (From Kessel D. Photodynamic therapy. *Sci Med* 1998;5:46, with permission.) (See Color Figure 24.1.)

Components of Photodynamic Therapy

Light

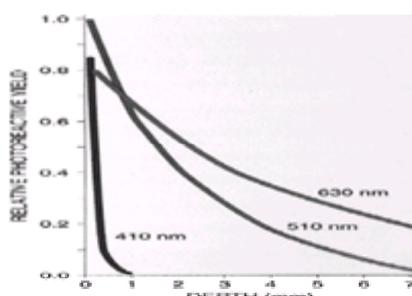
Light is high-velocity energy transmitted in electromagnetic waves, which displays particulate characteristics by delivering energy in discrete measurable units called photons. The absorption of photons by a photosensitizer is the first reaction of a photodynamic system, and photochemical reactions can occur only if light is absorbed.[17] The *action spectrum* of a sensitizer defines the rate of a photochemical reaction when the sensitizer is stimulated by a given wavelength of light and usually corresponds to the absorption spectrum of the sensitizer. The *absorption spectrum* of a sensitizer determines the wavelength of light, measured in nanometers (nm), which is used to achieve the maximum photodynamic effect, and generally falls within the visible light spectrum between ultraviolet (UV) and infrared (IR) light. *Porphyrin sensitizers* have an intense absorption band at the UV end of the spectrum called the Soret band,[17] which maximally excites a sensitizer. The energy of light is *inversely related to its wavelength,* with lower wavelengths delivering more energy. However, shorter wavelengths are attenuated by hemoglobin as they pass through tissue, and the depth of tissue penetration by light is also inversely proportional to wavelength (Figure 24.2). Therefore, light at the *infrared* end of the spectrum penetrates much deeper into a tumor than *UV* light. Although stimulation of a porphyrin sensitizer with blue-violet light may result in more energy production, the tissue penetration of less than 1 mm is inadequate to treat malignancy. Therefore, PDT with porphyrin-based sensitizers is usually performed with 630 nm red light or higher wavelengths, which give tissue penetration of at least 10 mm.


FIGURE 24.2. The relative phototoxic effect of a sensitizer is a function of irradiation wavelength. Longer wavelengths penetrate tissue to a greater depth. (From Kessel D. Photodynamic therapy. *Sci Med* 1998;5:46, with permission.) (See Color Figure 24.2.)

The *total energy delivered* depends on the *duration* of light delivery and the *dose-rate* of light. The dose-rate, or power density, of light is usually expressed in mW/cm.[2] *In vitro,* higher dose-rate delivery to tumor cells at a given total energy results in greater PDT cytotoxicity.[18] The relative inefficiency of PDT at lower dose-rates may result from the ability of tumor cells to repair sublethal damage or buffer toxic oxidative stresses.

Light Delivery

The appropriate method of light delivery for PDT depends on the experimental or clinical situation. An x-ray view box covered with a ruby red acetate filter can be used for *in vitro* PDT experiments,[18] whereas an argon-pumped dye laser exciting either Kiton Red or rhodamine B producing up to 15 watts of red light or a less expensive diode laser or LED array will be used as a typical light source for PDT in the clinical environment. The light source is coupled to one or more fiberoptic cables used to convey light with minimal energy loss to the treatment field. The end of the cable is fitted with a tip designed to disperse light in a pattern appropriate for the clinical application. A cleaved tip projects light forward for treating flat surfaces, and a bulbous tip projects light in an isotropic spherical distribution for illuminating large cavities. A tip specially coated with cylindrical scattering material disperses light perpendicular to the axis of the fiber. This type of tip can be used for intraluminal applications, such as endobronchial PDT.

Oxygen

Although a few photodynamic systems are oxygen-independent, molecular oxygen is required to achieve cytotoxicity with porphyrin-based PDT.[19,20] PDT kills cells by selective destruction of essential molecules through photooxidative reactions via the production of singlet oxygen (see following sections). Several studies corroborate the importance of oxygen to photochemical systems. Using sodium dithionate to remove oxygen from the system, Lee showed that tumor cytotoxicity correlates directly with oxygen concentration.[20] Mitchell used a customized glass Petri system to demonstrate that cells treated in hypoxic conditions are extremely resistant to PDT.[19] Similar studies have been performed *in vivo.* Gomer found that restricting the blood flow to the hind limb of albino mice inhibited the photosensitizing effects of porphyrin PDT.[21] Although attempts to directly quantitate singlet oxygen *in vivo* have been unsuccessful,[22,23] investigators have used transcutaneous oxygen-detecting electrodes to measure microcirculatory damage after PDT.[24,25] This technology may one day be used to determine the clinical effectiveness of photochemical systems.

Photosensitizers

Maximal quantum yield of a photochemical system occurs with light wavelengths that correspond to the sensitizer's Soret band, which for porphyrin sensitizers such as Photofrin II (PII) is in the 400 nm region. The absorption spectra for PII is characterized by this absorption peak at 405 nm that stimulates *fluorescence,* enabling the chemical to act as a tumor marker. To balance maximal quantum yield with deepest tissue penetration, PDT is performed at higher wavelengths (more than 590 nm) corresponding to minor peaks further along the absorption spectrum of the sensitizer. Under these conditions, PDT sensitizers generate singlet oxygen with quantum yield of 0.2 to 0.6 with tissue penetration up to 10 mm.

Uptake and retention of the porphyrin compounds has been studied in murine models. Levels are highest in the liver, adrenal glands, and urinary bladder, with lower levels declining in the following order: pancreas, kidney, spleen, stomach, bone, lung, heart, muscle, and brain.[26,27,28] In these animal models, intravenous injections result in higher tumor concentration than is obtained by intraperitoneal injections. In addition, these chemicals are heavily concentrated in phagocytic cells, lymphoid tissue, and regenerating tissues such as biopsy sites. Importantly, PII accumulates and is retained by vascular endothelium through the mechanism of endocytosis.[29] In addition, PII appears to be associated predominantly with low-density lipoproteins, but some components are also bound to albumin.[30,31] Structural proteins, such as collagen, also may have an effect on the distribution of PII. Ultimately, the intracellular accumulation of these photosensitizers is the result of a complex relation of all of these factors, which include both vascular and cellular components. The serum half-life in humans is 20 to 30 hours, but the photosensitizing component is retained in the skin, at low levels, for up to 6 weeks. Other photosensitizing agents under investigation include chlorins, phthalocyanines, tetraphenylporphine sulfate, the texaphyrins, benzoporphyrins, and cationic sensitizers, such as Rhodamine-123. Some of these second-generation sensitizers have an increased quantum yield at longer wavelengths and have much shorter periods for skin photosensitivity.[32]

Biophysical Basis for Photodynamic Therapy

Selective Retention of Photosensitizers

Selective retention of photosensitizer by malignant tissue is the central and most intriguing component of PDT. In 1948, Figge and colleagues[33] showed that crude hematoporphyrin was retained in tumors. In the 1960s, Lipson and colleagues[5,8,34,35] showed that HpD was retained by tumor tissue to a greater extent than crude hematoporphyrin. The measurements were based on fluorescence yield when tumor-containing HpD was irradiated with light of the appropriate wavelength. Since then, several investigators have demonstrated that both HpD and PII have a greater retention in tumor than in normal tissues by measuring fluorescence as a function of time after injection of the photosensitizer. However, the ratios of fluorescence within solid tumors versus various normal tissues varies widely. Overall, it appears that the tumor/normal tissue ratio is greater than 1 for PII 24 to 48 hours after intravenous injection in humans. However, some of the earliest work by Lipson and colleagues[34] showed that malignant tissue fluoresced within three hours of intravenous injection, well before normal tissue began to fluoresce. In fact, the three-hour time interval has been used for the detection and localization of lung cancer.[36,37] For purposes of cancer therapy, a time interval of between 24 and 72 hours is commonly used.

The reasons that tumor tissues selectively retain PII are unknown. There are several theories, but the explanation is still a subject of ongoing research. *In vitro* cell culture studies show that both normal and cancerous cells concentrate the photosensitizers and are killed by PDT. Transformed and nontransformed cells have identical PDT survival curves.[38] Perry and colleagues[39] found no differences in survival for thoracic cancer cells compared to normal lung fibroblasts during *in vitro* PDT experiments. This information would indicate that cancer and transformed cells do not selectively increase or retain photosensitizers in the *in vitro* situation. However, differences in *in vivo* retention of sensitizer between tumor and normal tissues have been demonstrated on numerous occasions. Selective retention within tumor tissue and cells may be related *in vivo* to a low pH found in tumors. Sensitizers are more soluble at low pH and, therefore, may be selectively retained. Neoplastic angiogenesis results in blood vessels with incomplete endothelium, which may have an increased permeability to porphyrin macromolecules. Increased concentrations of porphyrin have been noted along the vascular stroma of solid tumor tissue. The lack of normal lymphatic drainage could increase sensitizer concentration within tumor interstitial spaces. Proliferating cancer cells have higher levels of low-density lipoprotein receptors, which may facilitate the endocytosis of low-density lipoprotein-bound sensitizer components relative to normal tissues. Finally, macrophages and tumor-associated monocytes reconcentrate and retain photosensitizers within tumors. Intravenous injection of these photosensitizers leads to a higher uptake than that obtainable by intraperitoneal injection when tumors are located outside the abdominal cavity. On the other hand, Tochner and colleagues[40] found that intraperitoneal injection of HpD in an ovarian cancer ascites model resulted in higher therapeutic effect because there was no dependence on vascular delivery. Some components of photosensitizers, such as monomers, bind to albumin and globulin and are found to localize in the stroma of tumor tissue, whereas other components bind to lipoproteins. Albumin and high-density lipoprotein-bound components are not transported into the cell directly but are deposited on the cell membrane. Low-density lipoprotein-bound sensitizers appear to be transported into the cytoplasm quickly and accumulate in the lysosomal compartments.

Effects of Photodynamic Therapy in Vitro Cytotoxicity

A wide variety of cell lines show sensitivity to PDT.[2,39,41 and 49] Comparison of different lung cancer histologies reveals few real differences in the characteristics that influence PDT cytotoxicity,[39] and the survival curves for a variety of thoracic malignancies, including adenocarcinoma, squamous cell carcinoma, large cell carcinoma, small cell carcinoma, and mesothelioma, are quite similar.[39]

The most impressive effect seen *in vitro* soon after cells are treated with PDT is damage to the plasma membrane.[49,59] Membranes are the primary targets of PDT,

partly because of the water-lipid partition coefficient of PII. Porphyrins bind initially to the plasma membrane, followed by migration to intracellular regions. In only a few hours after PDT, normal cellular movement stops and large membrane blebs form on the cell surface.[51] These large balloonlike structures, often as large as the cell itself, indicate severe membrane damage and are the first visible sign of photooxidation in the cell. [52],[53] This disruption of the integrity of the plasma membrane results in leakage of intracellular contents out of the cell. [54],[55] After membrane blebbing occurs, cell division comes to a halt and cell lysis begins. As alluded to earlier, PDT damages other membranes in addition to the plasma membrane. Because of these effects on cell membranes, PDT may injure the nucleus, lysosomes, Golgi apparatus, endoplasmic reticulum, and mitochondria. Mitochondrial damage after PDT may involve inhibition of oxidative phosphorylation and electron transport with subsequent reduction in ATP production.[56],[57] One cellular target that appears to escape serious damage by PDT is nuclear DNA. Although PDT can induce DNA strand breaks, this reaction does not lead to cell death. PDT does not appear to be mutagenic. [58]

Resistance of cells to PDT may one day determine the clinical efficacy of PDT in cancer treatment. Several investigators have begun to examine the role of the multidrug resistance (MDR) phenotype in PDT resistance. In MDR associated with chemotherapy, a membrane pump actively transports drug out of the cell. Conceivably, this mechanism could transport photosensitizer out of the cell, thereby reducing the photodynamic effect at treatment. This process could become a particular problem when treating patients with combined chemotherapy-photodynamic therapy regimens. Similarly, patients who have previously failed chemotherapy might likewise develop cross-resistance to PDT. Studies comparing the sensitivities of cells that express MDR versus wild-type cells from the same cell line revealed no cross-resistance to PDT.[59] Using cells made resistant to PDT by repeated exposure to PDT, investigators have shown that this resistance is not caused by decreased intracellular levels of sensitizer, the mechanism of action of classic MDR. [60],[61] MDR may be associated with cross-resistance to PDT depending on the sensitizer used.[62] A more plausible explanation for PDT resistance involves the mechanism of action of PDT. Buffering of toxic oxygen radicals by free-radical scavengers could explain the induced resistance of cells to PDT. Studies by Ryter have shown that PDT can enhance transcription and translation of oxidative stress genes.[83] Many studies involving chemotherapy resistance have shown that free-radical buffering enzymes such as glutathione can protect cells against drugs that produce free radicals. Although no one knows how cells become resistant to PDT, mechanisms other than MDR are probably involved.

In Vivo *Cytotoxicity*

Flank tumors in mice regress completely by 2 days after treatment with PDT. Soon after PDT, blood flow stasis occurs in both arterioles and venules. [64],[65] A vascular effect is one of the main components of tumor destruction with many of the presently investigated sensitizers. Vasoconstriction of arterioles, thrombosis of venules, and edema of perivascular tissues accompany the reduction in blood flow. Ben Hur suggests that PDT induces the endothelium to release vasoconstrictors and clotting factors, which cause local coagulation and stasis. [29] This reaction begins a cascade in which local blood flow stasis and endothelial damage retain red blood cells in the treatment field longer, thereby exposing them to higher doses of PDT. Subsequent damage results in red cell agglutination, which further exacerbates the low-flow state. Neutrophils and platelets bind to damaged endothelium with release of prostaglandins and arichidonates, which also act on the microvasculature. Other factors such as von Willebrands factor, platelet-activating factor, and nitric oxide may also be involved. The photodynamic process itself may lead to alterations in tumor blood flow.[66] A positive feedback cycle of oxygen depletion by the photooxidative system, acidosis, increased intratumoral swelling with decreased blood flow, and worsening hypoxia could account for static blood flow followed by tumor necrosis. Nuclear magnetic resonance studies examining tumor energy substrate levels during and after PDT indicate that ATP levels are virtually undetectable by 2 to 4 hours [67],[68] and [69] and appear to decline in a dose-dependent fashion. [70]

The antitumor effect of PDT may be partly caused by modulation of the immune system. Various studies have documented the release of vasoactive agents such as prostaglandins, thromboxane, and histamine from murine peritoneal macrophages and mast cells. [71],[72] and [73] These mediators could contribute to the vascular and metabolic effects of PDT in mediating tumor necrosis. PDT also induces macrophages to release tumor necrosis factor (TNF) in a dose-dependent fashion [74] and conversely, PDT may exert a net inhibitory effect on the immune system. Contact hypersensitivity remains suppressed 2 weeks after PDT, [75] and this effect is adoptively transferred by macrophages.[76] PDT also inhibits the mitogen-stimulated division of human peripheral blood lymphocytes. [77] Therefore, although PDT can induce nonspecific immune cells to produce substances such as TNF, prostaglandins, thromboxanes, and histamines that could either directly or indirectly mediate tumor necrosis, the overall effect of PDT on the immune system is unknown.

Increased specificity and sensitivity of photodynamic therapy resulting in an improved tumor/normal treatment index may result by treating tumors with antibody-sensitizer conjugates. A photosensitizing agent could be combined with a monoclonal antibody with idiotypic specificity for a known tumor. Theoretically, this treatment would increase the specificity of the sensitizer for the tumor, resulting in increased tumor cytoxicity with reduced side effects in normal tissues. Mew demonstrated this concept by showing that monoclonal antibody-photosensitizer conjugates effectively mediated tumor regression *in vivc* and kills a variety of cell lines *in vitro*.[78],[79] PDT using monoclonal antibody-sensitizer conjugates appears to result in greater tumor specificity, longer remission, and less normal tissue toxicity in murine subcutaneous tumors.[80] Similar constructs have demonstrated selective killing of human ovarian carcinoma and melanoma cells [81],[82] but work in this area remains highly investigational.

CLINICAL APPLICATIONS OF PDT IN THORACIC CANCER

Detection of *In Situ* Lung Cancer

Localization of lung cancer at the *in situ* or microinvasive stage can generally be accomplished by direct visual examination of the tracheobronchial tree using the flexible fiberoptic bronchoscope. The procedure is usually done with only topical anesthesia. Occasionally a cancer is difficult to see at its earliest stage, and, therefore, a more detailed and careful endoscopic examination using general anesthesia is necessary. General anesthesia permits the endoscopist time to inspect the mucosal surfaces for signs of early cancer, such as thickening, irregularity, erythema, and pallor.

Rarely, these routine bronchoscopy procedures fail to confirm the localization of an early-stage squamous cell carcinoma, either *in situ* or early microinvasive, because they are difficult to see. To facilitate the localization of these tumors, various bronchoscopic instruments have been devised during the past 15 years. The earliest instruments used laser-induced fluorescence from PII or HpD-containing tumor. Historically, low-dose PII techniques were described, and most recently, a new technique relying on tissue autofluorescence without the use of a sensitizer has revolutionized this discipline.

In the early 1980s, special instrumentation systems were developed to be used with the photosensitizers PII and HpD. These systems were necessary to overcome technical problems of fluorescence detection and now serve as an historical footnote. Nevertheless, the principles guiding their development remain intact. It was known that chemical fluorescence from small superficial tumors could not be seen with the conventional flexible fiber bronchoscope because of the combination of a low concentration of chemical in the tumor, a low fluorescence yield, and high optical losses in the fiberoptic bundles. Each of the detection systems developed relied on amplification of a fluorescence signal, which was then displayed as either an audio signal or visual image. With the use of an image-intensifying, wavelength-detecting device, wavelengths of approximately 405 nM (blue-violet) were used to selectively produce characteristic reddish fluorescence from tissue containing significant amounts of the sensitizer. Either the endoscopist could image the areas of red fluorescence as distinct from the green autofluoresence, or a ratio for different areas of red to green fluorescence were calculated with the areas of highest ratios indicating the likely sites of tumor. The overall experience using these detection systems demonstrated that HpD and PII may be helpful in localizing tumors that are both roentgenographically and bronchoscopically occult. The detection of fluorescence, however, was not specific for carcinoma. Areas of cellular atypia ranging from moderate to marked were also sites of low-level fluorescence. Therefore, the bronchoscopist must biopsy all suspicious areas of fluorescence in order to confirm the localization of a cancer to a specific site.

The original Tokyo Medical College system, the University of California system, and the Mayo system were each successful in detecting the fluorescence from cancer foci; however, distinguishing between tumor fluorescence and nonspecific autofluorescence of the normal bronchial mucosa was difficult. A Japanese system actually displayed the wave pattern of light detected and distinguished the fluorescence between HpD and that of autofluorescence. The endoscopist alternated between white light for visual confirmation and a Krypton or excimer dye laser system to excite the sensitizer. Other systems described by Lam, Profio, and Balchum were variations on the theme of a "ratioing fluorometer probe." The probe consisted of two fiberoptics of a two-channel bronchoscope: one for conducting the exciting violet light to the tip of the scope and the other to transmit the emitted light. The emitted light was split by a beam splitter through a red filter and a green filter. An analog divider ratioed the red fluorescence to the green autofluorescent intensity. An audio signal pitch in this system was proportional to the red/green ratio. By using this probe, there was decreased dependence on distance or angle from the end of the scope to the lesion. Bronchi with increased red/green ratios were presumed to be involved with tumor. After taking readings throughout the bronchial tree, all surfaces were next inspected under white light and fluorescence bronchoscopy to correlate positive localized fluorescence with increased ratios. This system was similar to another system developed by Laser Therapeutics, which allowed video images of the red and green fluorescence.

The most striking disadvantage of this technique was the requirement that patients receiving the sensitizer avoid sunlight for 4 to 6 weeks to avoid severe skin burn. Lam subsequently reported the use of low-dose (0.25 mg/kg) PII instead of the usual 2 to 3 mg/kg dose in conjunction with a ratioing fluorometer probe. The red/green

ratios of known normal areas was .9 to 1.8, whereas the red/green ratios in biopsy-proven tumor areas was 4.8 (3.0 to 9.5). Increasing the dose of PII by 700% (to 2 mg/kgm) increased the ratio in the tumor area by only 64% (to 7.9). Moreover, skin photosensitivity testing after the .25 mg/km PII but prior to the additional 1.75 mg/gm revealed no skin reaction to as high a dose as 30 J/cm^2, a light dose commonly used to eradicate recurrent skin malignancies (after giving the patient the usual 2 mg/kg dose of sensitizer). Lam's involvement with autofluorescence (see following sections) relegated these observations to historical interest.

The original system used by the Mayo Clinic used violet excitation alternating with white light to illuminate the areas in question. The resulting fluorescence of the tissue caused by excitation of the previously given sensitizer was detected by a fiberoptic guide linked to a photomultiplier. The fluorescence signal was amplified as an audio signal whose intensity was proportional to the amount of fluorescence detected. The system allowed the endoscopist to view the field using the white light and to guide brushings and biopsies by the intensity of the "fluorescence pitch."

Success in detecting these occult neoplasms was reported from all centers involved in their development. Nevertheless, the systems lacked specificity because areas of cellular atypia or moderate or marked degrees would also concentrate sensitizer and have low levels of fluorescence. Moreover, the improvement in the signal-to-noise ratio in small, thin preinvasive lesion was only 1.5 to 2-fold at best, [83] and false positives in areas of inflammation or metaplasia were on the order of 27% to 50%.

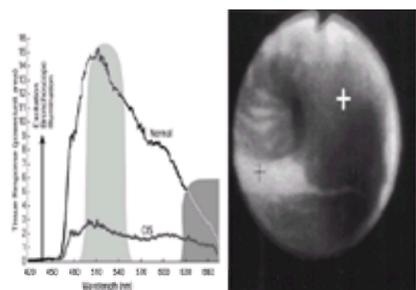
At the same time that Lam and colleagues were working on low-dose fluorescence detection with the sensitive-ratio fluorometric measurements, they extended their observations to the possibility of using *in vivc* spectroscopy. The guiding principle was to explore the use of autofluorescence spectra of normal tissue and carcinoma *in situ* to facilitate localizing cancer in the bronchial tree. A difference exists between the *in vivc* autofluorescence spectra of normal bronchial mucosa and carcinoma *in situ* induced by a helium-cadmium laser at 442 nm (Figure 24.3). Fluorescence spectroscopy for normal tissue characteristically has a high intensity at 500 nm, which gradually decreases at longer wavelengths. On the other hand, *in situ* carcinoma demonstrates a relatively low intensity of fluorescence at 500 nm and remains low throughout the longer wavelengths. The investigators developed a device called the lung imaging fluorescence endoscope (LIFE). LIFE consists of a helium cadmium laser as a light source (442nm), two image-intensified CCD cameras with green (520 nm) and red (more than 630 nm) filters, respectively, a computer with an imaging board, and a color video monitor. Two images at different wavelengths are simultaneously captured in precise registration by the imaging board. The images are then combined and processed by an imaging board using a specially designed algorithm that allows normal tissue to be clearly distinguished from malignant tissue when displayed as a pseudocolor image on the video monitor. The computed image is displayed in real time. The detection of lung tumors is based on the observation that tumors *in vivc* have considerably lower autofluorescence in the green range than normal tissue, whereas emission in the red range is similar. The computed image is independent of the distance between the bronchoscope tip and the bronchial wall. The processed image can be displayed as desired (e.g., normal tissue as green and tumor as brown or brownish red) allowing guided biopsy under direct vision for pathologic confirmation.


FIGURE 24.3. **A:** Autofluorescence spectra of normal bronchial mucosa and squamous cell carcinoma *in situ.* **B:** Reddish brown fluorescence of carcinoma *in situ* distinguished from the green fluorescence of normal bronchial mucosa. (Courtesy of XILLIX Technologies Corporation, British Columbia, Canada.) (See Color Figure 24.3B.)

This technique was first described by Profio and colleagues [84] in 1984 for use with sensitizer-induced fluorescence and is now used to differentiate cancer from normal tissue based on tissue autofluorescence. The system was tested *in vivc* by using it to detect squamous cell cancers and precancerous lesion in a hamster cheek pouch mode,[85] and spectral differences between precancerous, cancerous, and normal bronchial mucosa in 32 patients were documented using the LIFE system. [86] These observations were validated[87] in 82 volunteers recruited from occupational groups at risk for development of lung cancer. The premise was that one could determine differences in tissue autofluorescence between normal and malignant bronchial tissues in order to improve the sensitivity of standard fiberoptic bronchoscopy in detecting dysplasic and carcinoma *in situ* (CIS). This study consisted of 25 nonsmokers, 40 ex-smokers, and 17 current smokers with mean ages of 52, 55, and 49 years, respectively. One or more sites of moderate or severe dysplasia were found in 12% of the ex-smokers and current smokers but in none of the nonsmoker volunteers. CIS was found in two of the ex-smokers. The sensitivity of fluorescence bronchoscopy (86%) was found to be 50% better than that of conventional white light bronchoscopy (52%) in detecting dysplasia and CIS.

Most recently, a multicenter trial was performed to determine if autofluorescence bronchoscopy, when used as an adjunct to white light bronchoscopy, could improve the bronchoscopist's ability to locate and remove biopsy specimens from areas suspicious of intraepithelial neoplasia. [88] White light bronchoscopy was followed by fluorescence examination with the lung imaging device in 173 subjects known or suspected to have lung cancer. Biopsy specimens were taken from all areas suspicious of moderate dysplasia or worse on white light bronchoscopy or LIFE examination. In addition, random biopsy specimens were also taken from other parts of the bronchial tree. The relative sensitivity for the combination of white light and LIFE bronchoscopy compared to white light examination alone was 6.3 for intraepithelial neoplastic lesions and 2.71 when invasive carcinomas were also included. This translated to a 171% increase in sensitivity for the combination of white light and LIFE bronchoscopy over white light examination alone. The positive predictive value was 0.33 and 0.39 and the negative predictive value was 0.89 and 0.83, respectively, for the combination versus white light bronchoscopy alone. These studies led to FDA approval of this device for the detection of preneoplastic lesions of the airway.

This technology is an important addition to the armamentarium for early detection and prevention of lung cancer; however, its limitations must be noted. These include: (a) limitation to the detection of high-grade preinvasive lesions such as moderate/severe dysplasia and carcinoma *in situ.* Autofluorescence is not useful in the detection of metaplasia or mild dysplasia; (b) pathologic interpretation must be consistent with classification of airway lesions; (c) a learning curve probably exists with the instrument so that subjective interpretation of fluorescence images becomes uniformly objective; and (d) the population studied influences the results of the examination for former smokers and has a lower prevalence of mild dysplasia and metaplasia compared to current smokers, whereas high-grade lesions persist after smoking stops. Moreover, women have a lower prevalence of high-grade lesions than men (13% versus 31%). [89]

The early detection of lung cancer with PDT will probably be reserved for those difficult clinical situations such as high-risk asymptomatic patients with positive sputum cytologies but negative radiologic evaluations and negative bronchoscopy. Other potential beneficiaries of these techniques might be patients with positive margins for carcinoma *in situ* after resection for bronchial carcinoma. These techniques are limited, however, in specificity because cellular atypia and metaplasia retain sensitizer and fluoresce on stimulation. Sensitivity is also restricted in that current systems require bronchoscopes too large to examine small diameter airways. Continued investigation into digital imaging combined with fluorescence detection and miniaturization of equipment may one day obviate these current weaknesses.

Photodynamic Therapy as a Treatment for Lung Cancer

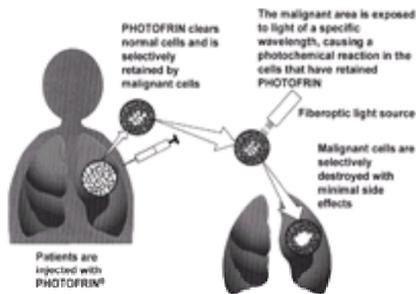
Bronchoscopic PDT has been an investigational treatment for lung cancer since 1980. The technique is relatively simple and can be performed under local or general anesthesia using a standard flexible bronchoscope (Figure 24.4). The treatment does not result in the loss of lung tissue and can be used safely in patients with complicating medical illnesses such as heart disease and chronic obstructive lung disease. Empirical observations have shown that light doses as high as 600 J/cm and intravenous Photofrin doses of 2 mg/kg were not associated with any serious complications. *In vivc* animal experiments investigating the effect of PDT on a normal trachea have shown no apparent damage to the cartilage and suggest that PDT is unlikely to cause perforation or collapse of normal major airways. [90] Bronchoscopic PDT is presently approved for use in the the palliation of symptoms caused by endobronchial disease in higher stage lung cancer, as well as for primary treatment of microinvasive lung cancer in nonsurgical candidates.


FIGURE 24.4. Schema of photodynamic therapy for bronchial lesions. See text for details. (Courtesy of Dr. Jeffrey Wiemann, Louisville, Kentucky.) (See Color Figure 24.4.)

Photodynamic Treatment of Early-Stage Lung Cancer

Several findings from the large-scale U.S. lung cancer screening projects indicate that a treatment modality such as PDT might be perfect for the treatment of early, superficial squamous cell cancers.[91] In patients with positive sputum cytologies and negative chest films, most lesions are confined to the bronchial wall with no extrabronchial involvement. The depth of these lesions, approximately 5 mm, corresponds to the tissue penetration of red light. These lesions detected by screening techniques tend to be centrally located squamous cell cancers. Because of their central location, major operations such as sleeve resection or even pneumonectomy are often required to manage early, noninvasive lesions. Photodynamic therapy possesses the ability to selectively treat large surface areas at risk without the problems associated with major resections that may not be curative. After an initial curative attempt, many patients, approximately 4% per year, will recur with second primary lesions, indicating the failure of localized surgery to cure a more generalized disease. If large-scale screening efforts are targeted to this high-risk population (i.e., patients who have had a previous curative stage I resection) localization of the endobronchial source of the abnormal sputums could be followed by PDT.

Other candidates for endobronchial PDT besides those found to have radiographically occult lung cancer would be those patients who refuse operative therapy or who are unable to have surgical resection because of high surgical risk limited pulmonary function, or multicentricity of lesions.

Several phase II clinical trials have examined the role of PDT in the treatment of early-stage lung bronchial cancer. Since 1980 at the Tokyo Medical College, 251 patients have had 297 lung cancers treated with photocynamic therapy. These data led to the approval of PDT for early-stage lung cancer in Japan in 1994, and have been updated since a previous report of the experience.[92] Ninety-five patients with 116 early cancers have been treated with endobronchial PDT. An argon laser coupled to a dye laser employing Rhodamine-B dye or an Excimer dye laser was used to generate 630-nm laser light. Endoscopic PDT was performed with topical anesthesia and intravenous sedation approximately 48 hours after an intravenous injection of 2 mg/kg of Photofrin II. A laser beam was transmitted through a fiber inserted through the instrument channel of a fiberoptic bronchoscope. The fiber tip was maintained 1 to 2 cm from the lesion, yielding a circular area of illumination estimated to be between 4 and 8 mm. Power output at the fiber tip was adjusted to range from 80 to 400mW when using the argon dye laser. When the Excimer laser was used, the frequency was set at 30 Hz with the energy adjusted to 4 mJ/pulse. Illumination time ranged from 10 to 40 minutes, giving energy densities of 100 to 800 J/cm^2. Tumor response to PDT was evaluated endoscopically, roentgenographically, cytologically, and histologically at periodic intervals after treatment. In resected specimens or at autopsy, the treated areas were examined macroscopically and histologically. After PDT complete remission, no evidence of tumor by any of the previously mentioned criteria was obtained in 77 patients (81%). Patients who ultimately had a complete remission often required an additional course of PDT to accomplish this outcome. The recurrence rate has been recorded as 16%. Complete remission was not obtained in the lesions that were anatomically difficult to photoradiate, in those lesions in which it was not possible to obtain an angle of irradiation of 90 degrees to the surface, or in lesions invading beyond the cartilage. Furuse reported similar results in 54 patients with 64 centrally located early-stage lung cancers. An 85% complete response rate was reported after a single session of PDT, and length of the longitudinal tumor was the only independent prognostic factor for a complete response.[93] In summarizing his experience with endobronchial PDT, McCaughan reported 16 patients with clinical stage I disease treated with PDT because they were ineligible for surgery. A remarkable estimated five-year survival of 93% was reported, but median time of follow-up was only 39 months for the 11 patients reported as still alive with no evidence of disease.[94]

The Mayo experience with PDT in patients with lung cancer has been slightly different than the Tokyo experience. However, the clinical observations are similar and complementary in nature. PDT at Mayo Clinic uses HpD rather than Photofrin. The laser technology is an argon pump dye laser using Rhodamine-B dye. The fiberoptics are the same. Photoradiation is usually delivered between 3 and 5 days (usually 3 days) after intravenous injection of 2.5 to 5 mg/kg of HpD. Laser power and total joules are similar to those described by the Tokyo group. Since 1980, more than 120 patients have been treated with this therapy at the Mayo Clinic. This experience includes a subset of 58 nonsurgical patients with an 84% complete response and fulfills the following criteria: (a) are roentgenographically occult, (b) are squamous cell carcinoma, (c) appear to be superficial mucosal tumors by bronchoscopic examination, and (d) are less than estimated 3 cm^2 in surface area. Nineteen patients (39%) have recurred after a single treatment, with a median time to tumor recurrence of 4.1 years. Eleven patients (22%) have recurred after a second treatment, and the median survival is 3.5 years (Edell, personal communication, 1999).

A comparison of the long-term results of surgery or PDT in patients who could have a potentially curative surgical resection has not been subjected to a randomized trial. In a preliminary study, however, 13 patients, with a total of 14 cancers, were considered surgical candidates and underwent PDT as an alternative to surgery.[95] The patients were treated with the understanding that if residual cancer was present after no more than two sessions of PDT, performed at three-month intervals, they would receive standard surgical therapy. In the group of 13 patients, 12 (92%) demonstrated a complete response, meaning that the carcinoma had disappeared bronchoscopically, by biopsy of the treated region, by brushings, and by washing cytology. Ten of the fourteen cancers (70%) demonstrated a complete response after the first photodynamic treatment. Three other cancers demonstrated a complete response after the second treatment. In total, 13 of the 14 cancers (93%) demonstrated a complete response after the two treatments. All 13 cancers were superficial and appeared to be spreading over the mucosa based on bronchoscopic examination. One cancer of the 14 (7%) failed to show a complete response. This cancer was a bulky, exfoliative lesion by bronchoscopic examination.

Of the 13 cancers that demonstrated a complete response, 3 (23%) recurred during the first 2 years of follow-up. Two of the cancers were then surgically resected. The third cancer, which initially demonstrated complete response after only one session of PDT, underwent a second PDT treatment and has not recurred since. Ten of the thirteen cancers that showed a complete response have not recurred for up to 5 years of follow-up. In total, 10 of the 13 patients (77%) were spared an operation. The three patients with persistent cancer underwent surgical resection, and in each case, the postsurgical stage for each cancer was T1, N0, M0.

These data from the Mayo Clinic have now been extended to 21 patients, of which 15 (71%) had a complete response after one PDT treatment. With a follow-up of 24 to 116 months (median, 72 months), 4 patients (19%) have recurred after their first PDT session.[109]

In September 1997, the Oncologic Drug Advisory Committee recommended approval of PDT for *microinvasive lung cancer* for nonsurgical candidates in the United States. This approval was based on the data from three open label studies involving a total of 102 patients receiving PDT for early-stage lung cancer. On review of the data, 24 of the 102 patients, by external review, were thought to be neither radiation nor surgical candidates. Analysis of the data with regard to histologic complete tumor response, time to recurrence, overall survival and disease-specific survival revealed striking similarities between the whole group and the subset, as well as when the data were compared to the previously mentioned Japanese and Mayo data. Complete response rate after one PDT course was 92% and 75%, recurrences were 46% and 44% at median times to recurrence of 2.7 and 2.8 years, and median survivals were 3.4 and 2.5 years, for the subset versus all patients, respectively (Quadralogics Technologies, personal communication, 1999).

The most common complication after PDT treatment of early lung cancer remains photosensitivity reactions (23%). Other mild adverse events include transient obstructive symptoms caused by exudate and edema formation related to the PDT inflammatory response. Dyspnea can be life-threatening in a minority (4%) of cases and is usually related to bilateral PDT treatments simultaneously. Frequent clean-up bronchoscopies with attention to debridement may be necessary.

Palliation of Endobronchial Obstruction

The most common use of PDT in the treatment of patients with lung cancer has been in the palliation of symptoms caused by endobronchial tumor[36] (Figure 24.5).

Multiple phase II studies documenting the safety and efficacy of PDT for relieving endobronchial obstruction have been performed. [96,97,98,99,100,101,102,103] and [104]

FIGURE 24.5. Photodynamic therapy for a patient with partial obstruction of the right mainstem bronchus. **A:** 90% obstructive non–small cell lung cancer 0.5 cm from the main carina. **B:** Laser fiber is positioned for interstitial treatment 48 hours after the patient received Photofrin II. **C:** Appearance of the lesion 48 hours after treatment before any debridement of the avascular base. **D:** Appearance of the lesion base after bronchoscopic debridement revealing the right upper lobe orifice to the right and the bronchus intermedius straight ahead. **E:** Appearance of the airway 2 months later. Only a superficial ulcer is present at the site of the original lesion **F:** Appearance of the airway 3 months after treatment. A histological complete response was documented. (See Color Figure 24.5.)

In attempting to summarize the overall experience in treating patients with obstructing carcinoma of the tracheobronchial tree, PDT appears to be most effective in the treatment of polypoid tumors. A poor response occurs with submucosal and peribronchial disease. [105,106] The median duration of complete response appears to be approximately 22 weeks if more than one-half of the airway obstruction is caused by a mucosal process. However, the median duration is only 7 weeks if the tumor is predominantly submucosal or peribronchial. In addition, lack of perfusion or reduced perfusion out of proportion to the reduction in ventilation is associated with peribronchial involvement and poor outcome. Extraluminal tumor compression on CT scan also indicates a poor response. [107,108] One of the largest and most representative series of patients who had PDT for obstructing airway cancers has been reported by McCaughan. [94] Patients were treated with Photofrin, 2 mg/kg administered intravenously 48 hours before surface irradiation, as well as implantation techniques using power densities chiefly at 400 mW/cm of fiber. Light doses were modified depending on the airway treated: 400 J/cm of fiber for trachea and main bronchi, 300 J/cm for lobar bronchi, and 200 J/cm for segmental bronchi. A total of 492 bronchoscopic sessions delivering the therapy to 673 airway sites with 1,128 treatments, were performed in 175 patients over a 14-year period. Aggressive clean-up bronchoscopies were performed on the first and third days after treatment, and repeat endoscopic evaluation was performed 1 month after the treatment. The indications for PDT use in this population include endobronchial obstruction, hemoptysis of a chronic and not massive nature, and treatment of bronchial stump recurrences. Although no intraoperative deaths occurred in McCaughan's series, eight patients died within the first 30 days, four from pulmonary hemorrhage. In fact, fatal massive hemoptysis (FMH) has been described in this treatment setting by several different investigators, and the rate of FMH is comparable to that seen with endobronchial brachytherapy and YAG laser therapy. It is generally agreed that in experienced hands, the FMH seen with PDT is probably caused by progression of disease.

FDA approval of endobronchial phototherapy for malignant disease came in 1999 after reviewing the results of a phase III trial comparing Photofrin PDT to YAG laser for the palliation of endobronchial lung cancer for 211 patients, of whom 75% had stage III–IV disease (Wiemann J, personal communication, 1999). Patients were randomized to receive either PDT or YAG. At month 1 or later after treatment, the objective tumor response rate was significantly higher with PDT (60%, 60/102) compared to Nd:YAG (41%, 45/109). Marked improvement ($\geq$2 grades) in dyspnea was observed in 23% (14/60) of PDT-treated patients with moderate to severe symptoms at baseline compared to 13% (9/68) of Nd:YAG-treated patients. Cough improved in 24% (15/63) of PDT-treated patients versus 8% (5/65) of patients who received Nd:YAG. Hemoptysis improved in 79% (19/24) of PDT-treated patients compared to 35% (11/31) of Nd:YAG-treated patients. Adverse events reported in patients receiving PDT (n = 99) were dyspnea (32%), hemoptysis (18%), bronchitis (11%), and photosensitivity reactions (20%). Patients receiving Nd:YAG (n = 99) reported dyspnea (17%), hemoptysis (12%), and bronchitis (3%). Life-threatening adverse effects including FMH and respiratory insufficiency were comparable in both populations. Early deaths and overall survival were similar. Based on these results, PDT with porfimer sodium was considered to be as effective as YAG for palliation of symptoms from obstructing endobronchial non–small cell lung cancer and in reduction of luminal obstruction. The PDT safety profile in this patient population was acceptable, and clinically important benefit was seen in approximately one-third of patients with moderate to severe symptoms at baseline.

CONCLUSIONS

The early detection of lung cancer using photodynamic techniques is evolving, and the LIFE scope has had FDA approval since the first edition of this book. The complementary nature of the LIFE scope and similar systems with PDT now add a powerful tool not only in the detection of lung cancer but also in defining airway carcinogenesis. More accurate means of biopsying and immortalizing bronchial cells reflective of airway events will eventually help in the definition of lung cancer biomarkers.

Photodynamic therapy for the treatment of lung cancer in various settings has been approved in France, the Netherlands, Japan, the United States, and the United Kingdom. The therapy is still in its infancy with regard to appropriate sensitizers and light delivery systems, and it is predicted that all components of the therapy will be more efficient and, in fact, less morbid in the future. The morbidity at the present time is limited to transient inflammatory events in the airway as well as photosensitivity of the skin. Fatal massive hemoptysis, although a rare associated event, must be carefully explained to the patient as a possibility. One can foresee a future in which new sensitizers will have better tumor-associated retention and localizing properties and will have skin photosensitivity measured in hours. Future sensitizers will be able to be activated at greater depths within tissue. Moreover, total outpatient treatment, with sensitizer and light delivery performed only hours apart, will probably be the norm within the next 5 years.

CHEMOPREVENTION: SCIENTIFIC RATIONALE AND CLINICAL STUDIES

ROY S. HERBST
FADLO R. KHURI
WAUN KI HONG

Lung cancer is among the most common malignancies in the world and the leading cause of cancer-related mortality. [1] Although the five-year survival rate for patients with lung cancer has improved significantly since the early 1970s, this disease has retained a high mortality rate, making all aspects of lung cancer research a priority for clinicians, researchers, and the public. Despite advances in standard therapies—surgery, radiotherapy, and chemotherapy—the five-year survival rate of patients with lung cancer remains approximately 14%. For many years the number one cancer killer in men, lung cancer has just recently (within the last five years) become the preeminent cause of cancer-related death in women. This is due to an increased incidence of smoking in women during the late sixties and early seventies. As detailed in Chapter 20, there is usually a 20-year lag between increases in smoking patterns and subsequent increases in lung cancer incidence. Most patients present with metastatic or locally advanced disease for which therapy has demonstrated limited benefit. Ongoing clinical trials continue to be the method by which new compounds and new combinations of chemotherapy and radiation treatments are evaluated; however, given the slow progress, there has been an increased focus on lung cancer prevention strategies.

Since 90% of lung cancers are tobacco-related, primary prevention of lung cancer by smoking cessation remains an important objective. However, given the rising trend in worldwide tobacco consumption and the fact that former smokers still have higher lung cancer risk than nonsmokers (more than 50% of lung cancer occurs in former smokers),[2] lung cancer will remain a formidable problem well into the next century. We now know from molecular studies that, even after the cessation of tobacco use, genetic scars and alterations persist. [3] Chemoprevention is defined by Michael A. Sporn as the use of specific natural or synthetic compounds to reverse, suppress, or prevent carcinogenic progression to invasive cancer. [4]

Chemoprevention using 13-cis-retinoic acid (13cRA) has been demonstrated to be effective in preventing second primary tumors of the head and neck, [5] and this pivotal study, albeit small, set the stage for numerous clinical trials to evaluate similar agents for their chemopreventive ability in a variety of solid tumors, including those of the breast, colon, rectum, cervix, prostate, bladder, head and neck, and, of course, lung. In this chapter, we will review chemopreventive strategies exclusively as they relate to the prevention of lung cancer and second primary tumors in lung cancer patients.

THE RELATIONSHIP OF LUNG CANCER AND SMOKING: PRIMARY PREVENTION

The relationship between lung cancer and smoking has been established in an increasingly compelling fashion over the last five decades, and few would question this association. The association between cigarette smoke and lung cancer was first observed and cited by Ochsner and DeBakey in their landmark treatise in 1942. [6] In the 1950s, two large, well-designed epidemiologic studies further established a strong link between smoking and lung cancer. [7,8 and 9] The importance, however, of the histologic changes that were observed in smokers with lung cancer was reported by Auerbach and colleagues. [10] This group sectioned the entire tracheobronchial trees of deceased smokers and of individuals in whom lung cancer had developed, reporting three major types of epithelial changes: an increase in hyperplasia, a primary loss of cilia, and the presence of atypical cells. Perhaps most striking was the finding of carcinoma *in situ;* lesions composed entirely of atypical cells without cilia, whose average thickness was five or more cell rows, were observed in 15% of the tissue sections from patients who died of lung cancer. Of note is that carcinoma *in situ* lesions were never found by Auerbach and his collaborators in the pathologic specimens of nonsmokers, and few were found in the bronchial trees of light smokers.[10] In addition, a dose-response effect was demonstrated, because the changes were observed in 4.3% of bronchial sections from patients who had smoked one to two packs of cigarettes per day and in 11.4% of the sections from those who smoked two or more packs of cigarettes per day. Others have subsequently established such findings in the bronchial tissue of passive smokers. [11]

Recent studies attribute approximately 87% of lung cancers to tobacco exposure. The relative risk for developing lung carcinoma in current smokers is 24-fold greater than that for people who have never smoked.[12] However, the relative lung carcinoma risk in all cohorts of former smokers, although lower than for current smokers, remains greater than for those who have never smoked.[12] This close correlation between smoking status and lung cancer resulted in the National Cancer Institute's Division of Cancer Prevention and Control's emphasis on instituting cancer prevention as the major strategy in the control of lung cancer. The result of these campaigns to educate the public about the hazards of cigarette smoking has been a substantial reduction in the percentages of adults who actively smoke in the United States.[13] A survey of data from 1965 through 1991 reveals that these and other campaigns have had a substantial impact. In fact, the most recent data available from 1998 reveal that 29.9% of adult men and 19% of adult women were estimated to be former smokers, representing a 77.2% decrease from 1965 in the percentage of Americans who actively smoke.[13] This change has been attributed both to smoking cessation (the rate of which has doubled over the last three to four decades) and a decrease in the number of people who actually commence smoking.

LUNG CANCER AND FORMER SMOKERS

With the decrease in smoking, it becomes even more imperative to develop strategies for at-risk former smokers. In the most recent estimate conducted in 1991, 43.5 million adults in the United States were estimated to be former smokers, of whom 15.3 million are 45 to 64 years old. Of this group, 10.9 million are above the age of 65.[13] Astonishingly, although smoking cessation has helped reduce the absolute number of smokers, as many as 48.5% of people who have ever smoked are now considered former smokers. While it is clear that the risk of developing lung cancer decreases in individuals who stop smoking, the magnitude of the problem in former smokers is great. Two surveys of patients with lung cancer performed recently at the University of Texas M. D. Anderson Cancer Center and the Brigham and Women's Hospital respectively [2,14] demonstrate that more than 50% of lung cancer cases seen at these centers occurred in former smokers. This clearly shows a population presenting a significant public health problem for the United States, where there appears to be an increasing number of former smokers who will remain at substantial lifetime risk of cancer development.

SCREENING FOR LUNG CANCER

Screening is another approach to decreasing lung cancer mortality. Because patients with early-stage disease have higher cure rates, there has been the theory that effective screening programs could potentially have a significant impact on overall survival. However, screening strategies with chest radiographs and standard sputum cytology have to date all failed to alter overall survival rates in this disease. [14]

While intense controversy regarding screening for breast, colorectal, and prostate cancer still exists, a consensus does exist regarding lung cancer screening. All major organizations involved in public health recommend against any efforts to detect early lung cancer because each of the four randomized controlled clinical trials has failed to demonstrate a significant reduction in lung cancer mortality as a result of screening. Trials for lung cancer screening conducted at Memorial Sloan-Kettering Cancer Center, John Hopkins Hospital, and the Mayo Clinic were negative. [15,16 and 17] Many physicians feel that with new screening techniques and

other diagnostic techniques, such as spiral low-dose CT scans, sputum cytology, and bronchial brushing, it may be possible to establish lung cancer diagnoses earlier enough to make an impact on overall survival rates in the context of this dreaded disease (for further details of lung cancer screening, see also Chapter 22).

FIELD CANCERIZATION

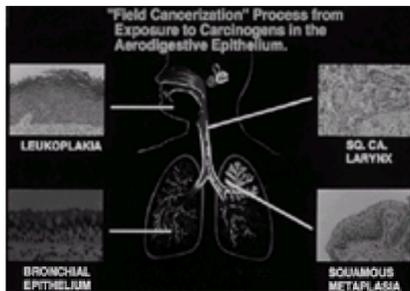
Chemoprevention represents an effort to arrest carcinogenesis and prevent the development of a malignancy by the administration of specific compounds. The rationale for chemoprevention of lung cancer is based on two principles of tumor biology common to most epithelial cancers: field cancerization and multi-step carcinogenesis, which are demonstrated in Figure 25.1 and Figure 25.2, respectively. Field cancerization (Figure 25.1) was first described by Slaughter and colleagues, who identified epithelial hyperplasia, hyperkeratinization, and atypia in grossly normal appearing epithelium adjacent to cancers of the oral cavity. Notably, multiple tissue sections were also found to contain carcinoma *in situ.* Such histologic changes throughout the oral epithelium suggest that steps in the development of malignancy occurred elsewhere in the aerodigestive tract (Figure 25.1). This concept is important in the chemoprevention of lung cancer, for it suggests that the development of an aerodigestive tract malignancy is not a random event but rather the result of diffuse changes that are present throughout the epithelium.


FIGURE 25.1. A schematic and pathologic representation of the Concept of Field Cancerization: Epithelium throughout the respiratory tract is affected by similar toxins, hence the concern about second primary cancer prevention. (See Color Figure 25.1.)
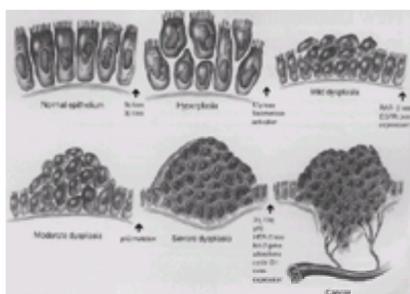

FIGURE 25.2. Multi-step process of lung carcinogenesis: A schema of molecular changes that have been reported to occur during the multi-step lung carcinogenic process. While representing potential points for intervention (i.e., chemoprevention), these events could potentially (once available) serve as biomarkers of cancer risk and intermediate end points for clinical studies. (From Papadimitrakopoulou VA. New developments in the chemoprevention of lung cancer. *Prim Care Cancer* 1998;18[Suppl. 1]:52, with permission.) (See Color Figure 25.2.)

The existence of diffuse premalignant changes in the aerodigestive tract suggests the important clinical finding that patients who survive an initial diagnosis of cancer in one region are subsequently susceptible to the development of second primary tumors. More specifically, it is now known that specific genetic alterations are most likely involved in this process. For example, Hung and colleagues [18] have demonstrated that highly specific deletions in the short arm of chromosome 3 occur during hyperplasia, the earliest stage in the pathogenesis of lung cancer, and that they can be found throughout the respiratory tract. Furthermore, Kishimoto and associates [19] noted similar evidence for allele-specific losses on the short arm of chromosome 9 in the earliest stages of lung cancer pathogenesis. This work was consistent with earlier work by Sozzi and co-workers, [20] who detected deletions of the short arm of chromosome 17 and of the *p53* gene in premalignant lung lesions. Further work by Sozzi and her colleagues has followed up on Hung's previous work and has demonstrated that one of the genes on chromosome 3p that is most likely lost in lung carcinogenesis is the fragile histidine triad (*FHIT*) gene [21,22] (See also Chapter 8).

Compelling evidence supporting the field carcinogenesis theory comes from studies of genetic alterations throughout the respiratory tract in paraffin-embedded tissue sections using a chromosome *in situ* hybridization technique [23,24] and in DNA content analyses after Feulgen staining. [25] Using biotinylated chromosome 7–17 specific centromeric DNA probes, investigators at the University of Texas M. D. Anderson Cancer Center demonstrated that chromosomal polysomies were found not only in tumor cells but also in histologically defined premalignant lesions such as oral leukoplakia [24] and in nonmalignant epithelial lesions adjacent to tumors.

MULTI-STEP CARCINOGENESIS

Although the series of genetic events leading to the development of lung cancer are not as well defined as in some systems (that is colorectal cancer), [26] lung cancer seems to result from multiple genetic events. Multiple studies have reported that invasive squamous cell carcinomas of the lung arise in association with areas of carcinoma *in situ.*[9,10,27,28] These progressive changes from metaplasia to carcinoma have been accepted as the hallmark of an orderly carcinogenic progress that ultimately leads to the development of squamous cell carcinoma (one such model is shown in Figure 25.2). Some initial findings in this regard were documented by Saccomanno and colleagues, [29] who examined serial sputum samples of uranium miners. Their subsequent cytologic examination of exfoliated bronchial cells in the sputum of these miners led the researchers to conclude that human lung cancers develop through a series of readily identifiable stages. Saccomanno and his colleagues further divided these stages into squamous cell metaplasia, squamous cell metaplasia with atypia (mild, moderate, or marked), carcinoma *in situ,* and invasive squamous cell carcinoma. Quantitative cytochemical studies in human and animal models have further supported these findings with the demonstration of increasing amounts of DNA in exfoliated cells from abnormal epithelia. [30,31] Thus mildly atypical cells were found to exhibit a diploid-tetraploid range of DNA content, thereby most likely representing normal proliferative activity, whereas moderately and severely dysplastic cells had DNA content that was far greater than that encountered in the diploid population.

The data supporting this rely on the facts that complex cytogenetic abnormalities are consistently found in tumor cells [32,33] and that similar genetic abnormalities are found in normal and nonmalignant lung tissue samples from patients with lung cancer. [34] Along these lines, work by Mao and associates [35] demonstrated that *ras* mutations could be detected in the sputum of smokers prior to the actual diagnosis of lung cancer, thereby postulating a potential role for molecular screening where radiographic screening had previously failed to be effective. This genetic evidence was further strengthened by the fact that the number of chromosomal or genetic alterations in lung cancers seems to involve both the activation of dominant cellular oncogenes and the inactivation or chromosomal deletion of tumor-suppressor genes. [36] Since the inactivation of tumor-suppressor genes requires at least two genetic changes to inactivate both alleles, lung cancer cells must undergo several distinct genetic events to progress from the premalignant stage to active lung cancer. Conservative estimates based on both the cytogenetic and molecular genetic changes place the total number of genetic events required for lung carcinogenesis at between ten and 20 events [34] (Figure 2). Data from Mao and associates [35] have demonstrated loss of heterozygosity (LOH) on chromosomes 3p, 9p, and also (but less frequently) 17p not only in the bronchial biopsy tissue of patients who have cancer but also in the bronchial tissue of current and former smokers in whom there is no clinical evidence of disease or even, in some cases, of histologic abnormalities. This data establishes that tobacco use produces long-term irreversible (and reversible) effects and illustrates the persistent genetic damage found in

the airways of former smokers. Mao's data indicate that 67% of former smokers demonstrate evidence of persistent genetic abnormalities in bronchial epithelium. These data lead one to believe that there are stable genetic alterations that can persist in the airway long after smoking cessation. Most critically, the fact that LOH at 9p and 17p persists even in patients who quit smoking suggests that these may be markers of stable genetic damage caused by cigarette smoke, unlike LOH at 3p, which appears to be largely reversible following smoking cessation. It is this persistent genetic injury that may, in fact, be the fingerprint of subsequent carcinogenic progression.

Mao and associates used microsatellite DNA studies at three specific loci—chromosomes 3p14, 9p21, and 17p13—to evaluate individual smokers (40 current smokers and 14 former smokers).[35] Genetic alterations at chromosomal sites containing putative tumor-suppressor genes (3p14 and the *FHIT* gene, 9p21 and the *p16* gene, and 17p13 and the *p53* gene) were frequently found even in the histologically normal or minimally altered bronchial epithelium of chronic or former smokers. Wistuba and colleagues[37] have verified that these and other similar genetic alterations, while present in the airways of current and former smokers, are never seen in the normal bronchial epithelium of nonsmokers (see also Chapter 23).

While squamous metaplasia was initially identified as a potentially reversible premalignant lesion and was studied in multiple chemopreventive trials, [30,31] the data of Mao and associates[35] and Wistuba and associates[37] demonstrated that persistent genetic abnormalities can be found even in the absence of squamous metaplasia. Therefore the reliability of squamous metaplasia as a putative premalignancy model for lung cancer has become questionable. The development of a comprehensive model of premalignancy will likely require integration of recent molecular observations of persistent genetic abnormalities such as those demonstrated by Mao and associates[3] with a reexamination of putative histologic subtypes of premalignancy, including bronchial metaplasia.

CHEMOPREVENTION

The rationale for a chemopreventive intervention in former smokers is clear from the evidence of persistent genetic damage in the airway as well as the etiologic role that tobacco plays in causing smoking-related genetic changes. With an increasing ability to detect and evaluate histologic abnormalities in bronchial tissue, the overall goal remains to develop agents that can be effective as chemopreventive compounds. [4]

The concept of using chemopreventive agents to reduce cancer risk stems both from epidemiologic and laboratory evidence. Epidemiological studies have demonstrated that vitamin A deficiency as well as decreased amounts of vitamin E and b-carotene are associated with an increased incidence of lung cancer in humans.[38] Vitamin A deficiency was long ago reported to induce squamous metaplasia in the mucosa of the upper aerodigestive tract [39] that is similar to the premalignant changes in this mucosa found in heavy smokers. [9] Dietary vitamin supplementation reversed squamous metaplasia in the trachea of vitamin A–deficient animals *in vivo*,[40] and various retinoids exhibited a similar activity *in vitro*.[41] Among other functions, these compounds are felt to exert anticarcinogenic activity by causing antioxidant effects and scavenging free radicals that are the by-products of many normal metabolic functions, thereby preventing cancer-causing damage to DNA. However, no clear-cut evidence of the specific effectiveness of vitamins A and E or b-carotene has been demonstrated, and epidemiologic data cannot discount the possibility that other constituents of vegetables and fruits may provide the anticarcinogenic effects of these foods. While suggestive of effect, epidemiologic evidence taken alone cannot substitute for a randomized, double-blind, clinical study.

A number of problems and pitfalls with lung cancer chemoprevention studies involve (or revolve around) using the end point of cancer incidence in patients at increased but still marginal risk of cancer. These studies generally require a large number of patients and take years to decades to complete. The intermediate end points, such as those discussed in this paper, are helpful; however, these biomarkers have yet to be fully validated. It will take the efforts of a large group of subjects and investigators to expedite the validation of intermediate end point biomarkers and tailor clinical chemopreventive trials along these lines.

Retinoids

Vitamin A derivatives, or retinoids, are a family of compounds that have complex biologic effects, including the modulation of differentiation, proliferation, and apoptosis within both normal and neoplastic tissues. [42,43] The complexity of their function depends not only on the diversity of the retinoid ligands but also on the diversity of the nuclear retinoid receptors that mediate their activity. Retinoids bind to DNA and activate retinoid receptors, which function then as cellular transcription factors. These receptors are expressed at varying levels in different cell types, and their differential expression affects downstream gene expression. There exist two classes of nuclear retinoid receptors: the retinoic acid receptors (RARs), and the retinoid X receptors (RXRs). Within these two classes, there are three subclasses—a, b, and g—which are subsequently divided further into a large number of isoforms produced through differential promoter usage and alternative splicing of receptor transcripts. [42,43] Specific isoforms of RARs and RXRs appear to have different functions, activating alternate downstream target genes. RXRs form homodimers and heterodimers with RARs or a host of other receptors, such as those for vitamin D and thyroid hormones, and with a variety of orphan receptors. [42] Because RXR is a ligand-binding partner in combination with orphan receptors, RXR ligands appear to be more versatile than RAR ligands in the activation of retinoic acid and other pathways.

The natural and synthetic retinoids, including all-trans, 13-cis, and 9-cis retinoic acid, all exist as stereoisomers, spontaneously interconverting in the intracellular space. For that reason, treatment with these retinoids nonselectively activates both RARs and RXRs. In contrast, several of newer synthetic retinoids are being developed that are capable of binding specifically to individual nuclear retinoids, thus allowing a degree of selectivity in the enhancement of the desired effects of certain retinoids with reduced side effects. For example, a retinoid specific only for RAR-b may avoid inducing dermatologic side effects that have been caused by activation of RAR-g. The overall goal is to enhance the potential therapeutic effects of specific retinoids while limiting the toxic effects caused by the widely used natural retinoids. [44]

Retinoid receptors affect gene transcription either directly or indirectly. This phenomenon is illustrated by the receptor interaction with activator protein-1 (AP-1), which is an important regulator of cellular proliferation and inflammation. [45,46 and 47] The mechanism of this interaction was explored by Kamei and co-workers[48] who demonstrated that retinoid-mediated inhibition of AP-1 activity appears to be the result of competition between nuclear retinoid receptors and AP-1 for binding to a transcriptional coactivator. This coactivator is found in limited quantities in the cell and thus is the rate-limiting step for both the retinoid receptors and AP-1. [48] Synthetic retinoids have been developed that selectively inhibit AP-1 without activating nuclear receptors. [49] These AP-1 (transcriptional activator protein-1) selective synthetic retinoids have been found to be potent antiproliferative agents in a number of tumor-derived cell lines [45,49] and are capable of reversing the squamous differentiation of bronchial epithelial cells. [50] Their toxicity profile may be favorable compared with their less-specific precursors, as retinoid toxicity has been linked to retinoid receptor activation.

Recent evidence suggests that the loss of specific of RARs might be involved in the promotion of lung carcinogenesis. Xu and colleagues examined transcripts of nuclear retinoid receptors using digoxigenin-labeled riboprobes specific for RAR-a, RAR-b, and RAR-g in formalin-fixed, paraffin-embedded specimens from 79 patients with non–small cell lung cancer (NSCLC) and as a control in specimens from 17 patients without lung cancer. [51] Northern blotting and *in situ* hybridization techniques were used. All receptors were expressed in at least 89% of control normal bronchial tissue. RAR-a, RXR-a, and RXR-g were expressed in more than 95% of the NSCLC specimens. In contrast, RAR-b, RAR-g, and RXR-b expression was detected in only 42%, 72%, and 76% of NSCLC samples, respectively. These data suggest that the expression of RAR-b and possibly also of RAR-g and RXR-b is suppressed in a large percentage of patients with lung cancer.

Further work in the area of retinoid biology and pharmacology has focused on the study of retinoid resistance. Clinical *de novo* retinoid resistance occurs in 40% of oral premalignant lesions and appears to develop over time in many lesions that had previously responded to retinoid treatment. [44] The mechanisms that underlie retinoid resistance are not yet well defined. However, the frequency with which clinical resistance is encountered has resulted in the evaluation of novel retinoids such as 4-N-(hydroxyphenyl) retinamide (4-HPR), which does not appear to bind any of the retinoid receptors but is a potent *in vitro* inducer of apoptosis. [44,52] Retinoids also appear to have potent effects when combined with other cytotoxic or cytostatic agents. Shalinsky and colleagues. [53] demonstrated that 9-cRA combined with cisplatin in human oral squamous carcinoma xenografts in nude mice shows enhanced antitumor efficacy bordering on synergism. Thus retinoids alone or in combination with other cytotoxic[53] or biologic[54,55] agents have the intriguing potential to reverse preneoplastic lesions. The preclinical demonstration of efficacy as well as the extensive epidemiologic data previously cited has led to the integration of retinoids into clinical chemoprevention trials in upper aerodigestive tract cancers as well as lung cancer.

Carotenoids

b-carotene is of interest because it is a natural agent with few toxic effects and is the prototype of a class of compounds known as carotenoids. Epidemiologically, several retrospective and prospective trials have demonstrated an inverse correlation between dietary carotenoid intake (largely in vegetables and fruits) and the

incidence of lung cancer, most specifically squamous cell carcinoma. [56],[57] and [58] The main known side effect of b-carotene was thought to be yellowing of the skin.

Other Agents

N-acetylcysteine, a substance that decreases glutathione levels, is also being evaluated in some lung cancer trials. [59] Another often-studied agent is a-tocopherol (vitamin E), which is a natural agent with strong antioxidant properties. Epidemiologic evidence suggests that a-tocopherol intake has an inverse correlation with the incidence of lung cancer. A recent clinical trial with this agent showed its efficacy in patients with oral leukoplakia. [60] The toxicity of a-tocopherol (vitamin E) is minimal, and there is some evidence to suggest a-tocopherol may abrogate the toxicity of retinoids, making this type of combination of a-tocopherol with a retinoid extremely promising for future clinical development. [61]

The success of chemopreventive clinical trials in patients with head and neck cancers spawned interest in chemopreventive strategies for lung cancer. Both cancers occur in the aerodigestive tract, and tobacco use is a likely cause in both diseases (Field Cancerization, Figure 25.1). Exposure of the entire aerodigestive tract to repeated carcinogenic insult (that is, smoke) results in field cancerization or changes throughout the field. These changes yield multiple independent foci of premalignant lesions that progress at different rates to form multiple primary cancers. The 4% to 7% annual incidence of second primary tumors in patients with lung and head and neck cancer supports this theory.

STUDY END POINTS IN CHEMOPREVENTION TRIALS

Using cancer development as an end point (still a rare event) results in large, costly randomized studies. One approach to reducing the number of subjects required to demonstrate activity in chemoprevention trials is to use intermediate biologic end points to define the activity of an agent before its evaluation in large clinical studies with cancer as a primary end point. This is often referred to as reversal of premalignancy. Potential intermediate markers could include general changes in the epithelium, such as metaplasia, or more specific markers, such as cytogenetic or molecular changes.

Reversal of Premalignancy

One of the major problems in studies attempting to reverse premalignancy has been the difficulty in defining consistent premalignant changes in the bronchial epithelium. Investigators have used both cytologic changes in sputum and histologic changes in bronchial biopsy samples from metaplasia to dysplasia as markers of risk. Reversal of these premalignant changes to normal tissue has been regarded as a potential intermediate end point for the chemoprevention of lung cancer. Saccomanno and colleagues were among the first to evaluate changes in sputum cytology induced by retinoids. [62] Patients with at least moderately atypical metaplasia were treated with 13cRA, 1 to 2.5 mg per kg per day. Sputum atypia did not improve with retinoid treatment, but alterations were noted in cellular morphology.

In general, studies focusing on sputum analysis from chronic smokers have shown a wide spontaneous variation in the degree of atypia over time and no consistent effect from retinoids[30],[31],[60],[61],[62],[63] and [64] (Table 25.1).

TABLE 25.1. COMPLETED RANDOMIZED CHEMOPREVENTION TRIALS IN LUNG CANCER

In an effort to develop a more dependable, semiquantitative assay, Mathe and co-workers described the metaplasia index (MI) to quantitate the degree of squamous metaplasia in bronchial biopsies from six specific anatomic sites. [63] The MI was defined as the number of samples with metaplasia divided by the total number of samples analyzed, multiplied by 100. MIs were documented pre- and posttreatment in a single-arm trial of smokers receiving etretinate (25 mg per day for six months).[63] This trial demonstrated a decrease in the MI following etretinate therapy from 34.57% to 26.96% after six months of treatment. Of note was that MI decreased to 0% in four patients who ceased smoking, though these patients were excluded from the overall analysis. While the difference was significant, there was unfortunately no control group to assess the natural history of bronchial metaplasia in untreated patients. Arnold and associates, in a study that evaluates the efficacy of etretinate, used atypia in sputum cytology specimens as an end point. [65] Patients with moderate or severe sputum atypia were randomized to receive either etretinate (25 mg per day) or a placebo. At the completion of six months of treatment, an improvement in sputum atypia was noted in subjects in both the etretinate and placebo groups (32.3% and 29.8% of the patients, respectively), and no real benefit was seen.

These findings, however, were confirmed by those of Lee and colleagues. [31] In this trial, 93 smokers with metaplasia or dysplasia quantitated at baseline using the MI were randomized to 13-cis retinoic acid (13cRA, 1 mg per kg per day) or placebo for six months. [31] Subjects completed the trial and underwent repeat bronchoscopy. Posttreatment biopsy samples demonstrated a similar rate of decrease in the MI in both trial arms that was most strongly associated with smoking cessation. Clearly, future trials of this sort will need to be placebo-controlled to correct for multiple variables such as smoking cessation, sampling differences, and spontaneous regression that can influence the final outcome.

PRIMARY PREVENTION IN HIGH-RISK POPULATIONS

Based on epidemiologic data, which indicated an inverse correlation between cancer risk and dietary b-carotene, b-carotene has been the major agent studied in primary prevention of lung cancer.[58],[66],[67],[68] and [69] Three large primary prevention trials using b-carotene with or without a-tocopherol or retinol have been completed. Interestingly, two of the three trials have documented an increased incidence of lung cancer in the treatment arms with b-carotene (Table 25.1), certainly an unexpected result.

The Finnish ATBC trial, the largest of its kind, randomized 29,133 male smokers in southwest Finland aged 50 to 69 years to one of four regimens, using a 2 × 2 factorial design. The regimens were a-tocopherol (50 mg per day) alone, b-carotene (20 mg per day) alone, both agents, or placebo. [66] The participants in the ATBC trial continued the interventions for five to eight years; compliance was excellent as more than 80% of subjects took at least 95% of their assigned medications. The median length of follow-up on the study was 6.1 years. Over the course of the study, 876 new cases of lung cancer were diagnosed. Patients receiving b-carotene had an 18% increased incidence of lung cancer (p = 0.01) and an 8% increased mortality rate. a-tocopherol administration failed significantly to alter either lung cancer incidence or overall mortality rate. The primary cause of increased mortality in the b-carotene group included lung cancer, ischemic heart disease, and hemorrhagic strokes. Subsequent analysis of these data demonstrated a trend to increased risk after b-carotene treatment in heavy smokers (more than or equal to one pack per day) and in those who had high ethanol intake (more than 11 g per day). [67] The surprising results from this study were not only the failure of b-carotene to demonstrate a protective effect but also the suggestion that supplemental pharmacologic doses of b-carotene might be harmful to smokers. Therefore, this study demonstrates that caution must be used when relying completely on epidemiologic data to design large randomized clinical trials.

Accrual to another primary prevention trial performed in the United States was stopped early due to similar findings. This study, conducted by the University of Washington at Seattle, was designated the Carotene and Retinol Efficacy Trial (CARET) study and randomized a total of 18,314 smokers, former smokers, and people with a history of asbestos exposure to a combination of b-carotene (30 mg per day) and retinol (25,000 IU per day), in the form of retinyl palmitate (vitamin A),

or placebo in a double-blind fashion. [68,70] Toxic effects were not a significant problem and consisted mostly of mild skin yellowing in subjects who received b-carotene. After a mean follow-up period of four years, accrual was suspended due to an increased relative risk of lung cancer and death due to lung cancer in the treatment arm (hazard ratio 1.28 versus 1.46, respectively). As in the ATBC trial, excess lung cancer incidence was most associated with current smoking and the highest quartile of ethanol intake.[70]

The mechanism of enhancement of lung carcinogenesis by supplemental b-carotene (alone or in combination with retinol) in smokers has not yet been defined. The most plausible theory at this time suggests a pro-oxidant effect of b-carotene in the damaged lungs of individuals who continue to smoke heavily, [71] but this has yet to be firmly established. In light of the data from the CARET and ATBC trials, current smokers should not use b-carotene supplements.

A third trial, of male physicians in the United States, of whom only 11% were current smokers, randomized 20,071 participants to b-carotene (50 mg four times per day) or placebo.[65] Neither benefit nor harm was demonstrated from the intervention in terms of the incidence of malignant neoplasms, cardiovascular disease, or death from all causes.

Several pilot studies are currently looking at patients previously exposed to asbestos fibers or tin dust. A pilot study of 816 patients was recently completed evaluating daily doses of retinyl palmitate (25,000 IU) and b-carotene (30 mg). [72] Tin miners in southern China have an annual incidence of lung cancer exceeding 1%. In a pilot study in this population, 358 people were randomized to receive vitamin A (25,000 IU), b-carotene (50 mg), vitamin E (800 IU), selenium (400 µg), or placebo in a trial with a 2 × 4 factorial design. Compliance has exceeded 90%, and toxicity has not been a problem. [72] Results from this study are pending.

PREVENTION OF SECOND PRIMARY TUMORS

As previously discussed, patients with a prior history of aerodigestive tract malignancies are at an increased risk of developing a second primary tumor (SPT), particularly lung cancer, making this population perhaps at the highest risk for developing lung cancers. Three randomized trials designed to reduce the incidence of second primary tumors in patients with an index cancer lesion of the head and neck or lung have now been completed. Two of these three trials have demonstrated an impact on tobacco-related cancer with retinoid treatment (Table 25.2).

TABLE 25.2. RANDOMIZED TRIALS OF RETINOIDS IN HUMAN CANCER CHEMOPREVENTION OF SECOND PRIMARY CANCERS

In a study by Hong and colleagues[5] in 1991, 103 patients with the prior diagnosis of squamous cell cancer of the head and neck treated with surgery, radiotherapy, or both were randomized to receive either high-dose 13cRA (50 to 100 mg per m^2 per day) or a placebo for one year. Although originally conceived as an adjuvant trial, this study did not demonstrate any impact of treatment on locoregional recurrence or metastatic disease. However, with a median follow-up period of 32 months, second primary tumors developed in only two (4%) of the treated patients as opposed to 12 (24%) of patients receiving placebo. Of particular note, 93% (13 of 14) of the second primary tumors observed were in the carcinogen-exposed field of the upper aerodigestive tract, lungs, and esophagus. Recent reanalysis of this trial at a median follow-up period of 4.5 years demonstrated 16 second primary tumors in the placebo group and only seven in the 13cRA group. [73] Three lung cancers were found in the retinoid group versus nine in the placebo group. Therefore the effect of 13cRA persisted for approximately two years after the cessation of 13cRA in the retinoid arm. These promising results are offset somewhat by the significant toxic effects on mucocutaneous tissues associated with 13cRA that necessitated a marked dose reduction among one third of the patients during one year of therapy (from 100 to 50 mg per m^2 per day). Despite the decreased dose, toxicity in this study remained significant. Unfortunately, 13cRA at the dose used is difficult to tolerate for extended periods of time, and many patients are unwilling to continue taking the medication, especially populations at lower risk of developing cancer. Recent trials of 13cRA in the treatment of patients with oral leukoplakia have demonstrated a possible way to decrease toxicity using lower doses for more prolonged periods. [74] Hence newer studies in lung cancer chemoprevention, including a large randomized phase III study, now use a lower dose.

A second trial, by Bolla and colleagues, [75] randomized 316 patients with prior squamous cell cancer of the oral cavity or oropharynx to etretinate (50 mg per day for one month, followed by 25 mg per day for two years) or a placebo. After a median follow-up time of 41 months, treatment was not observed to affect incidence of either SPT or recurrent disease. The results of this trial were notable for the high rate of SPT (23% of patients), 79% of which were clearly tobacco-related.

In the only completed chemoprevention study of patients with an index diagnosis of lung cancer, Pastorino et al. [76] randomized 307 patients who had been surgically cured of stage I NSCLC to receive either high-dose retinyl palmitate (300,000 IU per day for one year) or a placebo. The retinyl palmitate (vitamin A) was well tolerated in this study; only five patients required cessation of drug because of toxic effects. Fewer primary disease recurrences were noted in the group that received retinyl palmitate, but the difference was not statistically significant. The retinyl palmitate treatment was associated with an overall reduction in SPT: there were 18 in that group (12%) versus 29 (18%) in the retinyl palmitate and placebo arms, respectively. Considering only tobacco-related tumors, the data are more striking, with 13 SPT in the retinoid arm versus 25 in the placebo arm, and this difference achieved statistical significance. In contrast to 13cRA, the retinyl palmitate was well tolerated by patients, and compliance over one year of treatment exceeded 80%.

Building on the results of these two positive trials, two large trials are underway to determine definitively the role of retinoids in preventing second primary tumors (Table 25.3). These current trials include a National Cancer Institute (U.S.) sponsored phase III trial of low-dose 13cRA (30 mg per day for three years) versus placebo in patients who have undergone curative resection for stage I NSCLC. Patients will receive follow-up care for four years after treatment ends to assess reduction in SPT incidence. Accrual of patients to this study was completed in April of 1997, with approximately 1,485 patients registered. [77] Similarly, the Euroscan study is evaluating the efficacy of retinyl palmitate (300,000 IU per day) and the antioxidant N-acetylcysteine (600 mg per day) in the prevention of SPT following the definitive therapy of early-stage squamous cell carcinoma of the head and neck or fully resected stage I, II, or IIIA (T3N0 only) NSCLC (based on the prior study already described).[78] This study has a 2 × 2 factorial design; study participants received either retinyl palmitate alone or N-acetylcysteine alone, both drugs, or placebo for two years and then four years' follow-up care. [78] As of the most recent report of the data on 2,440 participants (1,449 head and neck cases, 991 lung cases), there have been 204 recurrences (27% in the patients with lung cancer). There were a total 133 SPTs (5.5%) with 83 in the head and neck group (5.7%) and 50 in lung group (5.0%).[78]

TABLE 25.3. SELECTED ONGOING CHEMOPREVENTION TRIALS IN LUNG CANCER AND HEAD AND NECK CANCER

FUTURE DIRECTIONS

Future directions include improved epidemiological models of lung cancer risk to identify high-risk patients for studies. Following this, we will need better to define those patients most likely to benefit from these interventions and target them for chemoprevention studies.

The ongoing phase III trials offer a combination of caution and promise. Given the dismal five-year survival rates of patients with an established diagnosis of lung cancer and the failure of early detection methods to affect overall survival rates, careful construction of a molecular model of lung carcinogenesis is vital to the development and testing of effective chemopreventive compounds. Although epidemiologic data have provided clues to compounds that may functionally retard the carcinogenic processing lung tissue, the b-carotene trials warn against the direct application of epidemiologic data into the clinical setting.

Most promising is the study of intermediate end point markers that could substantially reduce the cost, effort, and time required to complete large randomized chemoprevention trials. Trials that use cancer incidence as their primary end point usually require thousands of patients and cost several million dollars to complete. No less significant is the time required, with a minimum of five to ten years needed to ascertain whether the intervention was successful, equivocal, or harmful. The discovery of potentially valuable intermediate end point markers such as RAR-b is of pivotal importance. Other important genetic markers, including LOH at chromosomes 3p, 9p, and 17p and the potential role of the *p53* tumor-suppressor gene (as well as other tumor-suppressor genes such as the retinoblastoma gene) need to be carefully and prospectively studied to further clarify the biology and molecular genetics of lung carcinogenesis. With knowledge of lung cancer biology, the physician can select useful intermediate end point markers with which to study promising chemopreventive compounds. Once these compounds are shown to be effective in the reversal of preneoplastic disease, they can be taken to larger primary prevention trials. This careful marriage between molecular biology and clinical investigation is likely to provide the framework for development of chemopreventiveregimens for individuals at high risk for lung cancer.

The magnitude of the lung cancer problem (in most cases due to tobacco use) has inspired research into lung cancer causation and the active development of specific agents capable of reversing the carcinogenic process. The fact that former smokers remain at increased risk for lung cancer development [2,11,79,80] epidemiologically and the now proven fact that known genetic mechanisms for this process exist [20,37,80] have led to an increased focus on chemopreventive trials in former smokers. Given the increased lung cancer incidence in active smokers who received b-carotene [66,67,69,70] current chemopreventive interventions are increasingly targeting former smokers, and chemopreventive strategies at this time have no role in standard practice outside the context of a clinical trial.

Two large randomized lung cancer prevention trials are underway. Currently investigators at the M. D. Anderson Cancer Center have launched a randomized, placebo-controlled, double-blind trial of 13cRA plus a-tocopherol (to attenuate toxicity) [81] versus a novel retinoid, 9-cis-retinoic acid, which binds both RAR-RXR heterodimers and RXR-RXR homodimers, versus placebo in former smokers with or without cancer. Because former smokers can have persistent genetic deletions even in the absence of visible histologic abnormalities, all former smokers who have smoked at least 20 pack-years are eligible for participation in this study. The study population will comprise 225 former smokers, and accrual is expected to be complete in the year 2000. [81] Among the parameters being evaluated are the reversal of metaplasia, dysplasia, or both, the presence of persistent genetic lesions at the sites of specific tumor suppressor genes, and the loss of and possible upregulation of RAR-b.

Data from Oridate and associates[82] indicate that 4-HPR, a novel synthetic retinoid that does not appear to bind nuclear retinoid receptors, can induce apoptosis in cervical carcinoma cells by inducing reactive oxygen species. This work has been applied to lung cancer cell lines, and it appears that 4-HPR may be more effective than all-*trans* retinoic acid in inducing apoptosis in head and neck squamous carcinoma cell lines. [51] This has led to increased enthusiasm for the incorporation of such novel and nontoxic retinoids into chemoprevention trials.

Furthermore, recent data[49] have identified several synthetic retinoids that can specifically activate retinoid response networks, thereby selectively inducing specific biologic responses. These molecules appear preferentially to cause the induction of apoptosis in human lung cancer cells *in vivo* in animal models, thereby providing a potential role for selective retinoids in lung cancer therapy as well as chemoprevention.

Finally, other small molecules and routes of delivery may be equivalent and possibly even superior to oral retinoids. Recent compelling data from Wiedmann and colleagues on the use of budesonide, an aerosolized glucocorticoid, in the reversal of lung adenomas in mice, suggest that aerosolized delivery of chemopreventive compounds may be a provocative and ultimately more successful approach to lung chemoprevention. [83] The addition of other biologic agents, such as interferon or other antiangiogenic agents, is also being explored.

Hence the challenge of the next few years is to employ selective and highly specific chemopreventive compounds against new molecular targets. [84] The careful design and implementation of clinical chemoprevention trials, along with continued advances in the understanding of the principles of lung carcinogenesis and the development of novel, increasingly effective compounds with improved drug delivery techniques, should lead to significant advances in lung cancer chemoprevention.

CLASSIFICATION, HISTOLOGY, CYTOLOGY, AND ELECTRON MICROSCOPY

WILLIAM D. TRAVIS
JAMES LINDER
BRUCE MACKAY

CLASSIFICATION

Lung cancer is currently the most common worldwide cause of major cancer incidence and mortality.[1] It is estimated that lung cancer will account for more than 187,000 new cases in the United States during 1999 and more than 164,000 cancer deaths.[2] Although lung cancer incidence in the United States began to decline in males in the early 1980s,[3] it continues to increase in women.[4]

Accurate pathologic classification of lung cancer is essential for patients to receive the appropriate therapy. Although classification of the vast majority of lung cancers is straightforward, areas of controversy and diagnostic challenges remain. Lung cancer diagnosis is based primarily on light microscopy, but useful information can be obtained from special techniques such as immunohistochemistry and electron microscopy. This chapter focuses primarily on histologic and cytologic approaches to the diagnosis and classification of the major subtypes of lung cancer, with special attention on neuroendocrine lung tumors. Electron microscopy is also discussed in detail in this chapter. Immunohistochemistry, flow cytometry, and molecular biology are mentioned only briefly because they are addressed in other chapters.

The most widely accepted histologic classification for lung tumors is that proposed by the World Health Organization (WHO) which was revised in 1999 (Table 26.1). The major histologic types of lung cancer are squamous cell carcinoma, adenocarcinoma, small cell lung carcinoma (SCLC), and large cell carcinoma. These four tumors can be subclassified into more specific subtypes such as the bronchioloalveolar carcinoma (BAC) variant of adenocarcinoma. [6] In addition, there are other less common lung tumors, such as carcinoid tumors (Table 26.1). A more extensive discussion of the pathology of lung tumors with greater detail on uncommon lung tumors than is possible here can be found in several textbooks. [6,7,8,9 and 10]

TABLE 26.1. WHO/IASLC HISTOLOGIC CLASSIFICATION, 3rd ED., 1999*

SHIFTS IN HISTOLOGIC TYPE BY SEX, RACE, AND AGE

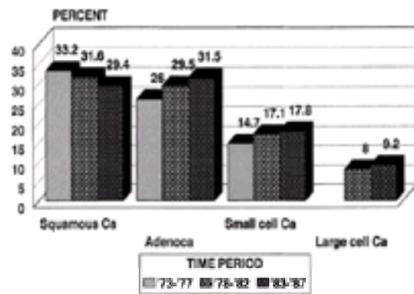
The sex and race distribution for the various histologic subtypes of lung cancer has shifted over the past several decades (Figure 26.1).[11] Population-based data gathered by the National Cancer Institute's (NCI) Surveillance, Epidemiology, and End Results (SEER) Program demonstrated that the age-adjusted rate (AAR) for lung cancer for all race-sex groups combined has risen sharply since 1950. [11,12] From 1969 to 1991, the overall AAR of lung cancer incidence rose from 37.8 to 68.2 per 100,000.[3] However, the percentage increase has diminished in recent years. [2,3 and 4] Lung cancer rates for both black and white men peaked and began to decrease around 1984. Although rates continue to increase for women of both races, this decrease has diminished in recent years. [3,4,11]


FIGURE 26.1. Age-adjusted rates per 100,000 person years for all races and both sexes for each five-year time period (1973–1977, 1978–1982, and 1983–1987) for all lung carcinomas as well as for the four major histologic subtypes of lung carcinoma. (From Travis WD, Travis LB, Devessa LS. Lung Cancer. *Cancer* 1995;75:191, with permission.)

In white and black males, the rates of squamous cell carcinoma, SCLC, and large cell carcinoma declined after peaks in 1981 and 1982, 1986 and 1987, and 1986 and 1988, respectively.[3] In addition, the rates for adenocarcinoma in black males peaked in 1987, whereas the rates in white males appeared to have plateaued between 1989 and 1991.[3] Lung carcinoma AAR among white and black females continued to increase for all histologic types, except for large cell carcinoma among whites and BAC among whites and blacks. Most of these changes reflect past cigarette smoking patterns. Demonstration of declines and tapering increases among several population subgroups suggests that reductions will occur soon in the overall incidence and mortality rate for this highly fatal cancer.

These shifts in the AAR have resulted in adenocarcinoma surpassing squamous cell carcinoma as the most common histologic type of lung cancer for all sex-race groups (Table 26.2, Figure 26.2).[13,14 and 15] The change is caused by not only an increase in adenocarcinoma but also a decrease in squamous cell carcinoma in men. Carcinoid tumors represent the most common lung malignancy in patients under 30 years of age.[11]

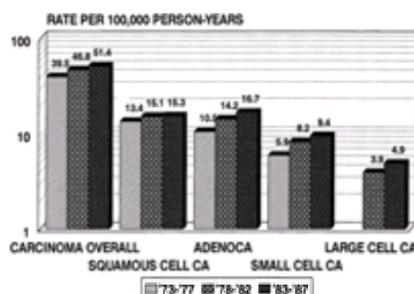
TABLE 26.2. FREQUENCY AND AGE-ADJUSTED RATE (AAR) PER 100,000 POPULATION FOR ALL RACES, BOTH SEXES: 1983–87*


FIGURE 26.2. Percent histology distribution of the four major subtypes of lung cancer for all races and both sexes over the three time intervals 1973–1977, 1978–1982, and 1983–1987. (From Travis WD, Travis LB. Devessa LS. Lung Cancer. *Cancer* 1995;75:191, with permission.)

One study by El-Torky et al. suggested a substantial increase in the frequency of SCLC in women.[16] Although data from the SEER program indicated that the AAR for SCLC increased between 1973–1987, only a slight increase occurred in its relative frequency in both men and women.[11]

Several studies have suggested that the frequency of BAC is increasing.[17,18] However, this theory was not confirmed by data from the SEER program, which showed a slight decrease in the percentage of lung cancers diagnosed as BAC and no significant change in the AAR.[11]

The peak age-specific rates for the 1983–1987 year period in the SEER data occurred at approximately 70 to 74 years of age for each major histologic type of lung cancer.[11] Squamous cell carcinoma was the most common histologic type among persons 65 years and older, whereas adenocarcinoma predominated among younger individuals.

These shifts in histologic types and sex/race distribution may result from differences in smoking habits or other dietary, host, environmental, and/or occupational factors.

PATHOLOGY

General Pathologic Features

The pathologic diagnosis of lung cancer can be established by examination of cytologic or surgical pathology specimens.[6] The certainty of the diagnosis may depend on the amount of tumor in the specimen and how well the tumor cells are preserved. In general, surgical pathology specimens are more likely to provide diagnostic material than cytologic specimens; however, in some cases cytology may provide more diagnostic information than the histology of biopsies. Histologic specimens may be from bronchoscopic or needle biopsies and open biopsy procedures such as thoracoscopy, excisional wedge biopsy, lobectomy, or pneumonectomy.

The location of the tumor and the condition of the patient may influence the type of specimen that can be obtained. Central tumors are often best sampled with bronchoscopic biopsies or sputum cytology, whereas specimens from peripheral tumors may be more readily procured sampled by transbronchial biopsies or fine-needle biopsies.

Pathologic Staging

Pathologic characteristics important for staging of lung cancer can be considered according to the various T categories (Table 26.3) (see also Chapter 32). TX tumors are diagnosed by cytology alone in patients without a radiographically detectable or bronchoscopically visible tumor. Tumor size is important in separating T1 from T2 lesions because T1 tumors are 3 cm or less in greatest dimension. Visceral pleural invasion is absent in T1 tumors, but its presence in a tumor of any size makes the tumor at least a T2 lesion. If a tumor involves the main bronchus, 2 cm or more distal to the carina, it is regarded as a T2 lesion. The presence of atelectasis or obstructive pneumonitis that extends to the hilar region but involves less than an entire lung also makes a tumor of any size at least a T2 lesion. A tumor of any size is regarded as a T3 lesion if it extends into the chest wall (including superior sulcus tumors), the diaphragm, the mediastinal pleura or parietal pericardium without involving the heart, great vessels, trachea, esophagus, or vertebral body. If it causes atelectasis or obstructive pneumonitis of the entire lung, it is also regarded as a T3 lesion. A tumor of any size is a T4 lesion if it invades the mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or the carina. Lung cancers are also regarded as T4 lesions if they cause separate tumor nodule(s) in the same lobe or a malignant pleural effusion. [19]

TABLE 26.3. ANATOMIC CHARACTERISTICS OF THE PRIMARY TUMOR IMPORTANT FOR STAGING

Assessment of lymph node involvement is also important. NX is applicable if regional lymph nodes cannot be assessed. N0 signifies no lymph node metastases. N1 indicates metastases to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension. N2 applies to cases with metastases to ipsilateral mediastinal lymph nodes or subcarinal lymph nodes. N3 corresponds to metastases to contralateral hilar or mediastinal, ipsilateral or contralateral scalene or supraclavicular lymph nodes. All lymph nodes submitted with a surgical resection specimen should be examined histologically. Grading of tumors is based on the area of worst differentiation. GX is used when the grade of differentiation cannot be assessed. G1, G2, and G3 represent well, moderately, and poorly differentiated, respectively. G4 represents an undifferentiated tumor. [6]

Synchronous Primary Lung Cancers and Intrapulmonary Satellite Lesions

Synchronous primary lung cancers occur in approximately 0.5% of lung cancer patients. [20,21,22,23 and 24] By definition, synchronous primary lung cancers consist of concurrent, separate, malignant lung epithelial neoplasms with different histology or tumors of similar histology arising in different locations (segments, lobes, or lung). [20] Some definitions also require that tumors of the same histology not only be in a different segment of a lobe or the lung, but that the following criteria also be met: (a) origin from carcinoma *in situ* (b) no carcinoma in lymphatics common to both, and (c) no extrapulmonary metastases at the time of diagnosis. [25] A recent study found synchronous non–small cell lung carcinoma (NSCLC) in 0.8% of 3,034 lung cancer patients and suggested that the prognosis for patients with synchronous NSCLC may not be dismal if both tumors are resectable and stage I or II. [26]

Satellite nodules can be encountered in 8% to 10% of resected lung cancer specimens. [27,28] They are defined as well-circumscribed foci of carcinoma adjacent to but clearly separated from the main tumor by normal lung parenchyma. [27] The satellite nodule should have the same histology as the main tumor, but it should not represent an intrapulmonary lymph node metastases. [27] The presence of satellite nodules has a significantly adverse effect on prognosis, especially for patients with stage I disease. [27]

General Histologic Features

The major histologic subtypes of lung cancer include squamous cell carcinoma, adenocarcinoma, SCLC, and large cell carcinoma (Table 26.1), [6] but because major differences exist in the therapeutic approach to patients with SCLC versus NSCLC, the major question often asked of pathologists is whether a lung cancer is an SCLC or an NSCLC. This differential diagnosis is discussed in a following section under the topic of SCLC.

The majority of lung cancers are histologically heterogeneous, which impacts on diagnosis of lung cancer because it is a potential source of variation in interobserver interpretation. [6] It is seldom recognized in bronchoscopic biopsy specimens because of the small sample of tissue. Histologic heterogeneity was thoroughly documented in a study of 100 surgically resected (n = 65) or autopsy (n = 35) lung cancer specimens reviewed by five lung pathologists. [28] Only 34% of the cases were homogeneous according to the majority of the panelists. Major heterogeneity (adenocarcinoma versus squamous cell carcinoma) was identified in 45% of the cases. Minor (subtype) heterogeneity (e.g., mixtures of acinar and papillary patterns in adenocarcinoma) was found in 21% of the cases. [28] Histologic heterogeneity also contributes to the "discrepancy" between the bronchoscopic biopsy interpretation compared to the pathologic diagnosis in subsequent resection specimens, which can occur in up to 38% of cases. [30] Therefore, in small bronchoscopic biopsy specimens, if unequivocal squamous cell or adenocarcinomatous differentiation is not seen and the tumor is an NSCLC, the best diagnosis is often " *non–small cell carcinoma.*"

Heterogeneity also exists at the ultrastructural level. [31,32,33,34 and 35] Several ultrastructural studies have shown that electron microscopy is more sensitive in detecting features of squamous or glandular differentiation than light microscopy. [31,32,33,34 and 35] Thus by electron microscopy, lung cancers appear even more heterogeneous than by light microscopy. Also, by electron microscopy a high percentage of large cell carcinomas show features of squamous cell or adenocarcinoma. [32,35] Thus the percentage of lung carcinomas classified as adenosquamous carcinomas by electron microscopy is much greater than by light microscopy. [31]

PREINVASIVE LESIONS

In the 1999 WHO International Association for the Study of Lung Cancer (ASLC) histologic classification of lung tumors, preinvasive lesions include squamous dysplasia/carcinoma *in situ* atypical adenomatous hyperplasia (AAH), and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH). [6] AAH and DIPNECH are two new lesions that were added since the 1981 classification was proposed. They are thought to be precursor lesions for adenocarcinomas and carcinoids, respectively.

In Situ Squamous Cell Carcinoma

In situ carcinoma of the bronchial epithelium is recognized for squamous cell carcinoma but not for the other histologic subtypes of lung carcinoma. It is the cytologically malignant end of the spectrum of squamous dysplasia and carcinoma *in situ.* By gross examination, *in situ* squamous cell carcinoma is characterized by loss of the normal longitudinal ridges of the bronchial mucosa, often with mucosal thickening and erythema. [36] In a resected specimen, careful mapping of the bronchial lesions and serial blocking of the bronchi may be helpful to document the extent of the process. Invasive carcinoma is often found in association with *in situ* carcinoma. If the invasion is early, it may appear grossly as a nodular mucosal thickening or ulceration.

Histologically, *in situ* carcinoma is characterized by full-thickness cytologic atypia of squamous epithelium. The cells show an increased nuclear to cytoplasmic ratio and nuclear hyperchromasia. Mitoses may be seen extending up to the surface of the squamous epithelium. Rarely, one may encounter a thin layer of maturation at the surface of the epithelium over the *in situ* carcinoma. Although the adjacent mucosa may show signs of dysplasia, in most cases an abrupt transition occurs from normal epithelium to *in situ* carcinoma. [36] *In situ* carcinoma can involve submucosal glands without penetrating the subepithelial basement membrane. Squamous

dysplasia and *in situ* carcinoma does not necessarily progress to invasive carcinoma; evidence suggests that they may regress to normal mucosa.[37,38,39 and 40]

The concept of roentgenographically occult carcinoma is applied to those lung cancers that are not visible on chest x-ray but shed tumor cells into the sputum.[41,42 and 43] Virtually all of these tumors are squamous cell carcinomas and many have some degree of *in situ* cancer.[41,42 and 43] In a study of 68 surgically resected specimens from such patients, Woolner et al. classified these cases into the following categories: carcinoma *in situ* (34%), intramucosal invasion: less than 0.1 cm (18%), invasion to bronchial cartilage: 0.11–0.30 cm (16%), deep invasion to full thickness of the bronchial wall: 0.31–0.5 cm (14%), and extrabronchial invasion: more than 0.5 cm (18%).[44] Nagamoto et al. divided occult squamous cell carcinoma into a creeping and a penetrating type.[45] Most cases are the creeping type, which shows extensive superficial growth. The penetrating type shows a marked downward growth and tends to become advanced more rapidly.[45] Metastases are not seen in tumors that do not invade beyond the subepithelial basement membrane.[44,46,47] According to Nagamoto, lymph node metastases are seen only in radiographically occult lung cancers with a length of longitudinal extension greater than 20 mm.[42] These patients are at increased risk for multicentric synchronous or metachronous lung carcinomas.[44,48]

Atypical Adenomatous Hyperplasia

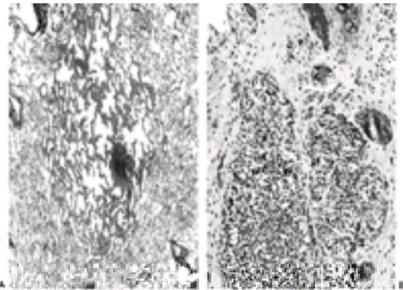
AAH is a bronchioloalveolar proliferation that is worrisome but does not meet criteria for bronchioloalveolar carcinoma.[48,49,50] It is considered a precursor to adenocarcinoma (Figure 26.3A and Figure 26.3B).[51] They are most often discovered incidentally as millimeter-sized histologic findings in lung cancer resection specimens.


FIGURE 26.3. Atypical adenomatous hyperplasia. **A:** This millimeter-sized bronchioloalveolar proliferation is ill defined with mild thickening of the alveolar walls. A lymphoid aggregate is present (hematoxylin and eosin, 30 × magnification). **B:** The alveolar walls show mild fibrous thickening, the hyperplastic pneumocytes show minimal atypia, and gaps are present between the cells (hematoxylin and eosin, 300 × magnification). (From Travis WD. Pathology of pulmonary incipient neoplasia. In: Albores-Saavedra J, Henson DE, eds. *Pathology of incipient neoplasia*. Philadelphia: WB Saunders, 2000 (*in press*), with permission. Case contributed by Dr. M. Noguchi, University of Tsukuba, Japan.)

Other published terminology for these lesions includes alveolar cell hyperplasia,[52] atypical alveolar hyperplasia,[53] atypical bronchioloalveolar cell hyperplasia,[54] alveolar epithelial hyperplasia,[55] and bronchioloalveolar adenoma.[56,50]

AAH may be found in 5.7% to 21.4% of lung cancer resection specimens. The variable percentage probably results from differences in effort made to look for the lesions as well as variation in diagnostic criteria.[50,54,55,57]

Because of their small size, AAH are usually incidental histologic findings, but they may be detected grossly, especially if they are 0.5 cm or larger. Processing the specimen in Bouin's fixative accentuates the gross visibility of AAH.[50] The lesions appear as ill-defined nodules usually less than 5 mm in diameter. Rarely, AAH may exceed 0.5 cm in diameter, and cases have been reported up to 1.0 cm.[50,54] Weng et al. found multiple lesions in 6.7% of lung cancer resection specimens and 2% of lung specimens resected for metastases.[54]

Histologically, AAH is a discrete, but ill-defined bronchioloalveolar proliferation (Figure 26.3A) in which the alveoli and respiratory bronchioles are lined by monotonous, slightly atypical cuboidal to low-columnar epithelial cells (Figure 26.3B). Focally, the alveolar walls may be altered to show a papillary growth pattern. Gaps usually exist between the cells. Nucleoli are inconspicuous or absent, but nuclear cytoplasmic inclusions may be seen. The alveolar septa may be slightly thickened with interstitial fibrosis, a mild lymphocytic infiltrate, and occasional lymphoid aggregates.

Although AAH has a distinct place in the classification of preinvasive lesions, in many cases it is very difficult to separate from nonmucinous BAC because of the great deal of morphologic overlap.[58] AAH must be distinguished primarily from the nonmucinous subtype of BAC and type II pneumocyte hyperplasia with interstitial inflammation and/or fibrosis.[59,60,61 and 62] Separation of AAH from small nonmucinous BAC may be very difficult.[6,49,63] The diagnosis of adenocarcinoma is favored if there is marked crowding of cells and/or overlapping of nuclei, nuclear atypia, and prominent papillary or invasive growth. Size is useful in that lesions 0.5 cm or greater in diameter with cytologic atypia are more likely to represent BAC, but in the absence of atypia, the diagnosis of AAH is still possible.[50]

It has not been shown that AAH alters the prognosis of patients with lung cancer.[64] Moreover, little data proves that AAH presenting in patients without lung carcinoma will subsequently develop a lung carcinoma. For this reason, a conservative approach is recommended in patients who are incidentally found to have AAH in the absence of an associated lung carcinoma.

Diffuse Idiopathic Pulmonary Neuroendocrine Cell Hyperplasia

DIPNECH is a rare condition in which neuroendocrine cells proliferate throughout the peripheral airways in the form of neuroendocrine cell hyperplasia, tumorlets, and sometimes carcinoid tumors.[6,65,66 and 67] Clinically, it is associated with obstructive airways disease because of the bronchiolar fibrosis. This condition is regarded as a precursor to carcinoid tumors because a subset of these patients has one or more carcinoid tumors.[6]

In DIPNECH, the neuroendocrine cell hyperplasia and tumorlets are thought to be a primary proliferation in contrast to the much more common situation where these lesions are seen as a reactive secondary lesion in the setting of airway inflammation and/or fibrosis.[68,69,70 and 71] Carcinoid tumors are arbitrarily separated from tumorlets if the neuroendocrine proliferation is 0.5 cm or larger.[6,10]

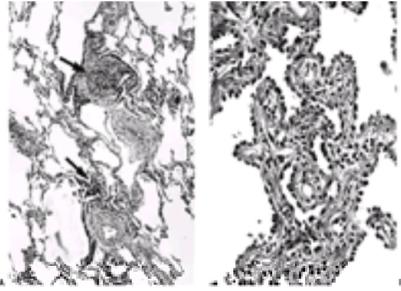
In DIPNECH, the histologic findings consist of increased numbers of scattered single cells, small nodules (neuroendocrine bodies), or linear proliferations of neuroendocrine cells within the bronchiolar epithelium (Figure 26.4A and Figure 26.4B). Confluent micronodular proliferations of neuroendocrine cells represent tumorlets, and if they are 0.5 cm in size or greater, they are called carcinoid tumors. Airway narrowing is often caused by fibrosis or the neuroendocrine proliferations and tumorlets (Figure 26.4B).


FIGURE 26.4. Diffuse idiopathic neuroendocrine cell hyperplasia. **A:** Nodules of hyperplastic neuroendocrine cells are present around the bronchioles *(arrows)*. **B:** This tumorlet is associated with a bronchus (cartilage— *top right*) and consists of a nodule of neuroendocrine cells. (Case contributed by Dr. Anthony A. Gal, Emory University, Atlanta, GA.)

Squamous Cell Carcinoma

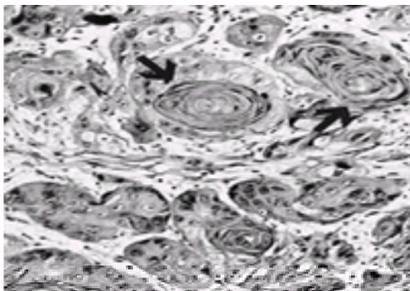
Squamous cell carcinoma accounts for approximately 30% of all lung cancers (Table 26.2).[1] Two-thirds of squamous cell carcinomas present as central lung tumors, whereas many among the remaining one-third are peripheral.[10,72] Most cavitating lung cancers are squamous cell carcinomas, and virtually all cases show intravascular tumor cells adjacent to the tumor.[73] Intercellular bridging, squamous pearl formation, and individual cell keratinization characterize squamous differentiation in squamous cell carcinomas. (Figure 26.5) In well-differentiated tumors, these features are readily apparent; however, in poorly differentiated tumors, they are difficult to find (Figure 26.6).[74] Squamous cell carcinomas are commonly believed to arise from a progression of squamous metaplasia or basal cell hyperplasia with atypia, through dysplasia, carcinoma *in situ,* and microinvasive carcinoma.[75] However, it is also possible that squamous cell carcinoma can develop *de novo* in normal bronchial mucosa.[46] Squamous cell carcinoma arises most often in segmental bronchi, and involvement of lobar and mainstem bronchi occurs by extension.[46] The histologic subtypes of squamous cell carcinoma include papillary, clear cell, small cell, [76] and basaloid variants.[6] Papillary squamous cell carcinomas often show a pattern of exophytic endobronchial growth. [77,78] Rarely, squamous cell carcinoma of the lung arises in nonirradiated patients with laryngotracheobronchial papillomatosis, and these tumors have been shown to contain human papillomavirus DNA. [79,80] A minute squamous cell carcinoma has been reported, arising in the wall of a congenital lung cyst.[81]


FIGURE 26.5. Squamous cell carcinoma, well differentiated. These tumor cells have abundant eosinophilic keratinized cytoplasm and form nests and keratin pearls *(arrows)* characteristic of squamous differentiation (hematoxylin and eosin, 200 × magnification).
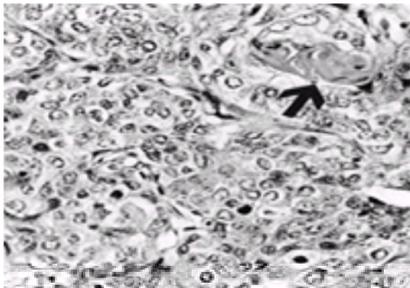

FIGURE 26.6. Squamous cell carcinoma, poorly differentiated. This tumor is growing in sheets and shows focal keratinization *(arrow)* (hematoxylin and eosin, 400 × magnification).

Adenocarcinoma

Adenocarcinomas account for a little more than 30% of all lung cancers (Table 26.2).[11] According to the 1999 World Health Organization (WHO) classification, adenocarcinomas can be subclassified into five major subtypes: acinar (gland forming), papillary, bronchioloalveolar, solid with mucous formation, and mixed adenocarcinoma.[5] In addition, several unusual variants of adenocarcinoma include well-differentiated fetal adenocarcinoma, [82] mucinous ("colloid") adenocarcinoma,[83] mucinous cystadenocarcinoma,[84,85,86 and 87] signet ring carcinoma,[88] and clear cell adenocarcinoma.[6] The WDFA was previously regarded as the epithelial pattern of pulmonary blastoma as defined in the 1981 WHO classification. [188] However, subsequent studies have shown that it represents a variant of adenocarcinoma. [8,90] The term *pulmonary blastoma* is reserved for the biphasic tumors that have a component of WDFA and a primitive sarcomatous component. [6] Two unusual gross patterns of adenocarcinoma include the endobronchial polypoid adenocarcinoma [91] and pseudomesotheliomatous adenocarcinoma.[92,93 and 94] A single case of adenocarcinoma involving the bronchial epithelium in a pattern similar to that of Paget's disease has been reported. [95] Adenocarcinomas have also been reported arising in cystic lung lesions.[96,97]

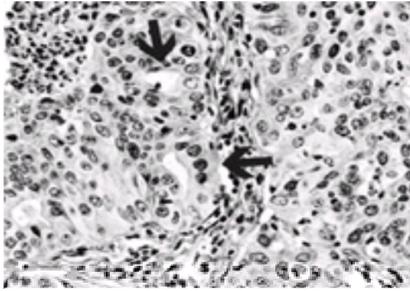
Most adenocarcinomas are histologically heterogeneous, consisting of two or more of the histologic subtypes; therefore, most adenocarcinomas fall into the mixed subtype. Adenocarcinomas form acinar (glandular) (Figure 26.7) or papillary structures. When they grow in a purely lepidic fashion, they are regarded as BAC (see following). Solid adenocarcinomas with mucin closely resemble large cell carcinoma, except for the production of intracytoplasmic mucin that should be present in at least five cells in at least two high-power fields. Adenocarcinomas are often associated with scarring fibrosis. At the periphery, many adenocarcinomas show a focal BAC-like pattern. Psammoma bodies may be seen in up to 10% of tumors with a papillary component.[98]


FIGURE 26.7. Adenocarcinoma, poorly differentiated. Focal gland formation *(arrows)* is present in this tumor, which otherwise consists of sheets of undifferentiated large cells (hematoxylin and eosin, 400 × magnification).

The concept of scar carcinoma was proposed for those lung cancers associated with dense fibrotic scars. [99,100 and 101] The classic description of a scar carcinoma is a peripheral tumor causing thickening and often puckering of the overlying pleura, with common anthracotic pigment and cholesterol clefts within the scar, and necrosis. [102] Although scars can be found in association with any histologic type of lung cancer, we have chosen to discuss this concept here because most of these tumors are adenocarcinomas. [99,100,103] Scar carcinomas reportedly have distinctive clinical features such as a higher distribution of adenocarcinoma, frequent presentation with nonpulmonary symptoms related to metastases, and presentation as radiographically occult lung cancer. [104] It has been proposed that patients with scar carcinomas have a worse prognosis than tumors without scarring, [104] although other studies suggest that no difference in prognosis exists compared to similar histologic cell types devoid of scarring. [105,106]

Shimosato and colleagues have shown that the scars in most of these tumors are most likely caused by the tumors, [100] and the concept that the lung cancer developed as a result of a pulmonary scar is incorrect. Multiple subsequent studies have supported this impression, [101,103,107] although it is likely that lung carcinomas may arise in the setting of certain pulmonary fibrotic conditions. [108,109,110,111 and 112]

Bronchioloalveolar Carcinoma

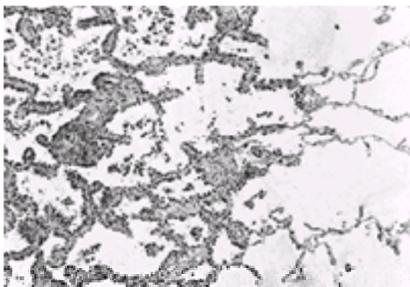
BAC is defined as an adenocarcinoma of the lung, which grows in a lepidic fashion along the alveolar septae without invasive growth (Figure 26.8). In the new 1999 WHO/IASLC classification, the lack of invasive growth was added as an essential criterion [6] because data suggests that such patients may be curable by surgical resection. [113] Although a BAC-like pattern of spread is common at the edge of conventional adenocarcinomas, histologically pure BAC is uncommon, accounting for only 3% of all invasive lung malignancies (Table 26.2). [11] Controversy exists whether histologic, histogenetic, or clinical dissimilarity is present between classic adenocarcinomas and bronchioloalveolar carcinoma. [114,115,116 and 117] However, much of the literature on the subject of BAC needs to be reevaluated based on the new definition of BAC. One of the problems resulting from the previous WHO classifications is that the percentage of lepidic growth pattern required to make the diagnosis of BAC was not specified. [89,118] As a result, some authors regarded tumors with only a minor component of lepidic growth to represent BAC. [118] Another problem with BAC is that metastatic adenocarcinomas can mimic the histologic appearance of BAC, especially the mucinous variant. [120]


FIGURE 26.8. Adenocarcinoma, bronchioloalveolar type, non–mucin-producing. This tumor consists of uniform cuboidal cells proliferating along the alveolar septae. The alveolar architecture is preserved. The tumor contrasts with the normal alveolar walls *(right)* (hematoxylin and eosin, 100 × magnification).

More than 50% of BACs may be associated with focal scars, and the tumor often grows around the edge of the scar. [121] However, if the tumor shows irregular tumor cell nests and a desmoplastic stromal reaction, it is regarded as having a component of acinar or solid adenocarcinoma and is no longer a pure BAC. [10,121]

There are two major histologic types of BAC: nonmucinous and mucinous. [8] Rarely, BAC may consist of a mixture of mucinous and nonmucinous subtypes, or it may be difficult to make a precise distinction between the two subtypes. [6] Approximately 41% to 60% are mucin-producing, 21% to 45% are non–mucin-producing, 12 to 14% are a mixture, and in up to 7% of cases, it may be difficult to classify the tumor. [121,122] The mucin-producing tumors show gross and microscopic mucin production and tend to be multicentric. [122] They may also cause lobar consolidation resembling pneumonia on gross examination. Histologically, these tumors consist of tall columnar cells with abundant apical cytoplasmic mucin and small basally oriented nuclei. The tumor cells grow along thin alveolar septae. The surrounding airspaces are often filled with mucin, sometimes creating a colloidlike appearance.

The nonmucinous BAC are more likely to be solitary. [122] Histologically, these tumors are composed of cuboidal cells proliferating along alveolar septae. A hobnail or saw-toothed appearance is often seen. Nuclear inclusions may be found in up to 56% of cases and are usually seen in nonmucinous tumor cells. These inclusions show the following properties: (a) they are PAS-positive; (b) they stain with immunohistochemistry for surfactant apoprotein; and (c) by ultrastructure they appear to consist of a network of 40-nm branching microtubules thought to arise from the inner nuclear membrane. [120,123] Nonmucinous BAC may consist of either Clara cells or type II pneumocytes; however, this distinction is not important for histologic classification.

Several pathologic variations of BAC may be encountered. A sclerosing variant is recognized, in which the alveolar septae are thickened by fibrosis without loss of the alveolar architecture. [124] The fibrosis in such cases may be rich in elastic fibers. [113] However, the presence of focal scarring within a BAC should raise concern for possible invasive growth. BAC may be cystic, and it rarely presents as multiple, diffuse, bilateral, cystic, cavitary lesions. [125] Tumors characterized by extensive mucin production have been described as mucinous or so-called colloid carcinomas. [83] Dekmezian et al. reported a single case of a BAC with myoepithelial cells. [126]

It can be difficult to separate BAC from a variety of other lesions, including reactive epithelial hyperplasias in fibrotic lung conditions, atypical adenomatous hyperplasia, [49,50,55,57] and metastatic carcinomas. Because of the new WHO/IASLC definition, a final diagnosis of BAC can be achieved only in a surgical resection specimen. For this reason, bronchoscopic or needle biopsies showing an adenocarcinoma with a lepidic growth pattern may suggest only the possibility of BAC and are insufficient to exclude the presence of invasive growth.

Various pathologic features have been described as prognostic factors for BAC. Many of these need to be reevaluated given the new definition of BAC. Formerly described prognostic factors included cell type, with nonmucinous tumors having a much better survival than mucinous tumors. [121,122] The presence of multiple tumors, [121] alveolar spread, [120,124] size greater than 3 cm, [124] the sclerosing variant of BAC, [124] high histologic grade, [127] pleural invasion, [124] and lymph node metastases [124] also were shown to correlate with a poor prognosis. Daly et al. found that the presence of dense collagen within the tumor was associated with a better prognosis. [121]

Linnoila et al. found that peripheral airway immunohistochemic markers such as surfactant-associated protein and 10kD Clara cell protein were independent prognostic factors for survival in patients with NSCLCs including BAC.[128] Although patients with solitary nonmucinous tumors less than 3 cm in diameter have an excellent prognosis, patients with advanced-stage BAC have a poor prognosis comparable to other lung adenocarcinomas.[129,130]

Small Cell Carcinoma

Pathologic Features

SCLC accounts for 20% of all lung cancers (Table 26.2), and approximately 30,000 new cases occur in the United States each year.[11] Approximately two-thirds of SCLCs present as a perihilar mass. SCLCs are typically situated in a peribronchial location with infiltration of the bronchial submucosa and peribronchial tissue. Bronchial obstruction is usually caused by circumferential compression, although rarely endobronchial lesions can occur. Because the diagnosis is usually established on transbronchial biopsy and/or cytology, it is unusual to encounter SCLC as a surgical specimen. Extensive lymph node metastases are common. The tumor is white-tan, soft, friable, and often shows extensive necrosis. With advanced disease, the bronchial lumen may be obstructed by extrinsic compression. In up to 5% of cases, SCLC presents as a peripheral coin lesion.[131,132]

Subclassification of SCLC has evolved considerably over the past two decades. In 1981 the WHO proposed that SCLC be subclassified into three subtypes: (a) oat cell carcinoma, (b) intermediate cell type, and (c) combined oat cell carcinoma.[5] However, expert lung cancer pathologists could not reproduce this subclassification, and significant differences in survival could not be shown. For these reasons, in 1988 the IASLC proposed that the intermediate cell type category be dropped and added the category of mixed small cell/large cell carcinoma because it appeared that these patients might have a worse prognosis than other SCLC patients.[133] They continued to use the category of combined SCLC for tumors mixed with adenocarcinoma or squamous cell carcinoma and proposed that all tumors lacking a non–small cell component be called SCLC.[133] Because subsequent data suggested that the prognosis for mixed small cell/large cell carcinoma might actually be better, and because there are problems in reproducibility for this subtype,[134] in the new WHO/IASLC classification, combined SCLC is the only subtype of SCLC (Table 26.1).[6]

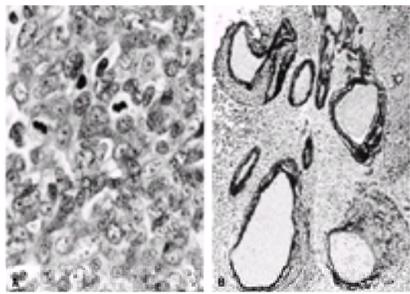
By light microscopy, SCLC consists of tumor cells characterized by small size, a round to fusiform shape, scant cytoplasm, finely granular nuclear chromatin, and absent or inconspicuous nucleoli (Figure 26.9A).[6] Nuclear molding and smearing of nuclear chromatin caused by crush artifact may be conspicuous. Mitotic figures are common, sometimes exceeding 100 mitoses per 10 high-power fields. The tumor often grows in sheets without a specific pattern, but rosettes, peripheral palisading, organoid nesting, streams, ribbons, and rarely, tubules or ductules may be present.[135] Necrosis is usually extensive. Mitotic rates are high. Hematoxyphilic encrustation of vessel walls (Azzopardi effect) is a common finding (Figure 26.9B).[135]


FIGURE 26.9. Small cell carcinoma. **A:** This tumor consists of densely packed small tumor cells with scant cytoplasm, finely granular nuclear chromatin, inconspicuous or absent nucleoli, and multiple mitoses (hematoxylin and eosin, 100 × magnification). **B:** This small cell carcinoma is extensively necrotic and shows the Azzopardi effect or hematoxyphillic staining of the vascular walls caused by DNA encrustation (hematoxylin and eosin, 100 × magnification).

Although no absolute upper limit exists for cell size in the diagnosis of SCLC, it has been suggested that the cells should measure approximately the diameter of two to three small resting lymphocytes.[136] Within the entity of SCLC, cell size range includes cases that have larger cells approaching the size of large cell carcinoma. This problem was addressed by the 1981 WHO/IASLC classification for lung tumors that proposed the category of intermediate cell type of SCLC.[133] Vollmer et al. used morphometry to demonstrate a gradual transition in cell size from the smallest SCLC to large cell carcinoma.[137] Thus cases that fall in the middle of the spectrum cannot be distinguished according to cell size alone. This finding may account, in part, for the difficulty in interobserver reproducibility of the intermediate subtype category of SCLC as proposed by the 1981 WHO classification.[137]

According to the morphometric study by Vollmer et al., the size of SCLC cells also appears greater in larger biopsy specimens.[137] Thus the tumor cells of SCLC appear larger in well-fixed open biopsies than in transbronchial biopsy specimens.

Subsequent to chemotherapy, biopsy specimens from 15% to 45% of patients with SCLC can show an admixture of components of large cell, squamous, giant cell, or adenocarcinoma.[138,139 and 140]

Combined SCLC

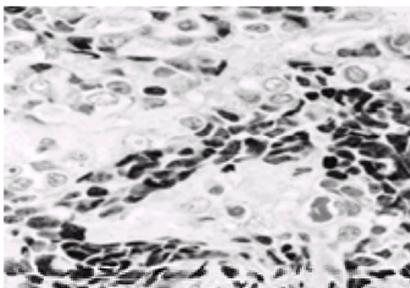
Less than 10% of SCLCs show a mixture with another histologic component type of NSCLC. A combination of SCLC and large cell carcinoma (Figure 26.10) is found in approximately 4% to 6% of cases.[133] Approximately 1% to 3% of SCLCs may be combined with adenocarcinoma or squamous cell carcinoma.[133,134,139,141] Mixtures of SCLC can also occur with spindle cell carcinoma,[142,143] giant cell carcinoma,[143] and carcinosarcoma.[144] It remains to be proven whether these patients have significant differences in clinical features, prognosis, and response to therapy.[141] Some evidence suggests a survival benefit for patients who undergo resection.[141]


FIGURE 26.10. Combined small cell and large cell carcinoma. This tumor consists of large cells with abundant cytoplasm and vesicular nuclei with prominent nucleoli admixed, with small cells having scant cytoplasm and finely granular chromatin (hematoxylin and eosin, 630 × magnification).

Clinical Features and Prognosis

SCLC has a very aggressive clinical course with frequent widespread metastases. It is considered a distinct clinicopathologic entity because of the many characteristic clinical manifestations, the unique pathologic features, and the sensitivity to chemotherapy.

Untreated patients with limited-stage and extensive-stage SCLC have a median survival of 3 and 1.5 months, respectively. With combination chemotherapy and chest radiotherapy, the median survival is improved to 10–16 months for patients with limited-stage disease, and 6–11 months for patients with high-stage disease.

Differential Diagnosis

Because major differences exist in therapeutic approach to patients with SCLC versus NSCLC, the major question asked of pathologists is whether the tumor is an SCLC or an NSCLC. The distinction of SCLC from large cell carcinoma or large cell neuroendocrine carcinoma (LCNEC) should not rest on a single criteria such as cell size or nucleoli; multiple additional features should be assessed, including nuclear to cytoplasmic ratio, nuclear chromatin, nucleoli, nuclear molding, cell shape (fusiform versus polygonal), and hematoxylin vascular staining (Table 26.4).[137,145]

Histologic Feature	Small Cell Carcinoma	Large Cell Neuroendocrine Carcinoma
Cell size	Smaller (less than diameter of 3 lymphocytes)	Larger
Nuclear/cytoplasmic ratio	Higher	Lower
Nuclear chromatin	Finely granular, uniform	Coarsely granular or vesicular; Less uniform
Nucleoli	Absent or faint	Often (not always) present; May be prominent or faint
Nuclear molding	Characteristic	Less prominent
Fusiform shape	Common	Uncommon
Polygonal shape with ample pink cytoplasm	Uncharacteristic	Characteristic
Nuclear smear	Frequent	Uncommon
Basophilic staining of vessels and stroma	Occasional	Rare

TABLE 26.4. LIGHT MICROSCOPIC FEATURES FOR DISTINGUISHING SMALL CELL CARCINOMA AND LARGE CELL NEUROENDOCRINE CARCINOMA

Morphologic separation of SCLC from NSCLC can be difficult. In the study by Reglue et al. agreement for the diagnosis of SCLCs for all five observers was 93% and for at least four or five observers it was 98%.[29] Disagreement among expert lung cancer pathologists over the distinction between SCLC and NSCLC may occur in up to 5% to 7% of cases.[28,145]

The poor agreement (only 72%) for the subtyping of SCLCs (e.g., oat cell versus intermediate) is one of the reasons for the recent revised classification of SCLC, which was proposed to replace the histologic subtyping in the second edition. WHO classification (Table 26.1).[133]

In small, crushed biopsy specimens, SCLC can be difficult to distinguish from carcinoid tumors, lymphocytic infiltrates, or poorly differentiated NSCLC. In some cases, comparison with cytology specimens taken at the time of bronchoscopy enables a definitive diagnosis. Lymphoid infiltrates, whether caused by small lymphocytic lymphoma or chronic inflammation, can be distinguished from SCLC by their discohesive pattern of growth, contrasting with the epithelial clustering and nuclear molding of SCLC. In addition, immunohistochemistry for keratin (epithelial marker) and common leukocyte antigen (lymphoid marker) can be very useful. If the biologic behavior of a tumor raises doubts about the diagnosis of SCLC, additional biopsies may be helpful to establish the diagnosis.[147]

Large Cell Carcinoma

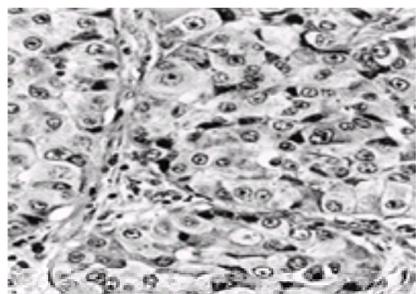
Large cell carcinoma is a poorly differentiated carcinoma that does not have features of squamous cell carcinoma, adenocarcinoma, or SCLC. Thus it is a diagnosis of exclusion, and a spectrum of morphology is encompassed by this histologic subtype. Most tumors consist of large cells with abundant cytoplasm and large nuclei with prominent nucleoli and/or vesicular nuclei (Figure 26.11).[10,148,149,150 and 151] Several variants of large cell carcinoma are recognized in the new WHO/IASLC histologic classification of lung cancer, including LCNEC[6,145,152] basaloid carcinoma,[153] lymphoepithelial-like carcinoma,[154,155 and 156] clear cell carcinoma,[157] and large cell carcinoma with rhabdoid phenotype.[158]


FIGURE 26.11. Large cell carcinoma. This tumor consists of sheets and nests of large cells with abundant cytoplasm and vesicular nuclei with prominent nucleoli (hematoxylin and eosin, 400 × magnification).

Many poorly differentiated adenocarcinomas or squamous cell carcinomas may show a component of large cell carcinoma. Because such tumors are classified according to their best differentiated component, no combined adenocarcinoma or squamous cell carcinoma/large cell carcinoma exists. Therefore, a small bronchial biopsy may reveal large cell carcinoma, whereas the subsequent resected specimen may enable more specific classification as a squamous cell carcinoma or an adenocarcinoma.[30,31,159] For this reason, if clear-cut morphologic criteria cannot be satisfied for subclassification as squamous cell or adenocarcinoma, the general diagnosis of "lung cancer, non–small cell type" should be made. Positive staining of intracytoplasmic mucin with the mucicarmine or periodic-acid-Schiff with diastase digestion (DPAS) stains separate the solid variant of adenocarcinoma with mucin production from large cell carcinoma. If large cell carcinoma is mixed with SCLC, it is regarded primarily as a variant of SCLC: mixed small cell/large cell carcinoma.[133]

Several variants of large cell carcinoma include clear cell carcinoma,[160] lymphoepithelioma-like carcinoma,[15,161,162] and LCNEC.[145] This discussion focuses primarily on LCNEC and its relationship to SCLC. Spindle and giant cell carcinomas and the concept of pleomorphic carcinoma are also mentioned.

Large cell carcinoma accounts for 9% of all lung carcinomas.[11] These tumors may be central or peripheral, and by gross examination they often appear as large necrotic tumors. Histologically, the tumors usually consist of sheets and nests of large polygonal cells with vesicular nuclei and prominent nucleoli.[5] They may have a somewhat squamous or adenocarcinoma appearance, but they fall short of criteria for those tumors. By electron microscopy, a high percentage of large cell carcinomas show features of squamous cell or adenocarcinoma.[32,35,163]

Large Cell Neuroendocrine Carcinoma

Pathologic Features

Approximately two-thirds of LCNECs are peripheral, with the remainder being centrally located. The average size is 4.0 cm with a range from 0.7 cm up to 9 cm. They are usually circumscribed, nodular masses with a necrotic, tan, red cut surface.

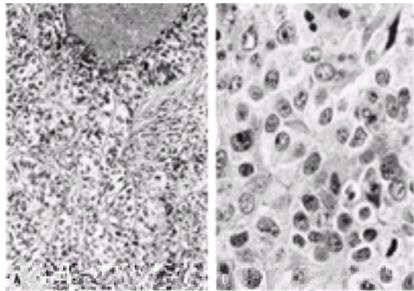
LCNECs are defined by the following histologic criteria: (a) light microscopic features commonly associated with neuroendocrine tumors such as organoid, palisading, trabecular, or rosettelike growth patterns (Figure 26.12A); (b) tumor cells of large size, polygonal shape, low nuclear to cytoplasmic ratio, coarse or vesicular nuclear chromatin, and frequent nucleoli (Figure 26.12B); (c) high mitotic rate (>10/10 HPF) with a mean of 60 mitoses per 10 HPF and some exceeding 100 per 10 HPF; (d) frequent necrosis; and (e) neuroendocrine features by immunohistochemistry (Figure 26.13) or electron microscopy.[145] The term *large cell carcinoma, with neuroendocrine morphology* can be used for tumors resembling LCNEC by light microscopy but lacking proof of neuroendocrine differentiation by electron microscopy or immunohistochemistry.


FIGURE 26.12. Large cell neuroendocrine carcinoma. **A:** Organoid nests and trabecular growth patterns give this tumor a neuroendocrine morphologic appearance. Necrosis is also conspicuous *(top, bottom)* (hematoxylin and eosin, 400 × magnification). **B:** The tumor cells have abundant cytoplasm and some show vesicular nuclei and/or prominent nucleoli. A mitotic FIGURE is present (hematoxylin and eosin, 800 × magnification).
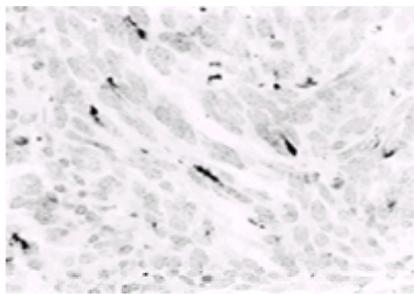

FIGURE 26.13. Large cell neuroendocrine carcinoma. Focally, the tumor cells stain positively for chromogranin (chromogranin, 630 × magnification).

The term *combined LCNEC* is used for those tumors associated with other histologic types of NSCLC (Table 26.1). Most often this represents a component of adenocarcinoma. If a component of SCLC exists, then the tumor becomes a combined SCLC.

Clinical Features

The median age for patients with LCNEC is 62 years (range 33 to 87 years). Virtually all patients are cigarette smokers and most have over a 40 pack-year history of smoking.[145] Ectopic hormone production is uncommon in cases of LCNEC and has not been observed in any reported cases. [145]

LCNEC is an aggressive malignancy with a prognosis approaching the dismal outlook for SCLC. Fifty percent of patients are dead at 1.2 years, and the 5- and 10-year survival is 23% and 11%, respectively. Therefore, patients with LCNEC also have a worse outlook than for adenocarcinoma. Some patients with LCNEC, particularly those with stage I or II tumors, may do well. The optimal therapy remains to be defined because these tumors are rare and few institutions have accumulated enough patients to make definite therapeutic recommendations. Until more information is known about the clinical behavior of LCNEC and its response to chemotherapy, resectable tumors should be removed surgically. Some patients with advanced-stage disease have responded to chemotherapy so that adjunctive chemotherapy may be beneficial following surgery.

Differential Diagnosis

LCNEC must be distinguished from adenocarcinoma, SCLC, large cell carcinoma, and large cell carcinoma with neuroendocrine differentiation (LCC-ND). Mitotic counts are one of the most useful criteria for distinguishing adenocarcinoma from LCNEC. [145] According to the new WHO/IASLC criteria for adenocarcinoma, the upper limit of mitoses should be 10 mitoses per 2 mm^2 (10 high-power fields on some microscopes).[6,164] This limit contrasts with the mitotic rate of LCNEC, which should have a mitotic count greater than 11 per 2 mm^2 (10 high-power fields, but typically ranges between 50 to 100 mitoses per 10 high-power fields. [145] The extent of necrosis in LCNEC is generally more extensive than in adenocarcinoma, where it usually consists of punctate foci within organoid nests of tumor cells. Nuclei of adenocarcinoma usually show a finely granular chromatin, whereas most LCNEC have a vesicular or coarse chromatin. Thus adenocarcinoma is histologically intermediate grade, whereas LCNEC is histologically high grade. Separation of LCNEC from SCLC requires consideration of multiple histologic features rather than a single criterion (Table 26.4).

Large cell carcinomas can be separated into those that have neuroendocrine features by light microscopy as well as immunohistochemistry and/or electron microscopy (LCNEC), those with a neuroendocrine morphology (NEM) but lacking neuroendocrine differentiation by electron microscopy or immunohistochemistry (LCC-NEM), those with no neuroendocrine pattern by light microscopy or special studies (classic LCC), and those with neuroendocrine differentiation (NED) by special studies (LCC-NED).[6,145] LCC-NEDs differ from LCNECs histologically in that they lack neuroendocrine morphologic characteristics by light microscopy, such as prominent organoid nesting, trabecular, palisading, or rosette-like patterns.

Further data regarding the spectrum of clinical and pathologic features of LCNEC are awaiting larger series of cases. We hope this research will further define the differences in survival and response to therapy for LCNEC compared to adenocarcinoma, large cell carcinoma, LCC with NEM, LCC-NED, and SCLC.

Data is conflicting regarding the issue of whether NSCLC-NED may be responsive to SCLC chemotherapy regimens [165,166 and 167] or whether expression of neuroendocrine markers may be an unfavorable prognostic factor. [168,169,170,171,172,173,174 and 175] The significance of separation of LCNEC, LCC-NEM, and LCC-NED remains to be determined.

Adenosquamous Carcinoma

Adenosquamous carcinoma accounts for 0.6% to 2.3% of all lung cancers. [176,177,178,179 and 180] According to the new WHO/IASLC criteria, the tumor should consist of a

mixture of at least 10% adenocarcinoma and squamous carcinoma.[8] Ishida described three subtypes of adenosquamous carcinoma, including a predominantly glandular type, a predominantly squamous type, and a mixed type.[177] Although some studies have suggested a worse survival for adenosquamous carcinoma,[178,180] others indicate no difference from other NSCLCs.[177,179]

Carcinomas with Pleomorphic, Sarcomatoid, or Sarcomatous Elements

Carcinomas with pleomorphic, sarcomatoid, and sarcomatous elements represent a continuum of differentiation in poorly differentiated carcinomas. In the 1981 WHO classification, spindle cell carcinoma was classified as a variant of squamous cell carcinoma, and giant cell carcinoma was regarded as a variant of large cell carcinoma.[5] However, the concept of pleomorphic carcinoma was reported by Fishback et al. and emphasized that most carcinomas with spindle cell and/or giant cell differentiation were associated with patterns of other major subtypes of lung carcinoma, such as squamous cell carcinoma, adenocarcinoma, or large cell carcinoma.[143] Pleomorphic carcinomas tend to be large, peripheral tumors that often invade the chest wall. Because of the prominent histologic heterogeneity of this tumor, adequate sampling is important and should consist of at least one section per centimeter of the tumor diameter. In the new WHO/IASLC classification, at least a 10% component of the spindle cell and/or giant cell component must be present for a diagnosis of pleomorphic carcinoma. [6]

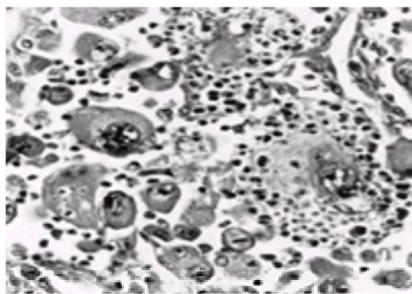
Giant and spindle cell carcinomas account for 0.3% of all invasive lung malignancies. [11] If the tumor has a pure giant cell pattern, the term *giant cell carcinoma* can be used. Giant cell carcinoma consists of huge, bizarre pleomorphic and multinucleated tumor giant cells (Figure 26.14).[181,182 and 183] The tumor cells of giant cell carcinoma are very large, measuring approximately two to three times the size of those in ordinary NSCLCs. [182] The nuclei may be single or multiple; sometimes they are bizarre with atypical mitotic figures. The cells are often discohesive and infiltrated by inflammatory cells. Neutrophil emperipolesis characterized by cytoplasmic infiltration by neutrophils is a distinctive feature (Figure 26.14). Fishback et al. recognized that 98% of giant cell carcinomas are associated with one or more other histologic subtypes such as spindle cell carcinoma (65%), adenocarcinoma (44%), large cell carcinoma (29%), squamous cell carcinoma (6%), and SCLC (2%). Therefore, pure giant cell carcinoma is rare, accounting for only 2% of cases of pleomorphic spindle and/or giant cell carcinomas. [143]


FIGURE 26.14. Giant cell carcinoma. These giant tumor cells are discohesive and infiltrated by numerous neutrophils, which show emperipolesis. Although none of these cells is multinucleated, they are huge with abundant eosinophilic cytoplasm and atypical large nuclei (hematoxylin and eosin, 400 × magnification).

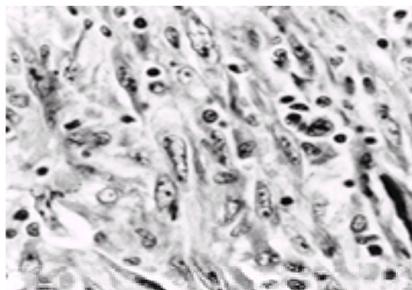
If the carcinoma consists of a pure spindle cell pattern, it can be regarded as spindle cell carcinoma (Figure 26.15).[184,185 and 186] however, Fishback et al. showed that only 9% of spindle cell carcinomas are associated with squamous cell carcinoma. Many cases were associated with a mixture of other histologic subtypes, with 52% showing a component of giant cell carcinoma, 47% adenocarcinoma, 24% large cell carcinoma, and 2% SCLC. [143] Only 10% of cases showed a pure spindle cell pattern.[143] Although immunohistochemistry for epithelial markers such as keratin can be helpful in confirming epithelial differentiation, the new WHO/IASLC requires only light microscopic criteria. [6] Nevertheless, immunohistochemistry and less often electron microscopy can be helpful. [184,185 and 186] In some cases, multiple epithelial markers may be necessary to demonstrate epithelial differentiation because these tumors are poorly differentiated. However, immunohistochemistry can be problematic because some sarcomas may express keratin. It is important to sample spindle cell carcinomas extensively to exclude the presence of recognizable carcinomatous foci that would allow for classification as pleomorphic carcinoma. If such foci cannot be found by light microscopy, one should perform immunohistochemistry for epithelial markers such as keratin, EMA, or CEA.


FIGURE 26.15. Spindle cell carcinoma. These spindle-shaped tumor cells have hyperchromatic atypical nuclei and were positive with immunohistochemic staining for keratin (hematoxylin and eosin, 630 × magnification).

The study by Fishback et al. of pleomorphic carcinomas showed that spindle cell and giant cell carcinoma coexist in 40% of cases. [143] These tumors were often associated with other histologic subtypes (more than 90% for spindle cell carcinoma and more than 97% for giant cell carcinoma). They typically presented as large peripheral lung masses in elderly male smokers and had a poor prognosis with a 10% five-year survival. [143]

Carcinosarcoma and Pulmonary Blastoma

Although carcinosarcoma and pulmonary blastoma were placed under the category of miscellaneous tumors in the 1981 WHO classification, [5] in the new WHO/IASLC classification they are regarded as types of carcinoma of the lung. [6] The new WHO/IASLC classification defines carcinosarcoma as a tumor consisting of a mixture of carcinoma and sarcoma that should show heterologous elements such as malignant cartilage, bone, or skeletal muscle. Pulmonary blastomas consist of a glandular component that resembles well-differentiated fetal adenocarcinoma and a primitive sarcomatous component. [6]

OTHER NEUROENDOCRINE TUMORS

Although SCLC represents one of the four major histologic subtypes of lung cancer, it is also generally regarded as a part of the spectrum of pulmonary neuroendocrine neoplasia. Other neuroendocrine lung tumors include typical and atypical carcinoid and LCNEC (Table 26.5). The clinical aspects of carcinoids and LCNEC are addressed briefly in this chapter because they are not specifically addressed elsewhere in this textbook.

TABLE 26.5. TERMINOLOGY FOR PULMONARY NEUROENDOCRINE LESIONS*

The classification of pulmonary neuroendocrine tumors of the lung is perplexing. Although a spectrum of clinical and histologic features of malignancy exist among these tumors, this complexity is compounded by a bewildering variety of terms and criteria in the literature. [6,10,145]

Lung tumors with neuroendocrine morphology include the low-grade typical carcinoid (TC), intermediate-grade atypical carcinoid (AC), and the high-grade LCNEC and SCLC. This classification has substantial reproducibility, with the greatest difficulty in separating TC from AC and LCNEC from SCLC.

Neuroendocrine differentiation may be detected by immunohistochemical or ultrastructural studies in 10% to 20% of histologically ordinary NSCLCs such as squamous cell carcinomas, adenocarcinomas, or large cell carcinomas (Table 26.5). The term *NSCLC-NE* is sometimes used for these cases. [145]

Typical and Atypical Carcinoid

Pathologic Features

Carcinoid tumors are often divided into central and peripheral tumors. The percentage of peripheral tumors varies from 16% to 40%, [187,188] with the remaining tumors being centrally located. Central carcinoids often have a large endobronchial component, with a fleshy, smooth, polypoid mass protruding into the bronchial lumen. Necrosis or extensive hemorrhage are characteristic of AC. Peripheral carcinoids are situated in the subpleural parenchyma, and they often do not bear an anatomic relationship to a bronchus.

Central carcinoids tend to be larger than peripheral tumors, with a mean diameter of 3.1 cm (range 0.5 to 10 cm) versus 2.4 cm (range 0.5 to 6 cm). [188] ACs are larger than TCs with a mean diameter of 3.6 cm for ACs compared to 2.3 cm for TCs. [188]

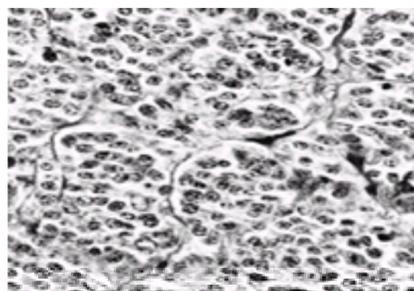
Both TCs and ACs are characterized histologically by an organoid growth pattern and uniform cytologic features, consisting of moderate eosinophilic, finely granular cytoplasm with nuclei possessing a finely granular chromatin pattern (Figure 26.16) (Table 26.6). Nucleoli are inconspicuous in most TCs but they may be more prominent in ACs. A variety of histologic patterns may occur in both AC and TC, including spindle cell (Figure 26.17), trabecular, palisading, rosettelike, papillary, sclerosing papillary, glandular, and follicular patterns. [145] The tumor cells of pulmonary carcinoid tumors may have oncocytic, acinic cell-like, signet-ring, mucin-producing, or melanocytic features. [145]


FIGURE 26.16. Typical carcinoid. This tumor is growing in organoid nests and consists of uniform medium-sized cells with a moderate amount of eosinophilic cytoplasm (hematoxylin and eosin, 500 × magnification).

Histologic or Clinical Feature	Typical Carcinoid	Atypical Carcinoid
Histologic patterns: organoid, trabecular, palisading, and spindle cell	Characteristic	Characteristic
Mitoses	Absent or <2 per 2 mm² area of viable tumor (10 high-power fields on some microscopes)	2–10 per 2 mm² of area of viable tumor (10 high-power fields on some microscopes)
Necrosis	Absent	Characteristic, usually focal or punctate
Nuclear pleomorphism, hyperchromatism	Usually absent, not sufficient by itself for diagnosis of AC	Often present
Regional lymph node metastasis at presentation	5–15%	40–48%
Distant metastasis at presentation	Rare	20%
Survival at 5 years	90–98%	58%
Disease-free survival at 10 years	90–95%	35%

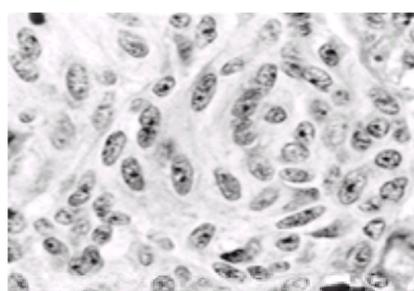
TABLE 26.6. TYPICAL AND ATYPICAL CARCINOID: DISTINGUISHING FEATURES


FIGURE 26.17. Carcinoid with spindle cell features. These tumor cells are prominently spindle-shaped and show the finely granular nuclear chromatin and moderate

amount of eosinophilic cytoplasm characteristic of carcinoid tumors (hematoxylin and eosin, 1,000 × magnification).

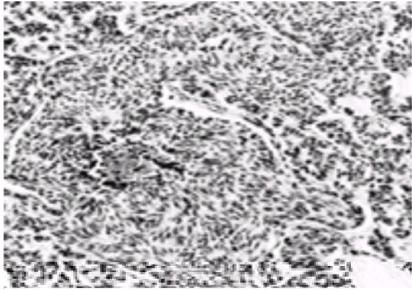
The original criteria for AC, as defined by Arrigoni et al. [164] were recently modified to a carcinoid tumor with mitoses between 2 and 10 per 2 mm^2 area of viable tumor (10 high-power fields in certain microscopes) or the presence of necrosis (Figure 26.18).[152] The presence of features such as pleomorphism, vascular invasion, and increased cellularity are not as helpful in separating TC from AC. In contrast, TC may have focal cytologic pleomorphism, but necrosis is absent and mitotic figures are rare (Table 26.6).[145,164] The necrosis in AC usually consists of small foci centrally located within organoid nests of tumor cells; uncommonly, the necrosis may form larger confluent zones. Criteria for separation of TC from AC are summarized in Table 26.6.


FIGURE 26.18. Atypical carcinoid. A punctate focus of necrosis is present in one of the organoid nests of spindle-shaped tumor cells. This feature is characteristic of atypical carcinoids (hematoxylin and eosin, 200 × magnification).

Clinical Features

Carcinoid tumors are low-grade malignant neoplasms of neuroendocrine cells, which constitute 1% to 2% of all lung tumors. [136] They are divided into typical and atypical types, with the latter possessing more malignant histologic and clinical features. [164]

The indolent nature of carcinoid tumors is reflected by the finding that 51% of patients are asymptomatic at presentation. [188] The most common pulmonary manifestations include hemoptysis in 18%, postobstructive pneumonitis in 17%, and dyspnea in 2% of patients. [188] Various paraneoplastic syndromes can occur with carcinoid tumors including the carcinoid syndrome, [188,189] Cushing's syndrome, [190] and acromegaly. [191] Bronchial carcinoids occur with equal frequency in men and women. [188,192] The mean age is 55 years with a range up to 82 years. [188] Bronchial carcinoids are the most common lung tumor in childhood. [183]

Surgery is the primary approach to management of bronchial carcinoids. [187,183] Patients with TC have an excellent prognosis and rarely die of tumor. [188,194] The finding of metastases should not be used as a criteria for distinguishing TC from AC because 5% to 20% of TCs have regional lymph node involvement.

Compared to TCs, ACs have a larger tumor size, a higher rate of metastases, and the survival is significantly reduced. The mortality reported in most series is approximately 30%, ranging from 27 to 47%.[164,188,195,196]

Prognosis in carcinoid tumors has been correlated with various clinical and pathologic features, including lack of surgical therapy, advanced stage, large tumor size (greater than 3 cm), lymph node metastases, vascular invasion, atypical versus typical histology, intraluminal versus extrabronchial spread, aneuploidy, S-phase, and integrated optical density measurement of nuclear DNA content. [188,192,195,196,197 and 198]

Differential Diagnosis

It can be difficult to distinguish TC from AC (and occasionally SCLC) in small, crushed biopsy specimens; therefore, one should be careful when interpreting transbronchial biopsies if the tumor cells are not well preserved. Although a spindle cell pattern is more common in AC and SCLC, it should not be used as a criterion for malignancy because it also occurs in TC. Spindle cell carcinoids differ from other non-neuroendocrine tumors composed of spindle-shaped cells, such as smooth muscle tumors (leiomyoma, leiomyosarcoma), chemodectoma, and spindle cell carcinoma. Separation of these tumors from carcinoid can be made by recognition in the latter of an organoid pattern, finely granular nuclear chromatin, and positive immunohistochemical staining for neuroendocrine markers or dense core granules by electron microscopy.

IMMUNOHISTOCHEMISTRY, AND FLOW CYTOMETRY

Immunohistochemistry plays an important role in the evaluation of neuroendocrine neoplasms of the lung. Many antibodies, including neuroendocrine, hormonal, epithelial, and other markers, can be used to immunohistochemically stain neuroendocrine lung tumors.

Small Cell Lung Carcinoma

Recent studies have shown that the most useful neuroendocrine markers for SCLC in formalin-fixed, paraffin-embedded tissue sections are chromogranin A, synaptophysin, Leu-7, and certain neural cell adhesion molecules (NCAMs). [145,199,200] Guinee et al. found staining for chromogranin in 60% versus 47%, NSE in 60% versus 33%, Leu-7 in 40% versus 24%, and synaptophysin in 5% versus 19% of open lung versus transbronchial biopsy specimens of SCLC. [199] The NCAM antibody 123C3 has shown promise in paraffin-embedded tissue sections. [201,202] Although NSE has been advocated as a useful marker for neuroendocrine differentiation, it is relatively nonspecific because it stains up to 60% of NSCLCs. [145] Bombesin or gastrin-related peptide (GRP) can be demonstrated immunohistochemically in a high percentage of SCLCs.[145,199]

Keratin (AE1/AE3) and membrane antigen (EMA) stain virtually all SCLCs in both open lung biopsy and transbronchial biopsy specimens. [145,199] Therefore, if keratin staining is negative in a suspected SCLC, one should be careful to exclude other possibilities, such as chronic inflammation, lymphoma, primitive neuroectodermal tumor, or small round cell sarcoma. Nevertheless, some SCLCs may be negative for keratin, and varied staining results may be caused by the antibody and/or methods used and the preservation of the material. Occasionally, a punctate perinuclear "do like" pattern of keratin staining may be encountered in SCLC, but this pattern is not specific and is found in the minority of keratin-positive cases.

Despite extensive efforts to identify monoclonal antibodies that will reliably distinguish SCLC from NSCLC, so far no antibodies have been proven to be effective in routinely processed, formalin-fixed, paraffin-embedded sections. [203,204] Up to 10% to 20% of NSCLCs exhibit neuroendocrine differentiation detectable by immunohistochemistry or electron microscopy. It is important, however, to remember that the WHO criteria for classification of lung cancer are based on conventional light microscopy, and data obtained by electron microscopy may not be comparable to data obtained by light microscopy alone.

DNA analysis of SCLC reveals a high percentage of aneuploidy, ranging up to 85% of cases, [145,197,205] but aneuploidy does not appear to correlate well with prognosis.[197,205] A high nuclear/cytoplasmic ratio in lung neuroendocrine tumors, which selects for SCLC, correlates strongly with prognosis. [206] High nucleolar organizer region values in lung neuroendocrine tumors also correlate with poor prognosis. [207]

Large Cell Neuroendocrine Carcinoma

LCNECs stain immunohistochemically with neuron specific enolase (NSE) (100%), chromogranin (80%), Leu-7 (40%), synaptophysin (40%), bombesin (40%), CEA (100%), and keratin (100%).[145] The immunohistochemic staining is often focal. Aneuploidy can be found in 75% of LCNECs.[145] Several molecular studies have shown that a high frequency of chromosomal abnormalities (p53, 3p, 9p, 5q and 11q) exist in the high-grade LCNECs and SCLCs with low and intermediate percentages of molecular changes in TC and AC, respectively.[208,209,210,211 and 212]

Carcinoid Tumors

Of the various types of pulmonary neuroendocrine tumors, the highest percentage, distribution, and intensity of immunohistochemic staining for neuroendocrine and hormonal markers can be found in TC. Chromogranin is the most useful immunohistochemic marker of neuroendocrine differentiation, followed by synaptophysin and Leu 7.[145]

Aneuploidy can occur in both TC and AC. It has been found in 5%–32% of TC and 16%–79% of AC.[145,192,197,213,214] Aneuploidy is significantly more frequent in AC than TC.[192,213,214] and it correlates with poor prognosis.[213] However, all aneuploid carcinoid tumors do not behave aggressively; in one study, 58% of patients with aneuploid carcinoid tumors survived five years.[213]

ELECTRON MICROSCOPY

Most lung carcinomas are diagnosed without the aid of ultrastructural study, but the electron microscope provides more information on the structure of the tumor cells than can be obtained from hematoxylin/eosin sections, and it is often helpful when the light microscopy alone is not adequate. A fine-needle aspiration biopsy can provide sufficient material, but the specimen must be handled properly to yield good results.[215] The electron microscope can also be useful in research studies on lung tumors. The detailed morphology of cell lines can be documented, and it is possible to perform precise immunocytochemistry, *in situ* hybridization, and image analysis using electron microscopic preparations. A brief account of the ultrastructure of the major types of primary lung tumors is included in this chapter to complement the descriptions of the light microscopy and cytology.

Squamous Carcinoma

Squamous cell carcinomas from different parts of the body look basically similar by light and electron microscopy. Variations in their appearance are mainly caused by the degree of keratinization and the level of differentiation. No specific differences separate a primary squamous cell carcinoma of the lung from one that has metastasized to the lung from a cutaneous or mucosal site. A considerable range of appearances can nonetheless be seen with the electron microscope among squamous cell lung carcinomas. This ability is partly because the fine structure of the tumor cells undergoes marked changes with loss of differentiation. It also reflects the fact that many NSCLCs of the lung are heterogeneous in their composition and show both squamous and glandular differentiation. A mixture of the two lines of maturation is sometimes evident by electron microscopy, so examination of only a few cells does not always reveal whether the tumor is predominantly a squamous cell or adenocarcinoma. The small sample studied by electron microscopy is nevertheless usually sufficiently representative to provide an accurate diagnosis.[34]

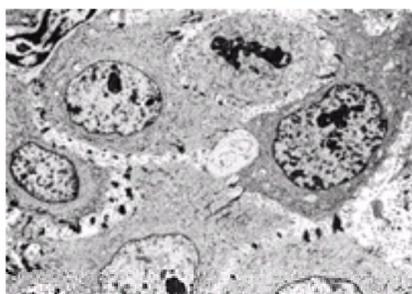
In a differentiated squamous carcinoma, the cells are more or less round, although they look polygonal when packed together. The cells are often separated from their neighbors by a slender gap (Figure 26.19). Nuclei have slightly irregular profiles, and the chromatin is coarsely clumped. The cells possess considerable amounts of cytoplasm, which contains the usual organelles—mitochondria, cisternae of endoplasmic reticulum—in moderate quantities. The better differentiated squamous tumors arising in the lung show evidence of keratinization, and the cells then contain thin bundles of cytokeratin filaments, which course through the cytoplasm and attach to the cell junctions. The latter are mature desmosomes, and when the cells are not intimately apposed, they are connected through short protrusions of the surface cytoplasm with desmosomes at their tips, creating the so-called intercellular bridges that are helpful to the light microscopist. Bridges will not be visible if the cell surfaces are closely apposed, so they are not always seen in well-differentiated tumors. Fragments of basal lamina may surround groups of tumor cells.[216]


FIGURE 26.19. Squamous carcinoma, moderately differentiated, ultrastructure. The cells of this tumor contain many thin bundles of tonofilaments. Within the clefts between the cells, desmosomes are conspicuous by their dense appearance (4,000 × magnification).

The distinctive features of the differentiated squamous tumors are progressively lost as the tumors dedifferentiate, and variations in the level of differentiation can often be seen within a small group of cells. Uniform spacing of the cells, abundant tonofilaments, and numerous mature desmosomes can, within the space of a few cells, be replaced by irregular gaps, wispy strands of keratin, and scattered, poorly constructed attachment sites. The number of cell junctions in lung carcinomas appears to relate to clinical stage and survival time.[217] The end stage of the process of dedifferentiation is cells with no cytokeratin and few or no junctions: attachment sites that are present are mere paired tiny densities of the cell membranes. Along with these alterations, the amount of cytoplasm and number of organelles diminish. The ultrastructure of truly dedifferentiated squamous cells thus does not betray their squamous lineage.

Adenocarcinoma

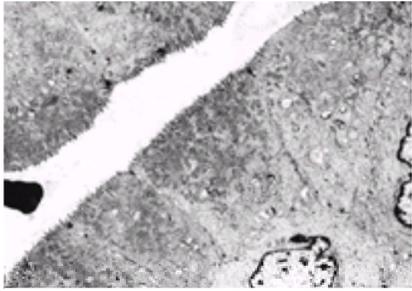
Much more variety in histology and ultrastructure is seen in the cells of bronchogenic adenocarcinomas compared to the squamous tumors. Cells in the better differentiated adenocarcinomas may contain some cytokeratin filaments, but they are rarely plentiful. The surfaces of adjacent cells are connected by desmosomes, which are fewer and smaller than in squamous carcinomas. Adenocarcinomas commonly have a glandular architecture that is manifested ultrastructurally by lumens bordered by cells with microvilli on their apical surfaces (Figure 26.20). The cell membranes, particularly when the cells are columnar, fuse where they reach the lumen, forming a tight junction that seals off the intercellular space from the lumen. The tight junctions are beltlike in that they encircle the cell, in contrast to desmosomes, which are small disks, like tiny spot welds between the cell surfaces.


FIGURE 26.20. Bronchioloalveolar adenocarcinoma, ultrastructure. These tumor cells border on a slender lumen. The indistinct bodies in the cytoplasm are mucin droplets. Microvilli are highlighted by cores of microfilaments that extend into the subjacent cytoplasm (6,000 × magnification).

The number, length, and appearance of the microvilli in bronchogenic adenocarcinomas is variable. They are often irregular in distribution and size, whereas in a typical epithelial mesothelioma, the long, slender, often curving and branching microvilli are distinctive. [218] In a few of the peripheral lung adenocarcinomas that show bronchioloalveolar differentiation, the microvilli are more numerous and straight, and they contain slender cores of actin filaments that extend downward into the apical cytoplasm (Figure 26.20). These microvilli are identical in appearance to the ones on gastrointestinal cells, therefore, using this feature to identify a metastatic gastric or intestinal adenocarcinoma within the lung is not reliable. [219]

Part of the variety in appearance among adenocarcinoma cells is produced by the presence of secretory products within their cytoplasm. There may be accumulations of glycogen or mucin, and the latter occupy diffuse electronlucent zones or form discrete droplets that accumulate in the apical cytoplasm (Figure 26.20).

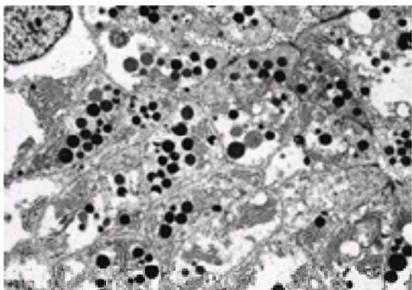
Bronchioloalveolar adenocarcinomas differentiate in the direction of cells found in the distal respiratory passages, and they consequently show a various appearances by electron microscopy. The most common form of differentiation in this type of adenocarcinoma is toward the nonciliated bronchiolar or Clara cell, which in the normal lung forms a protein secretion that contributes to the pulmonary surfactant. The dense-core granules in these cells are of exocrine caliber, and they gather in the apical cytoplasm (Figure 26.21). Mucin can also be present in small quantities in the apical cytoplasm in tumor cells with Clara-cell differentiation, but in some bronchioloalveolar adenocarcinoma, the cells are filled with mucin. Ciliated cells are unusual in a lung adenocarcinoma, [220] although they are rarely seen in a bronchioloalveolar adenocarcinoma. Another distal respiratory passage cell that is infrequently found in these tumors is the type II pneumocyte. Its distinctive lamellar bodies, which provide the lipid component of the surfactant, are found in the apical cytoplasm (Figure 26.22). It can be difficult to distinguish reactive type II pneumocytes from neoplastic cells because the former may be entrapped within the tumor, or they can be from the rim of reactive cells, which are commonly present around the mass of tumor cells. The nuclear inclusions that are seen in a small proportion of bronchioloalveolar adenocarcinomas are produced by an elaborate replication of the inner of the paired membranes that form the nuclear envelope. [7] Although myoepithelial cells occur in the ducts and acini of normal bronchial glands, they are only rarely a component of a bronchogenic adenocarcinoma. [126]


FIGURE 26.21. Bronchioloalveolar adenocarcinoma, ultrastructure. The plane of section passes through the apices of the tumor cells, and small slits of lumen are visible. This tumor is showing Clara cell differentiation, manifested by the large secretory granules (5,500 × magnification).
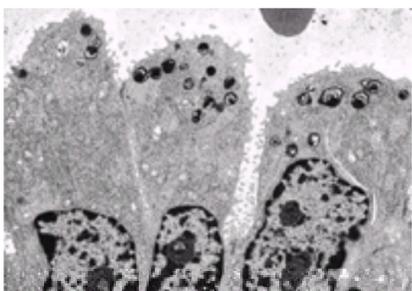

FIGURE 26.22. Bronchioloalveolar adenocarcinoma, ultrastructure. The presence of lamellar bodies in the upper cytoplasm of the cells of this tumor indicates type II pneumocyte differentiation. Note also how the cells protrude into the lumen (9,300 × magnification).

Small Cell Carcinoma

Ultrastructural studies have helped to define the light microscopic features of this tumor, and they have clarified its position in the classification of lung tumors and the validity of the subtypes that have been created by light microscopists. Information on the fine structure of SCLCs has also come from the study of cell lines, although it is not always possible to extrapolate *in vitrc* findings to *in vivc* observations.

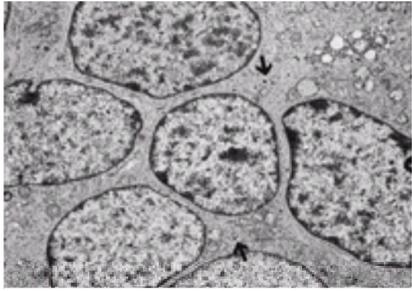
The typical SCLC cell is smaller than those of most NSCLCs, but morphometric studies performed on low-magnification electron micrographs have shown that overlap occurs in cell and nuclear size between the two groups, and the best discriminator is the nuclear/cytoplasmic ratio. [221] The amount of cytoplasm is SCLCs is generally scanty (Figure 26.23). The cells are ovoid rather than round, and they can become elongated. The shape of the nucleus parallels that of the cell, and the chromatin is generally finely aggregated and uniformly dispersed; its homogeneous distribution can often be appreciated in paraffin sections. The cell surface is smooth and devoid of microvilli, although in some cases the cytoplasm forms short, tubular extensions. Cells tend to be closely apposed, and some cell junctions can almost always be located. They range in maturity from small desmosomes to mere apposed densities on the cell membranes.


FIGURE 26.23. Small cell lung carcinoma, ultrastructure. The cells are closely apposed, and they have scanty cytoplasm and sparse organelles with only occasional small dense-core granules. The finely clumped but uniformly dispersed chromatin is characteristic (9,200 × magnification).

Generally only a few organelles are present in the cytoplasm of SCLC cells, in contrast to the moderate numbers that are seen in better differentiated NSCLCs. A few mitochondria and some slender cisternae can usually be found. Dense-core granules are plentiful in only a few tumors, and it is often necessary to examine several cells before granules are found. In approximately one-third of SCLCs granules cannot be detected, although they may subsequently become evident in cell lines. The granules are of neuroendocrine caliber and appearance, which means they are consistently small, of the order of 100 to 120 nm, with a distinct limiting membrane. If the granules in a tumor are larger than this limit, carcinoid should be suspected. Unlike the situation in many extrapulmonary SCLCs, granules do not commonly congregate in dendritic processes. Increasing numbers of SCLCs, with and without neuroendocrine features, are being described in extrapulmonary sites, and they must be considered in the differential diagnosis when SCLC is suspected in material procured from an apparent metastasis.

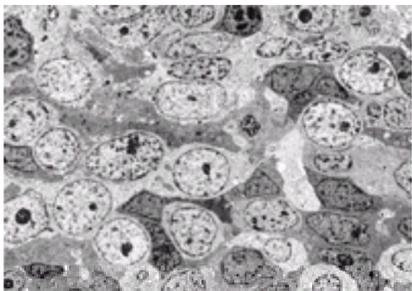
Most pathologists utilize the terminology for SCLC subtypes that has accumulated over the years from light microscopic observations. Electron microscopy has not shown any consistent features that will serve to subclassify SCLC, offering support for the view that the terms *oat-cell, lymphocyte-like,* and *intermediate cell* should be discarded.[133] The cells of SCLC can transform following therapy, showing more variability in cell and nuclear size and shape and even simulating a large cell carcinoma, so subtyping is of dubious value in material from a treated patient. It has been suggested that two variants of SCLC should continue to be recognized.[133] One, the combined form of SCLC, contains areas of differentiated NSCLC. The other has been designated as mixed small cell/large cell carcinoma, but it may be questioned whether such a tumor truly exists in untreated patients because the appearance can be simulated by a large cell carcinoma with a content of smaller cells (Figure 26.24).


FIGURE 26.24. Large cell carcinoma, ultrastructure. An intimate admixture of small dense cells is present in this large cell carcinoma, but their nuclear features are not typical of a small cell lung carcinoma and they did not contain neuroendocrine granules (3,000 × magnification).

Large Cell Carcinoma

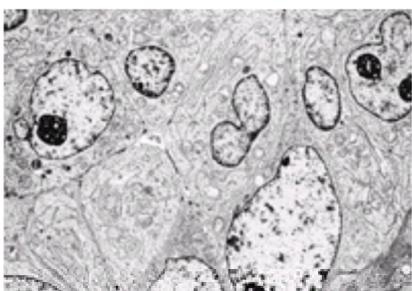
With loss of differentiation, the specific features that characterize squamous and glandular lung carcinomas are progressively lost, and the cells tend to become smaller with less cytoplasm and fewer organelles than more differentiated tumors. When this process of dedifferentiation is complete, no features will then serve to identify the tumor as either squamous or adenocarcinoma, and it is a true undifferentiated large cell carcinoma. The cells generally have sparse organelles, and cell junctions are hard to find. Some evidence of differentiation in the form of small collections of microvilli within tiny lumens (Figure 26.25) or sandwiched between cells, or collections of cytokeratin filaments, are often seen with the electron microscope in tumors that were called large cell carcinoma by light microscopy. This minimal level of differentiation probably does not have any significance as far as the behavior or response to therapy of the tumors are concerned, and no compelling reason suggests reclassifying the tumors based on the ultrastructural findings.


FIGURE 26.25. Large cell carcinoma, ultrastructure. In a large cell carcinoma, no evidence of differentiation exists at the light microscope level, but electron microscopy may reveal tiny lumens containing a few microvilli (5,000 × magnification).

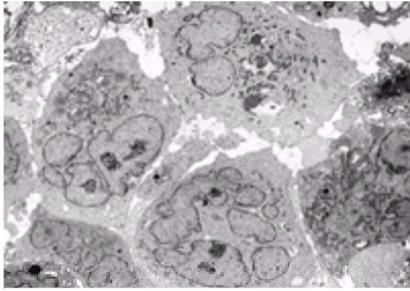
Electron microscopy can be helpful in the study of pleomorphic tumors in the lung.[222] The multilobated nuclei are seen to good advantage in electron micrographs (Figure 26.26). A few poorly constructed cell junctions are often found, where the pleomorphic cells come into contact, and some microvilli may be detected. The extensive cytoplasm often contains many organelles including lysosomes. These findings are not specific, and it may be impossible to distinguish between a primary lung tumor and a metastatic pleomorphic carcinoma or sarcoma by electron microscopy alone.


FIGURE 26.26. Large cell (pleomorphic) carcinoma, ultrastructure. The multilobated nuclei of a pleomorphic large cell carcinoma are seen to good advantage with the electron microscope (3,900 × magnification).

Sarcomatoid Carcinomas

A small percentage of NSCLCs undergo sarcomatoid change. This is a form of dedifferentiation, and the cytologic characteristics of the initial differentiated tumor are progressively lost in the transformation process. The cells become spindle-shaped and may form crude fascicles; the tumor must then be distinguished from a sarcoma or a spindle cell mesothelioma. This differential diagnosis can be difficult because a complex spectrum of fine structure is seen in sarcomas, and mesotheliomas show much variation in cell structure. Immunostaining is the best approach, but electron microscopy may reveal small wisps of cytokeratin filaments or scattered desmosomes and absence of the luxuriant microvilli of an epithelial mesothelioma, and therefore offer some support for a light microscopic diagnosis of carcinoma.[184,223]

Large Cell Neuroendocrine Carcinoma

Ultrastructurally, LCNECs have a few dense-core granules that are often focal or patchy in distribution [145] and show glandular differentiation or squamous features. [145] The distinction of LCNEC from NSCLC with neuroendocrine features is based on light microscopic morphology rather than electron microscopy.

Non–Small Cell Carcinoma With Neuroendocrine Features

This poorly understood variant of NSCLC has usually been identified by immunostaining for neuroendocrine markers, notably neuron-specific enolase and the more reliable chromogranin. The tumor cells are at least twice the size of those seen in SCLCs. [224] Electron microscopy has shown granules of endocrine caliber, although they are less numerous than in a typical carcinoid. The tumor is probably underdiagnosed because only a small minority of lung tumors are examined ultrastructurally, but as many as 10% of NSCLCs may possess some neuroendocrine features.[145,200,225] Insight into these tumors is also being obtained from studies of cell lines. [226] It can be anticipated that the current classification of neuroendocrine lung neoplasms will be modified as more information about the tumors is obtained. [227]

Carcinoid Tumors

A variety of patterns is seen among typical carcinoid tumors in light microscopic sections, but at the ultrastructural level, considerable uniformity in the appearance of the cells is present. In a particular tumor, they are predominantly either round or fusiform and compactly grouped. The smooth cell surfaces are apposed, but filopodia are sometimes seen, and a few tumors contain aggregates of microvilli on some cell surfaces, which may project into a small lumen.

Neighboring cells are fairly similar in appearance. The round or ovoid nuclei are centrally placed and surrounded by more cytoplasm than is seen in most SCLCs, and the cytoplasm is richer in organelles: mitochondria and slender cisternae can be abundant. The nuclear chromatin tends to form coarser clumps than in a typical SCLC cell. In atypical and more aggressive carcinoid tumors, variations in nuclear and cell size and shape are generally evident at the ultrastructural level, although they are seen to better advantage by light microscopy, where more cells can be examined and the pattern of the tumor is more readily assessed. Cell junctions in the typical carcinoids are mostly small desmosomes, which are present in moderate numbers. Cell junctions are fewer and more primitive in the atypical tumors, and they may only be minute thickenings of the cell membranes.

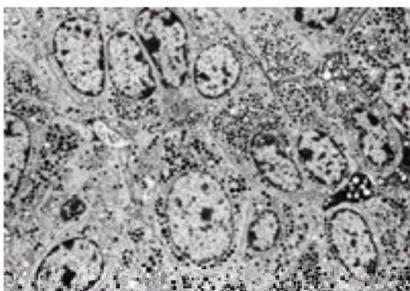
Carcinoid tumors form hormonal polypeptides and certain other products, and dense-core granules are a prominent feature of the cytoplasm (Figure 26.27). The granules are numerous in most of the cells of a tumor, but they can vary in number from cell to cell, and they are often sparse in the atypical carcinoids. Many mitochondria pack the cytoplasm in the so-called oncocytic variant. [228] A few carcinoids contain discrete aggregates of intermediate filaments within the cytoplasm of their cells, and granules are then fewer in number and more difficult to find. Cells of the uncommon chemodectoma of the lung also contain many filaments, but granules are not present.[229]


FIGURE 26.27. Typical carcinoid tumor, ultrastructure. Granules fill the cytoplasm in a typical carcinoid tumor. The granules are close to the upper limit of the size range seen in endocrine tumor cells (4,000 × magnification).

The size and appearance of the granules in carcinoid tumors is of some importance in differential diagnosis. The granules in lung carcinoid cells are generally round, but they are angular in approximately 5% of the tumors. Secretory granules in lung tumor cells range from large exocrine-type granules similar to those seen in Clara cells to the small uniform granules of some SCLCs and most endocrine cell granules are intermediate in caliber between these two extremes. Some overlap does occur, however. In a morphometric examination of granules in bronchial carcinoids, the range of diameters was found to be from 98 to 391 nm with a mean of 175 nm.[221] The smallest granules in carcinoids thus overlap in size those seen in SCLC, and consequently they alone do not serve to discriminate between the two tumors. It should still be possible to effect this distinction by electron microscopy from the other features of the cells, although it becomes more difficult with the loss of differentiation that takes place in the more aggressive carcinoid tumors.

CYTOLOGY

Historical Background

The diagnosis of lung cancer by cytologic methods is of historical interest because it was an early demonstration that malignancy could be diagnosed through the examination of exfoliated cells. As reviewed by Johnston, Donne and Walsh separately noted in 1845 that exfoliated respiratory cells occurred in sputum. [230] The first

major series of patients where the examination of sputum led to a diagnosis of lung cancer was by Hamplen in 1919. In this study, 13 of 25 cases were successfully diagnosed. After several years of quiescence, pulmonary cytology enjoyed a period of rapid development in the 1950s. Particularly important was the demonstration that lung cancer diagnosis was possible by percutaneous biopsy of the chest wall. In the 1960s, Dahlgren and Nordenstrom published a monograph reporting an 87% success rate in the diagnosis of lung tumors by transthoracic biopsy.[231] These important studies were part of a growing awareness that indicated fine-needle aspiration biopsy as a standard diagnostic tool. Further studies in the 1970s and 1980s validated needle aspiration as an alternative to open lung biopsy or transbronchial biopsy for the diagnosis of pulmonary malignancy, as well as other infectious and inflammatory lung diseases.[232,233] During this time, technical advances in radiologic technique permitted the imaging of small lesions and guided aspiration biopsy.[234,235 and 236] The design of bronchoscopes—improved smaller diameter, flexible bronchoscopes—opened an entirely new avenue for the investigation of lung disease.[237,238]

Diagnostic Techniques

Five major techniques are used to obtain cellular material for the diagnosis of carcinoma of the lung.[239,240] The oldest and most fundamental technique is sputum collection, which depends on the spontaneous exfoliation of cells. Three bronchoscopic techniques include bronchial washing, bronchial brushing, and bronchoalveolar lavage. Finally, needle aspiration techniques can be performed through the chest wall under radiographic guidance or transbronchoscopically. Cytology can also be performed on bronchial biopsy rinse fluid to improve the diagnostic yield.[241]

No single technique is necessarily superior to the others. The choice of cell collection technique is affected by many factors. The personal preference of the physician, which usually reflects where she or he received postgraduate training, is key. Thus some physicians are quick to opt for bronchoscopy or fine-needle aspiration, whereas others choose a more measured approach of collecting sputum on an outpatient basis. Understandably, the approach to the diagnosis of pulmonary disease may change with the economic effects of health-care reform.

The type of disorder that is clinically suspected may favor one sampling method over another. A diffuse abnormality in the lung that is presumed to be inflammatory may be better evaluated by the examination of sputum or bronchial washing or bronchoalveolar lavage than would a focal abnormality.[242,243] The location of a suspect lesion within the pulmonary or thoracic cavity affects the diagnosis method chosen. Different methods have potentially important differences in the diagnostic sensitivity, based on tumor location.[237,244] Finally, the clinical condition of the patient may also dictate the method chosen. Critically ill patients may require rapid diagnosis afforded by invasive procedures. Others, however, may be so debilitated that bronchoscopic procedures are hazardous, and the simple collection of sputum desired.

Although substantial similarity exists among the morphology of cells obtained by these different techniques, important differences relate to cell preservation. A discussion of the attributes of different specimen collection techniques and their effects on cellular morphology follows.

Sputum

The strongest appeal for sputum examination is the ease of specimen collection. Sputum examination also has relatively high diagnostic sensitivity, particularly when multiple specimens have been collected.[245,246] Sputum may be spontaneously expectorated or induced by artificial means. Spontaneous specimens are produced by a deep cough initiated by the patient without extrinsic stimuli, whereas induced sputa rely on irritation of the respiratory tract, usually through inhalation of vaporized saline and propylene glycol. With few exceptions, induced sputa provide a more representative sample of lower respiratory tract cells.[247] In a study of patients with proven cancer, Khajota et al. found that induced sputum was diagnostic in 84%, whereas only 52% of noninduced sputum specimens contained malignant cells.[248] This does not mean that spontaneous sputa are unacceptable, but a greater proportion of specimens is unsatisfactory for diagnostic purposes.[249] The number of carbon-containing macrophages in the material determines the adequacy of a sputum specimen.[250] Specimens lacking pulmonary macrophages are unsatisfactory for evaluation. The absence of cancer cells in a patient with a lung lesion may simply be caused by a sampling error, reflecting that the specimen is saliva rather than sputum.

Different options are available for the subsequent processing of the sputum specimen. If the specimen is brought to the laboratory soon after collection, fresh material can be processed without fixation. Fresh specimens should be examined for particulate material or blood-strained tissue fragments. These elements of the specimen, because they often harbor cancer cells, are selected with forceps and used to prepare a smear between two glass slides. These slides are immediately fixed in 95% ethanol for approximately 30 minutes. Air-drying of the slide should be vigorously avoided because this technique causes the loss of detailed nuclear morphology. After fixation, slides are stained by a Papanicolaou technique. This staining method, which uses a combination of orange-G, eosin, and hematoxylin, is favored by most cytopathologists. The Papanicolaou stain offers excellent rendition of nuclear morphology, which is essential for determining whether a cell is benign or malignant. It also differentially stains the cytoplasm of epithelial cells, permitting the classification of cells as squamous or nonsquamous in differentiation.

Alternatives for the fixation of specimens can be used if the sputum cannot be processed when fresh. The simplest alternative is providing the patient with a container of 70% solution of ethanol. Although this provides some cell preservation, the material unfortunately tends to congeal, which limits the exposure of cells to the ethanol. The variation in fixation causes artifacts in the nuclear morphology that can create difficulty in interpreting the cells. Also, the rubbery quality of alcohol-fixed sputum complicates the specimen processing because smears cannot be made.

Saccomanno proposed an alternative method for cell fixation in 1963.[251] This approach, which uses a mixture of 50% ethanol and 2% carbowax for the prefixation of cells, is particularly suited for the collection of sputa in an outpatient situation. The patient can expectorate consecutive deep morning cough specimens into the same container over several days. When this specimen is returned to the laboratory, it can be processed in aggregate. Blending of Saccomanno-preserved materials is required to homogenize the specimen. The resulting material can be used for the preparation of smears, membrane filters, or cytocentrifuge slides.

The sensitivity of detecting lung cancer differs between freshly smeared and fixed, blended sputum. Much of this difference is attributable to artifacts caused by the mechanical blending of the specimen. Studies differ on the issue of which technique has superior sensitivity.[252] Some suggest a similar sensitivity for detecting squamous carcinoma between fresh, unfixed sputum and material for the Saccomanno technique but lower sensitivity with small cell undifferentiated carcinoma and adenocarcinoma. The mechanical blending disrupts cell fragments and shears mucin-containing vacuoles from cells, thus complicating the diagnosis of adenocarcinoma. Blending also disperses the cells of small cell undifferentiated carcinoma, so that finding cells among a background of inflammatory cells is difficult. In a report by Rizzo et al., the blended technique had a greater sensitivity than the manual smearing method for the detection of lung cancer.[253] The addition of dithiothreitol to the sample may also aid processing and improve sensitivity.[254]

Another option for specimen processing that we mention for completeness more than for advocacy is the histologic sectioning of paraffin-embedded sputum. Bocking and colleagues recently described this approach to the screening of 1,889 patients, 219 of whom had bronchial carcinoma. A sensitivity of 84.5% was reported, when at least three specimens were collected. These authors suggest that this method might be suitable for mass screening programs.[255]

The decision of which processing method to use is dictated less by choice and more by whether or not the laboratory receives fresh or fixed specimens. A drawback to blending methods is the generation of aerosols that pose a risk to laboratory personnel, particularly if *Mycobacterium tuberculosis* or other infectious agents are present. For this reason, all respiratory specimens should be processed following universal precautions, including biohazard containment hoods, if available.

The sensitivity of detecting lung cancer by sputum examination increases with the number of specimens obtained.[230,250] Different studies suggest that the sensitivity of single sputum specimens for detection of lung cancer is approximately 50%, whereas the examination of three or more specimens raises sensitivity to nearly 90%. The type of tumor and anatomic location further affects sensitivity of lung cancer diagnosis in sputum specimens. The highest sensitivity can be expected with centrally located squamous carcinoma. These tumors often involve the bronchial mucosa, and when poorly differentiated, the poor cohesion between tumor cells results in the exfoliation of many tumor cells. By comparison, the sensitivity of sputum examination in the diagnosis of SCLC is low.[239,246] The bulk of the tumor is often in the bronchial submucosa, so that cells are not shed into respiratory secretions. Also, because individual cells of this tumor can resemble small lymphocytes, more cells may be required for their identification to be made with confidence.

The situation where sputum examination appears to be the preferred method for the diagnosis of lung carcinoma is when an immediate diagnosis is not mandatory, so that multiple specimens can be collected on an outpatient basis. A diagnosis is possible, without the cost of hospitalization or bronchoscopic lung examination. If one is successfully able to diagnose lung cancer by the examination of sputum, the cost of diagnosis may be dramatically reduced. Raab and Hornberger reported that sputum cytology, as a first test for central lesions, was cost effective and lowered mortality without affecting long-term survival.[257] Cytologic diagnosis requires an

experienced pathologist who is capable of rendering a definitive diagnosis of malignancy on sputum materials. Appropriate use of lung cytology presumes that surgeons, oncologists, or others responsible for the patient's management will pursue definitive therapy based on the cytologic diagnosis. If the pathologist is only willing to interpret such specimens as "suspicious," or the clinical staff requires tissue biopsy before therapy, the examination of sputum only duplicates other diagnostic efforts and adds to cost. The validity of using lung cytology as a definitive technique for the planning of therapy has been recently discussed by Caya et al.[258] Even when bronchoscopy is planned, the collection of prebronchoscopic sputa can increase the diagnostic yield. Miura et al. described 17 of 114 patients where the diagnosis of adenocarcinoma could be made in the prebronchoscopy sputum, but the bronchoscopic examination was normal. [259]

Sputum collection can also aid the diagnostic evaluation of elderly or debilitated patients in whom bronchoscopy might be considered hazardous, or where such facilities are not available. [247]

Bronchial Washing and Brushing

Bronchoscopy has been the most popular method to diagnose lung cancer in recent years. Increased numbers of internal medicine physicians have received training in pulmonology. Bronchoscopes have been improved, allowing the direct visualization of endobronchial abnormalities deeper into the lung. In addition modern bronchoscopic technique allows the bronchoscopist to collect multiple specimens during a single procedure, so that a transbronchial or endobronchial tissue biopsy can be taken in conjunction with any cytologic examination.

Bronchoscopes may be rigid or flexible and are available in various diameters. [260] Although flexible bronchoscopes are much more popular among pulmonologists, rigid bronchoscopy may be necessary to sample certain anatomic locations within the lung. Bronchial washing or brushing refers to the sampling of lesions arising in the first- second- and third-order bronchi that are directly visualized and sampled. [261],[262] Washing of the bronchi is achieved by the instillation of 3 to 10 mL of sterile saline, which is immediately reaspirated and taken for cytologic analysis. The resulting specimen is processed by the standard cytologic method for body fluids, which includes the preparation of cytocentrifuge slides, smears of large-tube centrifugation, or membrane filter preparations.

Bronchial brushing is suitable to sample any lesion that can be directly visualized by the bronchoscopist. [263],[264] Thus endobronchial tumors are relatively easily diagnosed by this method. Either a disposable or reusable brush may be used, both offering similar diagnostic yield. [265] The brush used to sample the lesion can be smeared onto a glass slide, which is rapidly fixed in ethanol and/or rinsed into normal saline. [266] In some laboratories, the material obtained by brushing is rinsed into Saccomanno's preservative. These specimens are then processed in the laboratory by the Papanicolaou technique. It is preferable to perform the washing before the brushing because brushing may lead to bleeding which obscures cellular material. Bronchial washing and brushing is often performed in conjunction with endobronchial biopsy of exophytic lesions within the lung. This method maximizes the quantity of material available for evaluation. In large studies, the sensitivity of single bronchial washing and brushing for detecting lung cancer is approximately 65%. This sensitivity is similar to endobronchial or transbronchial biopsy of the lung. Recent studies have shown that combining sputum examination with bronchial brushing achieves sensitivity greater than either method alone. [267]

Bronchoalveolar Lavage

Many similarities exist between bronchoalveolar lavage and bronchial washing. Both depend on bronchoscopic methods and use fluid to collect cells from the lung. The most substantive difference is that a narrow diameter bronchoscope used in the lavage procedure can be passed into fifth- or sixth-order bronchi. When the bronchoscope is placed into a wedged position, so that the lumen of the bronchus is obstructed, saline can be instilled through the bronchoscope. Saline mixes with the epithelial lining fluid of the bronchi and alveoli, effectively washing out normal and neoplastic cells, infectious organisms, and chemical constitutes from the lung.

The fluid obtained by lavage can be subjected to multiple types of chemical, microbiologic, immunologic, or cytologic analysis. [268],[269] The latter is achieved by the preparation of either membrane filters or cytocentrifuge slides for Papanicolaou staining and the preparation of cytocentrifuge slides for a Romanowsky stain, such as Diff-Quik or Wright-Giemsa.

Bronchoalveolar lavage is an important tool for the diagnosis of alveolar-based lung diseases. Interest in bronchoalveolar lavage grew out of the experimental studies of immunologic lung diseases, such as idiopathic pulmonary fibrosis in the 1960s and the 1970s. The historical development of lavage has been summarized by several authors.[268],[269] and [270] In the 1980s, the popularity of bronchoalveolar lavage grew because it offered a rapid and highly sensitive method to diagnose opportunistic infection in immunosuppressed individuals. The number of these patients grew exponentially during this time, reflecting the emergence of the acquired immune deficiency syndrome (AIDS) and large numbers of iatrogenically immunosuppressed individuals caused by cancer chemotherapy or organ transplantation. Not until the late 1980's was there substantial recognition that bronchoalveolar lavage was well suited for the diagnosis of lung cancer. [271],[272] and [273] Bronchoalveolar lavage for the diagnosis of lung cancer has been studied in several hundred patients. [271],[274],[275],[276] and [277] Different investigators have reported the sensitivity of lavage to range from 30% to 65% for the detection of pulmonary malignancy. The differences in these studies likely reflect methodologic variation because relatively little standardization of the lavage method or the manner that the specimen is processed after collection currently exists. Bronchoalveolar lavage can reasonably be expected to yield a diagnosis of lung cancer in approximately 60% of patients who have a tumor. In this sense, lavage has a similar sensitivity to other cytologic or bronchial biopsy methods. The sensitivity of cancer detection in an individual patient is related to the type of lung cancer. Lavage has a higher diagnostic yield for the diagnosis of peripheral lung lesions that cannot be reached by traditional bronchial washing or brushing. [275],[276] Lavage is particularly suited for the diagnosis of bronchoalveolar adenocarcinoma, where tumor cells within the alveoli are readily washed out by the procedure. [271],[277]

Fine-Needle Aspiration Biopsy

No technique has affected the utilization of diagnostic cytopathology more than fine-needle aspiration biopsy. Although fine-needle aspiration biopsy is best recognized for its suitability in the diagnosis of superficial tumors that arise in the breast and thyroid, transthoracic needle aspiration biopsy under fluoroscopic or computed topographic (CT) guidance is widely performed for the diagnosis of pulmonary masses [278],[279],[280] and [281] and can be coupled with CT examination for staging. [282] In the fine-needle aspiration procedure, a 22- to 28-gauge needle is passed into a mass, negative pressure is applied with a syringe, and a cutting motion is used to dislodge tumor cells from the mass. Cells and small tissue fragments are drawn into the hub of the needle or into the syringe. This material is expelled onto the glass slide, and then smeared between two slides. Optimally, both fixed and air-dried smears should be prepared. Rapid immersion of the slide in 95% ethanol is suitable for fixation of material that can be subsequently stained by the Papanicolaou technique. The air-dried slide can be stained by a Romanowsky method. Rapid assessment of the suitability of an aspirated specimen can also be performed in the radiology suite. [283],[284]

Often, visible tissue fragments are obtained by the aspiration, particularly if larger bore cutting needles are used in the aspiration procedure. [285],[286] These fragments contain valuable information, and they should always be embedded into a cell block for tissue sectioning and hematoxylin and eosin staining. The dual examination of the cytologic aspirate and the tissue section improves the sensitivity of the aspiration by several percentage points and can result in more accurate classification of the histologic type of malignancy.[287]

Another means to increase the sensitivity is by washing the bore of the needle used in the procedure. [288] Diagnostic material that coats the internal lumen can be rinsed out with saline, and then used to prepare membrane filters or liquid-based cytologic preparations (e.g., ThinPrep, Cytyc Corporation, Boxborough, MA; Autocyte Prep, Autocyte, Elon College, NC).[289] The importance of fine-needle aspiration biopsy as a diagnostic tool is its ability to sample localized lung lesions anywhere in the thoracic cavity. Peripheral lung lesions that are inaccessible by bronchoscopic methods can be sampled by fine-needle aspiration biopsy under radiographic guidance. Also, aspiration techniques can safely assess centrally located lesions that are next to vital organs. When small-diameter needles are used in the aspiration procedure, vital structures such as the aorta can usually be punctured without adverse consequence. Also, the technique is highly accurate. The sensitivity of fine-needle aspiration biopsy in the detection of lung cancer exceeds 85%. [278],[290]

Although most fine-needle aspiration biopsy procedures are done through the chest wall, a modification of the technique can sample mediastinal and peribronchial masses through transbronchial aspiration. This technique, pioneered by Wang, requires placement of the tip of the bronchoscope against the bronchial wall, then passage of the fine needle through the channel of the bronchoscope. [291] Wang needle biopsy has a diagnostic yield of 25% to 40%. [292],[293] This method is particularly helpful in the staging of patients with lung cancer and to assess mediastinal or peribronchial lymph nodes. In collecting such specimens, care must be taken not to contaminate the transbronchial specimen with intraluminal carcinoma, which results in false staging. [294]

Another use of fine-needle aspiration is in the intraoperative evaluation of tumors. The major advantage of this technique is its ability to sample a lesion that may be inaccessible to incisional biopsy or be located next to a blood vessel or vital structure. [295] In a recent study by Guarda, a large series of consecutive intraoperative

cytology was compared with the synchronous frozen section. Agreement of diagnosis occurred in approximately 99% of cases. [296] Another report described only two cases where the cytologic and frozen section results were discrepant. [297] The better morphologic detail of cytologic smears can aid the interpretation of frozen sections.

The contraindications of fine-needle aspiration biopsy are few. Aspiration should be avoided in patients with a hemorrhagic diathesis, with uncontrollable cough, or those who may harbor a pulmonary ecchinococcal cyst. A final word of caution is that the pathologist must maintain an open mind for all differential diagnostic possibilities because virtually any malignant or benign neoplasm or inflammatory process can be sampled by fine-needle aspiration biopsy. [298]

Normal and Reactive Cells

The cytomorphologic diagnosis of lung cancer requires an understanding of the normal and non-neoplastic reactive cells in respiratory cytology specimens. The broad categories of "normal" cells are bronchial epithelial cells, pneumocytes that line alveoli and terminal bronchi, macrophages, and inflammatory cells.

The bronchial epithelial cells, which provide a protective covering for the upper portions of the airways, are distinguished by their columnar shape, having a longer axis than width and a basally oriented nucleus. Bronchial epithelial cells may be either ciliated or nonciliated. The cilia that project from the apex of the columnar epithelial cell are an important morphologic feature of benign cells. Cilia are anchored to the cell by virtue of a terminal bar, which appears as a linear, eosinophilic thickening at the cell apex. Columnar epithelial cells can have extreme morphologic atypia in response to irritants, such as chemotherapy or inflammation. In cytologic material, columnar epithelial cells occur singly or in cohesive clusters. The latter pose a threat to be misinterpreted as carcinoma. However, the presence of cilia or a terminal bar in a cell constitutes an absolute cytomorphologic marker that the cell is benign no matter how atypical it may appear. If a single ciliated cell is observed within a cluster, it is best to interpret all cells in that cluster as benign. Reparative epithelial atypia is a significant consideration in lung cancer diagnosis, which is discussed subsequently.

Goblet cells are pear-shaped, nonciliated bronchial epithelial cells with a large mucin-containing cytoplasmic vacuole. This mucin causes cell fragility and accounts for their shearing during cytopreparation. Distorted goblet cells can potentially be mistaken for the mucin-containing cells of adenocarcinoma. This diagnosis is particularly problematic when increased numbers of goblet cells are present, such as occurs with bronchial irritation, chronic bronchitis, and asthma.

The cytomorphology of alveolar pneumocytes and macrophages is similar. Both are single cells, ranging from 10 to 15 microns in diameter, with a single centrally located nucleus. The rounded nucleus has pale, uniformly dispersed chromatin, which is often hypochromatic. Multinucleated macrophages are common, particularly in irritated airways caused by cigarette smoking. Often, a single small rounded nucleolus is present. The distinguishing feature of the pulmonary macrophage reflects its function. Intracytoplasmic debris, consisting of phagocytized carbon, dusts, red cells, iron, and other material indicate that the cell is a macrophage. Otherwise, it is difficult to discriminate macrophages from the type I or type II pneumocytes that line alveoli. [298] As discussed elsewhere in this text, pulmonary pneumocytes have the potential to assume bizarre morphologic appearance in response to lung injury, and reparative terminal bronchiolar cells can mimic the bronchioloalveolar type of adenocarcinoma.

Inflammatory cells are the final group of normal cells in respiratory material to discuss. Neutrophils, eosinophils, basophils, and lymphocytes are present in different proportions within the lung. Increased numbers of one or another type of inflammatory cells serves as a marker of pulmonary infection, immunologic lung disease, or nonspecific tissue injury. [299] It has been suggested that lymphocytic inflammation is a marker of cancer within the lung. [300] Inflammation may be a consequence of bronchial obstruction, reflect a yet undefined immunologic response against the carcinoma, or be incidental. In the routine practice of cytopathology, however, the identification of inflammatory cells provides little clue about the presence of pulmonary neoplasia. One possible exception may be the high percentage of lymphocytes seen in the differential cell count of the bronchoalveolar lavage of patients with primary or metastatic Hodgkin's disease, or in the slide background of fine-needle aspiration in Hodgkin's disease. [301,302]

One important aspect of lymphocytic inflammation is the potential of lymphocytes to be misinterpreted as SCLC, which is discussed in more detail in the following section.

Pulmonary Malignancy

Carcinomas of the lung, pulmonary sarcomas, extranodal lymphomas, and metastatic tumors constitute the gamut of malignancy within the lung. The morphology of lung tumors has been well described in books and monographs. [269,303,304] Our discussion focuses on lung carcinoma, except for the mention of differential diagnostic considerations.

Squamous Cell Carcinoma In Situ

As discussed elsewhere in this chapter, squamous cell carcinoma appears to arise from a multistage carcinogenesis model where reserve cell hyperplasia, squamous metaplasia, and atypical squamous metaplasia precede the development of *in situ* squamous carcinoma, which in turn precedes invasive carcinoma. [46] This sequence bears similarity to the process that occurs in the uterine cervix, although our understanding of the pulmonary counterpart is less complete. The classic cytologic studies of the development of squamous cell carcinoma *in situ* are those of Saccomanno, who documented progressive changes in the epithelial cells of uranium workers who smoked cigarettes. [251] Many others have described the occurrence of *in situ* carcinoma of the bronchi. [305,306] Morphologically, the tumor sheds small, rounded single cells, with nuclear features of malignancy—high nuclear to cytoplasmic ratio, hyperchromasia, and irregular thickening and thinning of the nuclear envelope. A thick band of chromatin is often present along the periphery of the nucleus. Bizarre cells, and a necrotic slide background that typifies invasive carcinoma, are not features of *in situ* squamous cell carcinoma.

There has been substantial interest in the use of cytologic screening to identify persons at risk for invasive squamous carcinoma, with the hope that the dramatic reduction in mortality that was observed with cervical cancer could be duplicated in the lung. [246,307,308 and 309] Several major lung cancer screening projects have been undertaken. Most notable are the Mayo Clinic Lung Project, and those at Johns Hopkin's University and Memorial Sloan-Kettering. These studies indicate that *in situ* or early invasive carcinoma can be detected by cytologic screening. While a tendency existed to identify patients with a lower stage of disease with a greater survivorship in those screened, no significant difference in lung cancer mortality rate existed between screened and control groups. The conclusion of these studies is that results do not justify recommending large-scale radiologic or cytologic screening for early lung cancer. [308] Recent reanalysis of these studies, however, has questioned this conclusion and advocated additional trials assessing the utility of screening (see also Chapter 22).

Squamous Cell Carcinoma

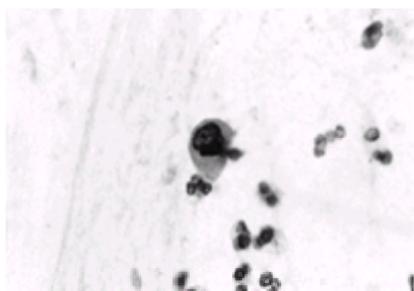
The cytologic diagnosis of this tumor rests on two separate observations: (a) the recognition of abnormal nuclear morphology to affirm that a population of malignant cells is present, and (b) the identification of squamous differentiation within the cytoplasm. In respiratory cytologic material, the nuclear morphology of squamous cell carcinoma is diverse. Nuclei may be large or small, round or irregularly shaped, and have chromatin that is dispersed throughout the nucleus, coarse, or condensed so that the nucleus is totally opacified (Figure 26.28). Cells with these sharply angulated and opacified nuclei most typify squamous cell carcinoma (Figure 26.28). Although macronucleoli are most characteristic for pulmonary adenocarcinomas, nucleoli are often present in cells with squamous differentiation.


FIGURE 26.28. Squamous cell carcinoma, cytology. Although this cell is not particularly large, it has atypical nuclear morphology. Squamous cell carcinoma is characterized by variably sized keratinized cells. The chromatin in this cell is heavily condensed, and the nucleus is irregularly shaped.

Cells of squamous cell carcinoma assume various shapes, from the classic polygonal cell to bizarre triangular or tadpole-shaped cells. The tadpole-shaped cells may contain a unique cytoplasmic manifestation—the Herxheimer spiral, which represents condensed keratin proteins. Cells may be single, or more commonly, in a sheet.

The defining quality of squamous cell carcinoma is cytoplasmic keratinization of tumor cells (Figure 26.28) that is morphologically manifested by cytoplasmic orangophilia or deep cytoplasmic cyanophilia with the Papanicolaou stain. The keratin imparts a refractile quality to the cytoplasm, which is best appreciated by lowering the condenser of the microscope. A hallmark feature of squamous cells is so-called endo-ectoplasmic ringing—a deep cyanophilic or eosinophilic band of keratin material that is deposited along the periphery of the cell. Ultrastructurally, this band corresponds to the tonofibrillar bundles that are involved in anchoring the cells through desmosomal attachments. The keratin fibrils are responsible for the well-defined, sharp cytoplasmic border of squamous cells. Although orangophilia is a feature of keratinization, it is incorrect to presume that all orangophilic cells are from a squamous cell carcinoma. Metaplastic cells, macrophages, or pneumocytes are deeply orangophilic when they are air-dried.

Squamous cell carcinoma undergoes cavitation more often than other primary lung tumors, which results in the exfoliation of many cells into respiratory specimens.[73,310] Tumor-rich specimens, combined with the tendency of squamous cell carcinoma to arise in the central portion of the lung, make the cytologic diagnosis of this tumor relatively straightforward.

The manner in which the cytologic specimen is collected affects tumor cell morphology. With squamous cell carcinoma, the major effect is degeneration of cells expectorated in the sputum. These cells are smaller, have opacified chromatin, and are more likely to be orangophilic than cells obtained by the direct sampling of a tumor by fine-needle aspiration or bronchoscopic techniques.

The differential diagnosis of invasive squamous cell carcinoma includes squamous cell carcinoma *in situ,* other types of lung cancer, atypical squamous metaplasia, and reparative cellular reactions. Each type is discussed elsewhere in this chapter.

Adenocarcinoma

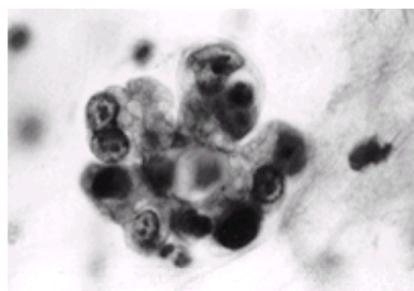
Three cytologic types of pulmonary adenocarcinoma are recognized: acinar, bronchioloalveolar, and papillary. The common acinar cell type typifies the general concept of adenocarcinoma as a gland-forming tumor. In cytologic material, glands are three-dimensional cell clusters (Figure 26.29). By changing the plane of focus of the microscope, the lumen of the glandular acinus can be demonstrated. Adenocarcinoma cells have a rounded to polygonal shape with a large nucleus. In comparison to squamous cell carcinoma, the chromatin of pulmonary adenocarcinoma is less condensed and may assume a bland, water-clear quality. This appearance often complicates the diagnosis of pulmonary adenocarcinoma because reactive bronchial epithelial cells and stimulated macrophages can have similar nuclear chromatin. A single rounded eosinophilic macronucleolus in the center of the nucleus is a feature of adenocarcinoma (Figure 26.29). Although nucleoli occur in other types of lung cancer, they are often multiple, smaller, or irregularly distributed throughout the cell.


FIGURE 26.29. Adenocarcinoma, cytology. This cluster of tumor cells has a broad depth of focus. Mucin within the cytoplasm imparts a soap-bubble quality. Tumor cells have centrally placed macronucleoli.

The cytoplasm of adenocarcinoma cells is cyanophilic, with cells having an indistinct border. Mucin within the cytoplasm can impart a foamy quality to the cytoplasm or coalesce into one or more large vacuoles (Figure 26.29). Complex internal structure to these vacuoles is an aid in distinguishing mucin-containing vacuoles from imbibition vacuoles that occur in the cytoplasm of macrophages as they drink in fluid. An assessment of the relationship between the large cytoplasmic vacuoles and the nucleus can aid the diagnosis of malignancy. The ease with which malignant nuclei are deformed allows the nucleus to mold around the vacuole, which imparts a sharp edge to the nucleus.

The bronchioloalveolar cell type of adenocarcinoma arises in the distal portions of the respiratory tract. This type of adenocarcinoma has several morphologic features that distinguish it from the acinar cell type. Although cell clusters with extreme depth of focus may be present, these do not contain three-dimensional acini. These cell clusters may assume a papillary configuration, although a central fibrovascular stalk is not present. Aside from numerous single cells, small flower petal or floret clusters of cells are typical of bronchioloalveolar cell carcinoma. If one word were chosen to describe the nuclear morphology of this tumor, it would be "bland." The nuclei are rounded or bean-shaped with gentle folds and contain finely granular chromatin and small nucleoli. The blandness of the tumor cells often proves challenging in separating macrophages and reactive cells that have originated in the terminal portions of the bronchus.

Reactive terminal bronchiolar cells are an enormous potential diagnostic pitfall, as discussed following. Psammoma bodies accompany some cases of bronchioloalveolar carcinoma. Although they are important to stimulate the search for tumor, they may occur with reactive bronchial epithelium or other pulmonary tumors.

The papillary type of adenocarcinoma is among the most uncommon primary pulmonary neoplasms, accounting for 9% of adenocarcinoma in a WHO series. [117] The defining feature of this tumor is the three-dimensional architectural structure of tumor cells supported on a fibrovascular stalk. [311] Only scattered reports of the cytology of this tumor exist, one of which described psammoma bodies within the tumor.[312] Similar to bronchioloalveolar cell carcinoma, the nuclear morphology of the cells is relatively bland. These two tumors can be difficult to distinguish because papillary structures occur in both.

As discussed elsewhere in this chapter, adenocarcinoma of the lung has been diagnosed with increasing frequency in recent years. Because the predominant location of pulmonary adenocarcinoma is in the periphery of the lung, techniques that are best suited toward this diagnosis include percutaneous needle aspiration and bronchoalveolar lavage.

Small Cell Carcinoma

At the opposite end of the size spectrum is SCLC. The WHO in 1981 described three subtypes, including the oat cell type, intermediate cell type, and combined type. [5] This classification was modified by the IASLC in 1988, who proposed three categories: (a) SCLC (b) mixed small cell/large cell carcinoma, and (c) combined SCLC.[133] The small cells are rounded or carrot-shaped (Figure 26.30). The diameter of cells from SCLC is approximately one-and-a-half to two times that of a small lymphocyte. At low magnification, tumor cells appear to lack cytoplasm, but at high magnification, a thin rim of cytoplasm can be discerned in well-preserved cells. Cells of SCLC can occur singly, in a linear arrangement within respiratory mucus, or in loosely cohesive clusters (Figure 26.30). The most characteristic features of

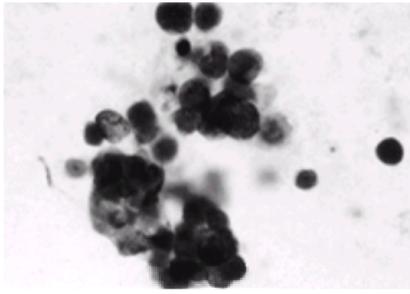
SCLC are found in these clusters. One feature is the molding of tumor cells around each other, the result of the rapid growth rate of the tumor within the confined space of the submucosa (Figure 26.30). Another diagnostic feature is the necrosis of individual tumor cells within cell clusters. These pyknotic tumor cells are surrounded by neutrophils. Cells within the cluster may have nuclear crush artifact, similar to the crush artifact well known to pathologists in bronchial biopsy material.[313]


FIGURE 26.30. Small cell carcinoma, cytology. Tumor cells from small cell carcinoma have negligible cytoplasm. Cells are closely apposed to each other, creating the nuclear molding that typifies this tumor.

SCLC includes cases that have a larger cell size, with a diameter approximately three times the diameter of a lymphocyte. These cases correspond to those cases regarded as the intermediate subtype of SCLC as defined by the WHO in 1981.[5] Distinguishing this tumor from poorly differentiated NSCLCs can be difficult. A particular challenge is the so-called large cell type of neuroendocrine carcinoma that has close similarity to large cell carcinoma.

The combined type of SCLC poses another diagnostic problem. This tumor harbors both SCLC and NSCLC in significant proportions. The latter component may be squamous cell carcinoma, adenocarcinoma, or large cell carcinoma, individually or in combination. This entity is relatively common because a NSCLC component occurs in 5% to 10% of cases of SCLC.[133] This percentage may be higher when more comprehensive evaluation is computed of the tumor by multiple sections. Patients with combined tumor may have a prognosis poor than those with SCLC.[314]

The major differential diagnostic considerations with SCLC are reserve cell hyperplasia, inspissated mucus, lymphocytes, and other small cell tumors. By far the most common problem is reserve cell hyperplasia. Reserve cells normally lie along the basement membrane of the epithelium, where they serve as progenitors for bronchial epithelial cells. Irritation of the airways stimulates reserve cell proliferation. Several features correctly identify reserve cells. They are approximately the size of a small lymphocyte, with dense chromatin that lacks the granularity or micronucleoli that can be found in SCLC. Reserve cells are almost always tightly clustered, and cells within the cluster usually retain cell boundaries, without the extreme nuclear molding that characterizes SCLC.

Although crushed lymphocytes are more often a differential diagnostic problem in bronchial biopsy specimens, they can be problematic in cytologic material. Of particular note are the changes of bronchial-associated lymphoid tissue that follow infection or bronchial irritation. The expansion of germinal centers with immune stimulation sheds lymphoid cells that are similar in size to SCLC. However, lymphoid cells are usually well-rounded and have a characteristic chromatin pattern.

Large Cell Carcinoma

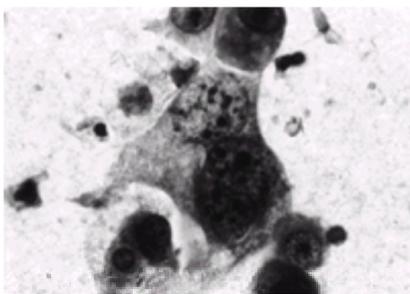
The cytologic diagnosis of large cell carcinoma is one of exclusion. This tumor is defined by the *absence* of cytologic features that are characteristic of either squamous cell carcinoma or adenocarcinoma. Thus the cells from this tumor lack evidence of cell keratinization, endoplasmic ringing, or cytoplasmic mucin. Large cell carcinomas usually display ample malignant characteristics within the nucleus. There are marked aberrations in the chromatin pattern, coarse chromatin, irregular nuclear contours, and large irregular nucleoli. The nuclear to cytoplasmic ratio is high, with tumor cells having a scant cytoplasm with an ill-defined cytoplasmic border (Figure 26.31). The tumor often exfoliates many highly malignant cells. However, poorly differentiated adenocarcinomas and squamous cell carcinomas can also exfoliate many single cells, so that further sampling of the tumor may reveal inconsistencies between the cytologic diagnosis of large cell carcinoma and the subsequent histologic diagnosis. A variation of large cell carcinoma is giant cell carcinoma, which consists of multinucleated tumor cells that are many-fold the diameter of surrounding cells.


FIGURE 26.31. Large cell carcinoma, cytology. Cells of large cell carcinoma are markedly pleomorphic with multiple nucleoli. No features of squamous or glandular differentiation are present.

Neuroendocrine Tumors

Pulmonary carcinoid tumors are well known to diagnostic pathologists. However, in a study by Anderson et al., approximately one-quarter of typical carcinoids were misdiagnosed as either non-Hodgkin's lymphoma or as normal lung cells in aspirated material.[315] Appreciating the cytologic features of this tumor, the stripped cytoplasm, course chromatin, and plexiform vascularity is important for correct diagnosis.[316,317] The spindle cell variant of carcinoid tumor poses a different problem in needle aspiration material because it may be mistaken for sarcoma, spindle cell variants of carcinoma, and benign mesenchymal cells.[318]

Accuracy of Lung Cancer Diagnosis by Cytologic Methods

Several aspects recur in any discussion of the diagnostic accuracy of lung cytology. The first is the issue of sensitivity—how often any one cytologic method accurately identifies lung cancer in a patient when tumor is actually present. This issue has been thoroughly reviewed by Johnston and Bossen, leading these authors to conclude that an unequivocal cytologic diagnosis could generally be made in approximately 50% of cases where sputum or bronchial material was obtained.[256] The diagnosis was facilitated by the examination of multiple lower respiratory tract specimens with optimum sensitivity, requiring examination of up to five specimens. These authors also noted that examination of multiple specimen types, a combination of both sputum and bronchial material, were essential for maximum diagnostic accuracy, and that sputum examination was equal to if not superior to bronchoscopic exam. Fine-needle aspiration, as mentioned previously, has a higher sensitivity of approximately 90%. The most comprehensive analysis of pulmonary fine-needle aspiration was reported as part of the College of American Pathologists Q-probe Quality Assurance Program. In this study of 13,094 lung fine-needle aspirates at 436 institutions, the sensitivity of the fine-needle aspiration procedure was 89%, with 96% specificity, 99% positive predictive value, and 70% negative predictive value. The false-positive rate was 0.8%, and the false-negative rate was 8%.[319] The issue of false-negative cytology is vexing for pathologists because the absence of abnormal cells may be caused by either sampling error (no abnormal cells were collected)

or interpretive errors (abnormal cells on the slide were not correctly identified).[320] In a recent study of negative predictive value of lung needle aspiration cytology by Zakowski et al. the recommendation of repeat aspiration was made when no specific benign diagnosis was made.[321]

The sensitivity of lung cancer detection may be aided by the simultaneous measurement of carcinoembryonic antigen in respiratory specimens.[322,323] Immunohistochemic staining for CEA, or other markers, can be performed directly on slides that have been previously stained by the Papanicolaou technique.[324]

Comparative studies have assessed the relative sensitivity of bronchial washing/brushing with bronchial biopsy. Naryshkin et al. described 224 cases where 75% correlated completely. In the remainder, biopsy and cytology were diagnostic in relatively equal proportions, leading the authors to conclude that a specific diagnosis was obtained more often from the combination of cytology and biopsy than from either alone.[325] Others, in comparing diagnostic techniques, have reached a similar conclusion.[237]

The issue of specificity has two elements (a) how often, when a diagnosis of malignancy is rendered, is this interpretation correct, and (b) how successful is cytology in predicting the classic histologic types of malignancy. Avoiding poor specificity, where many false-positive malignant diagnoses are made, requires a careful attention to the nuclear morphologic features that classically predict malignancy. Nevertheless, even expert cytopathologists may render a false-positive diagnosis. In large series, the reported false-positive rate because of atypical forms of metaplasia and reactive and reparative changes ranges from of 0% to 2%.

The other aspect of specificity relates to the correlation between different types of respiratory tract specimens. Comparisons may be made among sputum, bronchial cytologic specimens, fine-needle aspiration, and histologic materials. In a large study by Johnston, the prediction of histologic type of primary lung cancer from sputum and bronchial material was compared with histologic diagnosis. The rate of concordance was 85% with squamous cell carcinoma, 79% with adenocarcinoma, 30% with large cell carcinoma, 93% with SCLC, and 30% with adenosquamous carcinoma.[326] Recent studies have confirmed this observation.[327] As mentioned previously, the variable sampling of different areas within a tumor accounts for most of the poor correlation between cytologic and histologic diagnoses. Fortunately, a relatively high correlation rate exists between the histologic and cytologic diagnosis of SCLC. As discussed elsewhere in this book, the distinction between SCLC versus NSCLC is important for selection of therapy.

Previously, we mentioned the disadvantage of overusing the "suspicious" diagnosis. The definitive diagnosis and classification of cancer by cytology permits prompt planning of therapy. However, "suspicious" or "suspect" is useful as a diagnostic category because some respiratory specimens contain abnormal cells that lack definitive diagnostic features of malignancy.[328] At least 50% of these patients will have carcinoma on subsequent evaluation.

Differential Diagnostic Problems in Pulmonary Cytology

The preceding discussion has mentioned several problems that complicate the diagnosis of lung cancer. These issues have recently been reviewed in a monograph addressing errors and pitfalls in diagnostic cytology.[329] A common and treacherous problem is that of reactive airway epithelial cells from altered lining epithelium.[330] A wide variety of external stimuli of infectious agents and other relatively nonspecific factors can cause abnormal cell morphology. Previously, we discussed the problems posed by squamous metaplastic or by hyperplastic reserve cells, mimicking squamous carcinoma and SCLC, respectively. A greater problem is atypia of bronchial epithelial cells, where individual cells or cells in clusters simulate NSCLC. Reactive bronchial epithelial cells may have a nuclear diameter five to ten times that of a resting columnar epithelial cell. The cytoplasm does not proportionately increase in quantity, so that gross changes in nuclear to cytoplasmic ratio are common. As discussed previously, the presence of cilia or a terminal bar on these cells is key to correctly interpreting their reactive nature.

Unfortunately, a definitive marker such as cilia does not exist for atypical terminal bronchiolar cells. When irritated, cells that line alveoli and terminal bronchioles assume a morphology that is similar to bronchioloalveolar adenocarcinoma.[231] Reactive cells of terminal bronchiolar origin occur with pulmonary infection, pulmonary infarction, and virtually any cause of diffuse alveolar damage.[332]

The differential diagnosis of lung cancer must also include consideration of metastatic carcinoma, sarcomas, and hematolymphoid malignancies. Each of these diseases can shed cells that resemble lung carcinoma into the respiratory tract.[333]

TECHNIQUES AND APPLICATIONS OF TISSUE MICRODISSECTION

JOHN W. GILLESPIE
NICOLE L. SIMONE
ROBERT F. BONNER
LANCE A. LIOTTA
MICHAEL R. EMMERT-BUCK

Human tissues consist of multiple interacting cell populations in a complex three-dimensional arrangement, with each cellular phenotype determined by a unique profile of mRNA and protein expression. Molecular analysis of specimens geared toward an understanding of individual cell types requires methods and approaches that permit histopathologically defined cell types to be selectively studied. This approach is particularly important for pathologic processes where the diseased cells constitute only a small percentage of the total cells present in a sample, or, as in the case of tumor progression, the disease evolves through stages represented by discrete microscopic foci. To date, this goal has been accomplished primarily through immunohistochemical and *in situ* hybridization studies. Although these techniques have been useful tools to examine tissue specimens, they are limited to single gene analysis and in general do not allow qualitative studies (mutation, deletion analysis) of DNA, mRNA, or proteins to be performed. Thus microdissection has become an increasingly useful method to study defined cell types from tissue samples.[1] In concert with newly developing molecular analytical techniques, this approach allows for a highly sensitive and specific means to study disease processes as they exist *in vivo*. Many techniques of microdissection have been developed and are briefly described in following sections. The present chapter focuses primarily on laser capture microdissection, a new technology invented at the National Institutes of Health, which has been developed into an automated and high-throughput system, with examples of its use in lung neoplasms.

DEVELOPMENT OF TISSUE MICRODISSECTION TECHNIQUES

The concept of tissue microdissection is simple; that is, procuring a specific population of cells from a heterogeneous tissue sample under direct microscopic visualization. However, in practice the approach is technically challenging. Early efforts entailed grossly removing tissue from a frozen section slide or utilizing a scalpel blade to scrape sections and procure cells of interest.[2,3] Subsequently, the use of a manual or micromanipulator-guided needle with an adhesive tip was developed, which improved the accuracy and reliability of microdissection.[4,5] A technical advance known as selective ultraviolet radiation fractionation (SURF) was developed using ink to protect against ultraviolet irradiation and obliterating the genetic material of the unwanted surrounding tissue.[6] A similar method was developed for isolating single cells, which utilizes a high-energy ultraviolet laser microbeam to obliterate the unwanted cells. The desired cells are then retrieved by a needle.[7] Another laser-based method called non-contact laser microdissection of membrane-mounted native tissue was developed, which involves placing a tissue section onto a membrane on a glass slide and using a high-intensity ultraviolet beam to cut out an area of tissue/membrane that can subsequently be recovered.[8,9]

LASER CAPTURE MICRODISSECTION

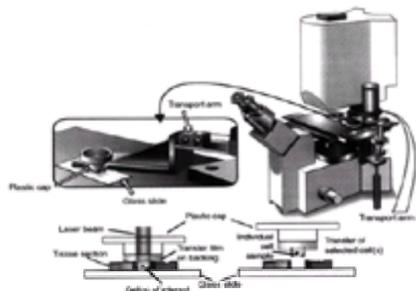
Laser capture microdissection (LCM) is a positive selection method that was developed at the National Institutes of Health (NIH) and designed to permit simple, fast, and reliable microdissection of tissue.[10,11] The system utilizes an infrared laser integrated into a standard microscope with alignment into the optics subsystem. The technique relies on the use of a thermoplastic transparent film, which lies on the surface of a routinely prepared tissue section on a glass slide. The investigator examines the tissue section microscopically and activates the laser when the desired cells underlie the target. This laser activates the film with subsequent binding and procurement of the cells of interest (Figure 27.1). The laser pulse is brief (approximately 5 msec) and the membrane is activated at 90°C, thus the tissue experiences only a brief thermal transient as the heat generated from the membrane is rapidly dissipated. LCM allows for visualization and image capturing of tissue as it is microdissected including images of the tissue before and after microdissection. This ability is critical in maintaining an accurate record of each dissection and correlating histopathology with subsequent molecular results. In the following sections, the principles of tissue handling, staining, and dissection using LCM are discussed. Current and regularly updated protocols can be found on the websites listed in the Web Resources section at the end of the chapter. Examples of research studies utilizing LCM are also presented at the end of the chapter in the References section.


FIGURE 27.1. Laser capture microdissection (LCM) system showing the process of microdissection of cells from tissue. The laser beam activates the thermoplastic film embedding the underlying cells, which can then be separated from the tissue. (See Color Figure 27.1.)

TISSUE PROCESSING FOR LCM

The importance of specimen handling for tissues to be used for molecular analysis cannot be overstated. Factors such as the time interval between surgical removal and sample processing, type of fixative and embedding medium, and length of fixation time have a significant impact on the recovery of nucleic acids and proteins. If the investigator is unaware of the time interval between surgery and sample processing, the quality of macromolecules in each specimen needs to be determined empirically. As a practical approach in this situation, we start with a scrape of a tissue section to assess the quality of DNA, RNA, or proteins of the specimen before utilization of the tissue in a study. Thus cases that are sufficient for a given analysis can be identified prior to the time and effort involved in microdissection.

After tissue is removed from a patient, it can be either frozen or placed in fixative and embedded. Both approaches have advantages and disadvantages. The major advantage of tissue freezing is the excellent preservation of DNA, RNA, and proteins, including active enzymes. The disadvantages include the relatively poor histologic detail on examination and the logistic problems associated with storing blocks and recut slides in freezers. The advantages of studying fixed and embedded tissue include ease of use, optimal histology, and generally abundant amount of archival patient material available for study. The major disadvantage is the generally

lower quality macromolecules that can be recovered from fixed and embedded samples.

Frozen Tissue

Immediately after removal from the patient, the tissue should be subdivided into thin pieces and immediately snap frozen in embedding compound and stored at -80°C. Cutting sections is performed using a standard cryostat at -20°C and standard noncoated glass slides. The recut sections can be temporarily stored in the cryostat while being cut; however, the slides must not be left at room temperature for any length of time because the tissue will stick irreversibly to the slide and interfere with subsequent LCM.

Embedded Tissue

The critical element of tissue fixation and embedding is to maintain excellent histologic detail while preserving the biomacromolecules and allow for practical handling of the embedded blocks. The standard protocol of formalin-fixation and paraffin-embedding of tissue seriously limits studies of mRNA and protein. However, the tissue can still be used for DNA analysis. If cases have been properly fixed and processed, then excellent polymerase chain reaction (PCR) amplification occurs in close to 100% of cases. We and other groups are currently examining the effects of various fixatives and embedding compounds on recovery of biomacromolecules. Strategies using non–cross-linking fixatives and low-temperature embedding compounds appear promising. [12],[13] and [14]

Staining

Slide staining should be conducted immediately before microdissection is performed. Hematoxylin and eosin staining as performed in a histopathology laboratory is the standard for LCM; however, elimination of hematoxylin improves subsequent DNA amplification by PCR. Recently, an adjunct protocol using immunohistochemical staining to improve cell targeting has been developed [15] Staining reagents are changed on a daily basis to avoid cross contamination between cases.

LCM

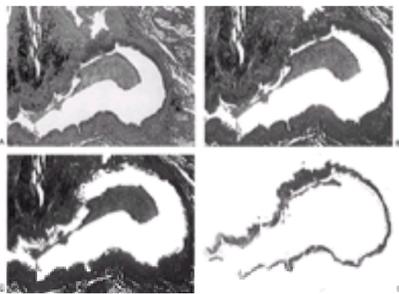
Once the tissue has been properly processed, sectioned, and stained, it is ready for microdissection. The tissue is visualized under the microscope and an initial roadmap image as well as predissection, postdissection, and cap images are taken to document the histology, the steps of microdissection, and the microdissected cells, respectively. The laser beam size may be adjusted from 7.5 mm to 30 mm to allow microdissection of either groups of cells or single cells depending on the investigator's needs. For example, Figure 27.2 shows microdissection of normal bronchiolar epithelium, and Figure 27.3 shows microdissection of a single bronchioloalveolar carcinoma cell. The total number of cells procured depends on the molecular analytical technique being employed. After the microdissection is complete, the cap with microdissected cells is placed onto an Eppendorf tube containing the appropriate buffer for molecular analysis. The tube is then inverted to allow the lysis of the cells, and the sample is ready for molecular analysis.


FIGURE 27.2. Microdissection of normal bronchiolar epithelium. **A:** roadmap, **(B)** before microdissection, **(C)** after microdissection, and **(D)** cap with dissected tissue (200 X magnification). (See Color Figure 27.2.)
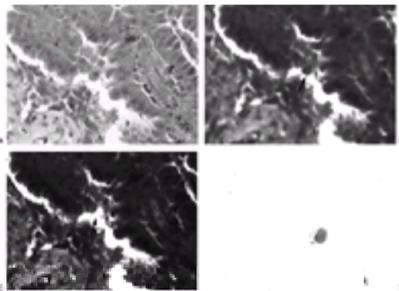

FIGURE 27.3. Microdissection of a single cell from bronchioloalveolar carcinoma *(arrow)*. **A:** roadmap, **(B)** before microdissection, **(C)** after microdissection, and **(D)** cap demonstrating microdissected cell (1000 X magnification). (See Color Figure 27.3.)

EXAMPLES OF TISSUE MICRODISSECTION

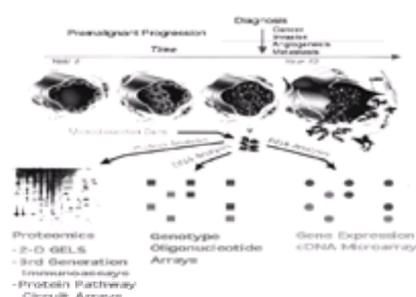
The combination of tissue microdissection and emerging molecular analysis technologies significantly expands the opportunities for study of pathologic processes such as cancer. For example, as illustrated in Figure 27.4 many techniques can be applied to LCM-derived cell samples to examine the DNA mutational events that occur during tumorigenesis as well as the patterns of gene expression at each stage of disease progression. Examples of two applications of tissue microdissection in cancer research performed in the Pathogenetics Unit of the Laboratory of Pathology, National Cancer Institute (NCI) are presented as follows.


FIGURE 27.4. Application of LCM to study the molecular events associated with cancer progression. The expression pattern of proteins (two-dimensional gel electrophoresis or immunoassays), RNA (differential display, microarray hybridization, or cDNA libraries), and DNA genotype (mutational analysis, loss of heterozygosity, comparative genomic hybridization) can be compared within the same patient. In the tissue section, normal precursor epithelium, premalignant

lesions, and invasive cancer foci can be microdissected and compared. (See Color Figure 27.4.)

Multiple Endocrine Neoplasia Type I

Multiple endocrine neoplasia type I (MENI) is an inherited syndrome characterized by development of multiple neuroendocrine (NE) tumors in affected individuals. To precisely localize the genomic location of the gene on chromosome 11q13, we performed loss of heterozygosity (LOH) analysis in 188 tumors from 81 patients using tissue microdissection.[16] Six tumors (three MENI, three sporadic) were identified, which provided important gene location boundaries and indicated that the gene was located between markers PYGM and D11S4936, a region of approximately 300 kb. Subsequent DNA sequencing from the identified minimal interval on chromosome 11q13 identified the *MENI* gene, which contains 10 exons and encodes a ubiquitously expressed 2.8 kb transcript.[17]

To investigate the role of the *MENI* gene in lung neuroendocrine cancers NE tumors, we studied a series of sporadic lung tumors (11 carcinoids, 13 large cell [LCNECs], 9 primary small cell lung cancer [SCLC], 35 SCLC cell lines) to determine if *MENI* gene inactivation was involved in the pathogenesis of these lesions.[18,19] Each tumor was analyzed for allelic deletions and mutations of the *MENI* gene using tissue microdisection combined with dideoxy fingerprinting (ddF) for mutational screening, and LOH analysis at the locus of the gene on chromosome 11q13. In 4 of 11 (36%) carcinoids both copies of the *MENI* gene were inactivated. All four tumors showed the presence of a mutation in one allele of the gene and LOH of the second allele. Observed mutations included a 1 bp insertion, a 1 bp deletion, a 13 bp deletion, and a single nucleotide substitution affecting a donor splice site. Each mutation predicts truncation of menin. The remaining seven carcinoids showed neither the presence of an *MENI* gene mutation nor 11q13 LOH. All SCLCs and cell lines were negative for *MENI* gene mutations. LOH at 11q13 was detected in 20% of SCLCs and cell lines, most likely a consequence of genomic instability not specifically related to *MENI* gene inactivation. None of the 13 LCNECs showed 11q13 LOH. Interestingly, one LCNEC case showed a 1 bp frameshift deletion of the *MENI* gene predicting protein truncation. This finding is the first demonstrated mutation in a tumor outside the usual MENI-associated realm, and the first mutation to be observed in a tumor that does not demonstrate loss of the second allele. In summary, the data implicate the *MENI* gene in the pathogenesis of sporadic lung carcinoids, representing the first defined genetic alteration in these tumors. *MENI* gene inactivation was found to occur infrequently in LCNEC, and was not observed in SCLC.

NCI Cancer Genome Anatomy Project

An understanding of the *in vivo* gene expression profiles that occur in normal and tumor cells has multiple uses in the fight against human cancer, from promoting new insights and hypotheses regarding fundamental tumor development to identifying new diagnostic and therapeutic markers.[20] To promote efforts to understand cancer development and progression at a molecular level, the NCI recently began the Cancer Genome Anatomy Project (CGAP). The primary goals of the project are: (a) discovery of novel human genes toward a complete human unigene set; and (b) assessment of the technical challenges associated with creating molecular fingerprints of cancer progression, and development of appropriate technologic and informatics tools to facilitate this process.

cDNA libraries were prepared from lung, colon, prostate, breast, and ovarian tumors using tissue microdissection and subjected to 3' end sequencing.[21,22] All data from the project are immediately made available to the public and can be viewed on the CGAP website (http://www.ncbi.nlm.nih.gov//ncicgap/) along with analysis tools to analyze patterns of gene expression.

GENOMIC IMBALANCES IN LUNG CANCER

ALESSANDRA TOSOLINI
JOSEPH R. TESTA

Clonal, somatic chromosome alterations are well documented in many human cancers and may be indicative of molecular events critical in tumorigenesis. Some of these chromosome abnormalities, mainly balanced reciprocal translocations, are associated specifically with certain types of leukemias, lymphomas, and sarcomas. [1,2] and [3] Specific reciprocal translocations have been found that alter the expression of dominantly acting oncogenes or other cell-growth-related genes located at or very near the site of chromosomal exchange. For example, in Burkitt's lymphoma, the translocation-mediated juxtaposition of the *MYC* protooncogene, located in chromosome 8, and one of the immunoglobulin loci, located in chromosomes 2, 14, and 22, leads to the deregulated expression of *MYC*. Other reciprocal translocations produce fusion genes, such as the *ABL-BCR* rearrangement, caused by a specific translocation between chromosomes 9 and 22, which is observed in some types of leukemia. As a result of this rearrangement, a hybrid mRNA transcript and a novel protein with tyrosine kinase activity are produced. In many of these malignancies, a balanced rearrangement is the only cytogenetic abnormality present. In contrast, in lung carcinomas and other common types of epithelial tumors, the karyotypes often exhibit multiple genetic alterations. Tumor-suppressor genes (TSGs) are important in these neoplasms, but oncogenes (e.g., members of the *RAS* and *MYC* families) can also be involved in these tumors. A paradigm for such malignancies is colorectal cancer, in which tumorigenesis proceeds through a stepwise series of genetic changes involving TSGs such as *APC* and *TP53* and oncogenes such as KRAS.[4]

Lung carcinomas are now the leading cause of cancer mortality among both men and women in the United States, projected to account for more than 171,000 deaths in 1998.[5] Cytogenetic and molecular cytogenetic analyses of lung tumors can reveal specific genomic imbalances that can have clinical significance with regard to prognosis and therapy. Despite the high incidence of lung cancer, the cytogenetic data available are rather limited in this neoplasm compared to that available for the hematologic malignancies.[3] Primary lung tumor specimens often have a low mitotic index, which makes obtaining an adequate number of metaphase cells suitable for detailed karyotypic analysis difficult. Moreover, the karyotypes can be extremely complex with many additional chromosomes, complicating efforts to identify consistent changes. Reports describing detailed karyotypes of primary small cell lung cancer (SCLC) specimens have been limited to only a few cases. [6,7 and 8] Whang-Peng and colleagues were the first to describe a consistent clonal abnormality, deletion of the short arm of chromosome 3 (3p), in tumor cells from SCLC patients.[9] Other recurrent deletions have also been reported in SCLC. [8,10] In addition, extrachromosomal double minutes (dmins) and intrachromosomal homogeneously staining regions (hsrs), two cytogenetic manifestations of gene amplification, have been observed in SCLC, particularly in cell lines derived from these tumors.[8,11,12] Prior to 1994, detailed reports of karyotypes of primary non–small cell lung cancers (NSCLCs) were limited to several small series, usually of fewer than 10 patients,[13,14,15,16 and 17] or several selected cases or case reports.[18,19,20,21,22 and 23] Other early descriptions of cytogenetic changes in NSCLC have been made,[24,25,26,27,28,29,30,31,32 and 33] but these either did not provide complete karyotypes or reported on metastatic tumors, effusions, or established cell lines that had been cultured for many passages. Since 1994, several large series have described karyotypes from short-term cultures of primary NSCLCs. [24,25,26 and 27] Even though karyotypes in NSCLC are generally very complex, recurrent cytogenetic changes have been identified. For example, Lukeis and colleagues described a nonrandom chromosomal abnormality, deletion of the short arm of 9, in 9 of 10 NSCLCs,;s[5] and frequent numerical loss of chromosome 9 has also been reported. [34,35] Recently, several other recurrent chromosome alterations have been identified in NSCLCs.

This chapter summarizes cytogenetic studies of lung carcinomas performed by the authors and by other investigators worldwide. In addition, the importance of recent advances in molecular cytogenetics, especially comparative genomic hybridization (CGH) analysis, [39] and their applications to the study of lung carcinomas are discussed. The karyotypic and molecular cytogenetic findings indicate that both SCLC and NSCLC are characterized by the accumulation of multiple genomic imbalances. The molecular implications of recurrent chromosomal changes found in lung tumors are discussed.

METHODOLOGY

Cell Culture Aspects

To ensure that any karyotypic alterations are representative of the *in vivo* situation, direct preparations of tumor specimens and short-term cultures are preferable to long-term cultures. In our experience, however, mitoses are generally very sparse in direct preparations, and most of our successful analyses are from tumor cells cultured for 1 day to several weeks. Because metastases are presumably representative of a more progressive form of the neoplasm, and because lengthy *in vitro* culture can lead to additional chromosomal abnormalities,[1] it is important to document aberrations in primary tumor specimens harvested after a short *in vitro* culture period.[40]

Solid lung tumor tissue obtained from resections can be disaggregated by mechanical means.[41] The specimen is placed in culture medium containing 10% fetal bovine serum (FBS) and minced using scalpels. Hard tissue that is refractory to mincing is incubated with gentle shaking for 3 to 5 hours in complete medium to which collagenase A (0.5 mg/ml) has been added. Cells are then washed in a balanced salt solution, and single cells and cell aggregates are plated directly into plastic tissue culture flasks containing medium plus 10% FBS. Individual cultures are harvested for karyotypic analysis after 1, 2, and 3 days *in vitro* by overnight exposure to 10 ng/ml colcemid. The growth of several additional cultures of NSCLC cells is monitored daily with an inverted microscope; harvesting of metaphases is performed when adequate numbers of dividing cells are present, as indicated by a rounded morphology.

Methods for establishing SCLC cell lines are described in detail elsewhere. [42,43 and 44] For solid tumor specimens, single-cell suspensions are prepared from tumor tissues by mincing the specimen, passing it through a stainless-steel mesh, and gently pipeting the cells in the presence of culture medium. Bone marrow specimens are diluted to 10 mL with medium, and tumor cells are obtained by layering the specimen over Ficoll-Hypaque, followed by centrifugation at 500 xg for 20 minutes. Cells are cultured at a density of approximately 1×10^6 cells/ml in culture medium consisting of serum-free medium (HITES),[42] HITES plus 5% FBS, or McCoy's modified 5A, 10% FBS, and 20% heat-inactivated human effusion fluid.[44] Once the cell lines are well established (i.e., in 3 to 6 months), they may be maintained in RPMI 1640 supplemented with 10% FBS. SCLC specimens and cell lines are harvested for cytogenetics as described previously.

Chromosome Banding and Karyotypic Analysis

Monolayers of NSCLC cells are removed from the culture surface by trypsinization prior to treatment with a hypotonic solution consisting of 0.075M KCl or a 4:1 mixture of 0.075M KCl and 1% sodium citrate for 20 minutes at 37°C. The cells are then fixed in three changes of a 3:1 mixture of methanol-glacial acetic acid chilled to -20°C. Metaphase spreads are prepared by dropping two to three drops of the fixed cell suspension onto clean, wet slides. The slide preparations are dried briefly (~1 minute) over a steam bath and then placed in a dry oven at 55°C for 5 to 7 days. Chromosomes are treated with trypsin-EDTA (0.006%) and Wright stain to produce G-bands. For each specimen, we attempt to obtain chromosome counts on at least 20 metaphase spreads, five to ten of which are photographed and used to prepare karyotypes.

Chromosome identification and karyotypic designations are based on the consensus reached at several international meetings and as published in two authoritative documents.[45,46] A tumor is considered to be karyotypically abnormal if a clone of aberrant cells is found. The observation of a minimum of two or more cells with the same extra chromosome or structural rearrangement or of three or more cells with the same missing chromosome is considered evidence for an abnormal clone.

Fluorescence *In Situ* Hybridization

Fluorescence *in situ* hybridization (FISH) permits investigators to rapidly map the chromosomal location of genes and is helpful in interpreting the centromeric origin and breakpoints of complicated structural abnormalities and in determining the identity of chromosomal material whose origin is uncertain by routine cytogenetic banding techniques. Interphase cytogenetics involves the use of nonisotopic DNA probes to examine interphase nuclei for chromosomal alterations. For example, FISH with satellite DNA probes to the centromere of specific chromosomes can be used to detect numeric abnormalities within interphase nuclei of human solid tumors. Using such a fluorescence-based detection system, hybridization of an alpha-satellite probe to a specific interphase chromosome appears as a brightly fluorescent spot. The number of spots corresponds to the centromeric copy number of a specific chromosome in a given cell nucleus.

For studies of interphase nuclei, we use cell suspensions of tumor specimens that have been disaggregated mechanically. The cell suspensions are processed directly, without culture, treated with 0.075 M KCl hypotonic solution for 20 minutes at 37°C, and then fixed in a 3:1 mixture of methanol:acetic acid. Chromosome-specific probes such as a-satellite centromere probes may be labeled with biotin or digoxigenin by nick translation. Hybridization of biotinylated probes may be detected with fluorescein isothiocyanate (FITC)-avidin. [47] Hybridization of digoxigenin-labeled probes may be detected with anti-digoxigenin-rhodamine. The probes can be hybridized individually to interphase nuclei, or they may be co-hybridized to the same slide preparation. For each specimen, several hundred nuclei are counted, and the number of bright fluorescent spots per nucleus is scored. For each probe, hybridization and counting are also carried out on a normal diploid control (e.g., normal lymphocytes or fibroblasts) to ensure the reliability of the probe and hybridization conditions.

Comparative Genomic Hybridization

Comparative genomic hybridization (CGH) analysis represents a valuable approach for overcoming the considerable technical difficulties encountered by cytogeneticists studying chromosome changes in lung cancers. This technique is a valuable molecular cytogenetic tool for identifying losses, gains, and amplification of chromosomal segments in solid tumors.[39,48]

In a CGH analysis, DNA from a tumor and from a normal reference tissue are labeled separately with different haptens, (e.g., biotin and digoxigenin). Identical amounts of both tumor DNA and reference DNA are hybridized simultaneously to normal metaphase chromosome spreads together with an excess of unlabeled Cot-1 blocking DNA to prevent the ubiquitous hybridization of interspersed repetitive sequences contained in the tumor and reference DNA probes. Hybridization of the labeled DNA is detected by two different fluorophores (e.g., green-fluorescing FITC for the tumor DNA and red-fluorescing rhodamine for the reference DNA). The relative amounts of tumor and reference DNA bound to a given chromosomal region depend on the relative abundance of those sequences in the respective DNA samples; these amounts can be quantified by measuring the ratio of green to red fluorescence, using a digital image analysis system. Under- or overrepresentation of chromosomal sequences in the tumor genome is reflected by differences in the fluorescence intensity values of the respective fluorochromes.

We perform CGH analyses basically according to the method described by Kallioniemi and colleagues. [39] Genomic DNA from a normal male donor is labeled with digoxigenin-11 -dUTP by nick translation or by random priming; tumor DNA is labeled accordingly with biotin-11-dUTP. After preannealing the specimens to an excess of Cot-1 DNA, biotinylated total tumor DNA and digoxigenin-labeled normal genomic reference DNA are hybridized simultaneously to normal male metaphase spreads for 3 to 4 days at 37°C. The Cot-1 DNA inhibits binding of labeled DNA to the centromeric and heterochromatic regions; therefore these regions are excluded from the analysis.[39] After posthybridization washing of the slides, biotinylated sequences are detected with FITC-avidin, and digoxigenin-labeled sequences are detected with anti-digoxigenin-rhodamine. Alternatively, tumor and normal DNAs can be directly labeled, using SpectrumGreen™-dUTP and TexasRed™-dUTP (Vysis). Chromosomes are counterstained with DAPI for chromosome identification. The FITC and rhodamine fluorescence specific for the tumor genome and reference genome, respectively, are quantified as gray level images by a cooled charge-coupled device camera interfaced to a computer workstation for image acquisition. A software program integrates the green and red fluorescence signals orthogonally to the chromosomal axis, subtracts local background fluorescence, and calculates the intensity profiles for each color and the ratio of the two colors along individual chromosomes to indicate gains or losses in tumor DNA. A software package is used to compute FITC-rhodamine ratio profiles along chromosomes, such that monosomy of a chromosome in a tumor would theoretically result in a ratio value of 0.5 and trisomy in a value of 1.5. The means of the individual ratio profiles from at least five metaphase spreads per tumor are calculated, and the average values are plotted as profiles alongside individual chromosome ideograms. The three vertical lines beside individual chromosome ideograms indicate different threshold values between tumor DNA and normal reference DNA. The line on the left corresponds to a threshold value of 0.75, which would exist if 50% of the cells from a near diploid tumor had monosomy of a given chromosome. The center line indicates a balanced state. The line on the right represents a threshold value of 1.25, which would occur if 50% of the cell population exhibited trisomy for that chromosome. Overrepresentation defined by a sharp peak is considered indicative of DNA amplification.

Loss of Heterozygosity Analysis

Frequent loss of heterozygosity (LOH) involving a specific chromosomal region, in a given malignancy, is often used as an indicator of the presence of a TSG, whose loss/inactivation can contribute to tumorigenesis. Such analyses of allelic loss are performed using highly polymorphic microsatellite DNA markers. DNA from tumor and blood pairs are amplified using the polymerase chain reaction (PCR) technique with appropriate primer sets. We customarily body label the PCR product with [^{32}P]-dCTP. The radiolabeled DNA is then size-fractionated by electrophoresis through a 6% denaturing polyacrylamide gel and subjected to autoradiography. Detailed examination of a series of lung tumors for LOH at various polymorphic loci distributed along a chromosome can reveal a common minimal region of deletion where a putative TSG potentially important in lung tumorigenesis may reside.

KARYOTYPIC CHANGES IN SMALL CELL LUNG CANCER

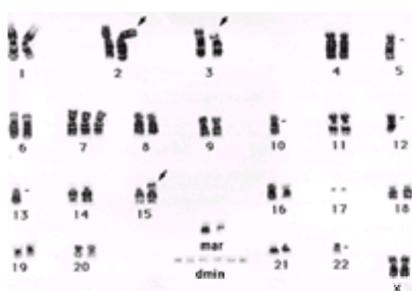
In SCLCs, karyotypic changes are usually quite extensive, even in newly diagnosed primary tumors. Our laboratory has performed karyotypic analyses of fresh specimens and early passage cell lines from 18 SCLC patients. [8,46] Many SCLCs have modal chromosome numbers in the triploid range (13 of 18 cases in our series). In many of these cases, most or all of the recurrent chromosome abnormalities described in the following sections occurred in combination (<u>Figure 28.1</u>). The total number of these changes ranged from 11 to more than 60 per tumor.


FIGURE 28.1. Karyotype of a Giemsa (G)-banded metaphase spread from a small cell lung cancer (SCLC) cell line that displays multiple cytogenetic alterations, including each of the abnormalities commonly found in SCLC (i.e., losses of 3p, 5q, 13q, 17p) and the presence of double minutes (dmin). An unbalanced translocation exists between 3p and 17q, monosomy 5 and monosomy 13 (numerical losses), and 17q and 15p. Both copies of 17p appear to be lost as a result of the two unbalanced translocations involving the two chromosome 17 homologues. This karyotype also has several other clonal changes, including a structurally altered chromosome 2 (2q+), trisomy 7, and monosomies of chromosomes 10, 12, and 22. Unidentified marker chromosomes (mar) and dmin are shown at the bottom. Arrows indicate structurally rearranged chromosomes 2, 3, and 15. (From Testa JR, Graziano SL. Molecular implications of recurrent cytogenetic alterations in human small cell lung cancer. *Cancer Detection Prevention* 1993;17:267, with permission.)

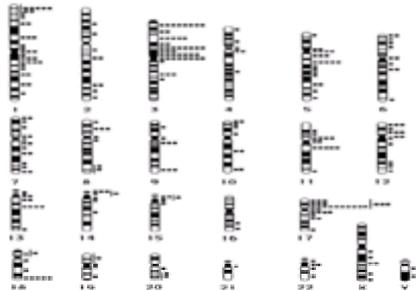
Figure 28.2 depicts the breakpoint sites of clonal chromosome rearrangements seen in a total of 38 fresh SCLC specimens and early passage SCLC cell lines for which complete karyotypic details have been reported. [6,9 and 8,10,49] As shown in Figure 28.2, some chromosomes often participate in structural rearrangements in SCLC; prominent among these are chromosomes 1, 3, 5, and 17. Among the 18 SCLC specimens that we have examined, breakpoints clustered at 3p, 5q, 1p, and 17p. Recurrent losses from each of these arms have been observed.


FIGURE 28.2. Ideogram depicting breakpoints (§) of clonal chromosome rearrangements seen in 38 reported small cell lung cancers (SCLCs) (see text). Whenever a single case contained two or more rearrangements with breaks at identical bands, only one of these breakpoints is shown. (From Testa JR, Liu Z, Feder M. Advances in the analysis of chromosome alterations in human lung carcinoma. *Cancer Genet Cytogenet* 1997;95:20, with permission.)

Chromosome Losses

Loss of 3p

In 1982, Whang-Peng and colleagues reported a nonrandom chromosomal alteration, del(3p), in tumor cells from patients with SCLC. [9] They observed this abnormality in 20 of 20 SCLC cell lines and fresh tumor specimens derived from bone marrow. An interstitial deletion of 3p in SCLC was consistently identified in several other studies as well. [6,8,11,43,44,50,51 and 52] However, in other reports only a minority of SCLC cell lines exhibited a 3p deletion. [10,12,24] DeFusco and colleagues examined fresh SCLC tumors grown in short-term culture and found alterations of 3p in only 5 of 11 cases. [7] However, LOH analysis of 3p markers confirms an almost universal loss of genetic material in this region. [53,54 and 55]

Of the 18 SCLC tumors and cell lines that we analyzed, cytogenetic evidence for loss of 3p was found in 16 cases. [8,49] Among cases with structural changes affecting 3p, three had terminal or interstitial deletions, seven had one or more unbalanced derivative chromosomes involving partial loss of 3p [i.e., der(3)], three had an i(3q)(q10), two had both a deletion and either a der(3) or an i(3q), and one near-tetraploid tumor had an i(3q), a der(3), and a numerical loss of 3. Another specimen had an unbalanced translocation derivative in which breakage occurred in the long arm of chromosome 3, resulting in loss of 3pter->q21. The deletions were large in 15 of these 16 cases, with the shortest region of overlap (SRO) of losses being 3p21->25; the remaining case had a derivative with loss of 3p25->pter. Two tumors did not have a visible alteration affecting 3p; LOH analysis performed on one of these cases revealed that allelic losses had occurred at both DNA markers tested, one located at 3p21 and the other at 3p25. Only one of the 18 SCLC specimens did not have a visible structural alteration of chromosome 3. LOH analysis of this case revealed allelic losses at both the DNF15S2 (chromosome band 3p21) and *RAF1* protooncogene (3p25) loci. [8] Taken collectively, the cytogenetic and LOH findings indicate that all 18 of these SCLC cases had losses involving 3p.

At least some of the discrepancies among laboratories may be explained by differences in the interpretation of karyotypes. [44] Thus whereas interstitial or terminal deletions of 3p are not uniformly seen in SCLC, losses of 3p by other mechanisms such as unbalanced translocations or isochromosome formation have a comparable net result. [56] In our series, only five cases had intrachromosomal deletions of 3p (accompanied by another altered chromosome 3 in two cases), and eleven others showed losses of 3p caused by other types of unbalanced rearrangements. The remaining case had allelic losses of 3p that were not evident from the karyotype. The SRO of 3p losses among these cases was found to be at 3p21-p25. In other reports, the SRO has been placed at 3p14-p23, [9] 3p21-p22, [55] or 3p23-p24. [57] Some of these interlaboratory differences can be attributed to difficulties in precisely assigning breakpoints in some cases, particularly when the quality of the chromosome preparation is suboptimal. In contrast to these reports, our interpretation of the minimal 3p deletion extends more distally to 3p25 and agrees with molecular analyses demonstrating consistent LOH at the *RAF1* locus at band 3p25 in SCLC. [44,58,59] In addition, other reports of LOH have demonstrated that almost all SCLC tumors exhibit allelic losses from the chromosomal region 3p14-p21, as well. [53,54 and 55] Virmani and colleagues identified three hot spots at 3p12, 3p14.2, and 1p13 in SCLC. [60] In many of their cases, most of the 3p arm was lost. Therefore, the deleted segment in SCLC usually is very large. This consistent allelic loss at 3p strongly supports the hypothesis that one or more TSGs important in the pathogenesis of SCLC reside within this chromosomal region. Several groups have searched for rare homozygous 3p deletions in lung cancers as an approach to locate such a gene(s). At least three distinct regions at homozygous losses have been identified. Rabbits and colleagues identified a homozygous deletion of 3p in the DNA of the SCLC cell line U2020; the deletion removed a chromosomal segment of approximately eight megabases within 3p12-p13. [61,62,63,64,65,66 and 67] Overlapping homozygous deletions have been observed in three SCLC cell lines, which have narrowed the localization of one of these putative TSGs to <350 kb within 3p21.3. [64,65,66 and 67] The semaphorin A(V) gene, which encodes a nerve growth cone guidance signaling protein, resides within this region and was found to be expressed in only one of 23 SCLC cell lines. [65] In addition, mutations of this gene were identified in 3 of 40 lung cancer cell lines. The function of the semaphorin A(V) gene in nonneural tissues and its possible role in lung carcinogenesis remains to be determined. A third, more distal site of homozygous deletions has been observed in several SCLC and NSCLC cell lines as well as in two direct tumor specimens. [64]

Besides these sites of homozygous losses, there has also been interest in several candidate TSGs located elsewhere in 3p. One prominent example is the *FHIT* gene, which encompasses the fragile site *FRA3B,* located at 3p14.2. Sozzi and colleagues reported abnormalities in RNA transcripts of *FHIT* in 80% of SCLCs and 40% of NSCLCs [68] (see also Chapter 8). In addition, 76% of their lung tumors exhibited loss of *FHIT* alleles, and Southern blot analysis revealed rearranged *Bam*HI fragments in several cases. Deletion within intron 5 of the *FHIT* gene was found in 100% of the SCLC cases analyzed by Virani and colleagues. [60] The role of *FHIT* in lung carcinogenesis is currently the subject of intense investigation.

Loss of 5q

We previously reported that alterations of 5q are often involved in SCLC. [8] In addition, our review of karyotypic data presented in two earlier reports revealed losses of 5q in approximately one-half of all SCLC specimens examined. [7,10] Among the 18 SCLC cases that we have analyzed, 16 showed either a numerical loss of chromosome 5, an i(5p) resulting in loss of the entire long arm of chromosome 5, a der(5) resulting in loss of part of 5q, or an interstitial deletion of 5q. In 15 cases, the SRO of deleted segments was 5q13->21; the remaining case had a breakpoint in 5q13, with loss of 5pter->q13. Thus losses involving 5q13 were found in 12 cases overall.

This recurrent loss of 5q13-q21 suggests that this region may contain a TSG contributing to the pathogenesis of SCLC. Several cell-regulatory genes are located at band 5q13, including the gene-encoding phosphatidylinositol-3 kinase-associated protein, p85a, which has been shown to modulate interactions between certain activated receptors and the phosphatidylinositol-3 kinase, [69],[70] and the *RASA* locus, which encodes the GTPase-activating protein involved in signal transduction. In addition, the putative TSGs *MCC* and *APC,* which have been shown to be somatically altered in some colorectal tumors, are located at 5q21.[71] Allelic losses of *MCC* and *APC* occur in approximately 80% of SCLCs; however, no mutations or homozygous deletions of these genes have been documented in SCLC. [72]

Loss of 13q

Loss of chromosome 13 has been described in some studies of SCLC.[8],[10] Numerical losses of chromosome 13 in the absence of structural change have been observed in 11 of the 18 SCLC cases we examined. Another three cases had structural alterations with breakpoints at 13q14, which is the site of the retinoblastoma susceptibility gene, *RB1.* Thus 14 of our 18 (78%) SCLC cases had changes that affect 13q14. Interestingly, a similar proportion (nearly 80%) of SCLC tumors exhibit absent or very low levels of expression of *RBI,*[73] suggesting that in many SCLC cases, cytogenetic changes could unveil an inactivated *RB1* gene on the remaining, karyotypically normal chromosome 13 homolog.

Loss of 17p

Morstyn and colleagues reported abnormalities of chromosome 17 in eight of ten SCLC cell lines they examined, [10] but the specific types of alterations and breakpoints were not described. In another report, rearrangements of chromosome 17 were described in four of eleven SCLC specimens, including three cases with breakpoints at 17p11-p13 resulting in losses of part of 17p. [7] Loss of part or all of 17p was observed in 14 of 18 specimens from my series. In four of these cases, the only alteration of chromosome 17 was a numerical loss. Another 10 specimens had structural alterations that were interpreted as unbalanced rearrangements that would result in loss of part or all of band 17p13; nine of these specimens had partial deletions or various derivative chromosomes with breakpoints in 17p or proximal 17q, and one tumor had both a dicentric (15p;17p) and a der(17).

Yokota and colleagues reported LOH from 17p in five of five SCLC specimens they examined.[74] *TP53* is located at band 17p13.1 and has been shown to be a common target for molecular alteration in lung cancer. [75],[76] The finding of common cytogenetic losses of 17p appears to be consistent with this molecular evidence because a mutated *TP53* allele may exist on the remaining copy of 17p. Virani and colleagues noted allelic losses at the *TP53* locus in all 11 informative SCLC cell lines they examined.[60] Loss of the intron 1 and the telomeric region of the *TP53* gene was documented in 86% of these cases.

Gene Amplification

Dmin and hsr have been reported in some SCLCs, particularly cell lines derived from these tumors. Such novel cytogenetic alterations were reported in 3 of 16 (19%) SCLC cell lines studied by Whang-Peng and colleagues [11] and in 5 of 18 (28%) cases examined by our research group. [8],[49] The incidence of dmins may be much higher in SCLC specimens obtained late in the disease course. For example, Wurster-Hill et al. observed dmins or hsrs in 11 of 15 SCLC specimens from heavily pretreated patients with extensive distant metastases; 7 of the 15 samples were obtained at autopsy. [12]

It is now well documented that dmin and hsr are associated with amplification of oncogenes and genes involved in drug resistance. [77],[78] Southern blot analysis revealed amplification of specific oncogenes in each of our four cell lines displaying dmin. Two of these cases exhibited a 5- to 10-fold level of amplification of either *MYC* or *MYCN* oncogenes. In each of the latter two cell lines, dmin were observed in a minority of the cells examined cytogenetically. The level of amplification of *MYC* or *MYCN* was approximately 60-fold in the other two cell lines. In each of the latter cases, all of the metaphase spreads examined contained a large hsr or multiple dmin, including a few mitoses with more than 100 of these tiny bodies. FISH of a nonisotopically labeled *MYCN* probe to metaphase cells of the SCLC tumor having -60-fold amplification of this gene demonstrated that the amplified sequences reside within the dmin and hsr.

In SCLC cell lines, amplification of various members of the *MYC* family of oncogenes is relatively common.[79],[80] and [81] However, such amplification appears to be less common in primary tumors. In a study of primary SCLCs, amplification of *MYC* or *MYCN* was reported in only 5 of 45 (11%) SCLC specimens.[82] In studies carried out in our laboratory, cytogenetic evidence for gene amplification was found in four of our eight established cell lines, but in only one of twelve fresh specimens. Among the four patients whose tumor cells contained dmin and hsr, three received prior cytotoxic therapy. Overall, such cytogenetic alterations were identified in four of six specimens from previously treated patients versus only one of twelve (8%) from untreated patients. Similarly, Brennan and colleagues detected amplification of one of the *MYC* family genes in 28% of tumor specimens from previously treated SCLC patients, compared to only 8% of specimens from untreated patients. [83] This finding and the relatively low incidence of *MYC* family gene amplification in primary tumors[82] implies that such amplification is unlikely to represent an initial, transformation-related event in SCLC.

KARYOTYPIC CHANGES IN NON–SMALL CELL LUNG CANCER

In NSCLC, cytogenetic changes are often extensive, with many numerical and structural changes. We have carried out detailed cytogenetic analyses of primary tumors from 70 NSCLC patients.[34] Only three of these tumors had fewer than 10 clonal chromosomal changes, and some tumors showed as many as 60 to 70 different structural and numerical changes. The number of cytogenetic changes per tumor was similar among different histologic subgroups. Other large series have also demonstrated numerous chromosomal alterations in most primary NSCLC cases.[15],[16],[31],[35],[36] and [37]

In some karyotypic studies of NSCLC, only clones displaying a single numerical change (i.e., gain of chromosomes 7 or 12) were observed. [13],[18],[22] The significance of these findings is uncertain because cell populations carrying an extra chromosome 7 as the only karyotypic change have been described in cultures from several malignant disorders of the bladder, brain, colon, and kidney as well as in cultured cells from nonneoplastic tissue obtained from the lung, brain, kidney, and placenta and in patients with Dupuytren contracture or Peyronie disease. [84],[85] In some series, approximately 10% of cultured cells from all nonneoplastic kidney samples examined displayed trisomy 7,[84],[85] and trisomy 7 and trisomy 10 have been shown to characterize subpopulations of tumor-infiltrating lymphocytes in kidney tumors and in the surrounding kidney tissue. [86] In ovarian cancer, trisomy 12 has been found to represent a recurrent chromosome aberration in benign ovarian tumors, particularly in fibromas, rather than in tumors of epithelial origin. [87] Thus in NSCLC it is presently unclear whether clones exhibiting simple karyotypes with gains of either chromosome 7 or chromosome 12 actually reflect changes in the malignant cell population. Johansson and colleagues reported pseudodiploid karyotypes with one or a few clonal structural rearrangements in two adenosquamous carcinomas, leading them to conclude that this relatively rare histologic subtype differs from other lung cancers by having simple pseudodiploid or near-diploid instead of massively aneuploid tumor cells. [22]

Among our 70 NSCLC cases, the modal chromosome number was near-diploid in 18 cases (26%), near-triploid in 40 cases (57%), and near-tetraploid to near-hexaploid in 12 cases (17%). Near-triploidy was the most common ploidy in each of the histologic categories (45% of adenocarcinomas, 63% of squamous cell carcinomas, and 83% of other NSCLCs).

Overall, the available data indicate that karyotypes in NSCLC generally are very complicated, even in newly diagnosed primary tumors. We have focused investigations on samples obtained prior to initiating cytotoxic therapy. Thus the complicated cytogenetic pattern seen in these cases appears to be part of the natural course of NSCLC. Moreover, it is unlikely that this genomic complexity can be attributed to *in vitro* karyotypic evolution because most of our analyses were from relatively short-term cultures of tumor cells.

Numerical Changes

In NSCLC, all chromosomes contribute to numerical changes. In our series of 70 cases, losses of chromosomes 9 (47 cases, 67%) and 13 (45 cases, 64%) were the two most common numerical changes. Loss of the Y chromosome was observed in 29 of 49 (59%) tumors from male patients. Gain of chromosome 7 was also a common numerical change (28 of 70 cases, 40%). Other chromosomes commonly involved in numerical gains were numbers 5 and 12, each of which was identified in approximately 20% of the cases examined. Polysomy for all or part of chromosome 7 in NSCLC has been reported at varying frequencies by several investigators. [13],[14] and [15],[19],[25],[33],[35],[36] and [37] Lee and colleagues proposed that trisomy 7 is a very early change in NSCLC that can be found in premalignant lung tissue in a subset of patients.[13] Lukeis and colleagues reported loss of material from the short arm of chromosome 9 in nine of ten NSCLCs suggesting that this change is a potentially important event in lung carcinogenesis. [15] In other reports, common numerical losses of chromosome 9 have been described. [14],[38] Losses of chromosomes 13 and Y

have also been observed in other studies of primary NSCLC. [14,15]

Structural Abnormalities

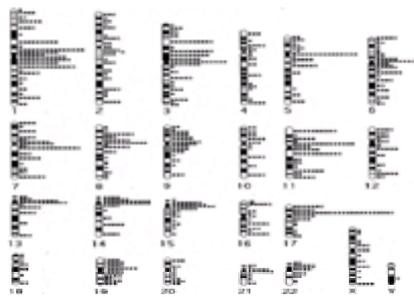
Balanced translocations are rarely reported in NSCLCs, whereas losses resulting from missing chromosomes or unbalanced rearrangements (i.e., deletions and derivative chromosomes) are often observed. Figure 28.3 depicts 1,826 breakpoint sites of clonal chromosome rearrangements seen in short-term cultures from 185 primary NSCLC specimens for which complete karyotypic details are available. Included in this summary are data from 70 specimens examined in our laboratory and 115 cases reported by other investigators. [13,14] and [15,17,18,19,20,21,22] and [23,35,36] and [37] The most common sites of chromosomal breakage were at or near the heterochromatic centromere regions of chromosomes 1, 3, 5, 6, 7, 8, 9, 11, 13, 14, 15, and 17. Other regions of chromosomes 1, 3, 6, 7, 9p, 11, and 19 were also prone to rearrangement.


FIGURE 28.3. Ideogram showing breakpoints of clonal chromosome rearrangements seen in short-term cultures of primary tumor specimens from 185 non–small cell lung cancers (NSCLCs). Each closed box (§) represents breakpoints in two different cases; each open box (˙) indicates a breakpoint from a single case. Whenever a single case had two or more rearrangements with breaks at the same band, only one of these breakpoints is depicted. (From Testa JR, Liu Z, Feder M. Advances in the analysis of chromosome alterations in human lung carcinoma. *Cancer Genet Cytogenet* 1997;95:20, with permission.)

The chromosome arm most often contributing to losses was 9p (59 of 70 tumors, 84%). Other chromosome arms lost in at least 60% of cases included 3p, 6q, 8p, 9q, 13q, 17p, 18q, 19p, 21q, 22q, and the short arms of each of the acrocentric chromosomes. The chromosome arms most often involved in gains were 7p and 7q. Among the entire 70 tumors, gains of part or all of 7p and 7q were observed in 61% and 60% of cases, respectively. Extra copies of chromosome arms 1p, 1q, 3q, 5p, 11q, and 12q were also common.

We evaluated the relationship between clonal chromosome alterations and various clinical parameters in 70 NSCLC patients for whom detailed karyotypic assessment was possible. [86] Clinical features investigated were diagnosis, tumor stage and grade, gender, smoking history measured in pack-years, and survival. Certain chromosome abnormalities were significantly associated with histologic subtype, tumor grade, stage, and prognosis. Rearrangements involving chromosome arms 2p and 3q were more common in squamous cell carcinoma than in adenocarcinoma. Loss of 3p was observed more often in squamous cell carcinomas. Gain of 7p was more common in adenocarcinomas. Rearrangement of 17p was associated with a lower tumor grade. Rearrangement of Xp and loss of chromosome 12 or 22 were each associated with higher tumor stage. Rearrangement of 3p or 6q was correlated with a better survival outlook. In contrast, loss of chromosomes 4 or 22 portended a poor prognosis. An increased number of marker chromosomes was observed in patients having a higher number of pack-years. Overall, our data indicate that chromosome abnormalities can have clinical and pathologic significance in NSCLC.

Chromosome Losses

Loss of 3p

Loss of all or part of the short arm of 3 was identified in approximately 75% of the NSCLC cases that we examined. LOH from 3p has been reported in 25% to 100% of NSCLC cases in different reports. [54,55,74,86,90 and 91] The SRO of chromosome losses appears to be at 3p21. [34] Allelic loss at 3p21 has been reported in all major types of lung cancer. [54,55] However, LOH from 3p can occur at a significantly higher frequency in squamous cell carcinomas than in adenocarcinoma. [92] Although deletion of 3p14-p23 was initially reported as a specific chromosome aberration in SCLC, [8] subsequent studies have revealed frequent deletions of 3p in several other malignancies, including renal cell carcinoma, mesothelioma, ovarian cancer, and breast cancer. [3] Thus loss of 3p may represent an important generalized tumorigenic event common to various solid tumors, including NSCLC.

Loss of 9p

As noted earlier, 9p was the most common lost chromosome segment in our NSCLC series, and deletion of 9p has been proposed as a critical change in this neoplasm. [15] Only a minority of our cases had either an interstitial deletion or terminal deletion of 9p, but many other tumors had either an apparently unbalanced rearrangement (i.e., various derivatives) affecting 9p or had less than the expected number of copies of chromosome 9 (e.g., only two copies of chromosome 9 in a triploid tumor). Homozygous losses of DNA sequences from 9p21-p22 have been reported in some NSCLCs, suggesting that loss or inactivation of a TSG(s) located within this region may contribute to the pathogenesis of some of these tumors. [93] The TSG *p16/CDKN2A* is located at 9p21, and homozygous deletions or mutations of this gene occur in many NSCLC cell lines and in 20% to 30% of tumor specimens from NSCLC patients. [94,95]

Loss of 17p

Rearrangement of 17p is a very common finding in NSCLC. In fact, 17p11 represents the most common chromosomal breakpoint site in karyotypic studies of NSCLC (Figure 28.3). The structural changes of 17p include partial deletions and various derivative chromosomes. DNA analyses have demonstrated that loss of alleles from 17p is a common occurrence in NSCLC. [86] Our data suggest that visible cytogenetic changes may be the cause of the allelic loss detected by molecular methods, at least in some cases. As in SCLC, the cytogenetic and molecular evidence suggests that loss of 17p containing a normal *TP53* allele could unmask a remaining, mutant allele on the other remaining, cytogenetically normal homolog.

Other Abnormalities

Isochromosomes

Although no nonrandom balanced reciprocal translocations have been reported in NSCLC, several recurrent isochromosomes have been found. In our studies, the most common isochromosome was an i(5p), which was observed in nine tumors, eight of which had adenomatous features. An i(8q) was identified in six of our NSCLC cases, including five adenocarcinomas and one large cell lung carcinoma. Several other groups have also reported isochromosomes of 5p and 8q in NSCLC. [14,15,19,27,28,30,31] Other isochromosomes seen in our series of NSCLCs include i(1q), i(3q), i(6p), i(7p), i(13q), and i(14q), each seen in several cases.

An association between i(8q) and adenocarcinoma of the lung has been reported by several investigators. [19,96] Even though i(8q) and i(5p) appear to be recurrent changes in adenocarcinoma of the lung, they are not specific for this tumor. An i(8q) has been reported in various types of leukemia and in several different solid tumors; likewise, i(5p) has been observed in several different solid malignancies and appears to be particularly common in tumors of the uterus and bladder. [3] Among the SCLC cases studied by our laboratory, one case had an i(5p) and another had an i(8q). [8] It has been suggested that i(8q) could represent a primary change in NSCLC. [19] However, in a NSCLC cell line that we studied, the only abnormality of chromosome 8 found at passage 9 was trisomy 8, whereas at a later passage, a minority of cells contained two normal homologs and an i(8q). [16] In addition, i(8q) was found in only a single cell or in a minority of karyotyped cells in another two

cases. Taken collectively, these findings suggest that i(8q) may be a secondary event in NSCLC.

Gene Amplification

Variable numbers of dmins were seen in 7 of our 70 (10%) specimens. Two cases had an hsr, including one of the seven cases that had dmins. Tumor material was available for Southern blot analysis in five of our eight NSCLC cases that exhibited dmins, hsrs, or both. The DNA studies revealed amplification of *MYC* in two cases and *EGFR* in one case. Eight different oncogene probes were tested in the other two cases, but an amplified sequence was not identified. In two other series of NSCLC specimens examined by Southern blot analysis, amplification of the *MYC* oncogene was documented in 3 of 36 (8%) and 4 of 25 (16%) cases.[97,98] Amplification of *KRAS2* has also been reported in a case of NSCLC having dmins.[99]

Metastatic Tumors

Two series focused on karyotypic changes in metastatic tumors from NSCLC patients.[31,33] In one study of NSCLC cell lines mostly derived from metastatic lesions, statistical analysis revealed that structural alterations were nonrandomly distributed among the chromosomes.[31] A statistically significant number of clonal breakpoints were observed at chromosome regions 1q1, 1q3, 3p1, 3p2, 3q1, 3q2, 7q1, 13p1, 14p1, 15p1, and 17q1. Most of these regions undergo frequent rearrangement in primary tumors as well, although breakage at 1q3 does not appear to be a prominent change in primary tumors (Figure 28.3). Furthermore, breakage at 5cen, 6p1->6q1, 8cen->8p1, 9p2, 11p1->11q1, 17p1, and 19p1 appeared to be much less common in these metastatic tumors than in primary tumors. Whether these discrepancies are caused by karyotypic evolution during tumor progression, evolution occurring during prolonged growth *in vitro,* or difference in cytogenetic interpretation is uncertain at this time.

In the second report, pleural effusions containing metastatic or invasive tumor cells were examined.[33] Recurrent breakpoint regions included 1p1, 3p10-p21, 3q11-q25, 6p11-p25, 6q13-q23, 7q11-q36, 9q32-q34, 11p1, 11q13-q24, 13p, 14p, 15p, 17p, and 19p. Most of these regions are also often involved in primary tumors, although breakage at 3q11-q25 and 6p11-p25 has not been reported to be nonrandomly involved in primary tumors. A lower frequency of 9p loss was observed in pleural effusions than in primary tumors, whereas breakpoints at 9q32-q34 were found almost exclusively in effusions and, therefore, could represent a change associated with tumor progression.[35] Four other metastatic tumors from NSCLC patients have been reported to have a breakpoint at this region.[30,31] Lukeis and colleagues also observed that loss of chromosome 8 or 8p, loss of Y, and rearrangement of 5q are less common in effusions than in primary tumors, whereas extra or rearranged chromosome 7, extra chromosome 20, loss of chromosome 22, and dmin occur at a higher frequency in effusions than in primary tumors.[15,33]

MOLECULAR CYTOGENETICS

Fluorescence *In Situ* Hybridization Analysis

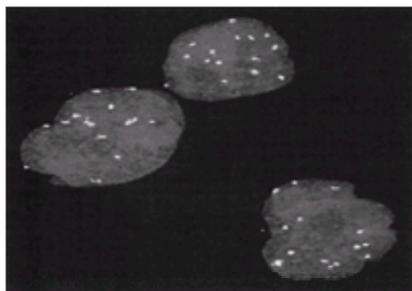
Although technical advances in cell culture and cytogenetics have improved the overall success rate and quality of chromosome studies in lung cancer, it has not been possible to examine karyotypes of the malignant cells in every specimen. In many cases, the mitotic rate of the tumor cells is very low, and analyzable abnormal metaphase spreads are not found. Karyotypic analysis is time consuming, and it is not feasible to routinely cut out karyotypes of large numbers of metaphase spreads. Furthermore, *in vitro* culturing of tumor cells may result in selective growth of cells that may not represent the whole tumor cell population. FISH can overcome many of these problems. This procedure permits investigators to directly examine interphase cells from tissue sections or cell suspensions of tumor specimens. Because of the relative ease of analyzing FISH preparations, it is possible to rapidly count the number of target sites in a large number of tumor cells. In addition to enhancing karyologic investigations of tumor specimens, such interphase cytogenetics techniques may represent a useful approach to assess "noninvolved" bronchial tissues and premalignant lesions for the presence of cells with early (primary) chromosome changes. Example of FISH analyses are seen in Figure 28.4, Figure 28.5, Figure 28.6.


FIGURE 28.4. Fluorescence *in situ* hybridization of two chromosome-specific centromere repeat probes to interphase cell nuclei, counterstained blue with diamidino-2-phenylindole, from a human non-small cell lung cancer specimen. DNA probes labeled with biotin or digoxigenin hybridizing to complementary centromere sequences within the nuclei were detected by immunofluorescence using fluorophores emitting green (fluorescein isothiocyanate) or red (rhodamine). The nuclei exhibit abnormally high numbers of chromosome 7 (red spots) and chromosome 18 (green) fluorescent signals, indicative of gains of these chromosomes. (See Color Figure 28.4.)

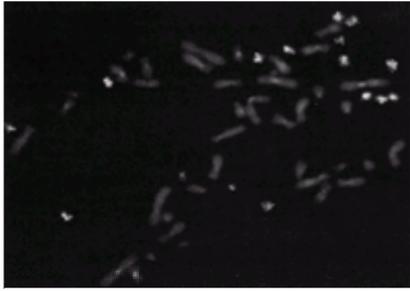
FIGURE 28.5. A: Computer-generated fluorescence ratio image of a normal human metaphase spread after comparative genome hybridization with biotin-labeled DNA, detected by fluorescein isothiocyanate (FITC), from a lung cancer cell line, and digoxigenin-labeled DNA, detected by rhodamine, from normal placenta. Yellow-green indicates balance between the FITC and rhodamine values. Bright green indicates overrepresentation of DNA in the tumor, and red represents underrepresentation of tumor DNA. Intense green fluorescence on chromosome 8q24 (*arrows*) suggests that the MYC protooncogene located in this band may be amplified in the lung cancer cells. **B:** The same metaphase spread, stained with diamidino-2-phenylindole, which permits the identification of each chromosome. The two copies of chromosome 8 are indicated by numbers. (See Color Figure 28.5.)


FIGURE 28.6. Fluorescence *in situ* hybridization of a MYCN probe to a partial metaphase spread from the small cell lung cancer cell line. Multiple fluorescent signals are observed on each of the double minutes, indicating that the amplified *MYCN* oncogene resides within these small chromatin bodies. (See Color Figure 28.6.)

To determine the feasibility of FISH for the analysis of genetic changes in lung cancer, we used a panel of centromeric DNA probes specific for the autosomes 6, 7, 8, 9, 12, 17, and 18 to analyze 17 primary NSCLCs.[100] Evidence for aneuploidy was obtained in all specimens. Gain of part or all of chromosome 7 was especially prominent, occurring in a large population of cells in each of 14 tumors (82%). Extra centromeric copies of chromosomes 6, 12, and 17 were also common, being observed in nine to eleven cases each. Gain of chromosome 9 was infrequent three tumors). In two cases, most of the nuclei had only a single chromosome 9 fluorescent signal. Karyotypic findings were available for six cases and were generally consistent with the FISH data. Both methods revealed considerable heterogeneity within individual tumors. NSCLC specimens from 26 males were assayed with a Y-specific centromeric sequence; loss of the Y was observed in 13 cases (50%). These investigations demonstrate the feasibility of interphase FISH for the successful analysis of numerical chromosome changes in NSCLCs.

Comparative Genomic Hybridization Analysis

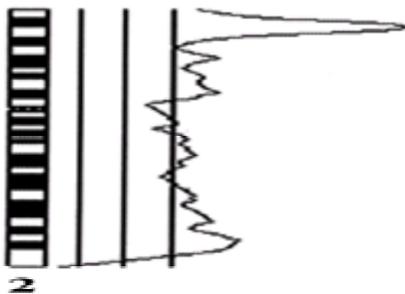
Reid and colleagues performed a CGH analysis of 13 primary SCLC specimens.[101] They demonstrated frequent chromosome losses expected in this tumor type (i.e., 3p-, 13q-, and 17p-), as well as several recurrent abnormalities that had not been recognized in previous karyotypic studies of SCLC: 4q-, 10q-, and amplification of 19q13. In another CGH analysis of 18 SCLC cell lines, Levin and colleagues observed recurrent decreases in the copy number of 3p, 13q, and 17p.[102] These investigators also identified overrepresentation of the chromosomal sites 1p22->32, 2p24->25, and 8q24, sites of the genes *MYCL, MYCN,* and *MYC,* respectively, which are often amplified in SCLC cell lines. Novel copy number increases were detected at 5p, 1q24, and Xq26, and decreases involved 22q12.1->13.1, 10q26, and 16p11.2. Some of the DNA copy number changes, including gains of 1p22->32, 2p24->25, and 3q22->25 and loss of 18p, were found to occur preferentially in "variant" SCLC lines, suggesting that genes may reside at these sites whose overexpression or inactivation contributes to the radiation-resistant phenotype or aggressive growth properties characteristic of this SCLC subtype. An example of amplification of 2p24-p25 in an SCLC cell line with 60-fold amplification of *MYCN* is shown in Figure 28.7. Levin and colleagues also used CGH to identify DNA copy number changes in seven primary tumors and three metastases from eight SCLC patients.[103] Frequent overrepresentation of chromosome arms 5p, 8q, 3q, and Xq, and underrepresentation of chromosome arms 3p, 17p, 5q, 8p, 10q, 13q, and 4p were identified, confirming the existence of many of the chromosome changes previously identified by conventional karyotypic analysis of SCLC lines. Each of the reports of CGH analyses of SCLCs has identified a recurrent region of chromosomal loss at 10q24->26, suggesting that a putative TSG important in the pathogenesis of SCLC may reside at this location.


FIGURE 28.7. Comparative genomic hybridization (CGH) analysis of chromosome 2 from a small cell lung cancer (SCLC) cell line displaying amplification of 2p23.3-p24, encompassing the site of the *MYCN* locus at 2p24. Most of the remainder of chromosome 2 is overrepresented, whereas the distal portion of the long arm of 2q is underrepresented. Southern blot analysis demonstrated that *MYCN* is amplified approximately 60-fold in this cell line (not shown). CGH ratio profile represents the average fluorescence ratios calculated for chromosome 2 from a total of five metaphase spreads. Note that the three vertical lines beside individual chromosome ideograms indicate different threshold values between tumor DNA and normal reference DNA. The line on the left represents the threshold value corresponding to a chromosomal loss. The center line indicates a balanced state. The line on the right represents the threshold value corresponding to a chromosomal gain. Overrepresentation defined by a sharp peak is considered indicative of DNA amplification. (From Testa JR, Liu Z, Feder M. Advances in the analysis of chromosome alterations in human lung carcinoma. *Cancer Genet Cytogenet* 1997;95:20, with permission.)

Recently, a putative TSG *PTEN/MMAC1* was identified at 10q23.3 and found to be deleted or mutated in a wide variety of human malignancies such as glioma, melanoma meningioma, glioblastoma, and carcinomas of the prostate, breast, and kidney. Yokomizo and colleagues found alterations in *PTEN/MMCA1,* gene in 18% of SCLC cell lines and in 10% of primary SCLC samples.[104] These abnormalities included point mutations, small fragment deletions, and large homozygous deletions. None of the 23 NSCLC specimens and cell lines tested displayed alterations of *PTEN/MMCA1,* suggesting that the inactivation of this gene contributes to the pathogenesis of SCLC but not NSCLC.

We performed CGH analysis on 20 NSCLC biopsies and cell lines to identify recurrent chromosomal imbalances in this malignancy.[105] The chromosome arms most often overrepresented were 3q (85%), 5p (70%), 7p (65%), and 8q (65%), which were observed at high copy numbers in many cases. Other common overrepresented sites were 1q, 2p, and 20p. DNA sequence amplification was often observed, with the most common site being 3q26 (six cases). Other recurrent sites of amplification included 8q24, 3q13, 3q28-qter, 7q11.2, 8p11-12, 12p12, and 19q13.1-13.2. The most common underrepresented segment was 3p21 (50%); other recurrent sites of autosomal loss included 8p21-pter, 15q11.2-13, 5q11.2-15, 9p, 13q12-14, 17p, and 18q21-qter (Figure 28.8). These regions of copy number decreases are also common sites of allelic loss, further implicating these sites as locations of TSGs. Although some of the overrepresented segments harbor known or suspected oncogenes/growth-regulatory genes, we have identified 3q and 5p as new sites that are often overrepresented in NSCLC. Many of the common genomic imbalances occurred in combination in a given tumor (Figure 28.9).

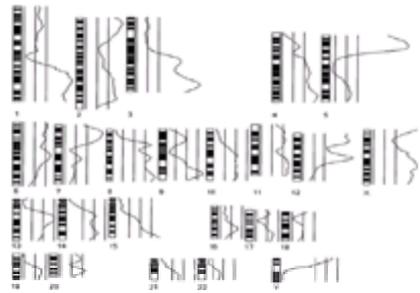
FIGURE 28.8. Summary of comparative genomic hybridization (CGH) imbalances detected in 20 non–small cell lung cancer (NSCLC) tumor specimens and early passage cell lines. Vertical lines on the left of each chromosome ideogram represent loss of genetic material in a given tumor, whereas those on the right correspond to gains. For each chromosome, smaller copy number aberrations (CNAs) are placed farthest from the ideogram for ease of identification of minimal regions of overlap (e.g., overrepresentation at 1q25–31, 2p16–21, 3q26–qter, 8q24, and 12p11.2–12). (From Balsara B, Sonoda G, du Manoir S, et al. Comparative genomic analysis detects frequent, often high-level overrepresentation of DNA sequences at 3q, 5p, 7p, and 8q in human non-small cell lung carcinoma. *Cancer Res* 1997;57:2116, with permission.)


FIGURE 28.9. CGH fluorescence ratio profile of a non–small cell lung cancer (NSCLC) cell line showing the recurrent alterations observed in NSCLC. Overrepresentation of part or all of chromosome arms 1q, 2p, 2q, 3q, 4q, 5p, 7p, 8q, 12p, and amplification of 3q13, 3q26–27, 8p11.2, 8q24, 9q33, 12q14–15, and underrepresentation of part or all of 8p, 9p. The profile represents the average fluorescence ratios calculated for each chromosome from a total of 10 metaphase spreads.

Petersen and colleagues carried out CGH analyses on 50 NSCLCs (25 adenocarcinomas and 25 squamous cell carcinomas).[106] The chromosome arms most often underrepresented were 1p, 3p, 4q, 5q, 6q, 8p, 9p, 13q, 18q, and 21q. The chromosomal sites most often overrepresented were 5p, 8q, 11q13, 16p, 17q, and 19q. Adenocarcinomas showed more common gains of chromosome 1q and losses of chromosomes 3q, 9q, 10p, and 19, whereas squamous cell carcinomas were characterized by an increased incidence of gains of chromosome arms 3q and 12p as well as losses of chromosome arm 2q. These investigators also reported a correlation between 20q13 gain and invasiveness in adenocarcinomas.

Gains of 1q, 3q, 5p, and 8q and loss of 3p were each observed in at least 50% of cases in each of these two CGH studies. Overrepresentation of 3q26 was the most prominent change observed, which appears to be particularly common in squamous cell carcinomas. Amplification of 3q26 was identified in three of nine squamous cell carcinomas of the lung analyzed by reverse chromosome painting.[107] Moreover, increased copy number at 3q26-27 has also been reported as a recurrent change in various other tumors including SCLCs,[101] ovarian cancers,[108] and advanced cervical carcinomas.[109] A candidate gene located at 3q26.3, whose product may contribute to the control of cell proliferation and malignant transformation, is *PIK3CA. PIK3CA* encodes the catalytic subunit of phosphatidylinositol-3 kinase, a critical component of several cell signaling pathways including those of epidermal growth factor and platelet-derived growth factor. *SKP2,* a potentially relevant gene located in 5p, encodes a protein associated with the CDK2–cyclin A complex. This protein has been found to be essential for S-phase entry.

CONCLUSIONS

Classic and molecular cytogenetic analysis has demonstrated that numerous somatic genetic events are involved in the pathogenesis of lung carcinomas. The karyotypes of these neoplasms often have extensive changes, even in newly diagnosed primary tumors, but the pattern and biologic implications of recurrent chromosome alterations are beginning to emerge. Chromosomal losses are often observed, and some of these changes (e.g., deletions of 3p, 5q, 10q, and 17p in SCLC; deletions of 3p, 9p, and 17p in NSCLC) occur at the location of known or suspected TSGs, whose loss and/or inactivation may play a fundamental role in lung tumorigenesis. Other alterations (e.g., dmins, hsrs) represent cytogenetic manifestations of oncogene amplification, and the net effect of such changes may be an increase in a gene product that provides an added proliferative advantage. Other chromosomal imbalances, (e.g., gains of 1q, 3q, 5p, 7, and 8q in NSCLC) could have a similar effect. The complex pattern of cytogenetic changes often seen in newly diagnosed lung carcinomas emphasizes the need for future investigations of "normal" bronchus or premalignant lesions in order to identify primary genetic changes important for early detection and intervention in this aggressive neoplasm.

In future cytogenetic investigations, it will be important to determine whether such genomic imbalances are correlated with clinical parameters such as metastatic behavior and prognosis. Furthermore, as the understanding of chromosome alterations in lung cancer increases, it should be possible to establish a useful panel of nonisotopic DNA probes to facilitate the rapid diagnostic assessment of lung tumor specimens. Germane to this achievement, considerable recent excitement has been generated regarding emerging microarray technologies.[110,111 and 112] It will now be possible to develop gridded arrays of relevant genomic fragments to quickly assess individual tumors for mutations or DNA copy at precise chromosomal locations. Similarly, arrays of cDNAs will facilitate comparisons of gene expression profiles of malignant versus normal lung tissues.

CLINICAL PRESENTATION

MICHAEL KRAUT
ANTOINETTE WOZNIAK

Lung cancer is a common disease, both in the United States and in those countries throughout the world in which cigarette smoking is prevalent. Although the incidence of the disease is about equal to that of breast cancer and prostate cancer, the lethality of lung cancer distinguishes it. Lung cancer is by far the most common cause of cancer death in the United States, representing the leading cause of cancer death in both men and women. In the United States approximately 171,000 new cases of lung cancer will be diagnosed in 1999, and nearly 160,000 will die of the disease. [1] An estimated more than one million people developed lung cancer in 1990, the most recent year for which worldwide statistics are available. [2] Given the trends in tobacco use, more than one million people will certainly die of lung cancer throughout the world during 1999.

Although lung cancer remains predominantly a disease of men in Europe, in the United States the number of women contracting lung cancer has risen dramatically over the past two decades. At present, the ratio of men to women with the disease is approximately three to two.

Because lung cancer is a common disease, all clinicians need to be familiar with its manifestations. Moreover, because so many patients are stricken with the disease, clinicians must be aware that a significant minority will present with unusual manifestations. The presentation of the lung cancer patient ranges from the asymptomatic and mundane to the difficult diagnostic dilemma.

MANIFESTATIONS OF LOCAL DISEASE

Asymptomatic

In its early stages, lung cancer is asymptomatic. The lung parenchyma is not generously supplied with pain fibers, and primary lung cancers can reach considerable size without causing any symptoms. This lack of symptoms is particularly true for more peripheral lesions. Less than 5% of lung cancers are discovered in patients who have no symptoms of the disease.[3] These lesions are often discovered during the investigation of an unrelated complaint, or on a chest radiograph done as part of a preoperative evaluation or as part of an extended physical examination. [4,5]

Methods to identify a greater proportion of lung cancer patients while still asymptomatic have been the focus of much effort. Screening of the entire adult population is not practical, and previous efforts were unable to demonstrate an increase in survival. [6] Attempts had been made to use high-resolution fast CT for screening [7] as well as autofluorescence endoscopy (see also Chapter 22, Chapter 24).

Cough

Cough is the most common symptom reported at presentation by patients with lung cancer. Cough is present at diagnosis in 50% or more of patients, and eventually develops in nearly all patients who are not successfully cured by surgery. [8] Because the majority of lung cancer patients are smokers, the cough may initially be no more than an insidious change from baseline. In most cases, however, worsening of cough leads patients to seek medical attention for presumed bronchitis or pneumonia. The typical patient receives one, two, or occasionally more courses of outpatient oral antibiotics before a chest x-ray is performed, revealing the true nature of the underlying pathology. Unfortunately, even after the clear demonstration of a mass lesion, some patients continue to receive antibiotic therapy, perhaps as an exercise in wishful thinking.

The development of a new or worsening cough in a patient with a significant (i.e., greater than 40 pack-years) smoking history should prompt the performance of a chest radiograph to assess for underlying lung cancer. This evaluation is particularly true if the cough is not associated with fever and coryza or other signs of upper respiratory infection (URI), or if the symptoms continue beyond the 5 to 7 days that a viral URI would be likely to persist. The patient who exhibits high fever, chills, and pleuritic chest pain in addition to cough warrants a chest x-ray for the evaluation of pneumonia, independent of other factors.

Hemoptysis

Hemoptysis varies greatly in severity, ranging from a few streaks to massive exsanguination. The typical presentation is that of blood-streaked or blood-tinged sputum. Because this symptom is far more likely to be caused by bronchitis than by cancer, patients with this symptom are typically managed with oral antibiotics initially. The index of suspicion is raised when the patient has a significant smoking history or when the problem persists or recurs despite conservative therapy. If a

chest radiograph does not reveal an obvious cause, these patients with persistent hemoptysis should undergo fiberoptic bronchoscopy. [9]

Symptom	Approx % Present at Diagnosis
Cough	45–75
Weight Loss	20–70
Dyspnea	40–60
Chest Pain	30–45
Hemoptysis	25–35
None	2–5

TABLE 29.1. PRINCIPAL SYMPTOMS OF LOCAL DISEASE[3,4,5,6]

The management of hemoptysis caused by lung cancer depends on the severity. Blood-streaked sputum is common and requires no specific therapy beyond reassurance. More serious hemoptysis, manifest as frank blood, often produced in the range of 5 to 10 mL per hour, requires more aggressive intervention. Cough suppression with narcotics is essential; acetaminophen with codeine (e.g., Tylenol #4) is a good choice because this drug is often easier for the patient to obtain than codeine alone. The patient should be instructed to keep the good (unaffected) side of the lung up when lying down. Fiberoptic bronchoscopy is sometimes necessary to localize the source of the bleeding. In patients with unresectable or metastatic disease, radiotherapy is the preferred treatment for moderately severe hemoptysis. This treatment is effective and generally well tolerated. [10]

The patient who develops hemoptysis after previous radiotherapy presents a greater challenge. In certain instances, an emergent thoracotomy with resection of the affected area may be the best therapy. More commonly, however, the technical difficulty of this intervention or the general condition of the patient dictates a different approach. In a clinical setting where skilled interventional radiologists are available, selective embolization of bronchial arteries feeding the area of hemorrhage can be very effective.[11,12]

Massive hemoptysis, such as occurs with tumor erosion into the main pulmonary arteries, is usually immediately fatal. If the patient survives the initial episode, intubation is required to protect the central airways and to allow effective suctioning because hypoxia caused by filling of alveoli with blood leads to rapid respiratory failure. The choices for management of the hemorrhage are as noted previously.

Management of hemoptysis requires experience and sound clinical judgement. Many patients with this problem have a limited life expectancy, and the interventions chosen must be consistent with realistic goals for the patient.

Chest Pain

Chest pain is a common symptom in early-stage lung cancer, and it is often present without frank evidence of invasion of the pleura, chest wall, or mediastinum. Because the lung parenchyma is not well supplied with pain fibers, the origin of this type of pain is not clear. This pain is not a poor prognostic sign and it typically responds well to management of the underlying tumor. Analgesics should be employed pending more definitive therapy; similar to management of any pain, the simplest treatment that is effective should be employed, but this should not preclude the use of narcotics if they are necessary to control the pain in an individual case.

It is not unusual for a patient with this type of pain to undergo an evaluation for angina, including coronary catheterization. Given the prevalence of coronary artery disease, especially among smokers, it is not surprising that such patients have been discovered to have lung cancer from chest radiographs performed pre- or postoperatively for coronary artery bypass grafting. Often, however, catheterization is negative or shows only minimal disease, prompting further investigation, which eventually uncovers the underlying lung malignancy.

Dyspnea

Dyspnea in lung cancer can result from a variety of causes and is often multifactorial. Many patients with lung cancer have some degree of underlying chronic lung disease, and the development of cancer may cause worsening of baseline dyspnea because of further loss of effective lung parenchyma. Obstructive airway disease is an independent risk factor for the development of lung cancer and is the most common concomitant lung disease in pulmonary malignancy. [13] The development of significant atelectasis, especially of an entire lobe, may result in dyspnea; this problem is also worse in patients with underlying lung disease. The differential diagnosis of dyspnea is wide and includes cardiac and pericardial disease in addition to pulmonary complications. Several complications of locally advanced disease can result in dyspnea (see Table 29.2).

Loss of Alveolar Space due to Extensive Tumor
Atelectasis-Obstruction
Lymphangitic Tumor Spread
Pleural Effusion
Pericardial Effusion or Constriction
Hemoptysis with Aspiration
Pneumonia (including Postobstructive)
Bronchospasm
Emphysema
Cardiac Failure
Pulmonary Embolism
Other

TABLE 29.2. CAUSES OF DYSPNEA

Management of dyspnea involves identification and treatment of any underlying bronchospasm and elimination, if possible, of the causative lesion. Specific intervention depends on the cause. Hypoxia can be treated with oxygen. In patients with dyspnea caused by uncorrectable underlying problems, such as pulmonary entrapment by diffuse pleural disease, or progressive parenchymal involvement by advancing tumor, small doses of morphine are most effective, with the dose titrated to the desired effect. In the patient who is near death, sedatives may be useful as well. Dyspnea is a symptom that is extremely distressing to patient and family alike; it is incumbent upon the physician to eliminate this unpleasant situation to the maximum extent possible. Unfortunately, many patients are inadequately treated for this problem.

Wheezing

Localized wheezing may be the presenting symptom in patients with disease in the major airways, particularly in the mainstem bronchi. This symptom should be distinguished from the generalized wheezing of bronchospasm; this type of wheezing is often localized, and the patient is often able to tell from which side it is emanating. This type of lesion is almost always associated with a debilitating cough.

Lesions that are primarily endobronchial but that are too proximal for resection often require special management techniques. The armamentarium of the radiation oncologist, thoracic surgeon, and pulmonologist has been expanded in recent years by the addition of new or improved treatments. High dose-rate brachytherapy can

be extremely effective in palliating central endobronchial lesions, either alone or in combination with external beam radiation (see also Chapter 49). Photodynamic therapy techniques have improved recently with the development of better photosensitizing agents and can be effectively employed in this setting (see also Chapter 24).[14] In skilled hands, laser therapy can also be useful for this problem, particularly when previous therapies have failed. [15]

Weight Loss

Weight loss is a common symptom of lung cancer at presentation, but it is not necessarily a sign of advanced disease. Among those with squamous cell carcinoma, approximately one-third of early-stage patients report weight loss of 10 pounds or more. Cachexia may develop in patients at all stages of disease when the tumor is actively synthesizing hormonally active compounds, such as tumor necrosis factor (see following section, Paraneoplastic Syndromes).

MANIFESTATIONS OF LOCALLY ADVANCED DISEASE

Hoarseness

Hoarseness in association with lung cancer is almost always caused by involvement of the left recurrent laryngeal nerve. Because of a quirk of embryogenesis, the left recurrent laryngeal nerve passes under the arch of the aorta; in this location, it is susceptible to damage from advanced primary tumors and from lymphadenopathy in the aorto-pulmonary window. New-onset hoarseness caused by left vocal cord paralysis is always indicative of surgically unresectable disease.

Some patients with left vocal cord paralysis develop significant problems of aspiration. This symptom can become a vexing clinical problem; occasionally, patients require a feeding tube to prevent recurrent bouts of pneumonitis. Teflon injection of the affected cord may be beneficial in some patients. [16]

Hoarseness occasionally improves with treatment of the causative malignancy, but more often it persists because of either inadequate control of the tumor or irreversible damage to the nerve. In the patient fortunate enough to survive locally advanced disease, Teflon injection of the paralyzed cord can improve voice quality.

Phrenic Nerve Paralysis

The phrenic nerve courses along the pericardium bilaterally and is subject to injury caused by invasion by primary tumor or bulky adenopathy. The left phrenic nerve is more commonly affected than the right, probably because of the relatively greater proximity of the left phrenic nerve to lymph nodes of the aorto-pulmonary window. Damage to the left phrenic nerve results in paralysis of the left hemidiaphragm, with consequent volume loss in the left hemithorax. Because the left hemidiaphragm is normally lower than the right, this condition has a rather characteristic x-ray appearance. The proximity of the left recurrent laryngeal nerve to the phrenic nerve in the aorto-pulmonary window occasionally results in coexisting hoarseness and left diaphragmatic paralysis. Phrenic nerve paralysis is always indicative of locally advanced disease. This condition is normally not reversible.

Dysphagia

Dysphagia can result from esophageal obstruction by bulky mediastinal adenopathy. Although bulky adenopathy is a relatively common occurrence, this symptom is surprisingly uncommon. Another potential cause of dysphagia is recurrent laryngeal nerve injury. In addition to hoarseness, recurrent laryngeal nerve damage can lead to dysfunction of the pharyngeal swallowing mechanism; this problem may be associated with aspiration as well (see previous section Hoarseness).

Treatment of the mediastinal adenopathy with radiotherapy (with or without concurrent chemotherapy) may improve dysphagia caused by this mechanism. Selected patients may require nutritional support until effective swallowing is reestablished.

Stridor

Stridor results from compromise of the lumen of the trachea. It can be caused by invasion of the trachea by tumor, or less commonly, bilateral vocal cord paralysis. An aggressive approach to management of stridor is necessary because this problem is life-threatening and extremely distressing. Prompt initiation of treatment, including radiotherapy or brachytherapy, with or without chemotherapy, is essential. For lesions located high in the trachea, or stridor caused by vocal cord paralysis, a tracheostomy may permit placement of a rigid canula beyond the obstruction. Because flow is related to diameter in an exponential fashion, a small increase in diameter can result in a dramatic improvement in symptoms; this increase can sometimes be accomplished via laser fulguration. [17,18]

Symptoms can be eased by the use of a helium-oxygen mixture (70 : 30) in place of room air or oxygen alone; helium has a much lower viscosity than nitrogen, thus reducing obstruction to flow.[19] Patients whose disease progresses despite therapy may require significant doses of morphine for control of symptoms.

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome is a relatively common complication of lung cancer. It is generally a consequence of obstruction of the superior vena cava by right paratracheal adenopathy or central extension of a primary tumor in the right upper lobe. The syndrome is characterized by facial swelling, flushing, cough, and neck and chest wall vein distention. The extent and severity of symptoms greatly depends on how rapidly the obstruction progresses and on the speed and extent of the development of collateral circulation. Rapidly developing obstruction is most dangerous because it can result in central nervous system symptoms, including coma and death. Much more commonly, however, the onset is insidious, with swelling of the face, upper extremities, and breasts, causing the patient to seek medical attention.

In the undiagnosed patient, the principal differential diagnosis is between lung cancer and lymphoma. Approximately 80% of patients with SVC syndrome in the United States have an underlying diagnosis of lung cancer, divided approximately equally between small cell and non–small cell histologies. [20] In countries where tuberculosis is more prevalent, this disease is also a significant cause of SVC syndrome. Once considered an emergency, current practice is to obtain a tissue diagnosis expeditiously prior to the initiation of appropriate therapy. [21] Bronchoscopy, mediastinoscopy, or mediastinotomy usually yields a diagnosis with little risk to the patient. Radiotherapy remains the preferred treatment for non–small cell lung cancer (NSCLC); in selected situations, concurrent chemotherapy may be appropriate. Small cell lung cancer (SCLC) is best approached with chemotherapy (with or without concurrent radiotherapy), [22] (see also Chapter 53, Chapter 54).

Pleural Effusion

Approximately 15% to 20% of lung cancer patients present with pleural effusion. Although most of these effusions are ultimately determined to be malignant, about one-half are initially cytologically negative. Diagnostic thoracentesis should be performed to determine the origin of the effusion, with an adequate amount of fluid sent for cytology. The differential diagnosis for causes of effusion can include atelectasis, pneumonia, tuberculosis, and congestive heart failure, among others. It is important to identify malignant effusion if possible. Proper classification of an effusion can both prevent the application of ineffective local measures (i.e., surgery or radiotherapy) as well as ensure that resectable patients are not denied the benefits of surgery.

The management of malignant pleural effusion varies greatly depending on the clinical situation. Patients with good performance status and reasonable life expectancy can benefit from aggressive interventions such as video-assisted thoracoscopy and talc insufflation. Traditional thoracostomy tube placement can also be beneficial to patients who are in good physical condition. [23,24,25] Patients with more advanced stages of disease are better served by placement of a flexible small-bore catheter, which does not require hospitalization.

Pleural effusions may resolve with effective chemotherapy, especially in patients with SCLC. In selected patients with NSCLC, chemotherapy may be tried as initial management of effusion, but most patients in this category require more aggressive local measures at some point (see also Chapter 59).

Pericardial Effusion

Pericardial effusion develops in 5% to 10% of patients with lung cancer. Its dramatic clinical symptoms can be readily alleviated by relatively simple interventions, so recognizing this complication is important. Pericardial effusion typically occurs in the setting of progressive locally advanced disease. The onset is usually insidious,

with shortness of breath and orthopnea as the initial symptoms. The symptoms and signs progress to severe dyspnea, anxiety, tachycardia, substernal chest tightness or pain, jugular venous distention, pulsus paradoxus, hepatomegaly, and azotemia, and ultimately hypotension and death.

It is important to recognize that pericardial tamponade can be difficult to diagnose, and that the diagnosis is missed antemortem in as many as one-third of patients. Patients can be relatively asymptomatic except for dyspnea and anxiety until very late in the course of the disease. The symptoms are relatively nonspecific and are often attributed to progression of parenchymal lung disease. The finding of dyspnea without concurrent hypoxia in an anxious, dyspneic patient with locally advanced lung cancer should always prompt an investigation for pericardial disease.

Two-dimensional echocardiography is the best diagnostic test in the evaluation of the patient with suspected pericardial tamponade. The test is universally available and gives rapid results. When a significant effusion is identified, the choice of therapy depends on whether right-sided collapse typical of tamponade is seen. The patient with tamponade requires immediate intervention; unless the patient's life expectancy is very limited, the preferred treatment is pericardiotomy (pericardial window) via a subxiphoid approach. [26] Patients with a very short expected survival, or in whom thoracic surgical intervention is not immediately available, can be approached with pericardiocentesis. In institutions where skilled radiologic interventional teams are available, the placement of a small-bore pericardial catheter can be effective. This catheter can be used to instill a pericardial sclerosing agent, with many patients achieving good control of the effusion [27] (see also Chapter 60).

Pericardial effusion is a late complication of radiation therapy and combined chemoradiotherapy to the mediastinum, particularly when significant portions of the pericardium are included in the field. [28] This complication can occur in patients who are cured of their malignancy; pericardial window is life-saving in this circumstance. As greater numbers of patients receive aggressive chemoradiotherapy regimens for stage III NSCLC, we can expect to see increasing numbers of patients with late benign pericardial effusion requiring intervention.

Pancoast Syndrome

Pancoast syndrome is the occurrence of shoulder and upper chest wall pain caused by the presence of a tumor in the apex of the lung with invasion of adjacent structures. It can be accompanied by Horner's syndrome, brachial plexopathy, and reflex sympathetic dystrophy. The typical patient has symptoms for one year or more before a diagnosis of malignancy is made. The patient is often evaluated by an orthopedic surgeon or a rheumatologist for persistent shoulder pain, and many patients receive steroid injections of the shoulder joint before a chest x-ray reveals the underlying cause of the problem.

The pain is usually caused by direct invasion of the chest wall and the first and second ribs, and in some cases by invasion of the transverse processes and bodies of the upper thoracic vertebrae. Spinal cord compression can occur by direct invasion of the spinal canal at this level, requiring aggressive intervention. Invasion of the lower roots of the brachial plexus results in pain in the arm, radiating down to the fourth and fifth digits. Destruction of the superior cervical ganglion causes Horner's syndrome, which is the triad of ipsilateral ptosis, meiosis, and anhydrosis that results from loss of sympathetic innervation of the affected side of the face. When the upper sympathetic chain is also destroyed, autonomic innervation to the affected limb is lost, leading to reflex sympathetic dystrophy, a condition characterized by pain and swelling resulting from loss of vascular tone regulation.

Patients with Pancoast tumors have often experienced long periods of poorly controlled pain by the time the diagnosis is made. Pain control can be problematic, and these patients often require large doses of long-acting narcotics to achieve comfort.

Treatment of Pancoast tumors depends on the stage at presentation. Patients without involvement of mediastinal lymph nodes can achieve long-term survival after preoperative radiotherapy or chemoradiotherapy followed by aggressive surgical resection. [29] When mediastinal lymph nodes are present, treatment is palliative, and the primary focus shifts to the significant problem of controlling symptoms, especially pain. Radiotherapy is the mainstay of treatment, with or without chemotherapy, in this setting (see also Chapter 39). Pain control is usually transient, however, and most patients require further intervention. Achieving adequate control of pain is challenging in this situation, and many patients require high doses of systemic narcotics. Some patients achieve significant relief by placement of an epidural or intradural catheter.

Lymphangitic Spread

Lymphangitic spread of the tumor through the parenchyma of the lung is an ominous development, usually portending the imminent demise of the patient. This problem is characterized by the development of progressive dyspnea, cough, and hypoxia associated with an expanding infiltrate. Fever is often a component as well. High-dose corticosteroids are often transiently effective in relieving dyspnea caused by this complication.

Lymphangitic spread often presents a diagnostic dilemma. The nonspecific nature of the infiltrate often results in uncertainty regarding the diagnosis, and the differential diagnosis typically includes infection and radiation pneumonitis. In some cases, high-resolution computed tomography (CT) scanning may reveal characteristic changes associated with lymphangitic spread. [30] Bronchoscopy with bronchoalveolar lavage can also be useful in establishing a diagnosis. Although open lung biopsy is usually definitive, its use must be weighed against the morbidity of the procedure. Empiric use of antibiotics and high-dose steroids may be preferable in many patients.

MANIFESTATIONS OF EXTRATHORACIC SPREAD

Brain Metastases

Lung cancer is the most common cause of brain metastases. Approximately one-half of SCLC patients develop brain metastases during the course of their disease. Lesser numbers of NSCLC patients develop this complication, but the incidence is increased in certain clinical settings, particularly after resection of locally advanced disease.

The manifestations of brain metastases are variable and depend on the location of the lesion and the amount of associated edema or hemorrhage. Patients may present with focal weakness, generalized or focal seizures, confusion or dementia, dysphasia, visual disturbances, or ataxia. Leptomeningeal disease may present as cranial nerve palsies or *cauda equina* syndrome.

CT scanning is useful in identifying the presence of metastases, especially in symptomatic patients. Magnetic resonance imaging (MRI) is clearly the gold standard for identifying central nervous system (CNS) disease, however, and is more sensitive than CT. MRI with gadolinium contrast is particularly important for identifying other, smaller lesions when resection is being contemplated; it is also useful for spotting potential leptomeningeal involvement.

Initial management of symptomatic brain metastases consists of corticosteroids (usually dexamethasone), given intravenously at first in very symptomatic patients, otherwise orally. Patients with seizures should receive diphenylhydantoin, but this drug is not recommended prophylactically because of a high potential for side effects. [30] Subsequent management depends on the size, number, and location of the lesions and general condition of the patient. Of particular importance in deciding on an aggressive intervention is the status of the lung cancer in the rest of the body; widespread uncontrolled disease contraindicates the use of resection or other aggressive measures. [31,32]

Resection of one to three metastatic lesions is reasonable in patients who are in good general condition. Resection followed by whole-brain irradiation results in better long-term control than radiotherapy alone. Patients with posterior fossa lesions are particularly likely to benefit from resection. Stereotactic radiosurgery (gamma knife) may have a similar role; studies to investigate this treatment are ongoing (see also Chapter 58).

Leptomeningeal carcinomatosis represents a particularly difficult challenge in patients with lung cancer. It is poorly responsive to treatment, and most patients deteriorate rapidly, even with aggressive interventions such as Ommaya reservoir placement and intrathecal chemotherapy. Except in carefully selected patients, leptomeningeal disease should be approached conservatively, with an emphasis on comfort. [34]

Bone Metastases

Bone is a common site of metastatic involvement in lung cancer. Management of metastases depends on the condition of the patient and the location of the disease. Metastases to weight-bearing areas should be considered for radiotherapy, whereas non–weight-bearing sites can be treated with systemic chemotherapy, with

radiotherapy reserved for progression. In contrast to breast cancer, lung cancer patients do not typically survive long enough to benefit from aggressive interventions such as hip joint replacement for metastatic disease; such approaches should be limited to carefully selected cases.

Bone pain caused by metastases may require significant doses of narcotics for control; these patients may benefit from the addition of a nonsteroidal antiinflammatory drug (NSAID), which can be quite effective and which may result in a reduction of the narcotic dose.

Liver and Adrenal Metastases

Lung cancer commonly spreads to the liver and adrenal glands in addition to the brain and skeletal system. Except for some reports regarding resection of solitary adrenal metastases, results of surgical resection are uniformly disappointing. [35] The sensitivity of the liver and surrounding organs to radiotherapy limits the use of this modality as well, although patients with rapidly expanding livers can sometimes obtain palliation of pain. Systemic therapy may be effective, but benefits tend to be short lived.

Other Metastatic Sites

Because lung cancer is so common, metastases are occasionally seen at a variety of other sites, some very unusual, including skin, soft tissue, bowel, thyroid, ovary, and pancreas, among others. Management of other metastatic sites is typically symptomatic.

PARANEOPLASTIC SYNDROMES

Carcinomas of the lung most often present with symptoms related to the locoregional effects of the primary tumor or to the manifestation of extrathoracic spread. However, remote effects of the primary cancer, termed paraneoplastic syndromes, result in organ dysfunction. [36] Several different paraneoplastic syndromes are clinically apparent in 10% to 20% of patients with bronchogenic carcinoma. The more common syndromes associated with lung cancer are listed in Table 29.3.

TABLE 29.3. PARANEOPLASTIC SYNDROMES ASSOCIATED WITH LUNG CANCER

Cachexia

Cancer cachexia syndrome is characterized by anorexia, weight loss and weakness resulting in impaired immune status, tissue wasting, and decline in performance status.[37] This syndrome occurs commonly in lung cancer patients but usually in the case of advanced disease. The origin of cancer cachexia is not totally understood but is probably multifactorial. Several cytokines, tumor factors, and hormones have been implicated, including tumor necrosis factor alpha, interleukins, proteoglycan, insulin, corticotropin, epinephrine, human growth factor and insulinlike growth factor. [38],[39] The cancer patient may also have a maladaptive metabolism resulting in a poor utilization of nutrients, in addition to decreased caloric intake. [40] Anorexia can be potentiated by pain, gastrointestinal involvement by tumor, development of food aversions, and the systemic effect of cancer treatment.[41]

The cachexia syndrome is not easily managed. Simply increasing nutritional support even by enteral or parenteral means is not clinically efficacious. [42] Several pharamacologic agents have been utilized to improve anorexia in cancer patients. The most commonly used agent is megestrol acetate. In a trial by Loprinzi, a positive dose-response effect on appetite resulted with increasing doses of megestrol acetate (no benefit beyond 800 mg/day), and a trend toward non–fluid weight gain was apparent.[43] Steroids have limited benefit; tetrahydrocannabinol derivatives may be useful in improving appetite and symptoms of nausea. A better understanding of the mechanism of cancer-related anorexia/cachexia will clearly be needed before more advances can be made.

ENDOCRINOLOGIC SYNDROMES

Hypercalcemia

Hypercalcemia is a fairly common metabolic problem associated with malignancies. Several pathologic mechanisms have been proposed, including osteolytic bone metastases or humoral and cytokine factors such as parathyroid hormone-related protein, transforming growth factor a, interleukin-1, tumor necrosis factor, prostaglandins, and lymphotoxin.[44] Some of the more common cancers associated with hypercalcemia include breast, lung, kidney, head, and neck, and hematologic malignancies such as multiple myeloma and lymphomas.[45] Bender and Hansen reviewed 200 consecutive cases of bronchogenic lung cancer and found a 12.5% incidence of hypercalcemia.[46] Hypercalcemia associated with carcinoma of the lung can occur with bone metastases but often occurs in the absence of osseous involvement. Squamous cell carcinoma is the most common histology associated with this paraneoplastic presentation, generally in advanced-stage disease. [47] Hypercalcemia rarely occurs in small cell carcinoma even though other paraneoplastic syndromes are common in this malignancy. [48] Benign conditions may be responsible for hypercalcemia in cancer patients. An example of this relationship would be coexistence of primary hyperparathyroidism with the malignancy. [49]

Calcium is controlled by the interaction of parathyroid hormone (PTH), 1,25-dihydroxyvitamin D, and calcitonin in the bone, kidney, and gastrointestinal tract. PTH stimulates bone resorption, renal calcium reabsorption in the distal renal tubules, and production of vitamin D by the kidney. Patients with cancer-related hypercalcemia can have increased PTH activity in their blood. [50] Immunoreactive PTH levels are usually low or normal, however a PTH-related protein (PTH-RP) can be detected in the serum. This protein product is homologous with PTH at the amino-terminus, which is the portion that binds to the PTH receptor. [51] The gene responsible for PTH-RP expression is located on the short arm of chromosome 12. PTH-RP acts as a hormone that stimulates bone resorption and renal phosphate wasting, resulting in hypercalcemia and hypophosphatemia.

Clinical symptoms associated with hypercalcemia can be variable depending on the level of serum calcium and rapidity with which the level was achieved. Early manifestations can include nausea and vomiting, fatigue, lethargy, anorexia, muscle weakness, constipation, pruritis, polyuria, and polydypsia. The symptoms may not be recognized because they can be related to the existing malignancy, treatment toxicities (i.e., chemotherapy, narcotics), and other comorbid conditions. If untreated, patients can become severely dehydrated, subsequently developing renal insufficiency. Glomerular filtration is decreased, and a reversible defect in the kidney can result in loss of urine-concentrating ability. [52] Neurologic manifestations can also be significantly worsened, resulting in confusion, obtundation, psychosis, seizures, and coma. Further effects on the gastrointestinal tract can lead to obstipation and ileus. Electrocardiographic changes can occur with a prolonged PR interval, shortened QT interval, and a wide T-wave. These changes can result in bradycardia and atrial or ventricular arrhythmias. Poor performance status, advanced age, and preexisting renal and hepatic dysfunction can add to the effects of hypercalcemia.

Patients who have serum calcium levels higher than 13 mg/dl or who exhibit symptoms related to hypercalcemia usually require treatment. Goals of treatment should include hydration, inhibition of bone resorption and/or promotion of calcium excretion, and treatment of the underlying malignancy. [53]

Because hypercalcemic patients are often dehydrated, rehydration has become a mainstay of treatment. Vigorous hydration with isotonic saline (200 to 400 mL/hr)

can be used for several hours to restore intravascular volume and glomerular filtration and to promote calcium excretion. [54] Care must be taken in the patient with cardiovascular compromise or renal insufficiency to avoid volume overload. Slower hydration may be more appropriate in this population. In cases of renal failure, dialysis may have to be employed. Diuretics should be used judiciously once rehydration is achieved. Thiazide diuretics should be avoided because they can increase calcium resorption in the distal tubule. Furosemide is the diuretic of choice and can promote calcium excretion by interfering with calcium reabsorption in the ascending limb of Henle's loop. Diuretics should be used primarily to balance fluid intake and output. The use of saline hydration and forced diuresis for treatment of hypercalcemia is no longer recommended. Along with hydration, a pharmaceutical agent that helps decrease bone resorption should be employed.

The biphosphonates are the most common drugs used for the treatment of hypercalcemia. These compounds are structural analogues of pyrophosphate and by binding to hydroxyapatite are potent inhibitors of bone crystal dissolution and osteoclast resorption. [54] Pamidroniate is the most widely used biphosphonate. It is generally administered at a dose of 60 or 90 mg as a 2- to 4-hour infusion. Onset of action is 24 to 48 hours and side effects are minimal (i.e., venous irritation, flu like symptoms). Pamidronate has been shown to be more effective than a first-generation biphosphonate etidronate. [55] Other more potent biphosphonates are currently undergoing clinical trials.

Gallium nitrate is a potent inhibitor of bone resorption via inhibition of an ATPase-dependent pump in the osteoclast. [56] It may also play a role in bone formation.[57] Gallium nitrate is usually administered at a dose of 100 to 200 mg/m^2/day by continuous infusion for up to five days. Onset of action is usually within 24 to 48 hours. Clinical trials indicate gallium's superiority over etidronate and calcitonin. [58,59] Urine output has to be maintained during administration, and nephrotoxic drugs should be avoided because of a potential for renal toxicity.

Calcitonin exerts its hypocalcemic effect by inhibiting bone resorption and promoting calcium excretion. [45] Its main advantage is that it has a rapid onset of action (2 to 4 hours) and can be used in critically ill patients even if they have renal insufficiency. A very rare incidence of hypersensitivity has been associated with administration. The main disadvantage of the drug is that the hypocalcemic effect is weak and rapidly wears off. It usually needs to be combined with another hypocalcemic agent for prolonged effect. The maximum dose of calcitonin is 8 IU/kg intramuscularly or subcutaneously every six hours. [60]

Plicamycin (mithramycin) is an antineoplastic agent that is toxic to osteoclasts. [61] The usual dose is 25 mg/kg given as a brief infusion. Dose adjustment have to be made in patients with renal and/or hepatic insufficiency. Because of potential side effects of nausea and vomiting, bone marrow suppression, nephrotoxicity, and hepatotoxicity, it is no longer commonly used unless the patient has hypercalcemia resistant to other agents.

Corticosteroids are useful agents in patients whose diseases are often treated with these drugs (i.e., hematologic malignancies, breast cancer). Steroids are not particularly effective in lung cancer–related hypercalcemia.

Ultimately successful treatment of the malignancy controls the hypercalcemia. This goal is particularly difficult in the case of advanced lung cancer. No effective oral agents, are available for maintenance of a desired serum calcium level. Patients who have continued problems with symptomatic hypercalcemia may require intermittent treatment with one of the hypocalcemic agents. Pamidronate can easily be given as an outpatient infusion for this purpose.

Syndrome of Inappropriate Antidiuretic Hormone

The syndrome of inappropriate antidiuretic hormone (SIADH) is most commonly associated with SCLC. Other cancers including NSCLC, prostate, adrenal cortex, esophageal, pancreas, colon, head and neck, thymoma, mesothelioma, bladder, carcinoid tumors, and hematologic malignancies have been associated with SIADH. [62] Nonmalignant conditions, such as an intracranial process (i.e., trauma, cerebral vascular accident, infection), pulmonary infection, or drug-related toxicity, can also be associated with SIADH. Chemotherapeutic agents (vincristine, cisplatin, cyclophosphamide), narcotics, chlorpropramide, thiazides, chlofibrate, and carbomazepines have all been implicated.[63] Other causes for hyponatremia in the lung cancer patient include cardiac, liver and renal disease, adrenal insufficiency, hypothyroidism, and gastrointestinal and renal losses that are not SIADH related.

The patient with SIADH usually presents with hyponatremia. The diagnosis requires several clinical criteria to be present, including euvolemia, serum hyposmolality with inappropriate urine hyperosmolality and urinary sodium, and normal renal, adrenal, and thyroid function. Other causes of hyponatremia need to be ruled out, particularly drug-related causes. A serum measurement of ADH is not necessary to make the diagnosis of SIADH.

Patients are generally asymptomatic, but the degree of symptoms is related to the rate of fall of the serum sodium. Patients often present with nonspecific complaints of nausea, generalized weakness, anorexia, headache, and lethargy. When the serum sodium falls below 115 mEq/L, altered mental status, psychosis, seizures, focal neurologic signs, and coma can result.

Mild hyponatremia with little or no symptoms can be managed by fluid restriction of 500 to 1,000 mL per day. [62] Because it is often difficult to accomplish fluid restriction on an outpatient basis, demeclocycline may be used. Demeclocycline at 600 mg/day partially inhibits the action of vasopressin by producing a reversible diabetes insipidus. [64] The drug can take up to two weeks to be effective. Patients may experience gastrointestinal upset, and renal function should be monitored while the patient is on treatment.

In patients with severe symptoms related to hyponatremia, such as mental status changes, treatment with hypertonic 3% saline and furosemide may be required. The goal is not to correct the serum sodium too rapidly. The recommended correction rate is 1 mEq/L/hour to avoid the potential complication of central pontine demyelinosis.[65,66] Patients must be monitored carefully in this situation, preferably in an intensive care unit setting.

Because the majority of cancer patients who present with SIADH have SCLC, treatment with systemic chemotherapy should be instituted. More than 80% of the patients will normalize their serum sodium within six weeks of treatment.[67] The presence of SIADH is not a prognostic factor with regard to tumor response or patient outcome.[68] Some patients actually develop SIADH postchemotherapy.[67] In the treated patient, the redevelopment of a low serum sodium may herald the recurrence of disease.

Ectopic Adrenocorticotropin Hormone Syndrome

Most normal tumor tissues produce a precursor adrenocorticotropin hormone (ACTH) molecule, whereas carcinomas produce this same precursor in much larger quantities. Some neoplasms convert the precursor ACTH to biologically active ACTH, resulting in clinically apparent Cushing's syndrome. [69] The most common malignancy associated with ectopic Cushing's syndrome is SCLC. Other lung cancer histologies tend to produce precursor ACTH that does not result in Cushing's. [70] Other neoplasms associated with ectopic ACTH production include carcinoid tumors, thymic cancer, islet cell tumors, pheochromocytoma, neuroblastoma, medullary carcinoma of the thyroid, and various malignancies.[71]

The clinical features associated with Cushing's disease and Cushing's syndrome from ectopic ACTH production are not entirely identical. Both may have truncal obesity, moon facies, weakness, hypertension, hirsutism, and metabolic disturbances. Purple striae and a buffalo hump are not usually seen in patients with malignancies because they do not live long enough to develop these physical findings. Hyperpigmentation occurs in ectopic ACTH related to Cushing's syndrome. Metabolic alkalosis, glucose intolerance, and hypokalemia are the biochemical abnormalities. The hypokalemia can be very severe. In cancer-related Cushing's, the hypokalemia is caused by the mineralocorticoid (aldosterone) receptor binding of cortisol. [72]

The goal of diagnosis is to distinguish between pituitary adenoma, ectopic ACTH production, and adrenal disorders. Radioassays of the ACTH plasma level are elevated in pituitary-related Cushing's and ectopic ACTH production. The elevated ACTH rules out primary adrenal disease. A dexamethasone suppression test is usually the next step.

The low-dose dexamethasone suppression test (0.5 mg every 6 hours for 8 doses) does not suppress either ectopic ACTH secretion or patients with Cushing's disease. The high-dose dexamethasone suppression test (2 mg every 6 hours for 8 doses) suppresses cortical production in patients with pituitary-related Cushing's disease and usually does not suppress production related to ectopic ACTH production. Because these tests do not ensure the origin of the ACTH production, metyrapone and corticotropins releasing hormone suppression tests have been used. [73,74] Inferior petrosal venous sampling, although invasive, can show a gradient as compared to peripheral samples in Cushing's disease. [75]

In patients with SCLC, approximately 5% develop Cushing's syndrome. [76] In these cases, treatment should initially include systemic chemotherapy. Patients with SCLC and Cushing's syndrome appear to have inferior response to treatment and shortened survival. [77] It is postulated that this observation may relate to increased complications, such as infections related to exposure to high-dose corticosteroids. For control of symptoms related to Cushing's syndrome, medications can be used along with antineoplastic treatment. Ketoconazole is probably the medical treatment of choice because of its effectiveness and low incidence of side effects. The drug exerts its effect by blocking corticosteroid production via inhibition of 17-hydroxylase and 11-hydroxylase. [78] The dose is 400 to 1,200 mg/day. Hypoadrenalism has been reported with prolonged treatment. Other agents such as mitotane, metyrapone, and aminoglutethemide have been used, but they either are not as effective as ketoconazole or they have less favorable toxicity profiles. The somatostatin analogue octreotide has been used in the suppression of ACTH release associated with carcinoid tumors. [79]

Other Endocrinologic Paraneoplastic Syndromes

Lung cancers, particularly SCLCs, can produce other hormonal substances, but this process does not always result in a clinically significant paraneoplastic syndrome. SCLCs and carcinoids can produce calcitonin, but hypocalcemia is rarely seen. [80] Gonadotropin secretion can occur from bronchogenic carcinomas. [80] Production of the b-subunit of human chronic gonadotropin can result in a male patient presenting with gynecomastia. Other causes of bhCG elevation, such as germ cell tumors, should be ruled out in this situation. Galactorrhea as a result of increased prolactin level has been reported. [81] Thyroid-stimulating hormone can be produced by tumors but rarely results in clinical hyperthyroidism. Acromegaly has been attributed to the release of a growth hormone–releasing factor by a bronchial carcinoid. [82] Hypoglycemia is rarely associated with non–islet cell malignancies. Mesothelioma is the most common neoplasm associated with hypoglycemia. The suspected cause is the tumor secretion of a nonsuppressable insulin-like substance. [83]

Neurologic Syndromes

Neurologic paraneoplastic syndromes are relatively rare and can involve any portion of the nervous system. Effects can be relatively focal or widespread. These syndromes may often develop before the actual diagnosis of the cancer. SCLC is the most common histologic type associated with neurologic paraneoplastic syndromes.

The origin of most neurologic paraneoplastic syndromes is thought to be related to an autoimmune process. The tumor produces substances that are similar to those normally expressed by the nervous system. It is hypothesized that autoantibodies are produced by the immune system in reaction to the foreign substances produced by the tumor, and these autoantibodies cross-react with neuronal antigens, thus causing damage to normal tissue.

Several autoantibodies have been characterized in patients with neurologic paraneoplastic syndromes. Anti-Hu antibodies are expressed in patients with SCLC. [84] The antibody is a 35 to 40 kD protein that has activity against the neuronal nucleus. Low titers are often present with no clinically evident paraneoplastic syndrome. Their presence may be indicative of better response to chemotherapy and improved survival. [85] Anti-Hu is associated with the clinical syndromes of encephalomyelitis, sensory neuropathy, cerebellar degeneration, autonomic neuropathy, limbic encephalitis, and opsoclonus/myoclonus. [84] Other antibodies that have been identified in SCLC include anti-Yo (cerebellar degeneration), anti-Ri (opsoclonus/myoclonus, cerebellar degeneration), anti-VGCC (Lambert-Eaton myasthenic syndrome), antiretinal (cancer-associated retinopathy), and antiamphiphisin (stiff-man syndrome). [86]

Lambert-Eaton Myasthenic Syndrome (LEMS) can occur in up to 3% of SCLC patients. [87] Most patients usually present with weakness of the proximal muscles associated with aches and stiffness. Patients may also complain of autonomic dysfunction (i.e., dry mouth, constipation, impotence) [88] and paresthesias. Cranial nerve findings can occur but are usually mild. The findings of a diminished compound muscle action potential at rest, and an incrementing response with rapid, repetitive nerve stimulation or maximum voluntary muscle contraction is pathonomonic of the syndrome. [89] Treatment of LEMS has included plasmapheresis, IVIG, 3–4 diaminopyridine, pryridostigmin, and immunosuppressive therapy. Successful treatment of the malignancy usually improves the symptoms.

Several types of peripheral neuropathy can occur as paraneoplastic syndromes: motor, sensory, sensorimotor, and autonomic. [90] The motor neuropathies have more often been seen in Hodgkin's and non-Hodgkin's lymphoma. The sensory neuropathies are more commonly associated with SCLC. The sensory loss usually begins distally and extends proximally. The symptoms can become quite severe, resulting in significant disability. No specific treatment is available, and antineoplastic therapy may or may not be beneficial. The syndrome of pseudo-obstruction of the bowel is the best-characterized autonomic neuropathy usually associated with SCLC. [91] Additional symptoms of autonomic neuropathy include gastroparesis, esophageal dismotility, orthostatic hypotension, urinary retention, impotence, and dry mouth.

Paraneoplastic cerebellar degeneration usually presents with abrupt onset of cerebellar symptoms, such as ataxia and dysarthria. Mild to moderate dementia can also develop. As previously described, several antibodies have been associated with this disorder. Pathologic changes are associated with loss of Purkinje cells. [92] This disorder is rare and usually predates the development of the malignancy. Cerebellar degeneration may be part of a more generalized encephalomyelitis in SCLC that is associated with anti-Hu antibody. [84] Limbic encephalitis is another rare paraneoplastic syndrome that may be isolated or associated with encephalomyelitis. [93] Symptoms can include memory loss, personality changes, confusion, hallucinations, and seizures.

Myotonia and stiff-man syndrome, consisting of severe muscle stiffness and cramping, have been reported with SCLC. [94] Treatment of the cancer and steroids may help the symptoms. Opsoclonus/myoclonus, which is a syndrome more common in children with neuroblastoma, has been seen in adults with lung cancer. [95] Finally, cancer-associated retinopathy is a rare paraneoplastic syndrome reported with SCLC. It is characterized by loss of the rods, cones, and ganglion cells of the retina. [96] Symptoms include photosensitivity, scotomatous visual loss, impaired color vision, and nightblindness. Steroids may help stabilize symptoms.

Musculoskeletal Paraneoplastic Syndromes

Hypertrophic pulmonary osteoarthopathy (HPO) has long been associated with carcinoma of the lung. It is characterized by both digital clubbing and periostosis of the tubular bones. [97] Digital clubbing involves paronychial soft tissue expansion with loss of the angle between the base of the nail bed and cuticle and can involve both fingers and toes. Clubbing can present as an isolated finding but must be associated with periostosis to diagnose HPO. Nonmalignant conditions can be associated with HPO, but the most common neoplastic cause is bronchogenic carcinoma. Adenocarcinoma and large cell are the most common histologies, with SCLC accounting for a small number of cases. [98] The origin of HPO is not really known. It has been suggested that a humoral mechanism, specifically growth hormone, may be involved. [99]

Diagnosis is made with radiographs of the long bones, which show periosteal elevation. A radioisotope bone scan can be very sensitive in detecting HPO before it is evident on radiographs. Patients often present with arthralgias, which can be very debilitating. Treatment of the malignancy does not usually alleviate symptoms because patients often have advanced NSCLC. NSAIDs can be useful in treating the pain.

Dermatoyositis and polymyositis are inflammatory conditions characterized by muscle weakness and tenderness, and skin changes, in the case of dermatomyositis. Breast and lung cancers are the most common associated malignancies. Most cases are idiopathic in nature and unrelated to cancer. Some controversy exists about whether an actual increase in cancer risk is related in patients who have either condition. [101,102] The course of these conditions may not parallel the course of the malignancy. Immunosuppressives, particularly steroids, have been used for treatment.

Mucocutaneous Manifestations

Many cutaneous syndromes are associated with cancer. Many of these skin lesions are uncommon, and the association with malignancy is stronger. Some of the cutaneous findings are common and may be associated with benign conditions. It is beyond the scope of this review to describe all of these mucocutaneous manifestations. Table 29.4 shows a compilation of the syndromes associated with lung cancer. [63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101] and [102]

TABLE 29.4. MUCOCUTANEOUS SYNDROMES ASSOCIATED WITH LUNG CANCER

Hematologic Syndromes and Vascular Manifestations

Anemia is a common problem in cancer patients, with many possible causes such as bleeding, nutritional deficiencies, and bone marrow involvement by the malignancy. Anemias with no apparent cause can be termed *paraneoplastic.* Red blood cells are usually normochromic or slightly hypochromic, ferritin levels and iron stores are normal or increased, and erythropoetin levels and reticulocyte counts are inappropriately low. The anemia may be related to several cytokines that blunt erythropoetin response.[103] Rarely, autoimmune hemolytic anemia, red cell aplasia, and microangiopathic hemolytic anemia have been associated with lung cancers.[104,105]

Leukocytosis is observed in some patients and may be related to the effects of IL-1 or granulocyte-stimulating factor.[106] Leukopenia is rare. Both eosinophilia and monocytosis can occur infrequently. Thrombocytosis is a fairly common occurrence and may be related to cytokine release of IL-6 or thrombopoetin.[107,108] An idiopathic thrombocytopenia purpuralike syndrome can rarely be seen in lung cancer.[109]

Trousseau's syndrome is one of the earliest paraneoplastic syndromes described. It represents an association between thrombosis and malignancy. It is seen in several malignancies, including gastrointestinal, lung, breast, ovarian, and prostate cancers.[110] Deep vein thrombosis of the lower extremities and pulmonary embolism are the most common presentations, although unusual location of thromboses can occur. The origin is probably multifactorial and can include release of procoagulant materials (particularly from mucin), release of cytokines that have procoagulant activity, platelet hyperactivity, and the release of tissue factors via abnormal tumor vasculature.[111] Therapy with heparin and/or coumadin may not provide satisfactory treatment.

Nonbacterial thrombotic endocarditis is associated with sterile verrucous fibrin platelet lesions in the left-sided heart valves. It is most commonly associated with adenocarcinoma of the lung.[112] This syndrome can cause tumor embolisms to the brain and other organs. Anticoagulants are usually not useful.

IMAGING

LESLIE E. QUINT
ISAAC R. FRANCIS
RICHARD L. WAHL
BARRY H. GROSS

Bronchogenic carcinoma is generally first imaged (and often first detected) by chest radiography. Chest radiography is the preferred initial imaging modality because of its availability, low cost, low radiation dose, and sensitivity. [1] Computed tomography (CT) and occasionally magnetic resonance (MR) imaging of the chest and abdomen are used to stage a known or suspected lung cancer. Various nuclear medicine procedures may be employed to aid in the staging process and to assess the patient's medical status for operability, including cardiac and pulmonary function. These techniques are all described in further detail in the following sections.

MORPHOLOGIC APPEARANCES OF LUNG CANCER

For the purpose of this discussion, solitary pulmonary nodule (SPN) is defined as a lesion up to four cm in diameter; larger lesions are designated as masses. Lung cancer morphology depends, to a certain extent, on cell type. Although prediction of cell type from morphology is far from 100% accurate, the following generalizations are often correct:[2]

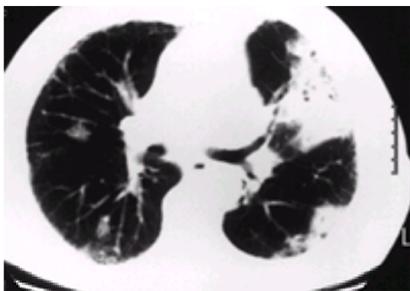
1. Adenocarcinoma usually presents as an SPN, and most malignant SPNs are adenocarcinomas. Squamous cell is also a common SPN, while SPN is the typical manifestation of alveolar cell carcinoma.
2. Large central masses frequently represent squamous cell carcinoma or small cell carcinoma; small cell especially involves mediastinal and hilar lymph nodes, sometimes without a recognizable parenchymal lesion, while squamous cell is generally centered at or adjacent to the hilum.
3. A large peripheral mass most commonly represents large cell carcinoma or squamous cell carcinoma; adenocarcinoma occasionally manifests this way. Large cell is usually a large a peripheral mass, but a large central mass is its next most common manifestation.
4. Multiple nodules generally occur with alveolar cell carcinoma; adenocarcinoma has also manifested this way. [3] With alveolar cell carcinoma, multiple nodules are a late manifestation, usually reflecting aerogenous (or less commonly hematogenous) dissemination.
5. Airspace disease is another late manifestation of alveolar cell carcinoma. It may be focal, lobar, or more diffuse (Figure 30.1).


FIGURE 30.1. Multifocal, bilateral airspace disease in alveolar cell carcinoma.

LUNG CANCER SCREENING

Given the success of mammographic screening for breast cancer, it seems intuitively obvious that there should be a similar benefit to chest radiographic screening for lung cancer. However, precise figures for sensitivity and specificity of chest radiography are nearly impossible to come by. In fact, sensitivity is particularly dependent on the size of the lesion, its position in the lung, and its morphology. Individual centers participating in large-scale screening of high-risk men for lung cancer have reported detection of more early stage lesions compared to newly diagnosed cancers in the typical nonscreened population. [1,4] For example, the Mayo Clinic screened men 45 years of age or older who smoked more than one pack of cigarettes per day, using chest radiography and sputum cytology every four months. In 4,593 screened patients, 92 lung cancers were detected, and more than half were American Joint Committee stage I lesions. [4] Screening at Memorial-Sloan Kettering Cancer Center produced similar results, with 40% of detected cancers still in stage I; in the two years following cessation of the screening program, this dropped to 20%.[1]

However, the real benefit of screening must be improved survival. Two analyses of the Mayo Lung Project have shown no such improvement; [5,6] the lung cancer death rate was calculated at 3.1 per 1000 person-years in the screened population, as opposed to 3.0 per 1000 person-years in a control group. [5] Furthermore, screening results in cost beyond the expense of radiography and the delivered radiation dose; there are false-positive results in 5% of screening chest radiographs and in 0.5% of screening sputum cytologies. [5] A separate lung cancer screening study[7] of 305,934 participants noted a low detectability rate of stage I adenocarcinoma and late recognition of rapidly growing small cell and squamous cell carcinomas. Thus these three studies [5,6 and 7] all concluded that "a policy of periodic screening cannot yet

be endorsed." In fact, the best description of lung cancer screening may be as an unproven but not a discredited practice. [8] Chapter 22 and Chapter 24 discuss new methods in lung cancer screening.

Recent studies have suggested that low-dose CT scanning might be an alternative way to screen for various pulmonary parenchymal abnormalities. [9,10 and 11] Based on initial small studies that demonstrated minimal (if any) decrement in detection of lung nodules with this technique compared to conventional-dose CT, [12,13 and 14] a recent report [15] specifically addressed the issue of low-dose CT detection of lung nodules in comparison to conventional CT images. Simulated nodules were displayed in 144 of 200 image panels, each reviewed by six radiologists independently. Nodules were detected with similar sensitivity (60% versus 63%) and specificity (88% versus 91%) by low-dose CT. Helical CT is a further technical refinement that may make low-dose CT screening a practical alternative [16,17,18,19 and 20] (see also Chapter 22).

MISSED LUNG CANCER

Experience teaches that larger lesions are more easily diagnosed than smaller lesions, and peripheral lesions are more readily detected than central lesions. Radiologic diagnosis is facilitated by the presence of typical radiographic features;uncommon manifestations of lung cancer (such as spontaneous regression) may prove misleading. [21,22] In one study of 27 missed lung cancers, the single most frequently identified cause of missed diagnoses was failure of the radiologist to compare the current chest radiographs with previous chest radiographs. [23] Other important factors were upper lobe location of the lesion (81%) and female gender of the patient (67%).

In the Mayo Clinic lung cancer screening article cited above, [4] each radiographic study was reviewed by two (and often three) trained and interested observers (chest radiologists or chest physicians) specifically to answer the question: "Is there lung cancer?" Amazingly, 45 of 50 peripheral carcinomas that they diagnosed were visible in retrospect, with 18 visible for more than one year and four for more than two years; one was visible in retrospect for 53 months! Furthermore, 12 of 16 perihilar carcinomas and 13 of 20 carcinomas presenting as hilar or paratracheal lymph node enlargement were visible in retrospect, although not generally for as long as the peripheral carcinomas. The authors concluded that ". . . failure to detect a small pulmonary nodule on a single examination should not constitute negligence or be the basis for malpractice litigation."

SOLITARY PULMONARY NODULE (SPN)

In the setting of a previous extrapulmonary primary cancer, the relative likelihood that a new SPN is a solitary metastasis versus a new lung cancer depends on the histology of the previous primary tumor. In some instances the odds favor a new lung primary, such as for head and neck carcinoma (15.8:1), bladder carcinoma (8.3:1), and cervical carcinoma (6:1). [11] In fact, with some primaries, all malignant SPNs in one series were lung cancers (prostate, 26 patients; stomach, 7 patients; esophagus, 4 patients; pancreas, three patients). In other cases, a solitary metastasis is favored, such as in patients with soft tissue sarcoma (17.5:1), osteosarcoma (6.7:1), melanoma (4.1:1), and testicular carcinoma (2:1). With most primaries the answer is in between, but slightly favoring lung cancer; examples include breast carcinoma (1.7:1), colon carcinoma (1.4:1), renal cell carcinoma (1.2:1), and endometrial carcinoma (1.1:1). [24]

The SPN is a common presentation of lung cancer. However, most SPNs are benign. Summarizing five large series [25,26,27,28 and 29] of resected SPNs, Siegelman [30] noted that 53.9% were granulomas, 28.3% were bronchogenic carcinomas or other primary malignancies, 6.6% were hamartomas, and 3.5% were metastases. An even higher percentage of all SPNs are presumably benign, because nodules that are clearly calcified on chest radiographs are rarely resected.

The challenge in evaluating SPNs is to avoid invasive procedures in patients who have benign nodules without allowing potentially curable bronchogenic carcinomas the time to progress to more advanced or even unresectable disease. This is an area of active, ongoing research. [31,32,33,34,35 and 36] The many approaches that have been tried attest to the lack of complete success for any one modality to date. A proper SPN evaluation acknowledges the following key points:

1. Imaging at a single point in time relies heavily on morphologic characteristics in distinguishing benign from malignant SPNs.
2. Calcification is the single best morphologic indicator of benignancy.
3. Behavior (that is, lack of growth) is *far* better than any morphologic criterion at predicting benignancy.
4. Any predictor of benignancy must err on the side of intervention—it is better to resect a benign SPN unnecessarily than erroneously to call a malignant SPN benign.

With the above in mind, and realizing the significant expense (and in some cases radiation dose) of radiologic tests, it is always best to start the evaluation of the SPN by seeking old radiographs for comparison. This saves money, radiation, and often time, and provides the possibility for proving that a lesion is benign, no matter what its morphology is. A lesion that is stable for two years or more *is* benign—end of discussion. The flip side is that almost no matter what the morphology is, a growing lesion has declared itself to be one that should be resected. The lack of vigor with which old films are pursued is generally disappointing; if the patient were a close relative, we would all try a lot harder to spare him/her unnecessary tests that involve (potentially fatal) injection of intravenous contrast. And consider this—how many adults 40 years of age or older have never had a prior chest radiograph? In the United States the number must be vanishingly small.

When a lesion is stable, but for less than two years, the situation is less clear-cut. Follow-up radiography to two years may suffice, especially when the period of stability is already close to that standard. If only short-term (that is, less than three months) stability is established, it may be best to proceed as though no prior studies had been available.

When comparison studies are not available, demonstration of calcification is the best way to attempt to establish a benign etiology. However, not all calcifications are benign; for example, eccentric calcification of a nodule at chest radiography is unrevealing as to the nature of the nodule. The demonstration of calcification on chest radiographs has been made more difficult by current widely used techniques that employ high kVp. For that reason, chest fluoroscopy with low kVp spot films would be a good next step in looking for calcification. Unfortunately, few centers still perform chest fluoroscopy. Computed chest radiography with selective windowing may be an alternative possibility. [37]

At the current time, most patients with an SPN at chest radiography and no previous comparison films go to CT. Thin-section CT densitometry with or without a reference phantom (a cylinder filled with a calcium-containing substance that serves as a standard of comparison to assess density of a patient's nodule) facilitates the detection of calcification that could be missed on chest radiographs. In a large cooperative study, 65 of 118 (55%) benign nodules were shown by CT to contain previously unsuspected calcification. [38] In 28 of these 65 patients, the calcification was directly visible on thin-section CT images; in 37, it was detected by comparison to the reference phantom. Many centers, however, have found the phantom to be significantly less helpful, and in current practice it is rarely used.

Thin-section CT without the reference phantom has significant potential to prevent unnecessary thoracotomies. At Johns Hopkins, more than 40% of SPNs without plain film evidence of calcification proved to be benign, and more than 50% of these were correctly assessed by CT by the detection of diffuse calcification; for lesions under 2 cm in size, the likelihood both of benignancy and of correct assessment by CT increased. [39] In the absence of nodule calcification, thin-section CT can still occasionally establish a benign diagnosis. Fat in a pulmonary nodule makes hamartoma the almost certain diagnosis. [40]

In some centers, nodules that are indeterminate at CT densitometry may be percutaneously aspirated; high accuracies have been reported, with a positive predictive value of 99%. The real challenge, of course, is to make a negative cytologic aspiration accurate and furthermore to establish a specific benign diagnosis. Using systematic staining and culture schemes, high negative predictive values have been reported for patients in whom a specific benign diagnosis could be made. [41] However, the negative predictive value is generally lower in patients with a biopsy showing nonspecific inflammation. Recent published studies have reported overall negative predictive values ranging from 52% to 84%. [42,43]

Given these results, surgeons at many institutions believe that a negative fine-needle aspiration biopsy of an SPN is not sufficiently reliable due to sampling error, and they will resect the nodule regardless of the biopsy results. Therefore, preoperative biopsy is generally not indicated at such institutions. An exception would occur in the patient with a history of previous extrathoracic primary neoplasm. At other institutions, it is advocated that a nonspecific negative fine-needle aspiration biopsy of an SPN be followed by a repeat biopsy. If the repeat biopsy is also negative for neoplasm, then close follow-up is advised. Some investigators have suggested the use of core biopsies to increase the yield of specific benign diagnoses. [44,45]

Before the SPN comes to thoracotomy there is still the possibility of following the lesion radiographically at close intervals. This is where the radiologic discussion

ends; follow-up radiography versus histologic sampling is a clinical, not a radiologic decision. If follow-up radiography is elected, it might start at two to three month intervals, which might later increase to six-month intervals if the SPN remains stable. The ultimate goal is to demonstrate two years of stability, proving benignancy.

An overview of the recent literature reveals many interesting and innovative approaches to proving that an SPN is benign. Preliminary studies with follow-up of noncalcified SPNs have reported that all or nearly all malignant SPNs enhance by at least 20 Hounsfield units (HU) within two to four minutes after contrast injection; few benign SPNs enhance to that degree.[45,47 and 48] Based on these promising preliminary results, a multicenter study recently evaluated 356 SPNs that were greater than or equal to 5 mm, solid, relatively spherical, homogeneous, and without calcification or fat on noncontrast images. Contrast-enhanced images were obtained at one, two, three, and four minutes after onset of injection (3 mm collimation, 420 mgl per kg, 300 mgl per ml administered at 2 ml per sec).[49] Although final results have not yet been published, an abstract of this study reports 98% sensitivity, 58% specificity, and 77% accuracy in diagnosing malignancy, using a threshold of 15 HU. Prevalence of malignancy in this patient group was 48% (171 of 356 nodules). Given the high sensitivity found by these studies, it is somewhat surprising that this has not become a standard tool in the workup of SPNs. A recent study demonstrated overlap in enhancement of malignant lesions and benign, active inflammatory lesions,[50] which may explain the low specificity and the current minor role of this technique.

Spiral (helical) CT is a new modality with greater ability to depict three-dimensional anatomy than conventional CT. Spiral CT surface evaluation of vascular involvement by SPNs was carried out in 29 patients with noncalcified SPNs of less than 3 cm in size.[36] Eighteen SPNs were malignant (nine bronchogenic carcinoma, nine metastatic) and eleven were benign (six granulomas, two hamartomas, one mixed granuloma, one arteriovenous malformation, one inflammatory infiltrate). Venous involvement was present in all 18 malignant SPNs, but also in four of 11 benign SPNs. Arterial involvement was seen in all nine bronchogenic carcinomas, in five of nine metastatic lesions, and in two of 11 benign SPNs. Thus vascular involvement does not distinguish between benign and malignant SPNs.

Magnetic resonance imaging findings in two patients with tuberculomas were potentially helpful in one study.[33] Imaging after injection of gadolinium-DTPA revealed thin rim enhancement with a low-intensity center. There was no similar appearance in a retrospective review of 20 bronchogenic carcinomas. Interestingly, the MR appearance of tuberculomas is strikingly similar to the CT appearance of tuberculous mediastinal lymph nodes after injection of intravenous contrast material.[51] Another study of 28 patients with SPNs has suggested that signal intensity measurements of nodules on dynamic contrast-enhanced MR studies may provide information about the nature of the nodules.[52]

There have been several interesting nuclear medicine approaches to the SPN using SPECT and positron emission tomography (PET). PET has shown significant promise in several studies due to its reliance on the metabolic behavior of the nodule rather than its morphology; these studies are described in the nuclear medicine section later in this chapter.

STAGING OF LUNG CANCER

Preoperative tumor staging in patients with non–small cell lung cancer (NSCLC) is important in order to identify those patients with localized disease who are likely to benefit from surgical resection. The TNM staging system, revised in 1997, is the most widely accepted and used classification system for pre- and postoperative staging.[53,54] In the TNM staging classification, T1 tumors are 3 cm or less in diameter, are surrounded by lung or visceral pleura, and are without bronchoscopic evidence of invasion more proximal than the lobar bronchus. T2 tumors show one or more of the following features: larger than 3 cm; involvement of a mainstem bronchus of 2 cm or more distal to the carina; invasion of visceral pleura; atelectasis extending to the hilum, without involvement of the entire lung. T3 tumors show invasion of the chest wall, diaphragm, pericardium, mediastinal pleura, or mainstem bronchus (less than 2 cm distal to the carina), or have atelectasis of an entire lung. T4 cancers invade the mediastinum, heart, great vessels, trachea, esophagus, or vertebral body, have an associated malignant pleural effusion, have satellite nodule(s) within the ipsilateral primary-tumor lobe of the lung. Metastatic spread to lymph nodes is classified as N1 for peribronchial or ipsilateral hilar nodes and for intrapulmonary nodes involved by direct extension of the primary tumor. Metastatic disease to ipsilateral mediastinal or subcarinal nodes falls into the N2 category, and into the N3 category for involvement of contralateral mediastinal or hilar nodes, and ipsilateral or contralateral scalene or supraclavicular lymph nodes.

Stage I tumors have no lymph node metastases. Stage II tumors either have no lymph node metastases or spread is confined to hilar lymph nodes. Stage IIIA includes tumors with spread to ipsilateral mediastinal or subcarinal nodes, whereas stage IIIB includes tumors with involvement of contralateral mediastinal or hilar nodes, and ipsilateral or contralateral scalene or supraclavicular lymph nodes. Tumors with distant metastases are classified as stage IV.

COMPUTED TOMOGRAPHY (CT)

Evaluation of the Primary Tumor

Pleural Invasion

A pleural effusion in a patient with lung cancer may be malignant, caused by pleural metastases, or it may be benign, particularly in a patient with postobstructive pneumonia. The hallmark for a malignant effusion is soft-tissue nodularity along the pleural surfaces, accompanying the effusion, although this finding is not always present. It has been reported that pleural nodularity and/or fissural thickening are indicative of pleural metastases, even in the absence of pleural effusion.[55] Pleural tumor dissemination is classified as T4 disease and is generally considered unresectable.

Chest Wall Invasion

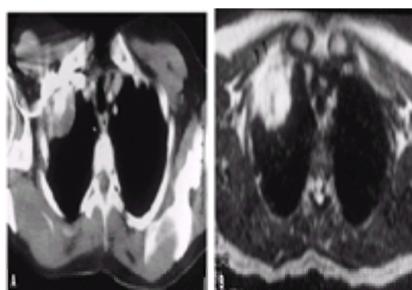
CT has shown somewhat disparate results in assessing for chest wall invasion by tumor, with sensitivity ranging from 38% to 87% and specificity from 40% to 90%.[56,57,58,59,60,61 and 62] Signs of invasion may include bone destruction with mass extending into the chest wall, pleural thickening, loss of the extrapleural fat plane, obtuse angle between mass and chest wall, and greater than 3 cm of contact between mass and chest wall (Figure 30.2, Figure 30.3, Figure 30.4). In a series of 112 patients with cancers adjacent to the pleural surface, Ratto and colleagues[56] found that CT was 83% sensitive and 80% specific for chest wall invasion using a cutoff of 0.9 for the ratio between the length of tumor-pleura contact and tumor diameter. They also found that obliteration of the extrapleural fat plane was 85% sensitive and 87% specific for invasion. However, they noted that the extrapleural fat plane was not always visible, particularly when the tumor contacted the ribs; on the other hand, this plane was usually visible when the tumor contacted the pleural surface in between the ribs. Length of tumor-pleura contact, angle between the tumor and the pleura, presence of soft tissue mass involving the chest wall, and rib destruction were less accurate indicators of chest wall invasion in this series. Pennes and associates[58] noted that in their series of 33 patients with peripheral pulmonary malignancies, five patients showed encroachment on or increased density of the extrapleural fat; however, only three of these five had chest wall or pleural invasion at surgery. In the other two patients, lymphoid aggregates were present in the extrapleural fat, suggesting that nonspecific inflammatory processes involving the pleura may extend into the adjacent extrapleural soft tissues. Pleural thickening was a very sensitive (100%) indicator of chest wall invasion in this study, although very poor specificity (44%) led to poor accuracy (58%). In the 20 patients with peripheral lung malignancies studied by Pearlberg and co-workers[62], definite bone destruction at CT showed 100% positive predictive value (11 of 11). Tumor extension around ribs into fat or muscle of the chest wall had a positive predictive value of 33% (three of nine). In each of these six false-positive cases, fibrous, inflammatory, and/or hemorrhagic changes were shown in the adjacent pleural or extrapleural tissues, but no tumor extension was seen.


FIGURE 30.2. A: CT shows right upper lobe mass encasing and destroying a rib. **B:** T2-weighted MR image reveals high-signal-intensity material within the anterior chest wall (*arrowheads*) indicative of tumor invasion.
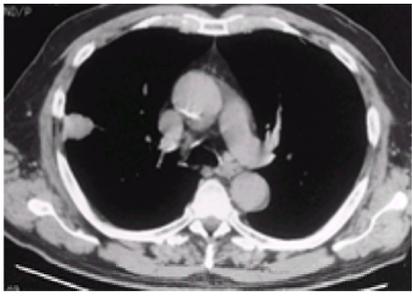

FIGURE 30.3. Peripheral right lung mass is indeterminate for chest wall invasion at CT. Surgical specimen showed no pleural invasion.

FIGURE 30.4. False-negative CT for spine invasion and mediastinal lymph node metastases (*arrows* point to normal-sized mediastinal nodes).

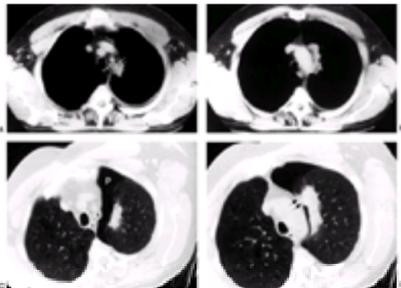
Some investigators have employed artificial (that is, induced) pneumothorax in order to increase the accuracy of CT in diagnosing chest wall and mediastinal pleural invasion (Figure 30.5). For example, Watanabe and colleagues [63] found 100% sensitivity, 80% specificity and 88% accuracy for CT using this technique in 12 patients. In one patient with no separation between the tumor and the mediastinal pleura, only adhesions were found at surgery, with no mediastinal tumor invasion. In a different study of 43 patients with equivocal chest wall invasion on routine CT, artificial pneumothorax yielded 100% accuracy for diagnosing chest wall invasion and 76% accuracy for mediastinal invasion. [64] These authors noted difficulty when the tumor was near the root of the pulmonary arteries and veins, because it was occasionally hard to introduce air into this region of the pleural space.


FIGURE 30.5. Prebiopsy CT images show left upper lobe mass touching left subclavian artery (s) (**A**) and mediastinal pleura (**B**), suggestive of invasion of these structures. Postbiopsy CT images reveal a left pneumothorax (*P*) with separation of the mass from the left subclavian artery (s) (**C**), proving lack of invasion of the artery. However, the mass remains adherent to the mediastinal pleura (*arrows*) (**D**). At surgery there was no mediastinal invasion. (From Quint L, Francis I. Radiologic staging of lung cancer. *J Thorac Imaging* 1999:14;235, with permission.)

Other techniques for diagnosing chest wall invasion rely on the absence of relative movement between the chest wall and the adjacent tumor during respiration. Investigators have used inspiratory/expiratory CT, ultrasonography, and cine-MR during deep breathing to evaluate this feature, with moderately successful results.[65,66 and 67]

In summary, these studies suggest that the best and the only reliable criterion for diagnosing chest wall invasion with routine CT is definite bone destruction, with or without tumor mass extending into the chest wall. Thin sections (3 to 5 mm) and bone window photography are often helpful in making this assessment. It should be noted that chest wall invasion does not preclude surgical resection, because the surgeon can perform en bloc resection and chest wall reconstruction. However, this procedure is associated with increased operative morbidity and mortality. In addition, patients with known mediastinal nodal metastases and chest wall invasion are felt to have a very poor prognosis (7% reported five-year survival following surgical resection), and surgery is usually not advocated in these patients. [68,69] Superior sulcus tumors invading extrapleurally are usually treated with radiation therapy followed by surgical resection.

Mediastinal Invasion

Although invasion of the mediastinum falls into the T4 category in the TNM staging classification, minimal invasion of fat only (without invasion of vascular or other structures) is generally considered resectable by many surgeons. Therefore it is not usually necessary preoperatively to diagnose mediastinal fat invasion. On the other hand, a reliable diagnosis of invasion of mediastinal vessels, trachea, esophagus, and/or vertebral body would preclude surgical resection. Several studies have investigated the usefulness of CT in detecting mediastinal invasion and in predicting resectability of the primary tumor. [56,60,70,71,72,73,74,75,76 and 77] Accuracy for distinguishing between T0–2 and T3–4 tumors has been reported to be 56% to 89%. [74,75,76 and 77] However, this information is not particularly helpful, because the clinically important distinction is between resectable (T3) and unresectable (T4) cancers.

In one retrospective study of 80 patients with an indeterminate CT for mediastinal invasion (that is, mass contiguous with the mediastinum but without definite infiltration into the mediastinal fat or extension around the central vessels or mainstem bronchi), the authors were able to identify a large group of masses that were likely to be technically resectable using one or more of the following criteria: contact of 3 cm or less with mediastinum, less than 90 degrees of contact with aorta, and mediastinal fat between the mass and mediastinal structure.[70] Thirty-six of 37 masses in this category were resectable; 28 of 36 masses had no mediastinal invasion, and eight of 36 had focal limited invasion. However, more than 3 cm contact with mediastinum, more than 90 degrees of contact with aorta, obliteration of the fat plane between the mass and mediastinal structures, presence of mass effect on adjacent mediastinal structures, and pleural or pericardial thickening were not reliable signs of either invasion or unresectability. Kameda and colleagues [72] studied 52 patients with lung cancer, including 21 with central tumors. CT was 100% sensitive although not specific (60% to 67%) in evaluating for superior vena cava or right pulmonary artery invasion. For the left pulmonary artery and the left atrium or pulmonary vein,

CT had high specificity (94% to 100%) but poor sensitivity (56% to 62%). In a CT study of 108 patients, Izbicki and associates reported one false-positive case for aortic invasion and multiple false-negative cases for invasion of an atrium, pulmonary artery, superior vena cava, or mediastinal bronchus. [73] Choe and colleagues found that obliteration of the superior pulmonary vein at CT was consistent with intrapericardial extension of tumor through the pulmonary vein in ten of ten patients. [78] On the other hand, only four of nine patients with obliteration of the inferior pulmonary vein at CT showed intrapericardial tumor extension at surgery.

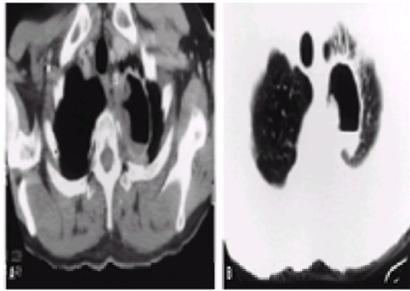
In summary, CT diagnosis of mediastinal fat or mediastinal structure invasion is generally unreliable, and a patient should not be denied surgery based on unproven CT findings (Figure 30.6, Figure 30.7, Figure 30.8, Figure 30.9). Gross mediastinal fat invasion may be proved via mediastinoscopy or transbronchial Wang needle biopsy. Findings suggestive of central tracheobronchial invasion at CT are usually further evaluated using bronchoscopy. CT and bronchoscopy are complementary procedures: bronchoscopy is superior to CT in evaluating the mucosal surface of the airway, whereas CT is superior in visualizing tumor spread extraluminally and occasionally within the wall of the bronchus.


FIGURE 30.6. A,B: Cavitary squamous cell carcinoma obliterates margins of left subclavian artery (s), suggesting invasion. No invasion present at surgery.
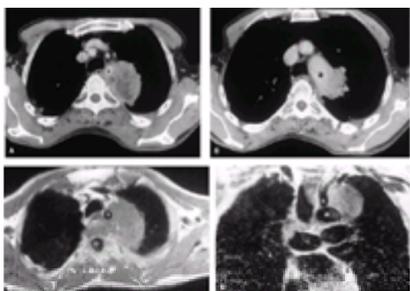

FIGURE 30.7. Lung mass invades mediastinal fat and touches left subclavian artery (s) and aortic arch (a) on axial CT (**A,B**), axial MR (**C**), and coronal MR (**D**) images. Surgery revealed left subclavian artery invasion, although the aortic arch was intact.

FIGURE 30.8. Left lower lobe mass contacts the aorta over a large portion of its circumsference, suggesting aortic invasion. At surgery the aorta was not invaded. (From Quint L, Francis I. Radiologic staging of lung cancer. *J Thorac Imaging* 1999:14;235, with permission.)

Prediction of Need for Lobectomy versus Pneumonectomy

Tumor invasion of central pulmonary arteries and veins, as well as tumor extension across the major fissure (anywhere on the left; above the minor fissure on the right), are findings that would generally require pneumonectomy for resection rather than lobectomy. In many cases, tumor involvement of a mainstem bronchus also necessitates pneumonectomy (Figure 30.10), although some of these tumors may be resected with lobectomy using a sleeve resection and bronchoplasty (Figure 30.11, Figure 30.12). The assessment of the need for lobectomy versus pneumonectomy is important in the patient with poor pulmonary function who cannot tolerate a pneumonectomy. Quint and colleagues[79] found CT to be inaccurate in making this assessment (Figure 30.13), although thin sections (1.5 to 3.0 mm) helped in evaluating for tumor spread across a fissure (Figure 30.14). Preliminary work done by this group suggested that three-dimensional CT reconstructions in this setting may improve accuracy in evaluating central pulmonary vascular invasion. [80] Thin sections (less than or equal to 3 mm) are probably necessary to evaluate the central bronchi optimally. Newer CT scanners using helical or spiral scanning modes will enable acquisition of large numbers of thin sections during a single breath hold. These capabilities may facilitate analysis of tumor invasion into adjacent structures, particularly using sagittal, coronal, and off-axis planar reconstructed images.

Differentiation between Tumor and Adjacent Atelectasis/Pneumonia

Another use for CT in evaluating local extension of the primary tumor is in distinguishing central tumor from adjacent collapsed lung. After an intravenous bolus of urographic contrast material, the atelectatic lung may enhance much more than the adjacent tumor, thus giving a more accurate assessment of tumor size [81] (Figure 30.15, Figure 30.16). However, in many cases it remains difficult to distinguish tumor from adjacent postobstructive atelectasis or pneumonia (Figure 30.17, Figure

CT Evaluation of Hilar and Mediastinal Lymph Nodes

Significance

Metastatic disease to hilar lymph nodes (N1 disease) adversely affects patient prognosis, although it does not generally affect resectability. Usually, involved hilar nodes can be easily removed from the hilar vessels at surgery. Thus, while preoperative detection of tumor spread to hilar nodes is useful, it is generally not crucial in directing surgical treatment planning. Moreover, the presence or absence of hilar node metastases is an unreliable indicator of mediastinal node metastases. [82,83]

In the past, the presence of mediastinal node metastases has been considered a contraindication to thoracotomy, and preoperative detection of mediastinal spread of disease has generally precluded surgical resection. However, some investigators have found reasonable three- and five-year survival rates for patients with positive ipsilateral mediastinal nodes, and many surgeons now feel that certain groups of patients with limited N2 disease may be surgical candidates. [84,85 and 86] Naruke and colleagues[87] found significantly increased five-year survival in patients with N2 disease (14%) as compared to patients with N3 disease (0%) following pulmonary resection in 1,479 patients with no distant metastatic disease. It has been suggested that resection may be worthwhile in patients with ipsilateral mediastinal nodal disease as long as the nodes are not in the high paratracheal region, are not numerous or bulky, and can be completely resected. [88,89] Some groups have advocated surgical resection in conjunction with postoperative radiation therapy in patients with mediastinal metastases. [82,90,91] Other investigators have suggested that patients with N2 or N3 disease may benefit from chemotherapy or combined chemotherapy and radiation, either alone or prior to surgical resection. [92,93,94,95,96 and 97]

CT Criteria for Detection of Lymph Node Metastases

Given the importance of preoperative nodal staging for treatment planning, a noninvasive imaging modality such as CT is of great potential value for assessment of mediastinal nodes, both ipsilateral and contralateral to the primary lung tumor. Mediastinal lymph nodes are generally identified on axial CT images as nonenhancing, oval, soft tissue densities surrounded by mediastinal fat. Nodal size can be estimated by measuring the short and long-axis diameters of a node as seen on the axial images. Glazer and colleagues[98] stated that the short-axis diameter is a more accurate predictor of nodal size than the long-axis diameter, because long-axis measurements are more dependent on the spatial orientation of the node. The long-axis diameter is accurate on transverse CT images only when the longest axis of the ovoid, three-dimensional lymph node is oriented in the plane of section that is, the transverse plane. If the lymph node is vertically oriented, the long-axis diameter on CT has no relation to the true long-axis measurement of the lymph node. Short-axis diameters are also affected by nodal orientation, although to a lesser extent. In a CT/autopsy correlation study, Quint and co-workers[99] found that the short-axis diameter of the nodes at CT was the best predictor of actual nodal volume.

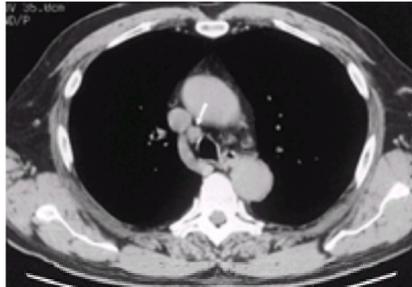
CT criteria for lymph node malignancy theoretically include morphological features such as nodal density and margination, as well as nodal size. In practice, however, most of these features are not helpful, and increased nodal size is the only useful criterion for malignancy (Figure 30.19). One exception to this rule is the occasional finding of central nodal low density, suggesting necrosis (Figure 30.20); this is a good indicator for malignant nodal disease. Rarely the central low density will show the attenuation of fat, and this finding is reliable for benignancy (Figure 30.21). In addition, a recent study has suggested that rounding of the contour of a hilar lymph node, where it meets the lung margin, is indicative of metastatic disease. [100]


FIGURE 30.19. Mildly enlarged right paratracheal lymph node (*arrow*) containing proven metastasis.

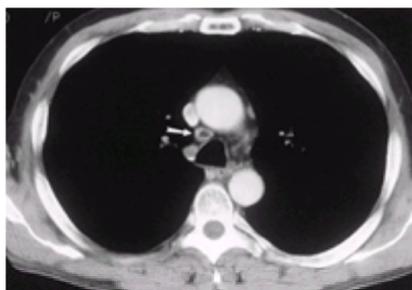
FIGURE 30.20. Mildly enlarged tumor containing right paratracheal lymph nodes, one showing central necrosis (*arrow*).


FIGURE 30.21. Central fat density within an enlarged mediastinal lymph node (*arrow*) is reliable for benignancy.

Several groups have investigated the normal size limits for mediastinal lymph nodes, studying normal patients and those with lung cancer. Genereux and Howie [101] studied CT scans of normal patients and compared their findings with dissection of 12 cadaver mediastina. The largest mediastinal nodes at CT were in the precarinal/subcarinal and aortopulmonary regions, and at autopsy, the largest nodes were in the pretracheal and precarinal/subcarinal regions. These authors measured long-axis lymph node diameters at CT and found that 95% were less than 11 mm. In another CT study by Schnyder and Gamsu,[102] the mean diameter of normal lymph nodes in the pretracheal, retrocaval space was 5.5 mm plus or minus 2.8 SD (short versus long axis not specified), with 91% (116 of 127) being less than or equal to 1 cm. A CT/autopsy study in five cadavers by Quint and colleagues [99] showed excellent correlation for the number of nodes in right-sided mediastinal regions, with poorer correlation in left-sided regions. Mean short-axis nodal diameters at CT ranged from 3.2 to 7.3 mm, depending on exact nodal location. Kiyono and colleagues[103] dissected 40 cadaver mediastina from patients without chest malignancy or infection, and recorded the number, size (short and long axes in the transverse plane), and ATS location of each lymph node identified. Based on their findings, these authors proposed standards for maximum short axis diameters as follows: 12 mm for ATS region 7 (subcarinal), 10 mm for ATS regions 4 (right lower paratracheal) and 10R (right tracheobronchial angle), and 8 mm for other regions. They found that maximum long-axis diameters showed a wider variation.

Glazer et al.[98] examined normal mediastinal lymph nodes on CT scans from 56 normal patients and tabulated the number and size of lymph nodes in each anatomical region as specified by the American Thoracic Society (ATS) lymph node mapping scheme. In this study, 1 cm was the optimal upper limit of normal for the short axis of a mediastinal node at CT, with slight variations according to specific location (range 7 to 11 mm). The largest nodes were in the subcarinal and right tracheobronchial regions, whereas the smallest nodes were in the upper paratracheal and left peribronchial regions. A prior CT study by the same group involving patients with NSCLC similarly found 1 cm as the optimal size threshold for diagnosing metastatic disease in mediastinal nodes. [104] Platt and colleagues[105] confirmed 11 mm as the upper limit of normal size at CT for subcarinal lymph nodes in 46 patients with NSCLC.

In order to address the issue of lymph node size versus presence/absence of metastases, Gallardo and colleagues conducted a pathological study of lymph nodes resected from 67 patients with NSCLC.[106] The authors correlated lymph node size (as measured on the fresh, resected nodes in the pathology department) with presence or absence of tumor at histological examination. Using a size threshold of 10 mm (short versus long axis not specified), 73 of 167 (44%) patients had enlarged mediastinal nodes and 58 of 167 (35%) had enlarged hilar nodes. Eighteen of 73 (25%) and 12 of 58 (21%) patients had neoplastic involvement of mediastinal and hilar nodes at pathological examination, respectively (25% mediastinal nodal PPV). The PPV for enlarged mediastinal lymph nodes in squamous cell carcinoma was 23% and in adenocarcinoma was 18%. These low values were reflective of the large number of false-positive cases due to enlarged, benign lymph

nodes.

These results highlight one pitfall in using a nodal size threshold to distinguish benign from malignant lymph nodes at CT. Benign nodes may be enlarged due to reactive hyperplasia, anthracosis, inflammation, or infection (Figure 30.22). Conversely, malignant nodes may be normal in size if they contain only microscopic metastases (Figure 30.4). Daly and associates[107] reported that enlarged, benign nodes were a particular problem for central tumors with postobstructive pneumonia. Gross and co-workers[108] addressed the issue of microscopic metastases to normal-sized nodes in a study of 39 patients with bronchogenic carcinoma. Five of 39 (13%) patients had metastases limited to normal-sized nodes as measured at surgery and pathology; however, two of these five patients showed enlarged nodes at CT owing to inaccurate CT depiction of nodal size in the subcarinal region. In one patient, multiple normal-sized subcarinal nodes containing metastatic tumor were visualized only as a single large mass at CT. In the second patient, a 10 × 9 mm subcarinal node containing metastatic tumor measured 12 × 11 mm at CT, and was therefore identified as abnormal. Thus metastatic disease to normal-sized mediastinal lymph nodes was missed at CT in only three of 39 (8%) patients, and the authors concluded that metastatic disease to normal-sized mediastinal lymph nodes is not a major problem in CT staging of lung cancer. Similarly, Daly and associates[107] reported that of 146 patients studied, only two of eight CT false-negative cases were attributable to microscopic metastases. On the other hand, ten of 25 (40%) patients with mediastinal metastases in one study[88] and seven of 11 (64%) patients in another study[109] had no enlarged nodes. There is no obvious explanation for these discrepant results.

FIGURE 30.22. A,B: Left upper lobe cancer, postobstructive pneumonia, and bilaterally enlarged mediastinal lymph nodes (*arrowheads*). Right paratracheal lymph nodes (sampled via mediastinoscopy) and aortopulmonary window lymph nodes (sampled via CT guided aspiration biopsy) were benign. A single left lower paratracheal lymph node contained metastatic disease at thoracotomy.

Regardless of the actual frequency of microscopic lymph node metastases, it has been suggested that microscopic disease may have a better prognosis than metastases to enlarged nodes, and thus it may not be as crucial to detect microscopic spread of tumor preoperatively.[85,110] For instance, Pearson and colleagues[89] reported that the survival rate in patients whose N2 status was established at mediastinoscopy was significantly worse than in those with a negative mediastinoscopy, in whom the N2 status was established at subsequent thoracotomy. Similarly, Cybulsky and co-workers found that patients with false-negative CT studies for mediastinal nodal metastases did better than those with true-positive CT studies (five-year survival following resection was 13.5% versus 6.6%, respectively). [111] These differences may relate to the distinction between normal-sized nodes with microscopic metastases versus enlarged metastatic lymph nodes, because enlarged nodes are more likely to be detected by mediastinoscopy and called abnormal at CT. Moreover, in a study of 115 patients who had undergone resection for NSCLC, Ishida and colleagues found increased survival for patients with microscopic nodal metastases compared to those with moderate or gross nodal metastases. [112] These findings are supported by one small CT series which suggested that metastases to enlarged mediastinal nodes were more likely to have extracapsular spread of tumor than microscopic metastases to normal-sized nodes.[108] Because extracapsular spread is thought to be a poor prognostic indicator, [113,114] microscopic metastases to normal-sized nodes may have a less dire prognosis than enlarged malignant nodes.

In summary, although different size threshold values for normal mediastinal lymph nodes have been suggested, the current consensus is that this figure should generally be approximately 1 cm in short-axis diameter.[98,99,101,102,104,110,115,116,117,118 and 119] Some authors have preferred to use nodal size criteria that vary with the precise mediastinal nodal location, based on the studies described above. [120,121]

Evaluation of Hilar Lymph Node Metastases (N1 Disease)

Conventional radiography and tomography have been used extensively in the past to evaluate patients with bronchogenic carcinoma. In one study of 47 lung cancer patients, the reported sensitivity of conventional radiography for hilar disease was 53%, with specificity of 84% and accuracy of 71%. [118] In a subsequent study of 84 patients with suspected intrathoracic neoplasm, sensitivity and accuracy were 64% and specificity was 65%. [122] Conventional tomography has been only slightly better. Reported sensitivities have ranged from 47% to 85%, specificities from 60% to 80%, and accuracies from 74% to 80% in three studies. [118,122,123] Accuracy was not reported and could not be calculated in one additional series, [124] but must have fallen between 47% and 72%.

The accuracy of CT in detecting hilar lymph node metastases is unclear. Three lung cancer studies reported low sensitivity (45% to 63%) and positive predictive value (38% to 68%) and moderately high negative predictive value (79% to 85%). [73,125,126] Two of these studies showed high specificity (92% to 93%), whereas the other reported only 58% specificity. Accuracies ranged from 59% to 82%. One older report was more sanguine, with 90% accuracy, 88% positive predictive value, and 100% negative predictive value. [8]

Evaluation of Mediastinal Lymph Node Metastases (N2/N3 Disease)

The accuracy of conventional radiography and tomography in diagnosing mediastinal lymph node metastases has generally been quite low due to poor sensitivity (6% to 81% sensitivity for conventional radiographs and 20% to 73% for tomography). [75,107,110,117,118,124,127,128,129,130 and 131] Disparate results have been reported regarding the accuracy of CT in this setting (Table 30.1). Many studies have found fairly high sensitivity for CT (>85%) [8,61,76,104,116,118,120,124,131,132,133 and 134] and high negative predictive value (>85%)[8,120,121,126,132,133,135,136 and 137] (Table 30.1). Others have found high specificty (>85%). [73,107,119,120 and 121,128,132,133,136,137,138,139,140 and 141] On the other hand, other recent studies have shown low accuracy, resulting from both poor sensitivity and poor specificity. [56,74,125] Low sensitivity in some studies was attributed to the high frequency of microscopic metastases within normal-sized nodes.[75] Low specificity arose from the frequent occurrence of enlarged, hyperplastic nodes, particularly in patients with postobstructive pneumonitis.[125] Dales and colleagues[142] performed a metaanalysis of CT accuracy in staging mediastinal lymph nodes in NSCLC using data from studies published between 1980 and 1988. Pooled data revealed accuracy, sensitivity, and specificity figures that were approximately 80% each. They found no significant differences between the results from studies performed using fourth-generation versus third/second-generation CT scanners. Moreover, there is no data to suggest that the new helical/spiral scanners will improve CT accuracy in this setting.

TABLE 30.1. CT STAGING OF MEDIASTINAL LYMPH NODE METASTASES IN PATIENTS WITH KNOWN OR SUSPECTED LUNG CANCER

Results within some of the individual studies quoted above varied according to the size and morphologic criteria used for diagnosing metastatic disease to mediastinal lymph nodes. For example, Seely and associates[136] found that sensitivity increased and specificity decreased if long-axis diameter measurements were used instead of short-axis measurements or if adjacent nodal stations were considered together instead of considering each nodal station alone. Buy and co-workers [120] found maximal sensitivity when individual size thresholds were used for each individual nodal station, rather than using a uniform 10 mm size cutoff. In contrast, the data of Ikezoe and collegues showed slightly better sensitivity, albeit significantly worse specificity and accuracy, using a uniform 10 mm threshold rather than two separate criteria (13 mm for nodes in the subcarinal, precarinal, and tracheobronchial regions and 10 mm for nodes in other regions). [121] Specificity in the study of Buy and co-workers[120] was maximized when the criterion for nodal abnormality was defined as follows: the short axis of the largest mediastinal node in the lymphatic drainage territory of the cancer was greater than or equal to 10 mm and the difference between this node and the largest node in the other territories was greater than 5 mm. According to the investigation of Ratto and colleagues, [133] specificity increased dramatically if nodes 10 to 15 mm in short-axis diameter were considered indeterminate and excluded from analysis. However, 36% (44 of 123) of patients fell into this category, limiting the usefulness of this criterion. These authors also found increased specificity if the criterion for abnormal nodes was modified to include nodes 10 to 20 mm in short axis diameter with central necrosis and/or a discontinuous capsule.

In some studies, CT accuracy also appeared to depend on the precise anatomic location within the mediastinum being analyzed. In the study of McLoud and colleagues,[125] sensitivity of CT using a single size criterion (10 mm short-axis diameter) varied for individual nodal stations, ranging from 17% to 83%. Highest sensitivity was found in ATS regions 4R and 5, and lowest in 7, 4L, 10R, 10L. Specificity ranged from 72% to 94%, being highest in 10L and lowest in 10R. Platt and associates compared staging of right and left lung tumors. [115] Although prior reports have shown that CT is more accurate in evaluating right-sided mediastinal lymph nodes,[99,143] Platt and colleagues found no statistically significant difference in staging accuracy between left and right lung cancers. [115] This is probably due to involvement of subcarinal and contralateral mediastinal lymph nodes, which are present more often in left lung cancers as compared to right-sided lesions. [144]

There were also some reported differences when the data were broken down according to cell type of the tumor. Ikezoe and colleagues [121] found that sensitivity for cases of adenocarcinoma (61%) was lower than that for squamous cell carcinoma (86%), but specificity for these two groups was almost the same (93% to 94%). There was an increased number of false-negative cases for adenocarcinomas, as compared to squamous cell carcinomas in both this study and two others;[73,111] the authors postulated that this probably indicated a higher frequency of microscopic metastases in adenocarcinomas. On the other hand, Ratto and colleagues [133] reported no difference in staging accuracy between squamous cell carcinoma and adenocarcinoma.

When calculated on a nodal station-by-station basis, results in some studies varied according to whether or not adjacent nodal stations were included in the analysis. For instance, inclusion of adjacent nodal stations led to an increase in sensitivity and a decrease in specificity in one investigation. [136] However, it is important to note that the clinical usefulness of a staging modality does not depend upon accurate detection of disease in any individual node or nodal group, but rather upon accurate detection of mediastinal nodal malignancy in the individual patient, either ipsilateral or contralateral to the neoplasm. Moreover, several authors have reported increased sensitivity in mediastinal lymph node evaluation when calculated on a patient-by-patient basis rather than on a nodal station-by-station basis. [108,125,136]

There are many possible reasons for the different reported CT accuracies among studies in detecting mediastinal metastases. Differences in patient populations and prevalence of mediastinal nodal disease would affect CT accuracy. Some investigations included all patients with known or suspected lung cancer, and some included only those with biopsy proven cancer. Others focused on clinical T1NOMO cancers, that is, small lesions surrounded by lung parenchyma, with no conventional radiographic signs of mediastinal disease. Seely and colleagues [136] found higher specificity in their study of T1 cancers as compared to historical controls for all cancers. They postulated that this was partly due to lack of obstructive pneumonitis with resultant enlarged, hyperplastic nodes.

In addition, there were substantial variations in scanning techniques. Some studies used older CT scanners (second-generation) with long scan times (18 to 20 seconds), resulting in image blur from biologic motion; studies done on third- and fourth-generation scanners did not have this problem. CT examinations were performed using different section thicknesses, section spacing, and methods of administration of intravenous urographic contrast material. Gaps between slices[139,140,145] and motion artifact from long scan times[117,138,139 and 140] probably contributed to insensitive detection of enlarged lymph nodes. There were no uniform criteria for interpreting the scans, and definitions of nodal enlargement ranged from "any visible node" to 2 cm diameter, with or without morphological nodal changes. Some investigators interpreted their results on a patient-by-patient basis, some on a nodal station-by-station basis, and some on a nodal station-by-station basis including adjacent nodal stations. It can be quite difficult at CT and surgery to precisely determine the boundaries between one nodal station and an adjacent one, and some studies, including the recent, large study of McLoud and associates [125] made no allowances for this pitfall. Many studies appeared to lack precise radiologic/surgical/pathologic correlation, and different methods of proof were employed. This is important because certain mediastinal node groups are accessible only at thoracotomy and would be missed at mediastinoscopy. Moreover, it is plausible that those studies employing thorough mediastinal lymph node dissection rather than nodal palpation and biopsy would show decreased CT sensitivity, due to the inability to detect microscopic metastases within normal sized lymph nodes. However, Daly and co-workers[107] were unable to substantiate this premise. They divided their patients into two surgical groups: in group I (51 cases) mediastinal nodes were removed only if palpably abnormal, if CT showed enlarged nodes, or if hilar nodes were grossly tumorous. In group II (97 cases) the mediastinum was explored in every patient and all nodes were resected. There was no statistically significant difference in CT sensitivity between these two groups (88% and 75%, respectively).

CT Evaluation of Distant Metastases

Several autopsy series have demonstrated an overall prevalence of distant metastases in patients with end-stage lung cancer as high as 93%. Key sites involved include liver (33% to 40%), adrenal (18% to 38%), brain (15% to 43%), bone (19% to 33%), kidney (16% to 23%), and abdominal lymph nodes (29%). [146,147 and 148] Autopsy studies performed in the immediate postoperative period as well as one report of abdominal exploratory surgery prior to thoracotomy for bronchogenic carcinoma have shown lower prevalences of metastatic spread to individual organs (liver 7% to 14%, adrenal 1% to 9%, brain 4%, bone 1% to 5%, kidney 0% to 4%, abdominal lymph nodes 5% to 8%). Nonetheless, the overall prevalence of occult metastatic disease was fairly high (18% to 36%) in these pre-CT-era studies [149,150,151 and 152]. One of these studies found that extrathoracic metastases were more common among men with adenocarcinoma than among those with squamous cell carcinoma.[149] A more recent autopsy report also found a moderately high frequency (19% of 103, = 18%) of distant metastases in patients dying in the perioperative period after lung cancer resection.[150]

Out of 95 patients with newly diagnosed NSCLC and N0 disease at CT, one report demonstrated CT evidence of extrathoracic tumor spread in 24 of 95 (25%) patients. These included metastases to brain (ten), bone (eight), liver (six), adrenal (six), and soft tissue (two) (some patients had involvement at more than one site).[153] An additional, prospective study of 146 patients with potentially resectable NSCLC (clinical T3 or less and N2 or less) [154] revealed distant metastatic disease in 30 of 146 (30%) patients. These metastases were detected by chest or abdominal CT, brain CT, abdominal ultrasonography, and/or bone scan, and presumably each finding was proved. The lesions were distributed as follows: 13% bone, 13% brain, 12.3% liver, 7.5% adrenal, 1.4% kidney, and 1.4% subdiaphragmatic nodules (in 17 patients the metastases were "multiorganic"). The authors indicated that patients with nonsquamous cell carcinomas (adenocarcinoma or large cell carcinoma) were at significantly greater risk for metastases outside the thorax than those with squamous cell cancer (p = less than 0.5). No relationship was detected between the TN stage and the existence of metastases in adenocarcinoma and large cell adenocarcinoma. There was, however, an association between advanced N stage (IIIa) and presence of extrathoracic metastases for squamous cell cancers. None of the stage I intrathoracic squamous cell cancers had metastases. Many patients with metastases to brain, bone, liver, and adrenal were asymptomatic. Thus these authors advocated the routine performance of preoperative upper abdominal CT and/or ultrasonography in all patients except those with asymptomatic stage I squamous cell cancers. Brain CTs were suggested for all patients with adenocarcinoma and large cell carcinoma, as well as for those with squamous cell cancer and neurologic symptoms. Bone scanning was suggested only in those patients with clinical and laboratory indications of possible bone involvement by metastatic disease.

A recent study by Quint and colleagues found 21% overall prevalence of distant metastases in 348 patients with newly diagnosed NSCLC. [155] In 56% of patients with distant metastases, the lesions were detected using chest or abdominal CT. Brain, bone, liver, and adrenal glands were the most common sites of disease, in decreasing order. Brain metastases often occurred as an isolated finding. On the other hand, isolated liver metastases were uncommon, and therefore the incremental yield of abdominal CT over chest CT was quite small. Thus these authors concluded that abdominal CT does not appear to be an effective method of screening for

metastases if chest CT has been performed.

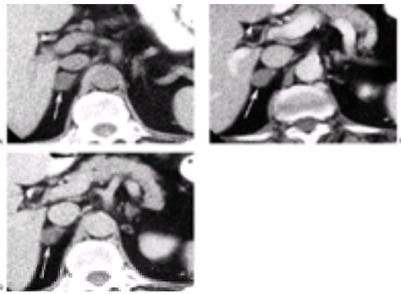
Despite the high prevalence of adrenal metastases from bronchogenic carcinoma, approximately two thirds of adrenal masses in patients with NSCLC actually represent adenomas, rather than metastases.[156] Adrenal adenomas are found in about 3% to 9% of autopsies on adults,[157,158] and approximately 1% of patients undergoing abdominal CT have benign incidental adrenal masses larger than 1 cm.[159] In a recent study of 546 patients with lung cancer, 22 of 546 (4%) patients had one or more adrenal masses on preoperative CT.[160] Seventeen of 22 had proof of adrenal status via either biopsy or follow-up. Five of these 17 were malignant (29%) and 12 of 17 were benign (71%). These authors reported that adenomas were well defined and low in attenuation and showed a smooth, high attenuation rim and involvement of only part of gland. Features of metastases included a low attenuation, large (over 5 cm) mass without a rim and irregular, mixed attenuation.[160] Unfortunately, there is significant overlap in the appearance of adrenal metastases and benign adenomas on routine, contrast-enhanced CT. Therefore detection of an adrenal mass on such a study requires further workup. Considerable work has recently been done using noncontrast CT delayed enhanced CT, and MR in evaluating adrenal masses[161,162,163,164 and 165] (Figure 30.23, Figure 30.24). Using these techniques, it is often possible definitively to diagnose benign adrenal cortical adenomas without biopsy. If these imaging studies suggest the presence of a metastasis, biopsy proof is generally required before altering therapy.


FIGURE 30.23. A: Benign adrenal cortical adenoma (arrow) showing typical density and enhancement characteristics at CT. Right adrenal nodule shows low density (14 HU) on a precontrast image. B: The nodule enhances significantly (65 HU) during administration of intravenous contrast. C: There is substantial washout on a 15-minute delayed image (29 HU).
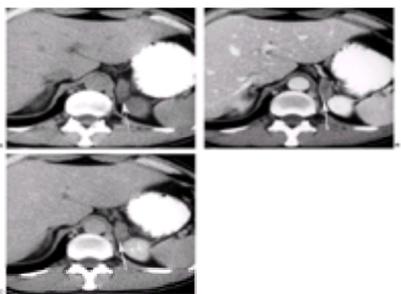

FIGURE 30.24. A: Adrenal metastasis (*arrow*) showing typical density and enhancement characteristics at CT. Right adrenal nodule shows soft tissue density (25 HU) on a precontrast image. B: The nodule enhances significantly (54 HU) during administration of intravenous contrast. C: There is little washout on a 15-minute delayed image (53 HU).

Usefulness of CT in Clinical T1N0M0 Patients

There is substantial controversy over the usefulness of CT in the preoperative evaluation of patients with radiographic T1N0M0 cancers. Reports in the surgical and radiologic literature give varying figures for the prevalence of proven mediastinal lymph node or distant metastases in this set of patients, ranging from 3% to 33%.[104,127,166,167,168,169,170,171 and 172] The lower prevalences may be underestimations, reflecting incomplete mediastinal nodal sampling and/or lack of good-quality preoperative abdominal CT scanning. Because distant metastases remain a contraindication to thoracotomy, and known mediastinal metastases will alter treatment at many institutions, CT is potentially useful by detecting such occult disease. In the series of Parker and associates[167] CT evidence for unresectable spread of disease was obtained in 12 of 36 patients with radiographic T1N0M0 disease, including metastases to the liver (four patients), the adrenal (one patient), an axillary lymph node (one patient), and mediastinal lymph nodes (eight patients). Conces and colleagues[172] reported CT signs of inoperability in 7 of 26 radiographic T1N0M0 cases with surgical correlation (27%). Metastatic disease was confirmed in four of these seven cases, including mediastinal metastases in three (3 of 26, 12% prevalence) and one contralateral lung malignancy. Of 31 radiographic T1N0M0 patients reported by Heavey and co-workers,[171] eight (26%) had proven spread of disease, including six patients with malignant mediastinal lymph nodes (19% prevalence), one with an adrenal metastasis, and one patient with a metastasis to the contralateral lung. CT detected five of these eight cases, thus preventing thoracotomy in five of 31 (16%) patients. As noted by Heavey and co-workers,[171] preventing thoracotomy in only 16% of patients resulted in significant overall cost savings, even when the cost of CT scans and prethoracotomy biopsies is taken into account. Thus these studies suggest that CT is highly useful in the preoperative workup of such patients.

On the other hand, another study of radiographic T1N0M0 tumors by Pearlberg and colleagues[170] found only two of 23 (8.7%) patients with proven mediastinal metastases; however, these patients did not undergo total mediastinal nodal sampling, and thus the true prevalence may have been somewhat higher. CT findings averted thoracotomy in only one patient, due to mediastinal adenopathy subsequently proven at mediastinotomy to contain metastatic disease. Becker et al.[168] in a prospective investigation of thirty-eight patients with presumed lung cancer (radiographic T1N0M0), found proven mediastinal nodal metastases in only one patient. Eleven of thirty-eight lesions turned out to be benign. Thus, preliminary data indicate that CT may be helpful and cost-effective in the preoperative assessment of patients with radiographic T1N0M0 lesions when the diagnosis of lung cancer has been proven.

Predicting Resectability with CT

Prediction of resectability depends upon accurate detection of T4, N3, and/or M1 tumors. One prospective study of 96 patients with lung cancer and preoperative CT found a 12% prevalence of unresectability.[173] CT criteria for unresectability included encasement of the proximal pulmonary arteries or carina, or gross mediastinal involvement by tumor, or widespread lymphadenopathy or distant metastases. Using these criteria, CT was 96% accurate and showed 97% positive predictive value and 50% negative predictive value for resectability. Therefore CT was useful in the preoperative setting in this patient group.[173]

Current Usefulness of CT

In 1986, Epstein and associates surveyed 533 thoracic surgeons to see how CT has affected the preoperative evaluation of bronchogenic carcinoma in their practices.[174] Thirty-six percent of surgeons routinely requested CT and 62% requested CT selectively, depending on tumor size, location, and presence/absence of mediastinal abnormality on chest radiographs. Seventy-eight percent of surgeons used the CT information to direct nodal sampling at mediastinoscopy or mediastinotomy. However, nearly all (99%) would not accept enlarged mediastinal lymph nodes at CT as proof of unresectability. CT was used mainly to assess lymph node size, and secondarily to assess technical feasibility of tumor resection. Fifty-seven percent said a normal CT should eliminate prethoracotomy mediastinoscopy/mediastinotomy. Most surgeons still adhere to these premises, although it is now extremely rare for a patient to have lung cancer surgery without a preoperative CT.

It is important for the radiologist to know what treatment options are available at his or her particular institution and what features of the tumor or its spread would affect treatment decisions. At many institutions, proven T4, N3, or M1 disease is considered unresectable. Patients with N2 disease may be treated with preoperative chemotherapy and radiation therapy. CT findings are used to help define the extent of the primary mass, look for calcifications that might indicate benignancy, determine its relationships with nearby structures, assess for resectability, and suggest the type of surgery required for resection. If enlarged mediastinal lymph nodes are detected, CT may be used to direct preoperative lymph node sampling via transbronchoscopic Wang needle biopsy, mediastinoscopy, or mediastinotomy. Nodes accessible to transbronchoscopic Wang needle biopsy include the paratracheal, tracheobronchial, and subcarinal groups. Transbronchial Wang needle biopsy may be facilitated by ultrasound guidance. Nodes accessible to mediastinoscopy include pretracheal, anterior subcarinal, and anterior tracheobronchial groups. Lymph nodes in the aortopulmonary window are not accessible using these techniques, and tissue sampling requires other approaches such as thoracoscopy or anterior thoracotomy. As an alternative to surgical staging procedures, some groups advocate the use of CT-guided hilar and mediastinal lymph node biopsies, [174,175,176] and [177] although this is not common practice unless the nodal masses are large (Figure 30.22).

In summary, at many institutions, preoperative chest CT (including the adrenal glands) is routinely performed on all patients suspected of having NSCLC. Abdominal CT is not generally necessary, given the low frequency of isolated liver metastases. Intravenous contrast material is administered in order to help distinguish vessels from lymph nodes and to aid in evaluation of primary tumor extent.

Many CT studies have reported high negative predictive values in detecting metastatic disease to mediastinal lymph nodes. In addition, Daly and co-workers reported that overall projected two-year and five-year survival rates for 37 CT false-negative patients in their series were 40% and 28%, respectively. [135] Given this information, many investigators believe that a negative CT obviates the need for mediastinoscopy, and these patients should go directly to thoracotomy. [110,126,135] An exception may be made for patients with T3 tumors or central adenocarcinomas, due to the high incidence of positive mediastinal lymph nodes and low negative predictive value of CT in this setting. [135] In addition, patients with suspected chest wall invasion, including Pancoast tumors, should probably have mediastinoscopy regardless of CT findings, because mediastinal nodal metastases and chest wall invasion portend a poor prognosis, and these patients are not usually felt to be surgical candidates. [68,69] In a dissenting opinion, Pearson and colleagues recommended mediastinoscopy for all T2 and T3 tumors and for T1 adenocarcinomas and large cell carcinomas, even in the setting of a negative CT. [179] On the other hand, all patients with abnormal mediastinal lymph nodes at CT need lymph node biopsy; therapy should not be planned based upon unproven, positive CT findings.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) has been used by several investigators in the assessment of patients with lung cancer, although mainly as a problem-solving tool. Advantages of MRI over CT include superior contrast resolution, the ability directly to image in any desired plane, and the ability directly to image vascular structures without the use of intravascular contrast material. However, MRI has poorer spatial resolution, and calcifications are difficult to image. MRI quality suffers due to motion artifacts (mainly from cardiac and respiratory motion), as well as vascular pulsation and bulk patient motion. (Many of these artifacts, however, have been overcome by the recently introduced breath-hold techniques.) In addition, the relatively low signal from the air-containing lung parenchyma (on spin-echo MR images) hinders the evaluation of parenchymal abnormalities. Thus the role of MRI in the detection and staging of bronchogenic carcinoma has been limited. However, MRI maybe useful in certain circumstances for the staging of bronchogenic carcinoma. [180,181,182,183,184,185] and [186]

Primary Tumor

Differentiation between Tumor and Adjacent Atelectasis or Pneumonia

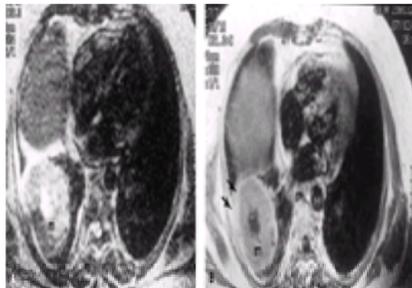
In central tumors associated with peripheral atelectasis or pneumonia due to endobronchial extension of tumor, MRI may be useful to differentiate between tumor and the associated parenchymal changes (Figure 30.25). Postobstructive pneumonitis appears as areas of high signal intensity on T2-weighted images due to the high water content, in contrast to the lower signal intensity of central tumors. This differentiation is possible in about 40% of cases. [81,187,188] However, if the patient develops organizing fibrous pneumonitis, the separation between tumor and atelectasis is not as readily performed, as areas of organizing pneumonitis may also have low signal intensity and thus resemble the central tumors. [189,190] Kono and colleagues used gadolinium-enhanced imaging to distinguish between central tumors and postobstructive atelectasis: accuracy improved from 77% on the spin-echo T2-weighted images to between 85% and 89% on the Gd-DTPA enhanced images. In 67% of these cases, the signal intensity of the central tumors was lower than that of the atelectasis, and in 18% it was higher. The tumors tended to show gradual enhancement, whereas the atelectatic areas demonstrated rapid enhancement, reaching a peak after three minutes. [191]


FIGURE 30.25. Right lower lobe tumor (*m*) with central necrosis and peripheral atelectasis. **A:** T2-weighted spin-echo image demonstrates difficulty in separating atelectasis from tumor. **B:** Atelectasis is of higher signal intensity (*arrows*) than tumor (*m*) on Gd-DTPA-enhanced T1-weighted image.

Superior Sulcus Tumors

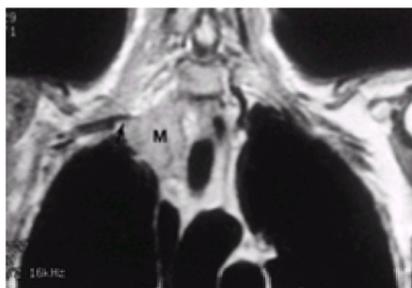
Superior sulcus tumors can result in chest wall extension and are considered clinically as a special category of lung carcinomas. They commonly involve the brachial plexus, and subclavian vessels as well as the vertebral bodies. Accurate assessment of tumor extension is critical for planning therapeutic options. CT has limitations in assessing the vertical extent of tumor due to the axial orientation of the images, the presence of beam-hardening artifacts from the adjacent bony structures, as well as poor contrast resolution. Sagittal and coronal MRIs often display the anatomic relationships in the apex more clearly than axial images, and thus are better suited to depicting apical tumor extent [192,193,194,195] and [196] (Figure 30.26). If MRI shows disruption or infiltration of the thin rim of extrapleural fat at the lung apex, tumor extension is to be suspected. These findings may be better depicted with the use of surface coils. Two published studies have reported on the relative merits of MRI as compared to CT in the evaluation of superior sulcus tumors. In a study of ten patients, seven of whom had surgical proof, MRI was accurate in depicting chest wall invasion in three, brachial plexus invasion in one, and subclavian artery encasement in one. In a study of superior sulcus tumors, Heelan and his colleagues demonstrated an accuracy rate of 94% with MRI as compared to 63% with CT for detecting tumor invasion beyond the lung apex. [197,198]


FIGURE 30.26. Relationships between apical tumor (*m*) and adjacent vascular structures (*arrow*) are clearly depicted on coronal T1-weighted spin-echo MR image.

Chest Wall Invasion

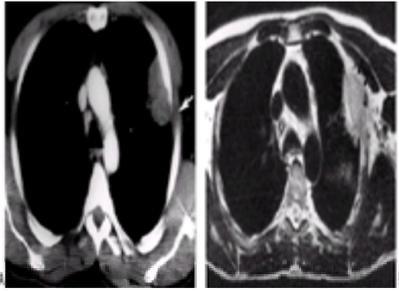
Computed tomography is limited in its ability to predict chest wall invasion. Due to its superior contrast resolution, MRI is potentially capable of demonstrating subtle chest wall invasion and may be superior to CT in this regard. Chest wall invasion is best depicted as disruption of the normal extrapleural fat by moderate-intensity soft tissue on spin-echo T1-weighted images or as high-signal-intensity tissue on T2-weighted images (Figure 30.27). The use of surface coils can provide high resolution images depicting these changes. However, inflammatory change and tumor extension into the chest wall may have similar appearances on MRI, making it difficult to distinguish between the two entities. It remains to be seen if the administration of intravascular contrast agents can help make this differentiation easier.[181,183,185,186]


FIGURE 30.27. Left upper lobe carcinoma. **A:** CT demonstrates asymmetric soft tissue in an intercostal space of the left lateral chest wall (*arrow*), suggestive of chest wall invasion. **B:** Axial cardiac-gated T1-weighted MR image shows tumor extension (*arrows*) into the chest wall musculature. Chest wall invasion was confirmed via surgery and pathology.

In a study of 13 patients with surgical and pathological proof, Haggar and colleagues demonstrated that spin-echo MRI had a negative predictive value of 100% for chest wall invasion (nine of nine patients). More importantly, in nine cases in which CT was equivocal, MRI accurately resolved the issue. [199] However, in the report of the Radiology Diagnostic Oncology Group trial (RDOG) involving twenty-three patients with surgical and pathological proof, CT and spin-echo MRI were equivalent. Areas under the receiver operating curve (ROC) were 0.857 (SE 0.036) for MRI as compared to 0.868 (SE 0.033) for CT. [74]

Padovani and colleagues reported their experience on the accuracy of MRI in detecting chest wall invasion in 34 patients with pathologic proof or CT evidence of bone destruction in areas contiguous with the tumor. Using spin-echo T1- and T2-weighted images, as well as gadolinium-enhanced T1-weighted spin-echo images, MRI had a sensitivity of 90% and a specificity of 86%. Contrast-enhanced and unenhanced spin-echo images showed equal sensitivity. [200]

Mediastinal Invasion

Both CT and MRI depict gross mediastinal invasion by lung carcinoma, although both techniques have the same limitations in distinguishing tumor contiguity from tumor extension into specific mediastinal structures.[70] Involvement of the cardiac chambers (although rare) and the pericardium can be easily evaluated with MRI. If the normal 2 to 3 mm curvilinear low-signal-intensity rim representing the pericardium is disrupted, then tumor extension into the pericardium is suspected, although this alone is not a contraindication to resection. [201,202]

In a surgical study that compared the accuracies of CT and MRI in detecting mediastinal invasion, the two modalities showed similarly poor sensitivities (55% for CT, 64% for MRI).[75] In a more recent study from the Radiology Diagnostic Oncology Group (RDOG) trials, MRI showed slightly better accuracy than CT in diagnosing mediastinal invasion in a small group of patients (n = 11): areas under the ROC curves were 0.924 (SE 0.034) for MRI and 0.832 (SE 0.034) for CT. [74]

Evaluation of Mediastinal Lymph Nodes

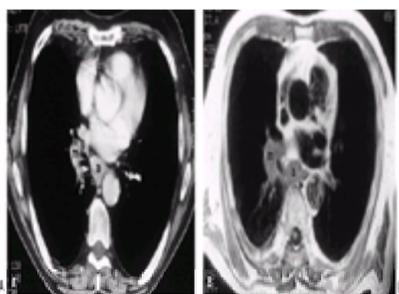
In several studies that compared CT and MRI for the detection of mediastinal nodal metastases, the two modalities have had similar results (Figure 30.28). Because both studies depend on nodal size, they show low sensitivity and low specificity. [8,74,75,187,202,203 and 204] However there are some differences between CT and MRI that need to be addressed. Because of the poorer spatial resolution with MRI, small adjacent nodes that are discrete on CT can appear as one large, indistinct mass at MRI, leading to an erroneous diagnosis of nodal enlargement. [187] In addition, MRI is poor for detecting calcification, and thus enlarged benign nodes containing calcification may be misclassified as being malignant. On the other hand, MRI has potential advantages in evaluating the aortopulmonary window and subcarinal region owing to its ability to image in the coronal plane: coronal imaging helps to eliminate the partial-volume-averaging problems that occur with axial CT images.


FIGURE 30.28. Right lower lobe mass (*m*) and enlarged mediastinal lymph nodes (*a*) are equally well seen at CT (**A**) and MRI (**B**).

CT is limited in its ability to detect normal-sized nodes containing metastases as well as in distinguishing between enlarged hyperplastic and enlarged malignant nodes. Early on, it was hoped that MRI could distinguish between normal or hyperplastic nodes and tumor-containing nodes based on differences on signal-intensity characteristics. However it later became clear that signal-intensity characteristics did not correlate with tissue type. [205,206] More recently, MRI has been performed using intravenous infusion of contrast agents that are taken up by the reticuloendothelial system, in order to evaluate for malignancy in lymph nodes. A study by Anzai and colleagues of patients with head and neck cancer found 95% sensitivity and 84% specificity for detecting malignancy in lymph nodes using MRI with dextran-coated ultrasmall superparamagnetic iron oxide particles. [207,208]

Evaluation for Distant Metastases

Conventional contrast-enhanced CT has limitations in distinguishing between adrenal adenomas and metastases. Early reports using low- and mid-field MRI scanners noted that most adenomas were hypointense or isointense with the liver on T2-weighted sequences, whereas metastases were hyperintense. [209],[210] On high-field-strength imagers, it was noted that some adenomas were of high signal intensity and thus simulated metastases. [211],[212] Thus distinction between adenomas and metastases was not possible in some cases using spin-echo MR imaging.

Krestin and colleagues have used Gd-DTPA-enhanced breath-held gradient-recalled fast imaging to attempt to separate adenomas from malignant tumors. In this study, most adenomas showed early mild enhancement with quick washout, in contrast to malignant tumors, which showed early, strong, and persistent enhancement. However, there was misclassification in nearly 10% of patients in this study. [213]

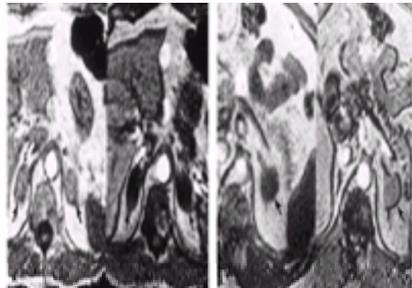
Leroy-Willig and colleagues demonstrated that adenomas contain more lipid in comparison to malignant tumors, and thus differentiation between these two groups was possible on MR spectroscopic imaging.[214] Mitchell and colleagues were one of the first groups to use chemical-shift MRI to distinguish between adenomas and metastases. They were able accurately to classify adenomas and metastases in 96% of patients. On lipid-sensitive out-of-phase images, lipid-rich adenomas showed signal loss and appeared dark in comparison to a reference organ such as the spleen. [215] Most metastases, however, do not show this change on the out-of-phase images. This early work has now been corroborated by several other investigators and has an accuracy rate of more than 90% in the diagnosis of a lipid-rich adenoma[216],[217] and [218] (Figure 30.29). More recently, unenhanced CT densitometry has been used to distinguish between lipid-rich adenomas and nonadenomatous masses. Using a threshold of 10 HU, an accuracy of over 90% can be achieved for the diagnosis of a lipid-rich adenoma. [162],[219] In cases where unenhanced CT shows an adrenal mass with a density measurement of more than 10 HU or MRI shows a mass which does not lose signal intensity on opposed-phase images, the mass is classified as non-lipid rich and needs a biopsy or resection for further evaluation.


FIGURE 30.29. MR phase imaging of adrenal masses (left images, in phase; right images, out of phase). **A:** Bilateral adrenal cortical adenomas (*arrows*) lose signal and become dark on out-of-phase MR images, confirming that they contain lipid. **B:** In a different patient, the left adrenal metastasis (*arrows*) does not lose signal on the out-of-phase image.

NUCLEAR MEDICINE

Introduction

As is discussed elsewhere in this chapter and text, after a pulmonary nodule is identified, it must be determined whether it is of malignant or benign etiology. If malignant, a careful assessment of the extent of the tumor is generally performed to determine if it is likely to be fully resectable. This is done because only about 15% of patients with lung cancer will survive five years following surgery. Patients who die do so because the disease was not fully removed at the time of surgery. If the disease appears to be resectable, it is also necessary to determine whether the patient's cardiac and pulmonary function are sufficiently good to allow for survival of the requisite surgical procedure. After surgery, or if nonsurgical approaches to management are undertaken, assessments for recurrent disease and/or treatment response are generally undertaken. Nuclear medicine procedures can contribute to the aforementioned assessments. Many of the applications of nuclear medicine in lung cancer imaging are described in the following section. The discussion is divided by type of scan and its current and potential methods of clinical application. This is a relatively rapidly emerging area with several new techniques recently entering clinical practice. With US Medicare reimbursement for FDG PET imaging for the evaluation of both the solitary pulmonary nodule and for lung cancer staging, there has been rapidly growing use of the PET imaging method.

Ventilation/Perfusion Scintigraphy

Assessments of pulmonary perfusion/ventilation are an important part of the algorithm for determining if a patient with lung cancer will have adequate pulmonary function following thoracotomy. Since many patients who have lung cancer also have moderate to severe obstructive airways disease, loss of an entire lung at surgery may be sufficient to compromise already borderline pulmonary function to such an extent that they would become pulmonary cripples or not survive the operation due to the loss of lung function. While assessments of pulmonary function by spirometry are quite useful, these assessments provide an index of whole-lung function, not lateralizing information regarding pulmonary function.

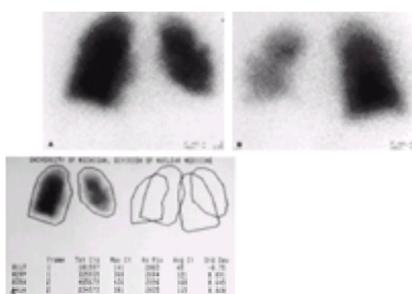
While not fully studied in a prospective manner, a variety of studies have indicated that a minimum pulmonary function level compatible with life is about 0.8 to 1.0 liters exhaled in 1 second (FEV1).[220] Thus, after curative resection of lung cancer, this level of pulmonary function should be present to allow for satisfactory oxygenation. The general approach taken in attempts to predict pulmonary function postoperatively is to perform a ventilation/perfusion (or just perfusion) lung scan preoperatively to ascertain what fraction of total pulmonary ventilation or perfusion is from the lung which is to be removed. In brief, the quantitative fraction of perfusion or ventilation in the proposed residual lung is multiplied times the pre-operative FEV1 to result in the predicted post-operative FEV1. [221] If this number is more than 0.8 liters, the patient's predicted pulmonary function is considered adequate. Whether perfusion, as determined by Tc99m macroaggregated albumin distribution, or ventilation is chosen does not appear to make a large difference in outcome, as ventilation and perfusion are generally comparably impaired. In practice, fractional perfusion is most commonly used as a predictor in most centers, as this parameter is quite easily measured. While aerosols are being more commonly used in ventilation studies, data on the predictive value of aerosol ventilation studies are not yet available. Thus, in many centers, predictions are based on the fractional perfusion.[222] An example of a quantitative lung perfusion study is shown in Figure 30.30.


FIGURE 30.30. Preoperative anterior (**A**) and posterior (**B**) pulmonary perfusion study (Tc99m MAA, lung scan) in a patient with left lung cancer scheduled for pneumonectomy. Twenty-eight percent of perfusion goes to the left lung as determined by region of interest analysis (**C**). With a preoperative FEV1 of 2.0 liters, this scan predicts a postoperative FEV1 of 1.44 liters, well above the 0.8 liters considered sufficient for survival postoperatively.

Bone Scanning

The use of the bone scan in the preoperative assessment of patients with newly diagnosed NSCLC cell lung cancer is somewhat variable based on practice locale. In general, it is agreed that surgical resection of the primary tumor in a patient with bone metastases is likely to be a fruitless undertaking. Gravenstein and colleagues reported death within six months in forty of forty-six patients with bone metastases.[223] Therefore, known bone metastases generally suggest an approach to therapy aimed at palliation, not cure. Thoracotomy entails the risk of death from surgery, pain, associated morbidity, and substantial costs of up to $40,000. Thus preventing an unnecessary thoracotomy can lead to large cost savings as well as improved medical care. Because a bone scan costs only about $400, to detect one patient with bone metastases, many studies can be performed potentially and still be cost-effective.

The literature surrounding this test is somewhat controversial, but two recent studies have suggested an incidence of bone metastases at presentation in patients with new NSCLC of about 15%.[222] With this level of prevalence, it is quite reasonable to believe that bone scanning would be a rational procedure in each patient prior to thoracotomy. Another study has suggested an approximately 9% prevalence of metastases in such patients.[225] Algorithms have emerged to suggest that, instead of performing a bone scan on all patients with newly diagnosed lung cancer, the numbers of scans could be reduced by 50% through selection of patients at "high risk" for metastases based on clinical and laboratory findings. These findings included bone pain, chest pain, pain or tenderness on motion, an elevated serum alkaline phosphatase, or an elevated serum calcium level. At least one of these findings was present in any patient identified with bone metastases in a series of 110 patients with NSCLC.[225] Others argue that a bone scan should be performed if the primary tumor is physically large or in any lung cancer with small cell histology.

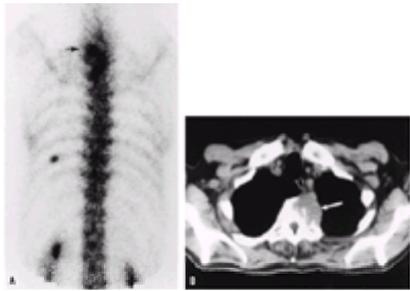
Thus it can be recommended that an algorithm be adapted in which bone scans are performed in a higher prevalence subset of patients, who number about half of the total referred with lung cancer. Cost-benefit analysis appears to support this approach, though practice patterns may differ by institution. It should also be realized that additional costs beyond the bone scan will be incurred with a pattern of care including the use of bone scans. For example, additional radiographs may be necessary in some instances to be certain that the abnormality seen on bone scan is a metastasis as opposed to a benign skeletal abnormality. A bone scan illustrating direct tumor involvement in the thoracic spine is shown in Figure 30.31.


FIGURE 30.31. Posterior view from bone scan performed three hours after intravenous injection of Tc99m methylene diphosphonate (MDP) **A:** Focal increased uptake noted in left upper thoracic spine (*arrow*) and left seventh rib. CT showed tumor invasion into spine **B:** Patient judged unresectable and treated with radiation therapy.

The bone scan is also important in follow-up and is capable of demonstrating metastases to bone in symptomatic and asymptomatic patients. The degree of vigor chosen in pursuing skeletal metastases postoperatively is generally less than in the preoperative patient. As in most neoplasms, identification of large metastases in weight-bearing bones which are at increased risk of fracture and the detection of destructive vertebral lesions are of greatest importance. These lesions can be irradiated before damage such as spinal cord encroachment or pathological fracture occurs. Recently it has been suggested that PET imaging with FDG could supplant the bone scan for staging, but in most institutions PET is not available, so the bone scan remains very commonly performed as a staging procedure.

Gallium, Thallium, and MIBI Imaging

67 gallium and 201 thallium have been used in lung cancer imaging for a number of years with variable clinical results. While there was substantial popularity of 67 Ga in the pre-CT era, its use has declined significantly with the availability of CT. The 67 Ga scan can, however, detect many primary and metastatic mediastinal foci of lung cancer.[226] In addition, SPECT imaging equipment is improving, and the use of multi-head SPECT systems should result in increased sensitivity for smaller lesions. At present, however, the relatively low uptake of 67 gallium in lung cancers makes reliable detection of tumor foci less than 2cm in diameter difficult. In addition to relatively poor sensitivity in small lesions, 67 gallium uptake occurs into some inflammatory lymph nodes, decreasing the specificity of the method. One prospective study showed 67 Ga to have a sensitivity of less than 25% and accuracy of about 60% in detecting mediastinal nodal metastases.[227] Thus, in most centers, 67 Ga is no longer used in the assessment of primary or metastatic lung cancer.

TI-201, a potassium analog, accumulates in viable cancer cells and can, especially with SPECT, image many larger primary lung cancers. The current literature suggests that the accuracy of lung cancer imaging with 201 TI appears to be somewhat superior to 67 Ga, but this tracer has not been as extensively explored in lung cancer imaging.[227] Preliminary data from two series of 9 and 37 patients, respectively, suggest that lesions in lymph nodes and primary tumors greater than 1.5 to 2 cm in diameter can be detected by tomographic techniques.[228,229] The detection sensitivity in smaller lesions is not as good, however.[228,229 and 230] In a larger series mainly using planar imaging, the sensitivity of TI-201 for primary lung cancers was 86%, but only a small fraction of mediastinal lymph node metastases was detected.[231] These observations led Sehwell and colleagues to conclude that TI-201, at least with planar imaging, was probably of limited value in lung cancer staging.[231] TI-201 has also been preliminarily evaluated in monitoring therapy for lung cancer patients.[232]

Suga and associates have examined the ability of TI-201 scintigraphy to separate benign from malignant solitary pulmonary nodules.[233] Images obtained fifteen minutes after TI-201 injection showed no differential uptake between malignant and benign lesions, but imaging at three hours postinjection showed an 81% accuracy in separating the lesions of differing histologies. This difference was due to more avid retention of TI-201 in malignant than benign lesions. Additional studies in larger patient populations will be needed to determine the role of TI-201 in lung cancer imaging and staging. At present, in most clinical practices it remains an investigative tool.

SPECT using technetium-99m methoxyisobutylisonitrile (MIBI) has been used in the assessment of SPNs, with limited success. For example, Kao and colleagues used SPECT to evaluate fifty-four patients with SPNs and ten controls.[35] Of the SPNs, 46 were bronchogenic carcinomas and eight were benign. SPECT detected only thirty of the forty-six carcinomas, and also detected six of eight benign lesions. Thus this technique did not appear to be particularly helpful.

Myocardial Perfusion Imaging

While a major concern in the management of patients with newly diagnosed lung cancer is whether the disease is surgically resectable, it must also be determined whether the patient has an acceptable risk of surgery. A determination of operative risk as regards loss of pulmonary function using ventilation/perfusion scanning was discussed earlier in this chapter. However, an additional consideration is the potential of death during surgery or in the perioperative period due to a cardiac event such as myocardial infarction. Many patients with lung cancer are smokers. Smoking is a risk factor for lung cancer and coronary artery disease. Thus some patients will have both coronary artery disease and lung cancer. Patients with severe coronary artery disease are at an increased risk of death during major surgeries. While most of the literature regarding risk stratification for surgery has emerged in the setting of preoperative vascular surgery, it is clear that many physicians now apply preoperative myocardial perfusion imaging in an attempt to define patients at high and low risk of cardiac death following thoracotomy.[234] Brown has recently reviewed this general area, and concludes that patients considered for major surgery who have significant cardiac risk factors should be considered for myocardial perfusion scintigraphy preoperatively.[234] Patients with reversible myocardial perfusion defects on TI-201 stress scintigraphy are considered to be at a high risk of infarction/death, versus the group with normal or fixed defects on scan. Eagle and colleagues reported that, in 116 patients undergoing major abdominal vascular surgery, in an intermediate risk group those without redistribution on TI-201 scans showed a 3.2% risk of a cardiac event, while those with TI-201 redistribution had a

much higher 29.6% risk of a cardiac event.[235] It is generally believed that correcting the cardiac perfusion defect will reduce the risk of perioperative morbidity/mortality, though this is not as well studied as the risk stratification power of TI-201. While detailed prospective study of the predictive value of myocardial perfusion scintigraphy in lung cancer patients is lacking, myocardial perfusion imaging is a powerful predictor of outcomes in patients who undergo other major surgical procedures. This technique is being applied to assessing patients who are considered for surgery who may have coexistent coronary artery disease.

Adrenal and Hepatic Imaging

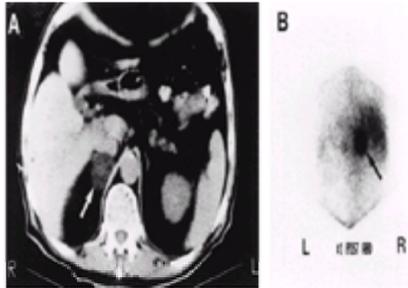
CT has revolutionized the anatomic evaluation of the upper abdomen, but despite its power, it is not a perfect test. Two areas of difficulty include adrenal masses and liver lesions. It has been possible to distinguish between malignant and benign adrenal lesions in many instances by evaluating the adrenal uptake of 131 I NP-59, an iodocholesterol analog. Metastases to the adrenal are not uncommon in patients with newly diagnosed lung cancer, presenting as an enlarged adrenal; however, benign nodules in the adrenal are common as well. Francis and associates studied this issue in twenty-eight patients with known cancer who had adrenal masses identified during their staging CT exam.[236] In this study, 131 NP-59 was administered intravenously, and several days later gamma images of the adrenals were obtained. Biopsy confirmation of diagnosis was obtained. Of the fourteen cases with increased ^{131}I NP-59 tracer uptake in the enlarged adrenal, all were adenomas. If there was decreased or symmetric uptake of tracer, metastatic tumor could not be excluded and was present on biopsy in ten cases. Adrenal cysts could also have diminished uptake. In some very large adrenal lesions, larger than 5 cm, increased tracer uptake can be seen due to adrenal cancer, though this is a rare occurrence. In brief, if there is increased uptake of NP-59 into a moderately enlarged adrenal gland, there is a very low probability that the lesion represents a lung cancer metastasis (Figure 30.32). If the adrenal is "cold" on NP-59, a biopsy would be necessary to determine the etiology of the lesion (Figure 30.33). Recent studies of the cost-benefit of adrenal imaging with NP-59 have shown the method to be cost-effective. At present, this scan is available at only a few institutions, and many institutions without this agent perform CT-guided adrenal needle biopsies to resolve this problem. PET, however, is showing considerable promise as a radionuclide method to evaluate the adrenals and is already more widely available than the NP-59 method.


FIGURE 30.32. A: CT shows right adrenal mass in a patient with normal adrenal function. **B:** Posterior images four days postinjection of 131 I NP-59, an iodocholesterol analog, demonstrate intense tracer uptake in right adrenal mass ("concordant" pattern). Thus the mass represents functional adrenal tissue consistent with benign adrenal cortical adenoma, not a metastasis.
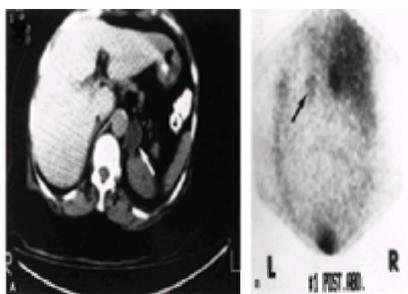

FIGURE 30.33. A: CT demonstrates left adrenal mass in a patient with lung cancer. **B:** NP-59 scan shows diminished tracer uptake on left and normal uptake on right ("discordant" pattern). This suggests that the left adrenal mass represents a metastasis. (From Gross M, Shapiro B, Bouffard J, et al. Distinguishing benign from malignant adrenal masses. *Ann Intern Med* 1988;109:613, with permission.)

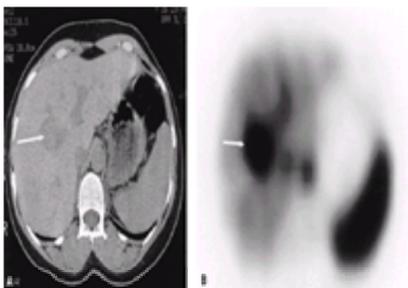
A second area of application of nuclear medicine studies is in the liver. Hepatic hemangiomas are commonly found in patients with cancer as incidental findings. While the CT findings are characteristic in most cases, 30% of these lesions are atypical in appearance. Ziessman and associates have shown, using triple-head SPECT, that imaging of red blood cells labeled with Tc99m allowed visualization of 20/20 hemangiomas greater than or equal to 1.4 cm in diameter. [237] This is in contrast to planar or single-head SPECT, where small lesions are commonly undetected. For example, with single-head SPECT, the sensitivity for hemangioma detection was only 38% for lesions between 1 and 2 cm in diameter, while for planar imaging, lesions under 3 cm in diameter were not uncommonly missed. [238] The hemangioma scan is highly specific for hemangioma in the liver, with only rare false positive cases including very large hepatomas, one carcinoid, and one hepatoblastoma reported to date. These are very uncommon, however, and in a series of 45 hepatomas studied in Japan, none of the patients had evidence of increased uptake of Tc-labeled red blood cells. This area has recently been reviewed by Rubin and colleagues. [239] Scan utilization patterns differ by institution, but the nuclear scan is much less expensive than an MRI scan and is the procedure of choice for lesions of over 1.5 cm in diameter (Figure 30.34).


FIGURE 30.34. A: CT scan shows 3.5 cm right hepatic lesion (arrow) which is of indeterminate etiology in this lung cancer patient. **B:** Tc99m-labeled red blood cell triple-head SPECT scan obtained one hour after the injection shows intense tracer uptake in the liver, diagnostic for hemangioma. Intense activity also noted in spleen, portal vessels, descending aorta, and inferior vena cava.

Antibody Scanning

The concept of imaging tumors with monoclonal antibodies reactive with specific tumor antigens is an attractive one which has been under study for the past 15 years.[240] The approach has clinical utility in imaging colorectal cancers and has been applied to lung cancer in several trials. At present, there is no FDA-approved

radiolabeled monoclonal antibody for lung cancer imaging, though several clinical trials have demonstrated that there is potential for this methodology. These studies have involved anti-CEA (anti–carcinoembryonic antigen) antibodies and antibodies reactive with high-molecular-weight mucins. In NSCLC, several studies have shown that primary tumors can be imaged with 75% to 100% sensitivity, although some accumulation also occurred in nonmalignant tissues with specificities in the 25% to 75% range[241,242] and there was a problem in detecting tumors less than 2 cm in size in many instances. Thus, while feasible, this technique did not appear particularly helpful for the assessment of primary lung nodules.

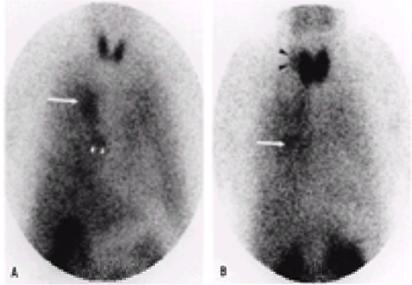
A large prospective trial of the NRLU-10 murine antibody, which recognizes a 40 kD cell surface glycoprotein expressed by many epithelial cancers, was performed in the United States. With a Tc99m label, the Fab fragment of this antibody demonstrated a sensitivity for detection of the primary lesion of over 90%, detection of several more nodal metastases than seen by CT.[243,244] In a presurgical series, Rusch and colleagues had five false-positive antibody scans of the mediastinum/hilum in a series of 21 patients.[245] Separation of blood pool activity from normal nodes has been problematic, but the results are at least as good as CT in staging the mediastinum (Figure 30.35).


FIGURE 30.35. A: Anterior view from Tc99m NRLU-10 Fab (monoclonal antibody fragment) scan 17 hours post tracer injection shows uptake into right lung NSCLC (*arrow*) and mediastinal metastases (*arrowheads*) (proven at surgery). Uptake in thyroid and clearance of radiotracer through the gut/billary tree are normal findings. B: Scan with the same reagent in a different patient with small cell lung cancer. Uptake demonstrated in right thoracic primary lesion (*arrow*) and in tumor adjacent to the right lobe of the thyroid (*arrowheads*). (Images, courtesy of Dr. H. Breitz, Virginia Mason Medical Center, Seattle, WA.)

An attractive aspect of nuclear medicine studies with tumor-avid agents is the potential for screening the entire body with a scan. This is becoming possible in NSCLC, with detection rates of known metastases in the area of the 90% range with the NRLU-10 mab, except in bone metastases, where the detection rate is substantially lower, with the antibody scan an inadequate substitute for the bone scan. [246]

Small cell lung cancer (SCLC) also expresses antigens on the surface which may be satisfactory targets for monoclonal antibody imaging. The staging procedure in SCLC is generally simpler than in NSCLC as SCLC is generally not a surgical condition. Rather, a decision has to be made if the disease is limited (to receive radiation therapy and chemotherapy) or extensive (to receive chemotherapy only). This decision is often made by bone marrow biopsy. An imaging study of 96 patients from 21 sites was performed with the Tc99m NRLU-10 mab. In this study, the antibody scan was the single most accurate test when compared to CT, bone scan, or bone marrow aspirate. False-positives in this study were rare, with a positive predictive value of the test of more than 95% with about a 10% understaging rate.[246,247] Thus it is possible that in SCLC, the antibody scan might replace standard imaging methods for staging.

With antibodies, a concern exists that a foreign protein is being administered and the patient receiving the antibody may develop an immune response to the antibody. Indeed, up to 25% of patients with NSCLC developed an antimouse response to the antibody infusion. [245] This may limit follow-up studies. The antibody infusion was safe, however. To date, however, the utilization of this monoclonal antibody scan in staging lung cancer has been quite modest, and this method has not found general acceptance, despite being FDA-approved.

Small peptides reactive with receptors on the surface of SCLC have recently been used in clinical imaging studies and have demonstrated feasibility of concept. One of the peptides, reactive with the somatostatin receptor, is already an approved agent in Europe. The exact role of this agent in SCLC imaging requires further study, as not all of the tumors are receptor-positive. [248] This type of approach is attractive in that the peptides generally do not cause an immune response due to their small size, and can be given repeatedly. Recently, a Tc99m-labeled peptide (P-829) reactive with somatostatin receptors has been shown to be promising in assessing both NSCLC and SCLC.[249] It is possible that this agent may be clinically available for lung cancer imaging in late 1999, although the exact method for using this agent will be in evolution as clinical experience has been relatively modest. Preliminary data suggest the agent to be most useful in characterizing pulmonary lesions as malignant or benign, and the data suggest the agent will be useful in the more common non–small cell phenotype of lung cancer. The precise role of this agent in staging lung cancer is not yet developed.

Antibody, and potentially peptide, imaging may assume a growing role in the detection of lung cancer, with data very promising in SCLC and encouraging in NSCLC, especially for the Tc99m-labeled P-829 peptide. Clinical experience in lung cancer with both the peptides and antibodies remains limited, however. Nonetheless, this area of imaging has substantial potential.

Positron Emission Tomography (PET)

The most rapidly emerging application of nuclear medicine techniques for the assessment of solitary pulmonary nodules and possible metastases of lung cancer is positron emission tomography (PET). This method differs from standard nuclear medicine imaging in that short-lived isotopes are used which emit positrons. The positrons then interact with normal tissue electrons to produce pairs of 511 KeV photons which then can be detected by the very sensitive positron emission tomographic camera.

Lung cancer has been successfully imaged in several trials using PET with both 11C methionine and FDG. Kubota and co-workers first reported successful imaging of lung cancer in eight of eight patients with primary lung cancers, with substantially more 11C methionine uptake in tumor than in normal lung tissue. [250] In a follow-up series of 16 patients, the investigative team from Tohoku University showed increased 11C methionine uptake in each case of primary lung cancer, with somewhat more 11C methionine uptake in the large cell than in the squamous cell carcinomas. [251]

Nolop and co-workers showed that FDG accumulated in 12 of 12 lung carcinomas studied with FDG, with all histologies imaging in the study. Mean tumor to nontumor ratios of over 6:1 were seen, and no obvious correlation was observed between tumor grade and FDG uptake in this small series. [252] Investigators from Tohoku University in Sendai, Japan, showed that about 85% to 90% of solitary pulmonary nodules are detected by PET with either FDG or methionine. They observed an elevated SUV (standardized uptake value) of tracer uptake with FDG and methionine in patients with lung cancer, while in benign lesions the SUV was significantly lower.[31] Similar results were recently reported by Gupta and colleagues, who showed that FDG uptake into primary lung cancers was significantly greater than that seen into benign pulmonary lesions, with SUV of 5.63 plus or minus 2.38 (SD) in malignant and 0.56 plus or minus 0.27 (SD) in benign lesions (p = less than 0.001). [32] Patz and colleagues demonstrated that FDG PET is very effective at separating primary lung cancers from inflammatory processes in the lung, based on the lesion SUV. In a series of 51 patients with focal pulmonary abnormalities (of which 38 were solitary pulmonary nodules), it was noted that the 33 malignant lesions had an SUV of 6.5 plus or minus 2.9 (SD), while benign lesions had an SUV of 1.7 plus or minus 1.2 (SD). Thus an excellent separation between benign and malignant lesions by SUV was possible.[253]

Kubota and colleagues also compared the accuracy of FDG and methionine PET in assessing pulmonary nodules. Both methionine and FDG were comparable in their imaging accuracies, with a 93% sensitivity, 60% specificity, and 79% accuracy for methionine, and an 83% sensitivity, 90% specificity, and 86% accuracy for FDG. Tumors less than 1 cm in diameter were noted to be particularly difficult to evaluate because of their small size relative to the resolution of the PET scanner. [31]

The ability of PET to separate malignant from benign lesions is high but not totally perfect. Thus high tracer uptake can sometimes be seen in an inflammatory or infectious process, such as aspergillosis or TB. Preliminary reports suggest that the smallest of pulmonary nodules may not be as well characterized by PET as larger

nodules, possibly due to their motion in the PET scanner field of view and the incomplete signal recovery from small lesions. This results in underestimation of their SUV, unless a correction for scanner resolution is applied. The whole-body PET technique has also been applied to the detection of intrathoracic masses, and in the eight patients with bronchogenic carcinoma, there was clear visualization of the tumors by PET as areas of increased focal tracer accumulation. [255] Several metastatic lung nodules could also be detected by this approach, though it must be realized that quantification is not possible with this method. This method allows evaluation of the entire body.

A prospective multicenter trial of FDG PET was performed in eighty-nine patients in the assessment of solitary pulmonary nodules by Lowe and colleagues. [256] This study showed that, using SUV data, PET had an overall sensitivity and specificity for detection of malignant nodules of 92% and 90%, respectively. Some differences in sensitivity were seen with smaller lesions, so that for the smaller lesions (less than 1.5 cm) visual analysis, as opposed to quantitative analysis, was of greater sensitivity. A trial from Germany in fifty-four pulmonary lesions-3 cm or less in diameter showed PET to be 90% sensitive and 83% specific in lesion characterization (as malignant or benign). [257] False-negatives included two bronchial carcinomas and one metastasis. With a prevalence of 4% to 10% false-negatives, there are risks of missing tumors if PET is the only test performed. Most would recommend follow-up imaging tests of solitary pulmonary nodules following a negative PET to exclude tumor growth, as a small percentage of patients with negative PET scans of SPN will have malignant tumors present. This seems to occur with greater frequency in bronchioloalveolar cell carcinomas, for example, which have considerably lower uptake of FDG than other lung cancers. [258] It is suggested that CT always be examined along with the PET study to be certain that bronchioloalveolar cell carcinomas are not missed on PET due to their lower tracer uptake. Nonetheless, PET is a very accurate, but not perfect, method for evaluating solitary pulmonary nodules noninvasively.

Another issue in lung cancer management is whether the tumor has spread to the mediastinal lymph nodes. This question is of substantial importance in NSCLC, where cure is generally possible only with complete excision of viable tumor from the thorax. In contrast, SCLC is more commonly treated nonsurgically by chemotherapy or irradiation. With NSCLC, it has been recognized that if there is tumor involvement of the mediastinum at the time of initial diagnosis, the patient's probability of survival for five years is reduced to just 5% to 10%. By contrast, if there is no mediastinal lymph node involvement, five-year survival is increased to a 40% to 50% probability. Knowing if there is mediastinal tumor involvement can alter the approach to management as in high-risk patients for surgery, thoracotomy may be inappropriately risky if there is a very high likelihood of mediastinal tumor involvement. There are only limited data published to date on this topic. A report on 25 patients studied with 11C methionine PET showed that there was higher 11C uptake in the tumor-involved lymph nodes than in the tumor-negative nodes (3.89 versus 2.38 mean SUV) (p = less than 0.001) and that with threshold setting post hoc, a nearly 90% accuracy in detecting mediastinal metastases could be defined. [259]

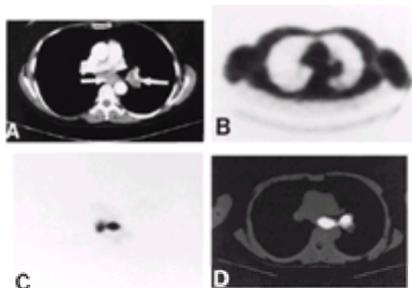
Data recently reported from the University of Michigan showed FDG PET to be significantly more accurate than CT in staging presumed NSCLC. In a prospective study of 23 patients, PET was about 82% accurate, while CT was 52% accurate (p = less than 0.05).[260] PET had the capability to detect tumor in some normal-sized lymph nodes and to exclude tumor involvement in enlarged lymph nodes in multiple instances. A preliminary report from Heidelberg, Germany, has shown even better accuracy for FDG PET but was performed with a PET scanner that had a limited field of view and thus was not able to evaluate the entire mediastinum at risk for metastases.[261] Application of quantification to the PET data may be of utility in additionally refining the accuracy of PET. It should be noted that accurately determining tracer uptake in mediastinal lymph nodes is difficult with PET, because count recovery is somewhat limited when the lymph nodes are small. Many studies on using PET for mediastinal staging have been reported in the past several years showing PET to be more accurate than CT for mediastinal staging. As an example, Vansteenkiste et al. showed the accuracy of CT and PET for mediastinal staging to be 68% and 94%, respectively. [262] A recent meta-analysis of the PET and CT literature by Dwamena, et al. has shown a sensitivity and specificity of 79% and 91%, respectively for PET, which is considerably higher than that for CT at 60% and 77%, respectively.[263] Examples of PET scan evaluating the mediastinum are shown in Figure 30.36, Figure 30.37 and Figure 30.38.


FIGURE 30.36. A: Enlarged hilar and mediastinal lymph nodes (*arrows*) on CT. **B:** Transmission PET image at the same level as in (**D**). This patient had proven metastastic NSCLC in the mediastinum. **C:** Intense uptake of FDG on emission PET. **D:** Fusion image showing increased activity in the enlarged nodes.
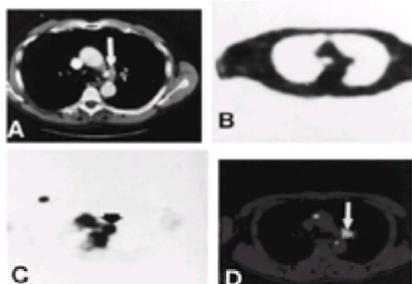

FIGURE 30.37. A: Normal-sized mediastinal lymph nodes in the aortopulmonary window (*arrow*) on CT. **B:** Transmission PET image at the same level as in (**D**). Tumor-involved, normal-sized nodes were proven at surgery in this patient with NSCLC. **C:** Increased FDG uptake in the left side of the mediastinum on emission PET. **D:** Fusion image showing increased activity in these normal sized lymph nodes (*arrow* and +).
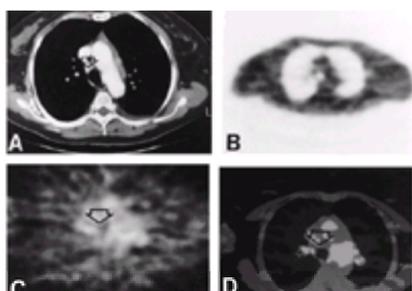

FIGURE 30.38. A: Enlarged lymph node in the right paratracheal region (*arrow*) on CT. **B:** Transmission PET image at the same level as in (**D**). This patient was found to have no tumor involvement of mediastinal lymph nodes. **C:** Enlarged lymph node in the right paratracheal region with no increased uptake over blood pool on emission PET. **D:** Fusion image confirms absence of increased FDG uptake within the enlarged node. (From Wahl R, Quint L, Greenough R, et al. Staging of mediastinal non–small cell lung cancer with FDG-PET, CT, and fusion images: preliminary prospective evaluation. *Radiology* 1994;191:371, with permission.)

Most recently, the prognostic importance of FDG PET in lung cancer has been investigated. In 125 potentially operable non-small cell lung cancer patients, the standardized uptake value (SUV), a semi-quantitative measurement of FDG uptake on PET scan, was analyzed. An SUV of greater than 7 was correlated with each survival. Moreover, the SUV of greater than 7 had the best discriminative value for prognoses, both in all patients and those detected. An SUV of less than 7 in stage Ia patients had a 2-year survival of 86%, but 2-year survival fell to 60% if the SUV was above 7. Nearly all detected tumors greater than 3 cm has SUVs of more than 7, with an expected 2-year survival of 43%.[264]

The published data regarding the ability of PET to detect visceral metastases from lung cancer are very encouraging. PET and bone scanning had, respectively, an accuracy of 96% and 66% in the evaluation of osseous involvement in 110 consecutive patients with NSCLC. The superior accuracy of PET was due to a much lower false-positive rate than bone scan.[264] The specificity of bone scans can, of course, be enhanced by comparison with skeletal radiographs. Recently, an approximately 14% rate of finding additional metastases during lung cancer staging was reported by Weder and colleagues suggesting that PET should have a growing role in staging NSCLC patients before major surgery is undertaken.[265] Specific evaluation of adrenal metastases by PET has been undertaken. As an example, in evaluating possible adrenal metastases in patients with bronchogenic carcinoma, PET has shown a sensitivity of 100% with a specificity of 80% in a study of 33 patients.[266] PET, while a very useful method for staging the entire body, can fail to detect brain metastases (for example, as their uptake can be very similar to that of normal brain, meaning lesions can be hard to detect in some instances).[267] Thus anatomic imaging is recommended for such suspected lesions. Cost analysis studies have shown that using PET to stage lung cancer is cost-effective.[268]

While FDG has been used in treatment monitoring, it should be noted that other tracers such as methionine have been employed. For example, in lung cancer treatment monitoring, declines in methionine uptake into tumors were commonly seen with effective therapy.[270] In some instances, the decline in methionine uptake was more predictive of the long-term survival of the patient than the change in tumor size. PET is rapidly emerging as a useful method in lung cancer management. Data are emerging to suggest PET plays a unique role in treatment management, both for chemotherapy and radiation therapy, but larger studies are needed to determine the precise role of PET in treatment response assessment.[271]

For all of the discussions of PET regarding lung cancer included in this chapter, the published literature has been based on dedicated PET scanning devices. In the last several years, lower-cost modified gamma camera devices capable of doing routine nuclear medicine studies (such as bone scans) and PET imaging have been developed and marketed. At present, the performance of these devices is not well characterized, but early data indicate they are considerably less accurate than dedicated PET for detecting small lesions in the chest and are particularly limited in the abdomen. As this technology emerges, performance will likely improve, but at present the limited literature available shows these devices to be inferior to dedicated PET in their accuracy. Thus, their place in clinical patient management will hinge on the accuracy determined for each device in prospective trials.

Summary

The role of nuclear medicine in the evaluation of the patient with a solitary pulmonary nodule suspected to represent lung cancer is rapidly evolving. PET and, to a somewhat lesser extent, SPECT techniques have demonstrated good accuracies in separating malignant from benign pulmonary nodules. At present, however, the accuracies are less than 100%, so they are not perfect substitutes for histological examination. At many centers, PET with a dedicated PET scanner is being applied in the more clinically difficult cases, such as the difficult-to-biopsy lesions or in patients who are a greater-than-usual risk of surgical assessment/biopsy. Data with SPECT and Tc99m-labeled peptides are emerging but are very limited as regards SPN characterization. Once the diagnosis of cancer is made, the bone scan is very important for assessing patients who have any signs or laboratory findings suggesting the presence of metastatic disease to bone. Detection of bone metastases would generally preclude operation. Recent data suggest PET to be more accurate than the bone scan in lung cancer staging. Staging the mediastinum and rest of the body with FDG PET alone is an increasingly attractive alternative to standard imaging methods. Staging of the entire patient with a single scan also appears to be possible with monoclonal antibodies reactive with SCLC—although this method is only infrequently applied at most centers. PET is expected to assume a greater role in lung cancer regional nodal staging, with recent data from many series indicating PET to be clearly more accurate than CT. It is not anticipated that PET will replace CT in the thorax, however, as anatomic information regarding the primary tumor stage will remain necessary to plan surgical procedures. Also, CT will help locate and characterize bronchioloalveolar cancers. PET can also survey the entire body with FDG, and it is possible that FDG whole-body imaging may become the only nuclear medicine staging test necessary for NSCLC (Figure 30.39, Figure 30.40). 131 NP-59 scanning has been shown to be effective in separating metastases to the adrenals from functioning adrenal tissue, saving patients from adrenal biopsies. But because of its limited availability, it is quite likely to be replaced by PET or other methods. Ventilation perfusion lung scanning can help determine whether the patient can be expected to have satisfactory pulmonary function postoperatively for respiratory survival, while myocardial perfusion studies can help identify patients at high risk for perioperative cardiac events, including death. In follow-up, bone scanning represents the most widely used nuclear medicine procedure, but the applications of PET are expected to grow rapidly as this technology becomes more widely available. Early data indicate a growing role for PET in assessing the postoperative or postradiation/chemotherapy-treated lung. Thus, nuclear medicine procedures are assuming increasing importance in the imaging management of patients with known or suspected lung cancer.

TISSUE PROCUREMENT: BRONCHOSCOPIC TECHNIQUES

DEBORAH SHURE
JOHN F. CONFORTI

Bronchoscopy has long had a role in the diagnosis of bronchogenic carcinoma, beginning with the use of rigid bronchoscopy and the increased incidence of lung cancer in the 1950s.[1,2] With the advent of flexible fiberoptic bronchoscopy, the role of bronchoscopy expanded beyond the recognition of endobronchial disease possible with rigid bronchoscopy to sampling of peripheral masses not visible in the central airways but evident fluoroscopically. More recently, the reincarnation of bronchoscopic aspirating needles (first used through rigid bronchoscopes) in a flexible form has opened the area of mediastinal staging and enhanced more standard sampling applications of bronchoscopy.

The roles of bronchoscopy in patients with bronchogenic carcinoma can be grouped into the areas of diagnosis, staging, evaluation of therapeutic outcome, and endoscopic therapeutic intervention. Varying techniques are applicable to each group, so that an overall organized strategy is important. Some exciting, as yet experimental, techniques may well alter these approaches in the next decade.

DIAGNOSIS

Endobronchial Masses

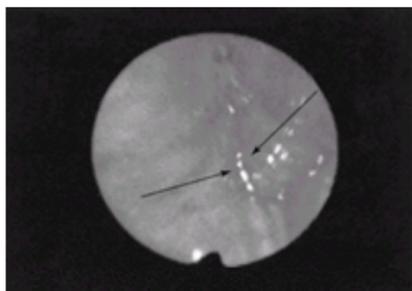
Bronchogenic carcinoma often presents as an endobronchial exophytic mass (Figure 31.1) in the central airways (mainstem to subsegmental bronchi).[1,3] This presentation is typical of squamous cell and small cell carcinoma but can occur with any cell type.[4] This form of bronchogenic carcinoma is easy to recognize endoscopically and usually easy to biopsy with standard biopsy forceps. The yield with a minimum of three biopsies should be close to 100%.[5,6] Washing and brushing do not substantially increase the yield but are inexpensive and are usually performed in addition to the biopsies for the occasional added case.


FIGURE 31.1. Endobronchial mass occluding a segmental bronchus. (See Color Figure 31.1)

Bronchoscopic needle aspiration can also be used to sample endobronchial masses, but the technique does not seem to offer an improved yield over traditional forceps biopsy. In one study of 60 patients with endobronchial lesions, forceps biopsy had an 85% diagnostic yield, whereas needle aspiration had a 65% yield.[1] Another study of 60 patients had opposite results: 80% yield with needle aspiration and 60% with forceps biopsy. Because most studies find very high yields with biopsy alone, bronchoscopic needle aspiration is unlikely to substitute for forceps biopsy in these lesions. Nonetheless, it would seem to have some limited applications in endobronchial masses. It has been suggested that bronchoscopic needle aspiration may be useful in lesions that are very friable and may bleed excessively with forceps biopsy.[8] Occasionally, endobronchial biopsies may be nondiagnostic because extensive necrosis results in sampling error. Bronchoscopic needle aspiration may improve yield by sampling deeper tissue. It may also be useful in sampling lesions located in areas in which forceps tend to slip off the bronchial wall. Finally, rapid on-site cytopathology may provide an immediate diagnosis when deemed necessary.

Submucosal and Peribronchial Tumor

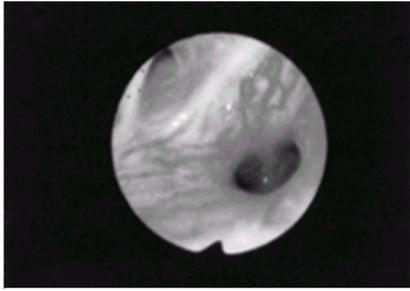
A less common presentation of bronchogenic carcinoma is submucosal spread or peribronchial involvement, which causes extrinsic compression or concentric narrowing of the bronchus.[1] In the case of submucosal spread, normal mucosal markings are often effaced and the surface may be covered with a fine network of engorged bronchial collateral vessels (Figure 31.2). This sort of tissue involvement is usually much firmer than the soft exophytic mass discussed previously and is consequently more difficult to biopsy. The diagnostic yield is considerably lower than with forceps biopsy of exophytic masses, probably because of the difficulty in sampling deeper tissue layers and because of a less dense carcinomatous process with a consequently greater sampling error.


FIGURE 31.2. Submucosal infiltration of bronchogenic carcinoma. Normal bronchial markings are lost and engorged bronchial collateral vessels are prominent. (See Color Figure 31.2)

Diagnosis of bronchogenic carcinoma in these lesions has been aided by the use of bronchoscopic needle aspiration. In one study, forceps biopsy detected 55% of such tumors, whereas bronchoscopic needle aspiration alone detected 71%. [9] The combination of forceps biopsy and needle aspiration detected 90%, and adding either a wash or a brush brought the yield to 97%. Interestingly, diagnostic yields are often incrementally increased by different sampling methods when the sampling error is higher.

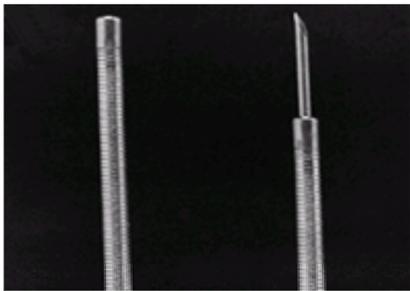
The technique for sampling submucosal or peribronchial tissue is straightforward. The needle device is advanced through the bronchoscope channel in the retracted position. Once the tip of the device is 2 cm above the area to be sampled, the needle can be advanced from its sheath (Figure 31.3). At this point, it is usually helpful to withdraw the needle's sheath into the bronchoscope channel so that only the needle remains exposed. This maneuver allows the sheath to be supported by the bronchoscope channel and gives the operator greater control over the exact placement and advancement of the needle. The needle is then inserted at an oblique angle into the submucosal layers or perpendicular to the wall in the case of suspected peribronchial disease. Once the needle is embedded in the tissue, it is moved vigorously back and forth (remaining in the site) while suction is applied to the proximal end of the device. It is, of course, important to remember to withdraw the needle into its sheath prior to removing the needle from the bronchoscope.


FIGURE 31.3. Bronchoscopic aspirating needle in retracted and advanced positions. (Olympus Corp. Lake Success, New York.)

The optimal number of aspirations has not been studied, but the percentage of adequate aspirations can be increased by on-site processing of the aspirate by a cytopathologist. In one study, the percentage of specimens with malignant cells increased from 31% to 56%. [10] This increase occurred regardless of the location of the lesion (i.e., endobronchial, submucosal, or peripheral). In the absence of rapid evaluation of the aspirate, it appears useful to do at least three aspirations in the involved area. [11] Handling of the specimen can be done in various ways that appear to be equivalent, so it is best to coordinate handling with the cytopathologist to fit individual institutional needs.

Bronchoscopic needle aspiration is also useful in nonmalignant disease, which may be relevant in the evaluation of suspected malignancy. One study found an 87% yield in patients with HIV infection and intrathoracic adenopathy secondary to mycobacterial disease. [12] In 32%, needle aspiration was the exclusive means of diagnosis. This method has also been studied extensively in the diagnosis of sarcoidosis. Optimal diagnostic yields occurred when transbronchial lung biopsy was combined with bronchoscopic needle aspiration. [13]

Despite the demonstrated utility of bronchoscopic needle aspiration, it remains an underutilized technique. A computerized survey performed at the 1995 American College of Chest Physicians Fellows' Conference found that only 10% reported routinely performing bronchoscopic needle aspiration. [14] Reported limitations at their institutions included suboptimal technique (30%), technician support (1%), cytopathology support (14%), and a combination of all of these factors (25%). Thirty percent felt that this technique was not useful. A learning curve is also necessary when performing bronchoscopic needle aspiration. One study recorded their results during a 3-year period with serial multifaceted educational interventions. Their yields increased significantly from 21.4% to 47.6%, and fewer cytologically unsatisfactory specimens were obtained. [15] Thus improved experience in training programs and ongoing education is necessary for this technique to achieve its maximum utility.

Peripheral Masses

Peripheral lung masses (including solitary pulmonary nodules) have always presented more of a diagnostic problem than lesions in central airways, and reported diagnostic yields have generally been lower, in the range of 30% to 50%. [16,17,18 and 19] Transbronchial biopsy has been the mainstay of specimen sampling of peripheral masses. Its yield is partly affected by the number of biopsies performed. Optimal yields require at least four adequate samples [5,20] with small or large biopsy forceps. Optimal yields in discrete mass lesions (as opposed to diffuse interstitial disease) require the use of fluoroscopy in more than one plane to ensure accurate placement of the biopsy instrument. Biplane fluoroscopy, rotation of the C-arm of a fluoroscope, or rotating the patient in a fixed fluoroscope all provide adequate assessment of placement.

The yield of transbronchial biopsy is affected most by lesion size. In general, poor yields (<35%) are obtained in sampling lesions smaller than 2 cm in diameter,[16,17,20,21 and 22] probably because only one bronchus tends to supply lesions this size, whereas two or more bronchi are involved in lesions 2 cm and larger, increasing the likelihood of the forceps reaching the mass. [23] Computed tomographic evidence of a bronchus leading to the lesion, "bronchus sign," predicts a higher diagnostic yield with biopsy techniques. [24] An exception to increasing yield with increasing lesion size is the case of lesions larger than 6 cm in diameter. Very large lesions tend to have significant components of inflammation and necrosis, which increase the sampling error and decrease the yield despite the generous size of the mass.[16]

Although the statement is often made that lesions in the outer third of the lung are too far out to reach with the transbronchial biopsy technique, this impression is actually mistaken. In fact, forceps can often be passed close to the pleural surface, creating one mechanism of pneumothorax with bronchoscopy. Lesions in the inner third of the lung may actually be more difficult to sample because of the tighter branching pattern of bronchi leading to the mass.

One remaining factor influencing diagnostic yield is the nature of the mass: primary versus metastatic. Primary bronchogenic carcinomas are bronchocentric in origin and, therefore, are more easily sampled by forceps passed through the airway. Metastatic nodules are usually hematogenous in origin and perivascular in location, [25] and the yield on transbronchial biopsy appears to be lower than for primary carcinomas. [19,26,27]

Two problems seem basic to the difficulty in sampling peripheral lesions: (a) the lack of direct peripheral visualization of the tumor and (b) the lack of adequate directional steering of the forceps in the periphery. Ultrathin bronchoscopes have been developed to achieve better peripheral visualization and appear to offer hope of increased range,[28] but they are unlikely to reach the level of most radiographically visible masses and have little prospect of offering any sampling capability. An older instrument, the single or double-hinged curette, actually provided some directional capability in the periphery but is somewhat fragile and has not met with widespread use, perhaps because of the cumbersomeness of the procedure.[29] Those using this device first use bronchography to map the bronchial tree leading to the mass. Because bronchography can effect cytologic results, the patients are not bronchoscoped for 2 weeks after the bronchogram. Fluoroscopy and the bronchogram are then used to manipulate the curette into the lesion. The ability to flex the hinges of the curette offers more directional control than traditional biopsy forceps. The process is, however, a long one and not clearly worth the time and expense considering other techniques.

More recently, two techniques have provided some improvement in sampling peripheral lesions without providing increased visualization or directional control. They are transbronchial needle aspiration and bronchoalveolar lavage (BAL). The technique of transbronchial needle aspiration of peripheral masses is similar to that of transbronchial biopsy. The device is passed under fluoroscopic guidance into the mass, and the needle is extended and moved back and forth in the lesion while aspirating at the proximal end. The needle is then removed from the mass, withdrawn into its sheath, and removed from the bronchoscope channel. It does not appear to be necessary to inject saline into the mass prior to aspiration.

Transbronchial needle aspiration significantly increases the yield of bronchoscopy in the diagnosis of peripheral masses 2 cm or larger in diameter. [20,23] In one study,[20] the yield for lesions less than 2 cm in diameter was the same with transbronchial biopsy and transbronchial needle aspiration (35%), but for larger lesions, transbronchial needle aspiration increased the yield over that of transbronchial biopsy from 52% to 76%. The technique was particularly useful for lesions that could not be penetrated by standard forceps so that transbronchial biopsies could not be performed. Such cases are probably caused by a tumor extrinsically compressing the bronchus leading to it or by the tumor being situated outside a bronchial branching point. In this subset, the yield of transbronchial needle aspiration was 80%. In other studies, the technique enhances the yield of bronchoscopy in the diagnosis of metastatic nodules, [30] again illustrating the ability of the needle to pass through areas difficult to access with traditional biopsy forceps.

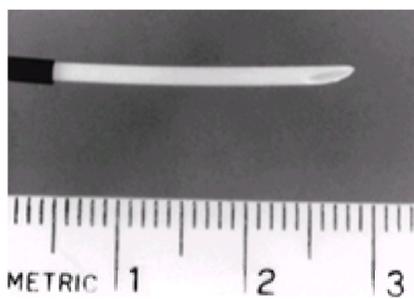
Two aspirating needles may particularly enhance the yield of bronchoscopy for peripheral lesions, although neither has been extensively studied. A plastic needle (Figure 31.4) with no rigid section at the distal end (e.g., SoftCor, Microvasive Corp, Watertown, Massachusetts) has been helpful in the authors' experience in accessing lesions in difficult locations such as the superior segment of the lower lobes or the medial aspect of the upper lobes. Maneuverability is improved by the absence of the 1- to 2-cm rigid distal section characteristic of most needles and forceps. It is also an 18-gauge device that offers the potential of a histologic specimen in addition to cytology. In most situations, the combination of histology and cytology produces a better yield than either alone. Using this needle, the author has achieved yields of 85% for lesions 2 cm or larger. The second needle is an 18-gauge metal needle that has been used primarily for mediastinal staging (see also Chapter 32, Chapter 35), again because of the potential for an improved yield with the added histology specimen.


FIGURE 31.4. Plastic bronchoscopic aspirating needle. The needle is 18 g with no rigid section. (SoftCor, Microvasive Corp. Watertown, Massachusetts.)

BAL has yet to be fully explored as an adjunct to transbronchial biopsy or transbronchial needle aspiration in the assessment of peripheral masses, but recent reports suggest that it at least enhances the yield over that of transbronchial biopsy, brushing, and washing. [31,32,33,34,35 and 36] BAL is theoretically appealing because it is known to be able to obtain material from the alveolar level in diffuse lung diseases such as *Pneumocystis pneumonia* and sarcoidosis.[35] So far, yields in bronchogenic carcinoma have varied significantly from 33%[31] to 65%,[33] and few studies have systematically compared yields from the common sampling procedures in the same patients. One study found a yield of 75% using a combination of transbronchial biopsy, BAL, and brushings. [37] In most studies, BAL provided the only bronchoscopic evidence of carcinoma in a meaningful number of cases (6% to 11%).[37] More studies will undoubtedly be published in the next few years, which we hope will sort out the best combination of sampling techniques. In the authors' experience (unpublished), the combination of transbronchial needle aspiration and BAL appears to provide a better yield than transbronchial biopsy with brushing and BAL.

Lymphangitic Carcinoma

Lymphangitic carcinoma represents a special case of diffuse lung disease and, as with other forms of diffuse disease, it is readily sampled by transbronchial biopsy. Transbronchial needle aspiration has not been tested in lymphangitic carcinoma, but it would appear unlikely to be useful in this setting because the technique is generally more suited to dense lesions than to diffuse parenchymal lesions. [38] BAL has been shown to add to the diagnostic yield in lymphangitic carcinoma,[32] although it has not been systematically compared to other sampling techniques.

Special Issues

Occasional disputes arise over the necessity for a preoperative diagnosis of lung cancer in cases of solitary pulmonary nodules, which are distinguished from a lung mass by the absence of radiographic findings other than a well-circumscribed round mass completely surrounded by lung. This particular presentation poses a dilemma because it can be caused by either benign or malignant processes, and surgery for benign disease should be avoided, if possible. Evidence of very long lesion doubling time (>2 years) from previous chest radiographs, radiographic evidence of a benign pattern of calcification, supports the diagnosis of a benign lesion. Many lesions (including benign ones) do not, however, meet these criteria.

In the absence of computed tomographic evidence of mediastinal adenopathy, some physicians have argued that bronchoscopy (or transthoracic needle aspiration) does not alter outcome.[39] Unfortunately, the issue is not clear-cut. In some populations, such as the Southwest United States, a significant number (up to 50%) of solitary nodules in patients over 50 years old may be caused by benign processes such as coccidioidomycosis, which can be detected by bronchoscopy, [40] so that the patient population must be considered. Second, the potential for mediastinal staging has not been accounted for in the algorithms. In addition, bronchogenic carcinoma is multicentric.[41] The reported incidence of simultaneous tumors has varied from 1.2%[42] to 10% to 22% in occult carcinoma.[43,44] Although a small study of solitary pulmonary nodules found no second (endobronchial lesions), [45] the actual incidence in the subset of patients with solitary nodules has not been reported. The ability to detect second lesions, which might influence the approach to therapy, would clearly affect the approach to preoperative diagnosis. One study using decision analysis to determine the effect of diagnostic strategy on survival found that immediate surgery had a very slight survival advantage if the likelihood of malignancy was very high; preoperative biopsy had a very slight advantage if the probability of cancer was intermediate; and observation had a very slight advantage if the probability of cancer was very low.[46]

A second special issue is the role of bronchoscopy in hemoptysis with a normal or nonlocalizing chest radiograph. A surprising number of studies have addressed this issue in the past ten years, with remarkably similar conclusions despite some small variations. [18,47,48,49,50,51,52,53,54,55 and 56] All studies have found that bronchoscopy is indicated in patients at risk for lung cancer: age over forty years, a significant smoking history, and male sex (although this factor has probably changed with the greatly increased incidence of bronchogenic carcinoma in women).

No consensus exists on the significance of the volume of hemoptysis. One study found a significant incidence of carcinoma only when the volume of hemoptysis was

greater than 30 mL,[53] another when the volume was greater than 60 mL,[51] and a third found no relation to volume.[57] Bronchoscopy appears to be indicated in the presence of hemoptysis and a normal chest radiograph when any risk of cancer exists or symptoms of cancer are present, regardless of the volume of the bleeding.

A third issue is that of occult bronchogenic carcinoma; that is, positive sputum cytology with a normal chest radiograph. Bronchoscopy is the diagnostic procedure of choice in such situations. The majority of lesions are found on the first bronchoscopy. [44] If not, then most can be found on repeated bronchoscopies every three months.[44] If repeat bronchoscopy is needed, computed tomography may be useful to indicate suspicious areas,[58,59] although computed tomography is not sensitive to submucosal disease.[56] In unusual circumstances, bronchography may also be helpful.[60] In any case, most occult tumors not found on the initial bronchoscopy are carcinomas *in situ,* or minimally invasive tumors that have a good prognosis even when diagnosed up to 5 years after the initial positive sputum cytology. [44] Some experimental techniques involving fluorescence bronchoscopy may, however, provide more rapid accurate localization in the future (see also Chapter 22, Chapter 24).

A final special issue is the role of bronchoscopy in patients with pneumonia. Bronchoscopy is commonly believed to be indicated in nonresolving segmental or lobar pneumonia to detect an endobronchial obstruction. One study of patients with community-acquired pneumonia found an incidence of bronchogenic carcinoma of 14% in patients over age fifty on early bronchoscopy. [61] Again, the optimal timing of bronchoscopy has not been examined.

STAGING

Proximal Extent

It has long been known that the proximal extent of bronchogenic carcinoma influences resectability, [2,62] yet this aspect of staging is often neglected in routine diagnostic bronchoscopies and determined instead at the time of surgery. In some cases, surgery may not be indicated if the tumor has spread too centrally. Carinal biopsy has been shown to be useful in the presence of endobronchial tumor, even when the carina itself appears visually normal. [62] Approximately 5% of so-called blind carinal biopsies are positive in the presence of a central endobronchial tumor. [63,64] Although the incidence of positive blind biopsies is not particularly high, the biopsy procedure is brief with very little risk, and the implications of a positive biopsy are important.

A second important aspect of determining proximal spread is the assessment of submucosal involvement in the more distal airways. Biopsy of the next proximal bronchus to the bronchus containing an endobronchial mass has been found to be useful in determining resectability and was often done through rigid bronchoscopes,[1,65] but the procedure has not been popular with fiberoptic bronchoscopy for unclear reasons. More recently, transbronchial needle aspiration has been found to be useful and to compare favorably with surgical findings in assessing proximal submucosal spread of endobronchial tumors. [51]

Second Lesions

A careful search for second lesions should be part of a diagnostic bronchoscopy for lung cancer. Although the incidence of second lesions in the presence of solitary pulmonary nodules may not be high (see previous section, Diagnosis, Special Issues), second lesions seem to occur with some frequency in patients presenting with occult carcinoma[43,44] and endobronchial primaries. Such a search is particularly important because chest radiographs are unlikely to detect endobronchial tumors until secondary signs of obstruction occur. In fact, even complete endobronchial obstruction may not be associated with radiographic signs of obstruction in up to 44% of patients.[66]

Mediastinal Staging

Transbronchial needle aspiration has enlarged the scope of bronchoscopy to include assessment of mediastinal adenopathy. Paratracheal, subcarinal, hilar, and aorticopulmonary window nodes can all be accessed through the flexible bronchoscope. The technique is similar regardless of the location. Similar to submucosal aspirates, the needle should be advanced proximal to the site to be aspirated, and the sheath should be pulled back to support the body of the device in the channel of the bronchoscope. The needle should then be moved to the area of interest determined either by the physical appearance of the area or by the suspicion of adenopathy based on chest radiographs or computed tomography. The needle should be firmly placed against the tissue to be aspirated to anchor it before advancing it with a jabbing motion into the deeper layers. [67] Aspiration is then performed while moving the needle back and forth within the tissue.

The most common problem with the transbronchial needle technique seems to be inadequate insertion of the needle in the tissue of interest. Because the insertion maneuver tends to push the distal tip of the bronchoscope back from the needle device, the operator can be too far from the needle to accurately determine its position. As a result, it is helpful to slide the bronchoscope over the needle to remain close enough to determine the depth of penetration. If the needle has not adequately penetrated, one simple maneuver is extremely helpful. With the needle embedded shallowly in the tissue, having the patient gently cough usually pushes the needle fully into the involved tissue. [68]

Aspiration of paratracheal lesions can also be problematic. It has been suggested that the needle should be passed perpendicular to the tracheal wall, [69] but this maneuver is often difficult to achieve. In practice, if the aspirating needle is long enough (approximately 1.3 cm), it can adequately penetrate the tracheal wall to sample surrounding nodes, even at an oblique angle. The needle must, however, be anchored between tracheal rings, rather than abutted against cartilage, before attempting to advance it. One technique that may be helpful in improving the angle of entry to the wall is to partially impale the needle at an oblique angle. Slowly advance the bronchoscope distally as the angle of the needle turns toward the wall, then advance the remainder of the needle and perform the aspiration as previously described. The coughing maneuver is almost essential to penetration of the tracheal wall. Again, it is important to confirm that the needle is adequately advanced in the site before performing the aspiration.

Various needle devices are available and suitable for transbronchial, transtracheal, or transcarinal aspiration. The length of the needle is important. Needles 1 cm in length tend to be inadequate, whereas 1.3 cm appears optimal. The needle gauge may also be important. Although good results have been reported with a 20-gauge (or 21-gauge thin-walled) needle, [70] larger gauge needles (18- or 19-gauge) offer the advantage of histologic specimens in addition to cytologic specimens and may increase the diagnostic yield of the procedure. [71,72,73,74 and 75] At least one study[75] has compared a 22-gauge needle to a 19-gauge needle in the same patients and found the 19-gauge needle superior in diagnostic yield (86% versus 53%).

The overall yield of bronchoscopic needle aspiration probably depends on the patient population and the screening procedures employed in determining the need for the aspiration. Studies in which all patients with suspected bronchogenic carcinoma undergo transcarinal needle aspiration have found an overall yield of 15%. [70,76] Using selective criteria can increase the yield. Limiting transcarinal aspirations to patients with either endobronchial lesions or a widened carina increased the specificity of the aspirate to 25% to 40%, respectively. [70] Computed tomographic evidence of mediastinal adenopathy appears to provide the greatest specificity. Using computed tomography to determine the need for mediastinal aspirates, most studies are able to detect approximately two-thirds of the true positive nodes in patients with bronchogenic carcinoma.[30,68,75,77,78 and 79] These yields have been similar in routine use of the procedure (outside of protocol studies) in community-based hospitals[80] and teaching hospitals.[81] These yields are sufficiently high to be able to spare a significant number of patients with unresectable disease the risk and expense of more invasive staging procedures.[76] Newer techniques for guiding bronchoscopic needle aspiration are now available with limited data supporting their use. Endoscopic ultrasound and virtual bronchoscopy may be particularly useful for this purpose.

Although false-positive results have rarely been reported with mediastinal bronchoscopic aspirations, [82,83 and 84] care must be taken to avoid them because they could adversely influence therapeutic decisions. Simple measures include avoidance of the primary tumor prior to sampling the mediastinal nodes to prevent contamination of the bronchoscope channel by tumor cells. If the patient has a positive sputum cytology, it may be safest not to perform mediastinal aspiration because its interpretation could be difficult if it were positive. Similarly, if secretions well up from the lower airways, covering the area to be aspirated, the chances of contamination are too great to perform the aspirate. In all cases, adequacy of cellularity should be assessed by the cytopathologist. A specimen with a few free-floating malignant cells may not be reasonably distinguishable from contamination. Whenever significant doubt about the adequacy of the aspirate exists, conventional staging should be used rather than make a possibly inappropriate therapeutic decision.

One additional role of mediastinal aspiration is the primary diagnosis of small cell carcinoma. Mediastinal aspiration is often the only diagnostic sample in bronchoscopic examination of patients presenting with bulky central disease in small cell carcinoma without evident endobronchial lesions. [30]

EVALUATION OF THERAPY

A less common application of the diagnostic capabilities of fiberoptic bronchoscopy in bronchogenic carcinoma is in the evaluation of treatment efficacy. This application has been studied in patients with small cell carcinoma in comparing bronchoscopic findings during and after treatment to chest radiographic findings in patients whose presenting disease was endobronchial. [36,85,86 and 87] All studies have found that a significant percentage (25% to 35%) of patients have radiographic clearing but still have endoscopically evident disease. These findings are, perhaps, not surprising considering the high percentage of patients who can have major endobronchial obstruction without radiographic signs of obstruction. [66] More subtle changes would be even less likely to be detectable by chest radiography.

The role of computed tomography in relation to bronchoscopy in this patient population has not been reported, but it is likely to have some limitations as well because it tends to be less sensitive than bronchoscopy to the detection of submucosal disease [56] or small endobronchial lesions. The utility of bronchoscopy in evaluating treatment of patients with non–small cell carcinoma also remains to be studied. Again, it seems probable that it would be similarly useful.

ENDOSCOPIC THERAPEUTIC INTERVENTION

Through recent technologic advancements and renewed interest in older techniques, several therapeutic procedures may be performed to palliate central airway obstruction, including laser photoresection, stent placement, cryotherapy, brachytherapy, balloon dilation, and photodynamic therapy. Because many of these topics are discussed elsewhere in this textbook, we focus on stents and cryotherapy.

Stents

The deployment of stents to maintain luminal patency is a concept borrowed from vascular and biliary interventional experiences. Early attempts to maintain airway caliber in patients with subglottic stenosis involved modifications of endotracheal tubes and the development of the Montgomery T-Tube. [88] This T-shaped silicone tube requires a permanent tracheotomy and a dual-operator rigid deployment technique. Surgical implantation of a silicone-based Neville stent was also performed in segments of stenosis and malacia.[89] It was sutured in place during thoracotomy.

With improved vascular stenting techniques and the development of metallic alloys, airway stenting gained popularity. Stents were deployed using fluoroscopic guidance and a balloon dilated to the appropriate luminal size. Self-expandable stents such as the Gianturco (Cook Inc., Bloomington, Indiana) became the standard metal stent used in the airway. These stents, however, were permanent and associated with complications, including airway perforation, hemorrhage, fistula formation, and plugging with tumor growth and secretion. [90] Interest in the development of a stent that would maintain airway caliber, be easily deployed, and minimize complications has lead to the numerous present-day stents, which can be grouped into three major classes: silicone, metallic alloys, and hybrid stents.

Silicone stents were developed initially as modifications of the Montgomery T-Tube. The addition of a carinal branch, [91] modifications in size, shape, and flexibility, [92] and newer deployment techniques increased usage in patients with central airway obstruction. Deployment techniques involved fitting the stent over a smaller endotracheal tube or rigid bronchoscope, pushing the stent through the vocal cords, and then fitting it into place with a larger caliber tube. The pitfalls of this technique included laryngeal and vocal chord damage, submaximal dilation, and smaller stent placement.

Dumon designed a patented silicone stent (Axion, Aubagne, France, distribution Bryan Corp., Woburn, Massachusetts) to palliate both malignant and benign airway obstruction.[93] Regularly placed surface studs allow for anchoring in the tracheobronchial tree and limit the surface contact to minimize mucosal ischemia. The development of a patented tube-pusher delivery system (i.e., EFER, La Ciotat, France) addressed many of the pitfalls of early silicone stent deployment. The technique involves loading the folded stent into an introducer, placing the introducer through the barrel of a rigid bronchoscope, and expelling the stent with a tube pusher while slowly withdrawing the rigid bronchoscope.

The Dumon group placed more than 502 stents between 1987 and 1992.[94] Indications for stent placement were predominantly malignant airway disease and stenosis. Central airways (trachea, right and left mainstem bronchi) were the main sites stented. The mean stent duration was 14.18 months for benign disease and 3.35 months for malignant disease. Complications included migration (8.8%), granuloma (8.5%), and obstruction by secretions (4.8%). The advantages of the Dumon stent are that it provides extensive airway support and is easily removed. The disadvantages are that it is a thick tube, which limits the luminal diameter, has the potential to migrate, and requires rigid bronchoscopic deployment.

The two most popular metallic mesh stents are the Wallstent and the Ultraflex (Microvasive, Boston Scientific). The Wallstent is made of a cobalt super alloy woven into a cylindrical wire mesh. The deployment apparatus consists of a compressed elongated stent covered by an outer sheath attached to a valve body. The area to be stented is fluoroscopically labeled with surface markers. After a guidewire is bronchoscopically placed through the desired segment, the bronchoscope is removed, leaving the guidewire in place. The stent is loaded over the guidewire until the markers on the stent correlate with the surface markers. Because the Wallstent is compressed and elongated, shortening needs to be considered as the stent is deployed. The deployment technique consists of pulling back the valve body while observing fluoroscopically. Some bronchoscopists reinsert the bronchoscope and visualize the stent deployment. After half of the stent is deployed, positioning should be reevaluated prior to completing the deployment.

The Wallstent has sharp, pointy edges that may result in granulation tissue formation. Because the compressed stent is longer than the deployed stent, malposition is a potential complication. The Wallstent is also permanent and does not allow for repositioning once deployed. Tumor growth through the walls and limitation of mucociliary clearance may result in potential obstruction.

The Ultraflex stent is composed of a nitinol single strand with looped edges. Although plagued by many of the same complications as the Wallstent, it has some theoretical advantages. The smooth edges may cause less granulation tissue formation. The memory properties of the nitinol allow for the compressed stent to be the same length as the expanded stent, which may lead to more accurate placement. By grasping the string edge, the stent may be repositioned even after deployment. Once epithelialization occurs, however, the stent is not movable.

Hybrid stents represent a combination of silastic and metallic stents. Wallstents and Ultraflex stents are available coated, in an attempt to decrease tumor growth through the wire-mesh structure. This feature may expand the potential use of these stents to support the airway when small fistula exist. Another hybrid stent called the Dynamic-Y-Stent has theoretical advantages favoring its use. It has both a tracheal and bronchial component that can be trimmed according to the individual airway characteristics. The posterior tracheal component is thin and collapsible, allowing for changes in airway caliber with respiration and cough, which may facilitate mucous clearance and decrease the risk of secretion accumulation. The anterior tracheal component is supported with metal rings, simulating cartilage. Potential uses for this stent include complex airway lesions, lesions involving the carina, diffuse malacia, and airway fistula.

Unfortunately, no controlled, randomized, comparative studies for stent placement have been conducted. The data for metallic stents are limited to small patient groups, poorly controlled with the lack of long term follow-up; therefore, no consensus exists regarding stent selection for a specific airway lesion. Until large, prospective, randomized studies are performed, we are left with expert opinion as our only guide to many therapeutic airway interventions.

Cryotherapy

Cryotherapy is the therapeutic application of extreme cold for local destruction of living tissue. Historically, its use in the treatment of malignancy dates back to 1848, when James Arnott used cold application to palliate uterine carcinoma. Endoscopic cryotherapy is relatively new, made possible by recent improvements in bronchoscopic equipment and the development of cryotherapy probes for direct application. Cryotherapy utilizes the reverse principles of cryogenics, which preserves cellular function. It induces selective cell necrosis by rapidly cooling tissue, typically at a rate less than -30° Celsius per minute, and by slowly thawing the tissue after a prolonged freeze time. Necrosis results from crystallization, cellular dehydration, and structural disruption followed by microthrombi formation.

Cryoprobes are utilized to directly administer cold to a specific location. The probe may be rigid, semirigid, or flexible. The rigid and semirigid probes can only be used through a rigid bronchoscope, whereas the flexible probes fit down the working channel of a flexible bronchoscope. The cryogen (cooling agent) used is typically nitrous oxide, although carbon dioxide and hydrocarbons are also effective. Capillary tubes inside the cryoprobe transfer the cryogen to the tip of the probe, where it expands from high pressure to atmospheric pressure. The gas expansion lowers the temperature of the fluid (the Joule effect) and produces droplets. This effect

allows for direct, low-temperature application at the tip of the probe, producing temperatures of -30° Celsius or lower.

Patient selection for cryotherapy requires an endoscopically visible lesion that is accessible to the bronchoscopist. The cryoprobe is inserted through the working channel and is advanced approximately 4 mm distal to the tip of the bronchoscope. The probe is applied to the lesion as the foot pedal is depressed, beginning the freeze cycle. Within fifteen seconds, an ice ball forms at the probe tip. One to three freeze-thaw cycles are applied to the tumor area, with each freeze lasting for one minute. At the end of each freeze cycle, the ice ball is observed until thawing is complete before the probe is removed. Gentle tugging of the probe safely facilitates removal.

The thrombotic and coagulation effects of cryotherapy are delayed, requiring approximately twenty-four to forty-eight hours. Thus debulking at the time of initial application is avoided because the tumor's vascular supply is intact and massive hemorrhage may result. Because cryotherapy may cause tissue swelling and edema, it is recommended that cryotherapy not be initially used for critical airway lesions that could obstruct completely.

Endoscopic cryotherapy is an excellent modality for the symptomatic improvement of malignant tracheobronchial lesions. More than 600 patients were treated with cryotherapy for malignant tracheobronchial lesions at the Harefield Hospital in Northern London. Overall, 78% noted subjective improvement. For those patients presenting with dyspnea, cough, hemoptysis, and stridor, approximately two-thirds noted improvement in their symptoms. [95]

EXPERIMENTAL TECHNIQUES AND FUTURE APPLICATIONS

Routine Bronchoscopy Interestingly, new nonbronchoscopic technology may expand the role of standard fiberoptic bronchoscopy with forceps biopsy. Studies are beginning to emerge, demonstrating the adequacy of standard forceps biopsy sample for various genetic analyses, such as detection of p53 [96] and the analysis of DNA content.[97] Others have explored the utility of BAL in the detection of several possibly significant markers for the diagnosis of lung cancer. [98,99 and 100]

Fluorescence Bronchoscopy

Fluorescence bronchoscopy emerged from the need to detect more subtle presentations of bronchogenic carcinoma, such as minimally invasive disease or carcinoma *in situ,* or to detect proximal submucosal spread of endobronchial disease for adequate staging. The bulk of the work has been done using a fluorescence-enhancing agent, a hematoporphyrin derivative (HpD), to concentrate a fluorescing agent in neoplastic tissue. HpD is injected intravenously and picked up by actively dividing tissue, including inflammatory tissue. After 3 days, it tends to concentrate in neoplastic or severely dysplastic cells. When exposed to an appropriate wavelength, usually delivered by a laser, the tissue concentrating the HpD produces a characteristic fluorescence. [101,102] This technique has also been used to treat carcinoma *in situ* and to debulk main airway obstruction. Oxidation reactions occur on treated surfaces, causing tissue destruction and tumor slough (see also Chapter 24). This technique is clearly capable of detecting lesions not visible by standard white light bronchoscopy, [103,104] but it has not become commonly applied. Possible reasons include the expense of the equipment and potential complications of HpD, mainly severe, prolonged photosensitivity. [106]

A newer technique, autofluorescence bronchoscopy, utilizes the well-known autofluorescence properties of neoplastic tissue [106,107,108 and 109] to achieve the same end. Neoplastic tissue fluorescs without a fluorescence-enhancing agent when exposed to the proper wavelengths. Detecting the fluorescence requires sophisticated image analysis and amplification. Using this technique, investigators have determined that autofluorescence bronchoscopy is 50% more sensitive than white light bronchoscopy in detecting severe dysplasia and carcinoma *in situ.*[110,111 and 112] A recent multicenter clinical trial was conducted in seven institutions in the United States and Canada, comparing white light bronchoscopy and fluorescence examination in 173 subjects with known or suspected lung cancer. Biopsy specimens taken from suspicious areas revealed that the relative sensitivity of white light bronchoscopy plus fluorescence endoscopy versus white light bronchoscopy alone was 6.3 for intraepithelial malignancy. [113]

Fluorescence endoscopy has great potential for detecting occult carcinoma and determining the true proximal spread of endobronchial disease. Further applications may include airway surveillance in high-risk patients, such as those in chemoprevention protocols or who have been previously treated for bronchogenic carcinoma (see also Chapter 24).

Ultrasound Bronchoscopy

Endoscopic applications of ultrasonography have been developed for intravascular use and are now beginning to be evaluated in the airways. The technique appears capable of detecting peripheral carcinomas, endobronchial tumors, mediastinal lymph nodes down to 3 mm in size, and hilar lesions. [114,115 and 116] It also has utility in determining the depth of tumor involvement in patients with carcinoma *in situ.*[117] Its greatest utility may be in improving diagnostic yields from bronchoscopic needle aspiration and decreasing the number of aspirates required. One study using on-site cytopathologic diagnosis found that bronchoscopic needle aspirations required fewer passes to diagnose carcinomas in paratracheal nodes. It will be interesting to see if the technique enhances diagnostic yields by providing better localization, particularly in peripheral carcinoma. Limitations to performing endoscopic ultrasound include equipment expense, appropriate training, technical difficulties in obtaining an adequate acoustic window, and the presence of anthracosilicosis. [115]

Virtual Bronchoscopy

Virtual bronchoscopy has emerged with the advent of improved techniques in thoracic imaging. Volumetric data acquisition offered by helical computed tomography has permitted the creation of computer-generated, three-dimensional surface renderings of the tracheobronchial tree. The ability to perform computer-simulated endoscopy has great potential in all facets of bronchoscopy. In preliminary studies, computer-simulated endoscopy accurately reflects major endobronchial anatomy when compared to standard bronchoscopy.[118] It is particularly useful in the diagnosis of high-grade stenosis, extraluminal compression, [119] and polypoid endobronchial lesions greater than 5 mm in diameter.[120] The technology is still, however, in developmental stages and awaits careful scientific scrutiny. Potential applications include guidance for bronchoscopic needle aspiration, improved diagnostic yields for peripheral carcinoma, precise airway measurements to plan stent placement and balloon dilation, and vascular localization to plan laser photoresection, cryotherapy, and electrocautery.

A DIAGNOSTIC APPROACH

Bronchoscopic diagnosis and staging of lung cancer can be approached systematically and tailored to the individual presentation. Patients presenting with endobronchial lesions should undergo biopsy of the primary lesion, a search for second lesions, and evaluation of the proximal spread of disease by submucosal aspirate of the proximal bronchus and biopsy of the carina. If computed tomography indicates the presence of significant adenopathy, bronchoscopic needle aspiration of the involved nodes (if accessible) can be performed during the initial diagnostic procedure.

Peripheral mass lesions can be sampled under fluoroscopic guidance by transbronchial biopsy, brushing, and transbronchial needle aspiration. BAL also appears to be very useful. Again, computed tomography can be used to guide aspiration of significant mediastinal adenopathy, and second lesions should be looked for routinely as part of the initial examination.

Similar to all procedures, their use should be conditioned by the individual case as well as the local skills and results of the operator. The patient's input is also important. Some patients would strongly prefer not to undergo more than one procedure, so that surgery, particularly for a solitary pulmonary nodule, may be appropriate without a preoperative diagnosis. Others may not consider surgery until a diagnosis of malignancy is clearly established. Here is where the art of medicine must merge with the statistics of procedure results to determine the best approach. Similarly, with the relatively new field of endoscopic palliative therapy, we must plan our therapeutic approaches with the individual clinical situation and anatomy in mind. We hope clearer guidelines will evolve with increasing clinical experience with these techniques.

INTERNATIONAL STAGING SYSTEM FOR LUNG CANCER

CLIFTON F. MOUNTAIN

CONSIDERATIONS IN STAGING

History, Purpose, and General Principles

Physicians have been concerned with the problem of the clinical classification of malignant tumors for half a century. [1] The relationship between prognosis and the extent of disease at diagnosis derived initially from observations that crude survival, or apparent recovery, rates were higher for patients in whom the disease was localized than for those in whom the disease had extended beyond the organ of origin. This observation gave rise to designating groups of patients as "early" and "late" cases, implying, erroneously, some fixed progression with time. In 1944, Denoix [2] first emphasized the need for a flexible, reliable cancer classification system based on a generally acceptable description of the facts of a case. He proposed that "the initial descriptions must be definitive, common to all, and based on findings which anyone can confirm with as little margin for personal interpretation among surgeons as possible." From concentration on this common minimum, Denoix and colleagues developed the TNM system for describing characteristics of the primary tumor (the "T" component), the status of regional lymph nodes (the "N" component), and the presence or absence of distant metastasis (the "M" component). [3] Stage grouping of the TNM anatomic subsets came later, and a uniform clinical classification for all cancer sites was subsequently developed by Union Internationale Contre le Cancer (UICC) study groups [4] and special site task forces of the American Joint Committee on Cancer (AJCC). [5] A twofold purpose of clinical stage classification was defined as follows: First, to facilitate the accurate, concise description of the apparent extent of disease in a way that can be readily communicated to others or reproduced by them (the TNM classification), and second, to facilitate comparison of differing therapeutic approaches by combining patients with certain common attributes (TNM anatomic subsets) into groups (stages) with generally similar prognoses and treatment options. [6] These principles served the clinical and research communities well over the years. Manuals published by the UICC[7 and 8] and the American Joint Committee AJCC,[9 and 10] and the works of others,[11,12 and 13] provided guidelines for clinical staging of lung cancer, recommendations for histopathologic staging, and data confirming the usefulness of the TNM and stage classifications.

THE INTERNATIONAL SYSTEM FOR STAGING LUNG CANCER

Staging and histologic classifications remain today as major indicators of the curative potential and limitations of available therapy for lung cancer. The value of these tools for predicting prognosis still depends on identifying consistent, reproducible patient groups that may be related to the end results of treatment. The International System for Staging Lung Cancer[14] was developed in response to a need for classification that would unify variations in staging definitions and that would have consistent meaning and interpretation among physicians and scientists throughout the world. The system proved effective for this purpose and has been used widely since 1986, when it was adopted by the UICC[15] and the AJCC.[16] In the subsequent decade, after ten years of applying the International System for Staging Lung Cancer, a requirement for more specific staging was recognized that (a) would meet clinical and sophisticated research needs, and (b) maintain the integrity of the present classification without major change, until diagnostic, treatment, and research advances could have a proven significant effect on prognosis. Two major problems emerged: First, heterogeneity existed with respect to the end results for the TNM subsets in stage I, stage II, and stage IIIA disease, and second, inconsistency resulted from the use of multiple systems for classifying regional lymph nodes. These problems were addressed with the least possible disruption of the International Staging System by revising the stage grouping rules for the TNM anatomic subsets and recommending a new schema for classifying regional lymph nodes.[17 and 18] The revisions in the staging system and recommendations for regional lymph node mapping were adopted by the UICC and the AJCC in May 1996, and have been published in the manuals of both organizations. [19,20 and 21]

THE REVISED INTERNATIONAL SYSTEM FOR STAGING LUNG CANCER

The revised staging system (Table 32.1,Table 32.2,Table 32.3,Table 32.4 and Table 32.5) consists of a change in the rules for stage grouping of the TNM anatomic subsets and an addition to the T4 and M1 descriptors to aid in classifying metastatic nodules (not lymph node metastasis) in the ipsilateral lung. Data that reconfirms the relationship of prognosis to specific disease extent categories [17] supports the revisions in stage grouping. (The data sources and statistical methods are documented in Table 32.6 at the end of this chapter.)

Any T Any N M1				

Overall comparison: p < 0.01; pairwise comparison, all stages p < 0.05 except for cIB versus cIIA; see Table 32.6 for data source and statistical methods.

TABLE 32.3. NON–SMALL CELL LUNG CANCER. CUMULATIVE PERCENT OF PATIENTS SURVIVING ACCORDING TO CLINICAL STAGING CRITERIA

pStage/TNM	Number	Cumulative % Surviving-Years After Treatment		
		1 Year	3 Years	5 Years
I A - T1N0M0	511	91	71	67
I B - T2N0M0	549	94	67	57
II A - T1N1M0	76	88	65	55
II B	375	77	47	39
T2N1M0	288	78	47	39
T3N0M0	87	76	47	38
III A	399	64	32	23
T3N1M0	55	65	30	25
T1-2-3N2M0	344	64	32	23

Overall comparison: p < 0.01; pairwise comparison, all stage groups p < 0.05 except for pIB versus pIIA; see Table 32.6 for data source and statistical methods. (From Mountain CF. Revisions in the international system for staging lung cancer. *Chest* 1997;111:1710, with permission.)

TABLE 32.4. NON–SMALL CELL LUNG CANCER. CUMULATIVE PERCENT OF PATIENTS SURVIVING ACCORDING TO SURGICAL-PATHOLOGIC STAGE OF DISEASE AND TNM SUBSET

TABLE 32.5. LYMPH NODE MAP DEFINITIONS[18]

Institution	Number of Cases
The University of Texas M. D. Anderson Cancer Center, 1975–1988*	4,351
Reference Center for Anatomic and Pathologic Classification of Lung Cancer, 1977–1982†	968
Total	5,319

* Consecutive patients treated for primary lung cancer, 1975–1988; surgical patients only, 1981–1982; consecutive patients (receiving no previous treatment) treated for non–small cell lung cancer, 1983–1988.
† Patients treated for primary lung cancer by the National Cancer Institute cooperative Lung Cancer Study Group—representative slide material and case documentation submitted to the Reference Center for Anatomic and Pathologic Classification of Lung Cancer at the University of Texas M. D. Anderson Cancer Center for confirmations of staging and histology. From Mountain CF. Revisions in the international staging system for lung cancer. *Chest* 1997;111:1710, with permission.
The Wilcoxon (Gehan) statistic was used for comparing the survival experience of patient groups.** Analysis was carried out using a software package (Statistical Program for the Social Sciences, SPSS, Inc., Chicago). The terminal event was death from cancer or unknown cause; deaths within 30 days of operation were excluded. The end results according to clinical stage are calculated from the date of first treatment or the decision for no treatment, and those according to surgical-pathologic stage are calculated from the date of first treatment.

TABLE 32.6. APPENDIX—COLLECTED DATABASE FOR CLASSIFICATION RESEARCH[17]

Relationship To Clinical and Research Objectives

New prognostic factors for lung cancer are under intensive investigation in many centers throughout the world. Studies of molecular genetic markers, of growth factors and receptors, and of pathologic factors, such as angiogenesis and cell proliferation, provide a body of literature that documents good or bad outcomes according to the presence or absence of tumor and host factors. [22 and 23] In this milieu of evolving knowledge of the molecular biology of lung cancer—its initiation, growth, and metastasis—the stage of disease remains as a benchmark for evaluating the effect on survival durations of new factors derived from the research. [24 and 26] Within the next decade, new markers of prognosis and reproducible, cost-effective methodologies undoubtedly will be identified and confirmed; new approaches to treatment could render the staging concept obsolete (see also Chapter 33). At this time, however, biologic prognostic markers are not yet a reliable and proven clinical reality. [27]

Anatomic staging continues to serve as the most valid indicator of prognosis, as a guide for treatment planning, and as a means for communicating the results of treatment for specific groups of patients.

Clinical, Surgical-Pathologic, and Retreatment Classifications

The clinical stage (cTNM-cStage), based on all information obtained before treatment is instituted or a decision for no treatment is made, is assigned to each patient, and is not changed throughout the course of the disease. Identical staging descriptors are useful and applicable at specific points in the life history of the cancer. For those patients assigned to undergo surgical treatment, surgical-pathologic staging (pTNM-pStage), based on information obtained from pathologic examination of resected specimens, is useful because of the more precise description of the extent of the primary tumor and regional lymph node metastasis. Except for identifying possible intrapulmonary metastasis, p-staging provides no additional information regarding the cM category. In multimodality therapy programs, retreatment staging (rTNM-rStage), evaluation of disease extent following initial or induction therapies, may be useful for assigning subsequent treatment steps, as well as for evaluating the end results. It is essential that identical definitions are used for each type of classification and that the type (i.e., clinical, c; surgical-pathologic, p; or retreatment, r) is specified in end results reports according to staging criteria.

Staging and Cell Type

The International System for Staging Lung Cancer is relevant for classifying the four major cell types of lung cancer; squamous cell carcinoma, adenocarcinoma (including bronchioalveolar carcinoma), large cell carcinoma, and small cell carcinoma. It also may be applied to "undifferentiated carcinomas" with no specific subtype identified. Although small cell carcinoma is commonly designated as "limited" or "extensive" disease, staging of this tumor according to the more specific TNM categories is useful and may be required for selecting patients for multimodality programs involving adjuvant surgery. [28] The proportion of patients achieving a complete response, the duration of the response, and recurrence after a complete response is directly related to the extent of the disease at diagnosis. New treatment plans are designed from the results achieved for specific groups of patients that are identified in terms of TNM and stage classifications.

TNM Descriptors and Stage Grouping

The numeric descriptors for each TNM component reflect increasing primary tumor size and invasiveness (T1-2-3-4), the absence or presence and extent of metastasis in regional lymph nodes (N0-1-2-3), and the absence or presence of tumor spread to distant lymph node or organ sites (M0-1). Definitions for the TNM descriptors, shown in Table 32.1, remain the same as defined in the International System for Staging Lung Cancer, [14] except for two minor additions to aid in classifying multiple lung nodules: T4 designates satellite tumor nodules in the ipsilateral primary tumor lobe of the lung; all other separate nodules in the nonprimary tumor lobes are classified M1.[17] Table 32.2 shows the 17 anatomic TNM subsets, according to stage group, that describe progressive levels of disease extent, from small, circumscribed "coin" lesions with no evidence of metastasis to the most extensive tumors with distant metastasis present.

Stage IA and Stage IB

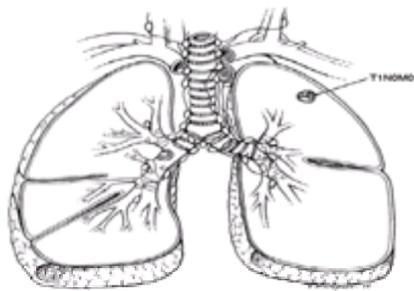
The revised stage grouping rules (Table 32.2) designate small tumors, less than or equal to 3 cm in greatest dimension with no evidence of metastasis, T1 N0 M0 disease, as stage IA (Figure 32.1). An individual stage designation for this anatomic subset is warranted because the prognosis for patients with T1 N0 M0 tumors is significantly better than the outcome achieved for any other group of patients—an observation confirmed by end results studies according to both clinical and surgical-pathologic staging criteria. Table 32.3 shows that 61% of patients with cStage IA non–small cell lung cancer (NSCLC) and 67% of those with pStage IA non–small cell (NSC) lung tumors are expected to survive five years or more. Higher rates may be reported for selected patients entered into special studies. [28]


FIGURE 32.1. Stage IA (*T1N0M0*) lung cancer identifies tumors 3 cm or less in greatest dimension, surrounded by lung parenchyma, with no evidence of invasion proximal to a lobar bronchus and no evidence of metastasis. (From Mountain CF, Libshitz HI, Hermes KE. Lung cancer—handbook for staging, imaging, and lymph node classification. Houston: Clifton F. Mountain Foundation, 1999, with permission.)

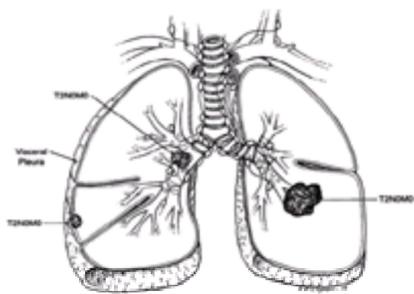
Patients with larger tumors or those of any size that invade the visceral pleura or main bronchus (>2 cm distal to the carina), with no evidence of metastasis, the T2 N0 M0 anatomic subset, are designated stage IB (Figure 32.2). A significant difference between the survival rates for patients with stage IA and those with stage IB NSCLC is documented (p < 0.05) according to both clinical and surgical-pathologic staging criteria; however, as shown in Table 32.3 and Table 32.4, the disparity is greater in the clinical category. Thirty-eight percent of patients with larger, more invasive tumors, the cStage IB NSC group, are expected to survive 5 years or more after treatment. In the surgical-treatment group of patients, pStage IB NSCLC, a 57% cumulative survival rate is documented (Table 32.4). The difference in outcome for the cStage IB and pStage IB groups may be related to stage migration, based on the surgical-pathologic evaluation of regional lymph nodes.


FIGURE 32.2. Stage IB (*T2N0M0*) lung cancer includes larger tumors or those of any size that invade the visceral pleura or main bronchus, greater than 2 cm from the carina, or that have atelectasis/pneumonitis extending to the hilar region. No evidence of metastasis is present. (From Mountain CF, Libshitz HI, Hermes KE. Lung cancer—handbook for staging, imaging, and lymph node classification. Houston: Clifton F. Mountain Foundation, 1999, with permission.)

Stage IIA and Stage IIB

Stage IIA includes patients with T1 tumors with metastasis present in peribronchial and/or hilar lymph nodes, the T1 N1 M0 anatomic subset (Figure 32.3). A clinical presentation of stage IIA lung cancer is seldom seen radiographically (n = 26 NSC tumors in this series) and, based on surgical findings, stage migration is a common observation. A larger proportion of patients classified pStage IIA was observed in the surgical treatment group than was observed at clinical presentation. Stage IIB includes two anatomic subsets: First, T2 tumors with metastasis in peribronchial or hilar lymph nodes, T2 N1 M0, and second, T3 tumors with limited, circumscribed

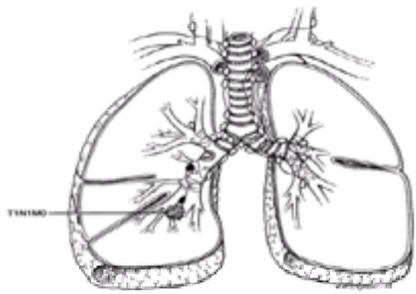
extrapulmonary extension, such as peripheral tumors invading the chest wall or mediastinum and with no evidence of metastasis, T3 N0 M0 (Figure 32.4) A significantly better prognosis (p < 0.03) is shown for patients with cStage IIA NSCLC compared to those classified as cStage IIB—37% and 24% of patients with NSCLC, respectively, expected to survive five years (Table 32.3). The difference in survival rates for patients with pStage IIA and pStage IIB tumors also is significant—55% and 39%, respectively, expected to survive five years after treatment, p < 0.05 (Table 32.4). The rationale for revised stage grouping rules that specifically identify T1 N1 M0 tumors as stage IIA is supported by the end results studies and because a specific category is needed to collect data for studying the outcome of a larger number of patients with a T1 N1 M0 clinical presentation.


FIGURE 32.3. Stage IIA (*T1N1MO*) lung cancer identifies T1 tumors involving peribronchial or hilar lymph nodes by direct extension or metastasis. No evidence of further lymph node or distant metastasis is present. (From Mountain CF, Libshitz HI, Hermes KE. Lung cancer—handbook for staging, imaging, and lymph node classification. Houston: Clifton F. Mountain Foundation, 1999, with permission.)
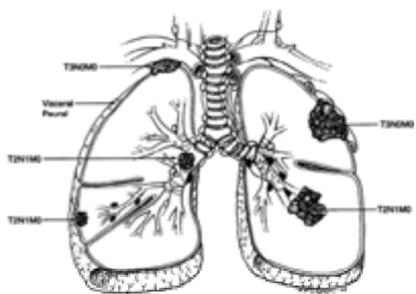

FIGURE 32.4. Stage IIB (*T2N1MO* and *T3NOMO*) lung cancer includes (1) tumors larger than 3 cm., or with other T2 characteristics, that involve peribronchial and/or hilar lymph nodes by direct extension or metastasis. No further lymph node or distant metastasis is present, and (2) tumors with limited, circumscribed, extrapulmonary extension, T3, such as peripheral tumors invading the chest wall or central tumors involving the pericardium, with no evidence of metastasis. (From Mountain CF, Libshitz HI, Hermes KE. Lung cancer—handbook for staging, imaging, and lymph node classification. Houston: Clifton F. Mountain Foundation, 1999, with permission.)

The revised stage grouping that places T3 N0 M0 tumors in stage IIB rather than in stage IIIA is based on the following observations of prognosis. The relationship to survival rates is similar for both the clinically staged and surgical-pathologically staged anatomic subsets of NSC lung tumors: cT2 N1 M0 and cT3 N0 M0, 26% and 21%, respectively, expected to survive five years; pT2 N1 M0 and pT3 N0 M0, 39% and 38%, respectively, expected to survive five years after treatment (Table 32.3 and Table 32.4). The rationale for the revision is also supported by a significant difference in the survival rates between the revised stage IIB and stage IIIA groups of patients.[17]

Stage IIIA

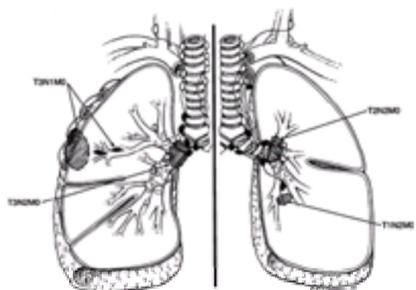
The stage IIIA category classifies tumors with limited, circumscribed extension of the primary tumor and involvement of intrapulmonary or hilar lymph nodes, T3 N1 M0 disease, and the presence of ipsilateral mediastinal lymph node metastasis, N2, in patients with T1, T2, or T3 primary tumors. Four subsets are involved: T3 N1 M0, T1 N2 M0, T2 N2 M0, and T3 N2 M0 (Figure 32.5). The deleterious effect on prognosis of clinically detectable lymph node metastasis is demonstrated in the cumulative survival rates for patients with NSCLC in the cT3 N1 M0 and cT1-2-3 N2 M0 anatomic subsets—9% and 13%, respectively, expected to survive five years (Table 32.3). In patients with N2 disease, the best outcome was shown for a small group with T1 primary tumors, whereas the poorest prognosis was observed for those with T3 tumors. The end results for the surgical-pathologically staged patients show the improved outcome that is achieved for selected patients with stage IIIA NSCLC whose disease is amenable to complete resection (Table 32.4). Similar cumulative survival rates were documented for patients with NSCLC in the pT3 N1 M0 and pT1-2-3 N2 M0 subsets, a cumulative 25% and 23%, respectively, surviving five years. The rationale for modifying the TNM subsets designated as stage IIIA is supported by the end results studies.


FIGURE 32.5. Stage IIIA (*T3N1MO* and *T1-2-3N2MO*) lung cancer identifies (1) tumors with localized, circumscribed extrapulmonary extension, T3, with metastasis involving peripbronchial and or hilar lymph nodes, and (2) T1-2-3 tumors with metastasis involving the ipsilateral mediastinal and subcarinal lymph nodes. No evidence of further lymph node or distant metastasis is present. Tumors involving the pericardium, with no evidence of metastasis. (From Mountain CF, Libshitz HI, Hermes KE. Lung cancer—handbook for staging, imaging, and lymph node classification. Houston: Clifton F. Mountain Foundation, 1999, with permission.)

Stage IIIB

Stage IIIB includes lung cancer with extensive extrapulmonary extension, such as tumor invading mediastinal structures—the esophagus, trachea, carina, heart, major vessels—or the vertebral body, or with malignant pleural effusion, all of which indicate T4 disease. Metastasis to contralateral hilar and ipsilateral and contralateral supraclavicular/scalene lymph nodes may be present, N3 disease; however, no evidence of distant metastasis is present. No revision in the stage grouping of the TNM subsets in stage IIIB was made, except for the modification of the T4 definition described earlier. The subsets include T4 N0 M0, T4 N1 M0, T4 N2 M0, and T1 N3 M0, T2 N3 M0, T3 N3 M0, and T4 N3 M0 (Figure 32.6). Only one-third of patients with cStage IIIB NSCLC are expected to survive 1 year and 5% for 5 years after

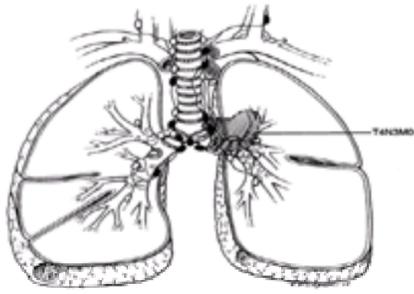
treatment (Table 32.3). This outcome varies slightly according to the TNM category—a 7% cumulative survival rate was shown for the group with cT4 N0-1-2 M0 tumors and 3% for the cAnyT N3 M0 group. Although it may not be clinically relevant, the difference in survival rates between the cStage IIIB subsets and cStage IV is statistically significant, p < 0.01 (Table 32.3).


FIGURE 32.6. Stage IIIB (*T4AnyNMO* and *Any TN3MO*) classi- fies extensive extrapulmonary tumor invasion of mediastinal structures such as the trachea, esophagus, heart and major vessels, and metastasis involving the contralateral mediastinal and hilar lymph nodes, and the ipsilateral and contralateral supraclavicular/scalene lymph nodes. No distant metastasis is present. (From Mountain CF, Libshitz HI, Hermes KE. Lung cancer—handbook for staging, imaging, and lymph node classification. Houston: Clifton F. Mountain Foundation, 1999, with permission.)

Stage IV

Stage IV is reserved for patients with distant metastasis, M1 disease. The M1 descriptor was modified by the addition of ipsilateral (non–lymph node) metastasis in nonprimary tumor lobe(s) as evidence for M1 disease. Clinical signs and symptoms of metastasis to distant organ sites usually are confirmed by imaging techniques; however, routine brain and bone scans have not proved cost-effective for patients with NSC tumors. The significance of adrenal nodules imaged on abdominal computed tomography (CT) should be determined by biopsy. Positron emission tomography (PET) holds promise for making clinical estimates of metastatic disease more reliable; however, specific indications for its use and application of the findings remain under study. [30] The disastrous effect of metastasis to distant organ sites, such as liver, bone, brain, contralateral lung, or distant lymph nodes, is reflected in the survival rates for patients with NSCLC with this manifestation—only 17% expected to survive one year after treatment and less than 1% for five years. (The present data does not include patients with intrapulmonary metastasis classified as M1.)

RECOMMENDATIONS FOR STAGING WHEN THE RULES DON'T FIT

The outcome in patients with lung cancer may be influenced by many factors, and it would be impossible to design a workable staging system that accounted for all of them. In practice, we can use only a classification system that discriminates most patients within a definable subgroup. Thus limitations are imposed on the definitions and, unless such limitations are accepted, a hopelessly complex and unmanageable number of subcategories could result.

In the absence of a body of data that describes the prognostic implications of tumors with no applicable specific staging rule, the TNM and stage classifications must be assigned according to logic or convention. Some common questions and problems in staging lung cancer are as follows:

Discontinuous Tumor Foci in Visceral or Parietal Pleura

Tumor foci in the parietal or visceral pleura that are discontinuous from direct pleural invasion by the primary tumor should be staged T4. Discontinuous tumor lesions *outside* the parietal pleura in the chest wall or in the diaphragm are classified M1.

Invasion of the Phrenic Nerve

Invasion of the phrenic nerve is apparent clinically and usually represents limited direct extension of the primary tumor. As such, it indicates T3 disease and does not preclude surgical treatment, if no criteria for T4 pertain.

Invasion of the Vagus Nerve

Measures of disease extent that cannot be identified and applied to clinical staging should not be considered as staging elements. One does not generally perceive involvement of the vagus nerve clinically unless its recurrent branch (i.e., the recurrent laryngeal nerve) is affected, in which case the involvement is readily detectable. Recurrent laryngeal nerve symptoms are often caused by mediastinal lymph node metastasis, although they can be caused by primary tumor invasion. It is important to note, however, that (a) recurrent laryngeal nerve involvement usually indicates inoperability, and (b) the survival for such patients is similar to that for the IIIB-T4 stage group. Accordingly, we recommend a T4 classification for tumors with evidence of recurrent laryngeal nerve involvement.

Great Vessels

Tumor involvement of the great vessels is classified T4. The following are defined as "great vessels": (a) aorta; (b) superior caval vein; (c) inferior caval vein; (d) main pulmonary artery; (e) *intrapericardial portions* of the trunk of the right or left pulmonary arteries, and (f) *intrapericardial portions* of the superior or inferior right or left pulmonary veins. Involvement of more distal branches of the main arterial and venous trunks would be classified T3.

By virtue of the prognosis and treatment options associated with vena caval syndrome and esophageal and tracheal compression, these manifestations indicate stage IIIB not IIIA disease. It would be contradictory to the T4 definition to routinely assign an N2 classification to these manifestations of disease extent. In the rare instance of a peripheral primary tumor that clearly is not in direct continuity with great vessels, evidence of compression of these structures may be caused by nodal disease. The T and N categories are then classified according to the established rules for these descriptors.

Involvement of the Vertebral Body

In most patients with superior sulcus or Pancoast's tumors with clinical evidence of vertebral body invasion, this extension of the disease indicates unresectability and a poor prognosis. Successful resection for tumors with localized invasion of a specific area of the vertebral body has been reported with a better prognosis than that anticipated for patients with unresectable disease. Investigational surgical programs, usually multidisciplinary efforts undertaken by thoracic and neurosurgeons, have addressed removal of part or all of the vertebra. Although a few patients may be found at operation to have resectable tumor invading the vertebral body, clinical evidence of this extent of disease is generally associated with nonsurgical treatment options and a prognosis consistent with the T4 category.

A tumor arising in the superior sulcus of the lung with evidence for a true Pancoast's syndrome (i.e., a Horner's syndrome and brachial plexus involvement) should be classified T4, whether or not vertebral body invasion is present.

Synchronous Multiple Primary Lung Cancers

Synchronous multiple primary lung cancers should be staged independently. The tumor with the highest stage of disease or more serious prognostic implications should be used for tumor registry entry of a single patient, and a specific field should be assigned for the identification of multiple primary lung cancers. Coding may then be expanded to include particular characteristics for each tumor, such as histology, treatment, and survival data. If synchronous multiple lung cancers have

similar prognoses and staging characteristics, the tumor receiving first treatment should be selected for tumor registry data entry.

REGIONAL LYMPH NODE CLASSIFICATION FOR LUNG CANCER STAGING

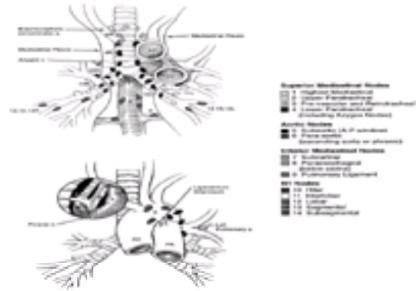
A classification for regional lymph nodes that is compatible with the International System for Staging Lung Cancer, and that incorporates features of multiple systems previously in use, is shown in Figure 32.7 and Table 32.5. This lymph node mapping schema, developed by Mountain and Dresler,[18] provides a single system that incorporates features of the most commonly used lymph node maps—the schema developed by Naruke and which was based on data,[31] and the map proposed by the North American Lung Cancer Study Group, based on recommendations of the American Thoracic Society.[32] The schema has been adopted and recommended by the UICC[20] and the AJCC.[21] For clinical research study of the relationships among specific lymph node metastasis and primary tumor growth, cell type, patterns of recurrence or further metastasis, and biologic factors, a consistent, reproducible method for collecting and reporting data is required.


FIGURE 32.7. Regional Lymph Node Stations for Lung Cancer Staging. (From Mountain CF and Dresler CM, from Naruke,[31] and The American Thoracic Society/North American Lung Cancer Study Group,[32] (copyright 1996, Mountain and Dresler; may be reproduced for educational purposes without permission).[18]

Lymph Node Mapping Schema

The definitions for staging the status of regional lymph nodes (the "N" component) in patients with lung cancer are shown in Table 32.1. Anatomic landmarks for 14 hilar, intrapulmonary, and mediastinal lymph node stations and their accompanying definitions illustrate that all N2 nodes are contained within the mediastinal pleural envelope and that all N1 nodes lie distal to the mediastinal pleural reflection (Figure 32.7). It is difficult to show the anatomic relationships of the three-dimensional structures in the chest in an artistic rendition; therefore, it is important to relate the anatomic landmarks for each station shown on the map to the definitions in Table 32.5. The N2 nodes are numbered 1 through 9 and include the superior mediastinal nodes (numbers 1–4), the aortic nodes (numbers 5–6), and the inferior mediastinal nodes (numbers 7–8). The N1 nodes are numbered 10–14. Numbers 10L and 10R are the most proximal nodes in the N1 category and are designated hilar nodes; numbers 11R/L–14R/L are designated intrapulmonary nodes, with specific designations related to the location on or between the bronchi (Table 32.5). Depending on the location of the primary tumor, the ipsilateral nodes are designated right or left; midline prevascular and retrotracheal lymph nodes are considered ipsilateral. As noted in Table 32.5, researchers may wish to divide the lower paratracheal nodes into superior (4s) and inferior (4i) groups, as an aid to the study of metastasis to specific lymph node levels.

To confirm the extent of N1 and N2 disease, extended or total resection of all lymph node groups accessible to the surgeon is essential (see also Chapter 35). Pathologic assessment of pulmonary resection and lymphadenectomy specimens represents the highest order of reliability. Although most patients with lung cancer are not candidates for surgical treatment, the lymph node mapping schema is useful for clinical staging and correlative studies of diagnostic and evaluative procedures.

The prognostic implications of lymph node metastasis are well known; however, within the spectrum of the N1 and N2 categories, the relationship of the presence and extent of metastasis to the primary tumor status, the status of the lymph nodes (i.e., intranodal or extranodal disease), the number of levels of metastasis, and various histologic and biologic features are not fully understood. A unified lymph node mapping schema provides a means for collecting data to study these important facets of metastatic disease and to apply the information to clinical practice. Table 32.6 lists the database for the staging system used by the authors.

SUMMARY

The recommendations for staging lung cancer and for classifying regional lymph nodes provide a consistent, reproducible method for communicating information and comparing the results of differing treatments for lung cancer. The total tumor burden for a given patient cannot be precisely quantitated, and the balance between host defenses and tumor agressiveness cannot be precisely measured. However, our data support the tenet that patients can be grouped according to certain measurable common features of their disease so that within each stage, treatment options and survival expectations are generally similar. Survival patterns according to staging criteria are a measure of the efficacy of currently available therapy; therefore, the staging information serves as a valuable guide for treatment planning.

CLINICAL AND MOLECULAR PROGNOSTIC FACTORS AND MODELS FOR NON–SMALL CELL LUNG CANCER

CHRISTINE L. LAU
THOMAS A. D'AMICO
DAVID H. HARPOLE, ꞏR

The most important predictor of survival in non–small cell lung cancer (NSCLC) is the TNM stage at diagnosis, with the best chance for cure remaining complete surgical resection. Patients with clinical stage I (pathologic stage I, II, and microscopic IIIA) NSCLC who have undergone resection with a curative intent have an estimated 50% recurrence and cancer death rate at five years.[1,2] An understanding of tumor virulence on a molecular level may identify subsets of early-stage patients with poorer prognosis. If a definitive set of tumor markers that document early recurrence could be identified, earlier intervention (radiation therapy or re-resection for a local recurrence, chemotherapy or a novel therapy for a distant recurrence) may increase the overall survival. Additionally, markers capable of identifying patients with advanced or metastatic disease would prevent unnecessary surgical procedures in this group. This section focuses on identification of clinicopathologic and molecular factors that may be used in combination with the TNM staging system to provide a more accurate substaging system, therefore allowing stratification within a stage of patients at high risk for recurrence and death.

CLINICAL FACTORS

The current staging system does not consider clinical symptoms, histology, or biologic aggressiveness of tumors. The presence of symptoms even when corrected for stage, particularly weight loss and poor performance status at the time of diagnosis of lung cancer, have been found to have a significantly negative impact on survival in patients with NSCLC.[2] Harpole et al.[2] reported that the presence of symptoms in stage I NSCLC was a significant factor in predicting overall survival. In their analysis of 289 patients, 189 without symptoms had a five-year survival rate of 74% versus a 41% survival rate in the 100 patients with symptoms (p < 0.001). The presence of hemoptysis, cough, and chest pain were all found to be predictive of decreased survival.

Male sex has been found to be an adverse prognostic indicator in some studies;[2,4,5 and 6] however, much of this difference may be the result of tumor size at presentation because women tend to present with smaller tumors (as well as less smoking history and increased percentage with adenocarcinoma).[2] Others series have not shown male sex to be an adverse prognostic factor.[2]

Although clinical factors are beneficial in terms of predicting prognosis, their use is limited because of their low prevalence in early-stage lung cancer. Patients with early-stage disease often remain asymptomatic despite having biologically aggressive tumors. Furthermore, symptoms are descriptive in nature and thus subject to patient and physician bias.

HISTOPATHOLOGIC FACTORS

T Status/Tumor Size

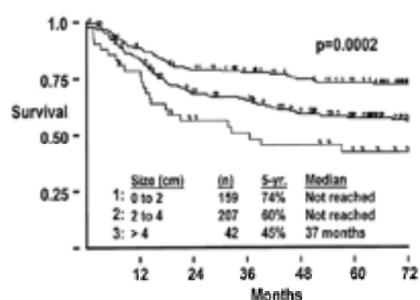
In stage I NSCLC, the size of the primary tumor has been shown to significantly impact survival.[2,8,9] Five-year survivals of 67% to 83% for stage 1A (T1N0) and 50% to 65% for stage IB (T2N0) are reported.[2,5,9] More precise sizing of stage I tumors has also been shown to be prognostically significant with tumors 0 to 2 cm, 2 to 4 cm, and more than 4 cm having five-year survivals of 74%, 60%, and 45%, respectively, as shown in Fig. 33.1 (Harpole, unpublished data). Padilla et al.[7] further substaged T1 stage I disease into tumors 0.1 to 1.0 cm 1.1 to 2.0 cm, and 2.1 to 3.0 cm in size with reported survivals of 90%, 86.1%, and 65.4% (p = 0.0092). Tumor size in stage II lung cancer has also been shown to impact survival with T1N1 tumors having five-year survivals of 55% compared to T2N1 with five-year survivals of 39% (p < 0.05).[9] Martini et al.;[10] however, did not report a statistically significant survival difference between T1 and T2 stage II lung cancer, but they did report improved survival in stage II NSCLC with primary tumors £3 cm compared to those whose primary was ³5 centimeters (p = 0.02). Based on the statistically significant survival advantage seen with T1 tumors, the revised international lung cancer staging system divides stage 1 into stage IA and IB and stage II into stage IIA (T1N1) and IIB (T2N1) (see also Chapter 32).


FIGURE 33.1. Survival by tumor size (cm).

In early-stage lung cancer, the location of the tumor has been shown to be a prognostic factor. Visceral pleural involvement has been shown to correlate with poorer overall survival.[2,8,11] Because of this prognostic significance, tumors with visceral pleural involvement are considered T2 even when they are £3 centimeters in size.[9]

Lymph Node Status

For patients with stage II NSCLC, the number of N1 nodes with cancer and the location of these nodes is more important than the size of the primary tumor. Martini

and colleagues[16] reported that single N1 node involvement in stage II NSCLC was a favorable prognostic factor compared to patients with multiple N1 node involvement (45% versus 31%; p = 0.016). Yano and colleagues[12] assessed 78 patients with stage II lung cancer and found a significant five-year survival advantage in patients with positive lobar N1 nodes (64.5%) compared to hilar N1 nodes (39.7%; p = 0.014). Additionally, in this study the patterns of metastatic spread were different based on location of involved N1 nodes; the brain was the most common site in patients with lobar N1 disease, whereas the lungs were the common site of spread in hilar N1 positive patients. Survival in stage IIIA (N2) NSCLC has also been shown to correlate with the number of lymph nodes involved. Five-year survivals of 43% following primary tumor resection and mediastinal lymph node dissection in patients found to have microscopic metastatic disease in only one mediastinal lymph node has been reported as compared to the 23% to 25% five-year survival for surgically resected stage IIIA disease as a whole. [9,13,14]

Histologic Subtypes

Whether histologic subtyping of NSCLC according to the World Health Organization [15] into squamous cell carcinoma, adenocarcinoma, or large cell carcinoma has prognostic significance regarding overall survival is controversial. Harpole and colleagues [2] and others[7] reported no significant survival advantage for any histologic tumor type in patients with stage I NSCLC. Other groups have shown a significant five-year survival advantage to patients with squamous cell cancers compared to adenocarcinomas.[5,8] The Lung Cancer Study Group reported an increase in recurrence rates in patients with nonsquamous NSCLC. [16] Kwiatkowski and colleagues[6] found no survival differences among stage I lung cancer patients with different histologic types; however, when they subtyped adenocarcinomas, patients with the solid tumor with mucin type had a significantly decreased survival (p = 0.019) compared to patients with the other subtypes of adenocarcinoma.

Martini and colleagues found no survival difference between squamous cell carcinoma and other histologies in 214 stage II NSCLC patients. This group did report a difference in patterns of recurrence based on histology, with squamous cell carcinomas recurring locally and adenocarcinomas distantly. In contrast to Martini et al. [10] Ichinose and colleagues[11] reported on 63 patients with stage II NSCLC and found that patients with squamous cell carcinomas had a significant survival advantage over patients with nonsquamous tumors. Looking at patients with N2 (stage IIIA), Martini and Flehinger [13] found no survival difference between patients with adenocarcinoma and patients with squamous cell carcinoma.

Tumor Differentiation

Tumors can be differentiated based on histologic and light microscopic findings into well, moderate, poor, or undifferentiated. Poorer differentiation is associated with decreased survival in NSCLC.[2,5,17,18] Ichinose and colleagues[11] reported that patients with well-differentiated stage I tumors had five-year survivals of 87% versus 71% five-year survival in patients with stage I tumors that were moderately or poorly differentiated (p = 0.0029). However, tumor differentiation was not found to be prognostically significant in patients with stage II or IIIA tumors in this study.

Lymphatic and Blood Vessel Invasion

The presence or absence of lymphatic or blood vessel invasion has been considered an indication of biologic aggressiveness in NSCLC. Kessler and colleagues [19] used light microscopy to assess blood vessel invasion, specifically the main venous or arterial parabronchial vessels. The presence of blood vessel invasion correlated with a significantly decreased survival in this series in agreement with others. [11,19,20] Ichinose and colleagues[11] reported that fifteen of seventeen patients with recurrence whose primary tumor had venous blood vessel invasion were distant, suggesting the veins as a source for metastatic spread. Harpole and colleagues [2] reported the presence of vascular invasion to be a highly significant factor in prognosis. More recently, Kwiatkowski and colleagues [6] found lymphatic invasion to be a significant negative predictor of survival, with five-year survival in stage I NSCLC patients of 74% if lymphatic invasion was absent, compared to a five-year survival of 54% if present (p = 0.0004).

Routine histologic and light microscopic techniques are used to evaluate tumor size, N-status, histology, differentiation, and vascular/lymphatic invasion, but these methods are limited by sensitivity and the experience of the pathologist. For example, histologically negative lymph nodes may contain micrometastatic disease in 15% of cases.[21]

MOLECULAR MARKERS

The change from normal bronchial epithelium to carcinoma is the end result of a series of acquired genetic mutations and alterations in normal cellular proteins. The critical regulatory genes mutated in NSCLC include various protooncogenes and tumor-suppressor genes. Carcinogenesis can occur with either activation or deletion of these important regulatory genes. Protooncogenes when altered may acquire transforming potential, leading to dysregulation of normal cell growth. Only one of the two alleles needs to be altered for the transforming effect and, therefore, protooncogenes are known as dominant genes. Tumor-suppressor genes have been implicated in lung cancer, with cellular transformation occurring by either elimination of both alleles or by mutation or functional abnormality of their protein products. The reader is referred to Chapter 1, Chapter 2, Chapter 3, Chapter 4, Chapter 5, Chapter 6, Chapter 7, Chapter 8, Chapter 9, Chapter 10 and Chapter 11 for greater detail.

Carcinogenesis

Growth-regulating Proteins

Several genes normally control cell growth and development. Alterations in these genes can change the phenotype of a cell, allow the expression of abnormal signal transduction proteins, and activate multiple enzyme cascades in the cell. Growth-regulating genes whose protein products have been implicated in NSCLC include *ras* oncogenes, epidermal growth factor receptor gene, and *erb*B-2/*Her*2-*neu* oncogenes.

Ras Oncogenes

Ras oncogenes are a family of genes that code for a protein located on the inner surface of the cell membrane (see also Chapter 4). The protein known as p21 is involved in signal transduction and has guanosine triphosphatase activity. Mutations of *ras* genes result in blockage of guanosine triphosphatase activity, allowing a continued signal for proliferation. There are three main members of the *ras* oncogene family (K-*ras,* H-*ras,* and N-*ras*), and the vast majority of mutations involved in NSCLC occur in K-*ras* at codon 12 (other codons 13, 61). Mutations in K-*ras* have been found most commonly in adenocarcinomas and are linked with smoking and asbestos exposure.[22] Slebos and colleagues initially reported activation of K-*ras* oncogene as a strong negative prognostic factor in patients with resected adenocarcinomas.[23] Fukuyama and colleagues[24] reported that NSCLC patients with K-*ras* mutations at codon 12 had a relative risk of death of 5.6 compared to patients without the mutation. In addition to the prognostic significance of K-*ras* gene mutations, the overexpression of p21 has similarly been found to correlate with a negative survival. Harada and colleagues[25] found that NSCLC patients with p21-negative tumors (stained immunohistochemically using anti-*ras* p21 monoclonal antibody rp-35) had significantly longer survival times compared to patients whose tumors were p21 positive. More recently, however, Nemunaitis and colleagues [26] did not attribute significant negative prognostic value to elevated p21 in adenocarcinoma patients with normal *ras*-oncogenes. The majority of evidence, albeit in retrospective studies, indicates that K-*ras* mutations correlate with decreased survival, and therefore little controversy exists that it has value as a molecular marker.

Protooncogenes c-*erbB*-1 and c-*erbB*-2 (HER-2/*neu*)

The protooncogene c-*erbB*-1 encodes for epidermal growth factor receptor (EGFr), a tyrosine kinase-type membrane receptor (see also Chapter 4). Ligand binding to EGFr results in receptor dimerization, autophosphorylation, activation of cytoplasmic proteins, and eventually DNA synthesis. [27] Mutations in c-*erbB*-1 can result in constitutive activation of EGFr despite the absence of ligand, with the result being uncontrolled tumor growth. In NSCLC, elevated levels of EGFr have been shown to be present compared to normal lung tissue. Additionally, elevated levels of EGFr are found in later stage lung cancers and in lung cancers with mediastinal involvement,[26] but these levels have not been found to correlate with prognosis. [22,27,29] However, subset analysis (TINO) in one study evaluating a panel of immunohistochemical markers in resected stage I NSCLC did find a decreased survival rate in EGFr overexpressing tumors. [30,31] Based on the available data, although EGFr may play a role in initial tumorgenesis and may be a marker for advanced disease, increased expression of EGFr cannot currently be considered as a significant prognostic molecular marker in NSCLC.

C-*erbB*-2/*HER*-2/*neu* shares extensive homology (80%) with c-*erbB*-1 and encodes for a transmembrane tyrosine kinase (p185neu), which also functions as a growth factor receptor. Kern and colleagues[32] found that ten of twenty-nine patients with adenocarcinoma overexpressed p185 *neu,* and this overexpression was associated

with decreased survival. Following this initial report, several additional studies have confirmed these results with adenocarcinomas and NSCLC as a group. [4,31,33,34] Overexpression of p185 *neu* is currently felt to be an independent negative prognostic factor in NSCLC.

Cell-cycle Specific Proteins

Normal bronchial epithelium is arrested in the G0 phase of the cell cycle, with a designated cell life. When it reaches the end of its life, an apoptotic cascade begins, allowing the senescent cell to die. Deletion or mutations in the genes involved in regulating the cell's lifespan can cause them to become resistant to apoptosis or "immortal." Apoptotic factors (p53, bcl-2) and cell cycle–regulating factors (Rb, Ki-67, and cyclins) are implicated in NSCLC (see also Chapter 2, Chapter 4, Chapter 6, Chapter 7).

P53 Tumor-Suppressor Gene

The tumor-suppressor gene *P53* encodes for a nuclear phosphoprotein involved in cell growth through regulation of transcriptional events. Mutations in *P53* are the most common mutations associated with human cancers,[3] and in NSCLC *P53* is found to be mutated or overexpressed in more than 50% of cases. Similar to abnormalities in K-*ras,* mutations in *P53* are associated with smoking.[22] Significant controversy remains over its use as a molecular prognostic indicator in NSCLC because in some studies mutation or protein expression of *P53* is associated with decreased survival, [4,6,31,34,35,36,37,38] and [39] some with no association to survival;[25,40] and some with increased survival.[41,42] Reasons for this controversy are unclear but may at least partially relate to whether gene mutation or protein expression is measured.[3,43] Overexpression does not necessarily mean that the *P53* gene is mutated, but it is an abnormal finding. Additionally, the group of NSCLC patients assessed may provide some explanation for the controversy. Dalquen and colleagues found *P53* expression to be a negative prognostic factor in node-negative but not node-positive NSCLC patients.[44] Along these lines, a study consisting of 408 stage I NSCLC patients confirmed the negative prognostic value of overexpression of *P53* with a 70% five-year survival for NSCLC patients with *P53* minus tumors compared to 52% survival for *P53*+ tumors (p = 0.001).[31]

BCL2 Protooncogene (Apoptotic Gene)

The protooncogene BCL2 encodes a protein that inhibits apoptosis (programmed cell death) and thus regulates cell viability. Overexpression of BCL2, surprisingly, has been associated with improved survival in NSCLC [45,46] or a trend toward improved survival.[6,31]

Retinoblastoma (RB) and p16^INK4a Tumor-Suppressor Genes

The *RB* gene encodes a nuclear protein that interacts with the protein product of *P53* in the nucleus and is involved with transcriptional events and cell cycle regulation (keeping the cell quiescent) (see also Chapter 7). This tumor-suppressor gene is located on a chromosomal region often found deleted in the childhood ocular cancer retinoblastoma. Loss of RB protein expression occurs commonly in NSCLC, most often seen in later stage tumors. Loss of RB protein expression has been associated with either a decrease in survival [31,47] or no correlation with survival. [6,48] Additionally, patients with both loss of RB protein expression and p53 protein overexpression (TP53 mutation) have an even worse prognosis. [31,47] D'Amico and colleagues[31] reported five-year survivals in 404 stage I NSCLC patients of 72%, 62%, and 48% for RB+/p53-; RB+/p53+; and RB-p53+ (protein expression) tumors, respectively. Therefore, the loss of RB is felt to be a negative prognostic factor.

A cyclin-dependent kinase inhibitor p16 ^{INK4a} is involved in keeping a cell in the quiescent state (G0). The mechanism by which the gene product of p16 ^{INK4a} inhibits entry into the cell cycle is through its inhibition of the cyclin-dependent kinase 4 mediated phosphorylation of the RB gene product. Inactivation of p16 ^{INK4a} results in unregulated cell growth and transformation. Worse survival has been seen in NSCLC patients whose tumors do not express p16 ^{INK4a}. Additionally, an inverse correlation has been appreciated between levels of RB and p16 ^{INK4a}.

Tumor Invasion

Two processes are necessary for a tumor colony to grow and become invasive: angiogenesis and basement membrane degradation. When a tumor colony expands, it outgrows its blood supply and central necrosis develops. The resultant ischemia stimulates angiogenesis within the cancer, resulting in ingrowth of capillaries and tumor growth. In order for an *in situ* tumor to invade surrounding tissues, the glycoprotein matrix that surrounds normal bronchial epithelium must be degraded by enzymes (matrix metalloproteinases, cathepsin B). These two processes allow cancer cells to enter the lymphatic or vascular spaces, thus setting the stage for the next phase: distant metastases.

Angiogenesis

Tumor-induced neovascularization (angiogenesis) is necessary for both tumor growth and metastatic spread, and a large research effort is currently being directed into studying its role in cancer development (see also Chapter 11). The number of microvessels in an NSCLC can be used to assess angiogenesis. Antibody to factor viii can be used to identify the number of microvessels in an NSCLC,[50] and the degree of angiogenesis as measured by viii staining has been shown to have significant negative prognostic implications. Harpole et al. [34] examined angiogenesis in 275 consecutive patients with stage I NSCLC and found that angiogenesis was the most significant prognostic factor in stage I NSCLC compared to *erb*B-2 (*HER*-2/*neu*), p53, and KI-67. Attempts to increase sensitivity and specificity using immunostaining for CD31(platelet/endothelial cell adhesion molecule) instead of factor viii did not prove successful, and its use did not correlate with prognosis. [51] Recently, an anti-CD34 monoclonal antibody specific for endothelial cells has been found useful in immunostaining of microvessels. [52,53] In contrast to anti-CD31, anti-CD34 antibody has been found to be more specific and reproducible than staining for factor viii. Fontanini et al. [52] prospectively analyzed a cohort of 407 patients with NSCLC, using anti-CD34 antibody to detect microvessels, and found that patients with more vascularized tumors experienced significantly decreased survivals (p < 0.00001). Patients with stage I lung cancers and highly vascularized tumors had 50% two-year survivals compared to 95% survival in this group of patients with the lowest microvessel counts. Besides using endothelial cell antigen antibodies to assess microvessel counts, Imoto et al. [54] reported on the prognostic significance of vascular endothelial growth factor expression in NSCLC and found it to be a significant prognostic indicator, especially with squamous cell cancer.

Invasion/Extracellular Matrix Degradation

Matrix metalloproteinases have been implicated in the breakdown of vascular barriers, allowing tumor cells to infiltrate blood vessels. The matrix metalloproteinase, stromelysin-3, has received the greatest attention in NSCLC and has been found to be more abundant in NSCLC than in normal lung tissue. [55]

Plasminogen activators are members of the serine protease family and convert plasminogen to plasmin. Plasmin can degrade various proteins in the extracellular matrix. Plasminogen activators are regulated by plasminogen activator inhibitors. Yoshino and colleagues have found that decreased levels of plasminogen activator inhibitor 2 correlate with decreased survival and increased lymph node metastases in NSCLC patients. [56]

Cathepsin B is a cellular protein located in the lysosome (cysteine proteinase), and it is involved in protein degradation within the cell. It has been implicated in tumor cells in the digestion of the extracellular matrix. Because it can digest the extracellular matrix, it is involved in tumor invasion and metastases. Higher grade expression of cathepsin B has been prognostically correlated with decreased survival in NSCLC. [3,57] Sukoh and colleagues[57] reported that patients with stage I NSCLC whose tumors strongly expressed cathepsin B had decreased survival compared to patients whose tumors did not express cathepsin B. In contrast, Mori and colleagues[58] did not find high expression of cathepsin B in stage I NSCLC patients to correlate with survival.

Formation of Metastases

A carcinoma can invade surrounding structures, including blood vessels and lymphatic channels, allowing tumor cells to circulate throughout the body. The formation of metastatic lesions, however, requires that circulating tumor cells adhere to the endothelium of a distant capillary or lymph vessel and transgress the endothelial membrane of the target organ. Paget in 1889 identified that tumors require both the "correct seed and soil" for metastatic spread. [59] Therefore, only tumor cells that express the correct adhesion molecules (CD-44, siayl-Tn, blood group A) are able to successfully attach and invade a new location in the body.

Adhesion Molecules

Cluster designation 44 (CD-44), an integral membrane glycoprotein, is a receptor for hyaluronan (component of the extracellular matrix). CD-44 is involved in cell-to-cell and cell-to-extracellular matrix interactions and is correlated with metastatic spread. Expression of CD44 has been shown to be a negative prognostic factor in NSCLC.[31] Hirata and colleagues[60] reported that expression of a variant isoform of CD-44 negatively correlated with survival in stage I NSCLC patients. D'Amico and colleagues reported a five-year survival of 54% in patients with CD44 expression compared to a 67% survival in patients without CD44 expression (p = 0.05).[31]

Blood Group Antigens and Precursor Antigens

The loss of expression of blood group A allows immature blood group antigens to be exposed; these antigens have been implicated in cell motility and, therefore, have been speculated to be involved with metastatic spread. Lee and colleagues[61] assessed the presence of blood group antigens immunohistochemically in 164 patients with completely resected NSCLC. In this study, survival of the twenty-eight patients with blood group A or AB whose lung cancers lacked the blood group A antigen was significantly worse than survivals of patients with the blood group A antigen on their tumors or patients with blood group B or O. Miyake and colleagues[62] stained for the precursors of blood group A and B antigens (H/Le ʸ/Leᵇ) using the monoclonal MIA-15-5 (migration-inhibitory antibody; named for its ability to inhibit motility and metastatic ability of cancer cells) and reported that MIA-positive tumors had a significantly worse prognosis than MIA-negative tumors. The MIA-positive tumor patients had a five-year survival of 20.9% versus 58.6% for patients with MIA-negative tumors (p < 0.001). Additionally, Matsumoto and colleagues[63] found that loss of blood group antigens on lung cancer correlated with increased metastatic potential and worse prognosis. More recently, however, reports have not shown this prognostic correlation in early-stage lung cancer, [6,64] and one report even found that MIA-15-5–positive tumors had an increased survival. [29] Thus blood group antigens and their precursors are currently not felt to be important in the biologic aggressiveness of NSCLC.

Detection of Micrometastases by Molecular Biologic Markers

Occult micrometastatic disease in the lymph nodes and bone marrow not appreciable by routine histologic staining can be detected with the use of immunohistochemic techniques and reverse transcriptase–polmerase chain reaction techniques (rt-PCR) (see also Chapter 1). These techniques are able to detect the presence of one tumor cell in 10^5 to 10^8 normal cells.[65] Rt-PCR may be more sensitive than immunohistochemic staining for detection of micrometastases. [65] The markers used to detect micrometastases include cytokeratins, mucins (cell surface glycoprotein), and various molecular markers such as epidermal growth factor receptor and P53 expression. The use of epithelial elements is particularly appealing because they are directed toward the identification of epithelial elements that are not present in normal lymph nodes and bone marrow. Detection of occult micrometastatic lymph node or bone marrow disease using rt-PCR or immunohistochemistry potentially may allow selection of a subset of patients who would benefit substantially from induction therapies.

Occult micrometastatic disease found using immunohistochemic staining has been shown to correlate with early relapse and worse prognosis. [66,67,68 and 69] Maruyama and colleagues[69] reported on the detection of micrometastases in lymph nodes using an anti-cytokeratin monoclonal antibody and the value of this detection in predicting early relapse in patients with stage I NSCLC. They identified cytokeratin-positive cells in lymph nodes of thirty-one out of forty-four (70.5%) stage I patients, restaging nineteen of these as N1 and 12 as N2 disease, respectively. In these patients with micrometastatic disease in the mediastinal lymph nodes, the disease-free survival rate was significantly shorter than in those with node-negative disease (p = 0.004). Immunohistochemic staining for the presence of EGFr or p53 has also been used in the detection of micrometastatic disease. The presence of these biologic markers in lymph nodes is correlated with decreased survival. [70]

Salerno and colleagues[65] used rt-PCR to detect the presence of messenger RNA transcripts for MUC1 in lymph nodes. Using this technique, they found occult metastases in 33 of 88 lymph nodes negative for metastatic disease based on light microscopy.

Several groups have been able to identify micrometastases of lung cancer in bone marrow. Using immunohistochemic techniques, Pantel and colleagues identified cytokeratin-positive cells in the bone marrow of patients with operable lung cancer and found that their presence correlated with cancer relapse (66.7% versus 36.6%, p < 0.05). This same group later[68] found that 60% with apparently localized disease had micrometastases in their bone marrow. Cote and colleagues, using immunohistochemic techniques to identify bone marrow metastases in 43 NSCLC patients, reported a significantly shorter time to tumor relapse with the presence of micrometastases in the bone marrow (7.3 versus 35.1 months, p = 0.0009).[71] Additionally, for patients with early-stage lung disease, the detection of occult bone marrow metastases was associated with a higher rate of recurrence. Most recently, in 139 patients with NSCLC of various stages, cytokeratin 18–positive cells were demonstrated in the bone marrow in 60%. In the sixty-six patients without lymph node metastases, occurence of two or more tumor cells in the bone marrow was an independent predictor of survival (B. Passlick, *personal communication*).

Markers of Tumor Proliferation

These markers estimate the proportion of tumor cells nearing mitosis and consist of assessment by light microscopy (mitotic index), flow cytometry (ploidy, S-phase), or immunohistochemic techniques (Ki-67, proliferating cell nuclear antigen.

Mitotic Index/Ploidy

Harpole and colleagues reported that tumors with ³15 mitosis per high-power field had a significantly worse survival rate than tumors with a lower number of mitotic figures present.[2] Recently, however, Kwiatkowski[6] found no survival differences in stage I NSCLC patients whose tumors had mitotic index of 0 to 10, 10 to 20, 21 to 30, or more than 30, with five-year survival rates of 68%, 67%, 72%, and 60%, respectively. Investigation into DNA content by flow cytometry initially suggested that more biologically aggressive tumors were aneuploid, whereas those associated with a better prognosis appeared to be diploid. [18,72] Subsequent studies, however, have not confirmed this survival advantage with diploid tumors. [22,73] The prognostic significance of the number of cells in the S-phase (S-phase fraction) of the cell cycle has not been extensively studied in NSCLC. High S-phase fraction has been associated either with a decrease in survival [72] or with no correlation to survival. [3,74] Volm and colleagues[72] reported on 187 predominantly advanced-stage NSCLC patients and found that patients whose tumors had £8% of their cells in the S-phase had significantly improved survival compared to patients whose tumors had >8% of their cells in S-phase (p = 0.041). In comparison, Schmidt and colleagues [74] found no prognostic significance to S-phase percentage in T1N0 tumors.

Ki-67 Proliferation Marker

The tumor proliferation marker Ki-67, a nonhistone nuclear protein, is expressed by cells near mitosis and can be used to identify rapidly dividing tumors. Several series have noted a decrease in survival in association with higher levels of expression of Ki-67. [4,34,73] Pence and colleagues[73] evaluated Ki-67 proliferation indices in 61 predominantly early-stage lung cancer patients (stage I: 39 patients; stage II: 12 patients; stage III/IV: 10 patients) and found that patients with Ki-67 proliferation indexes of less than 3.5 had two-year survivals of 54% compared to 8% for patients with Ki-67 proliferation indexes of more than 3.5 (p = 0.01). In patients with stage I NSCLC, Harpole and colleagues[4] reported a 52% five-year survival in patients with a Ki-67 index greater than 10%, compared to a 68% five-year survival in patients with a ki-67 index of 0% to 5% (p < 0.02). Additionally, Ki-67 proliferation had a highly significant correlation with p53 overexpression. In a larger group of patients, D'Amico and colleagues[31] reported a trend that did not reach significance toward decreased survival in high-versus low-level Ki-67 expression (p = 0.071). In conclusion, higher Ki-67 proliferation indexes appear to inversely correlate with prognosis.

Proliferating Cell Nuclear Antigen

Proliferating cell nuclear antigen (PCNA) is a nuclear protein that binds to DNA polymerase. Because of its involvement with DNA replication, its presence is highest in rapidly growing cells, whereas its level is undetectable in quiescent cells. Ishida and colleagues found that positive staining for PCNA correlated with decreased survival in NSCLC patients.[3,75]

Serum Markers for Early Detection

Various serum markers may eventually be used to identify patients with NSCLC, to identify those with more advanced disease, and to predict prognostic information. Potential serum markers showing promise in NSCLC[76] are carcinoembryonic antigen (CEA),[77,78] CA-125,[79] Cyra21-1,[80] and sialyl Lewis X-I antigen.[81]

MULTIVARIATE MODELS

Because the NSCLCs are a diverse group of tumors, one molecular marker invariably can not predict increased biologic virulence 100% of the time. Adenocarcinomas, large cell carcinomas, and squamous cell carcinomas preferentially express various markers. For these reasons, molecular model systems consisting of a panel of molecular markers have the ability to optimize the sensitivity of biologic markers across the spectrum of NSCLC.

Kwiatowski and colleagues[6] evaluated 244 patients with stage I NSCLC and identified six independent variables that predicted tumor recurrence: (a) adenocarcinoma solid tumor with mucin subtype, (b) tumor diameter ³4 cm, (c) lymphatic invasion, (d) p53 expression, (e) K- *ras* mutation, and (f) absence of H-*ras* expression. This group proposed a molecular pathologic substaging system in stage I NSCLC based on these variables. If patients had £ two factors, then they were assigned as grade 1a; if they had three factors, then they were assigned grade 1b; and if they had ³4 factors, then they were assigned grade 1c. The basis of this substaging was based on the detected five-year cancer-free survival rates of 87%, 58%, and 21% for each proposed substage, respectively. Additionally, they showed that wedge resections were associated with a decrease in cancer-free survival and recommended that lobectomy be performed for stage I NSCLC, unless medically contraindicated.

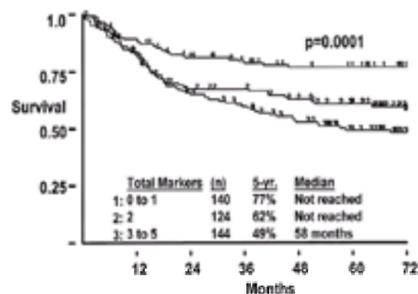
Recently, D'Amico and colleagues[31] proposed a molecular model system consisting of five biologic markers affecting various points in the metastatic sequence (growth regulation, cell cycle regulation, apoptosis, angiogenesis, and metastatic adhesion factor) to further risk-stratify patients with NSCLC. The five biologic factors found to be significant predictors of survival in multivariable analysis were *erb*B-2, RB, p53, factor viii staining for angiogenesis, and CD-44. Combining these factors, patients are stratified into substage 1, zero to one markers; substage 2, two markers, or substage 3, three to five markers, with five-year survivals of 77%, 62%, and 49%, respectively (p = 0.0001) (Figure 33.2).


FIGURE 33.2. Survival by Multivariate Model.

CONCLUSIONS

The TNM stage of NSCLC at diagnosis remains the most important determinant of survival. Clinical factors, including symptoms, performance status, and weight loss, have definitive prognostic value and may be used to supplement the current staging system. Certain pathologic characteristics (tumor size, nodal involvement) of the tumor can be used to stratify patients into risk categories, whereas the role of other factors (histology, differentiation) is currently less defined. Particularly in early-stage lung cancer, the size of the primary tumor correlates with survival. Identifying T2N0 as high-risk stage I disease, the Cancer and Leukemia group B (CALGB) is currently sponsoring an intergroup trial (CALGB 9633) to address the role of adjuvant chemotherapy (taxol and carboplatin) in addition to surgery in this group of NSCLC patients.

Significant research is ongoing, investigating the biology of NSCLC, and the roles of protooncogenes, tumor-suppressor genes, angiogenic factors, extracellular matrix proteases, and adhesion molecules are being elucidated. Although evidence is accumulating that K- *ras*, c-*erb*B-2, p53, *bcl*-2, RB, neovascularization, and extracellular matrix proteases are involved in NSCLC tumor virulence, the current studies are fraught with small sample sizes, heterogeneous populations, and variations in techniques. Other biologic markers, such as EGFr, blood group antigens, and blood group precursor antigens, were initially felt to have prognostic implications in NSCLC, but recent studies have not been able to confirm their value. Studies addressing the use of tumor proliferation markers as prognostic indicators have not conclusively proven their value. Prospective, large studies with homogenous groups designed to evaluate the role of these various markers should clarify their potential involvement in NSCLC.

STAGING AND PROGNOSTIC FACTORS FOR SMALL CELL LUNG CANCER

RONALD FELD
URI SAGMAN
MICHAEL LeBLANC

The emergence of strategies employing combination chemotherapy and radiotherapy have contributed significantly to the management of patients with small cell lung cancer (SCLC) during the last two decades. Most patients respond to initial treatment. Unfortunately, most also subsequently relapse, and cure for most patients with SCLC remains elusive. As with most patients with human malignancies, patients with SCLC undergo staging investigations. An attempt to define disease outcome determinants has also been a goal of management of patients with SCLC. This chapter highlights the traditional approaches to staging and the assessment of prognostic factors in SCLC. Emphasis is given to the limitations of the current staging system and the use of available prognostic factors. Finally, efforts to achieve a consensus for a staging classification for SCLC and novel statistical methodologies are outlined.

STAGING

Even though systemic chemotherapy is the mainstay of treatment for patients with all stages of SCLC, accurate clinical staging is important to determine whether it is necessary to add other treatment modalities, such as radiotherapy, and less frequently to identify the small subpopulation of patients who may be eligible for surgical resection or bone marrow transplantation protocols. Another reason for staging is to determine prognosis. This ability is particularly important for patients who are participating in clinical trials because accurate staging ensures comparability of the patients in each treatment arm and identifies subgroups of varying prognoses that should be stratified to provide balance in the arms. The first revised TNM staging system,[1] when applied to patients with non–small cell lung cancer (NSCLC) resulted in well-defined subgroups of patients whose prognosis depends on tumor size (T), extent of hilar or mediastinal node involvement (N), and presence or absence of distant metastases (M). Because the TNM staging system requires accurate surgical lymph node sampling, it has not been routinely applied to SCLC. Patients with this disease are seldom considered surgical candidates and commonly have radiologic evidence of hilar or mediastinal node involvement. At presentation, more than 90% of patients have stage III (locally advanced) or stage IV (systemic metastases) disease. For these reasons, patients are usually staged according to a simple two-stage system developed by the Veteran's Administration Lung Cancer Study Group.[2] This system classifies patients as having *limited disease* (LD) when the tumor is confined to one hemithorax and its regional lymph nodes, including the ipsilateral mediastinal, ipsilateral supraclavicular, and contralateral hilar nodes. In essence, LD may be defined simply as a localized tumor that may easily be encompassed within an acceptable radiotherapy portal. Tumors that present with ipsilateral pleura effusions, left laryngeal nerve involvement, or superior vena cava obstruction are still considered limited. Pericardial involvement and bilateral pulmonary parenchymal involvement are considered *extensive disease* (ED) because the radiotherapy portal required to encompass this bulk of disease would be too large and would be associated with a significant risk of unacceptable toxicity. Any evidence of disease outside the thorax is classified as ED. In 1982, an expert panel of the International Association for the Study of Lung Cancer (IASLC) reviewed the staging of SCLC and recommended no change in this two-stage system because no stage-specific treatment of lung cancer was required.[3]

Although this simple staging system has gained general acceptance, areas of controversy remain. With respect to nodal involvement, certain investigators believe that patients who have involvement of the contralateral mediastinal lymph nodes should be staged as ED, whereas others prefer to adopt a more liberal approach and recommend broadening the LD category to include not only contralateral mediastinal nodes but also contralateral supraclavicular nodes.[4] The staging of patients with ipsilateral pleural effusions also remains controversial. There is agreement that all patients with contralateral pleural effusions should be included in the ED category. Some investigators recommend inclusion of ipsilateral pleural effusions in the ED subgroup as well, whereas others suggest that such patients should be included only if the effusion demonstrates malignant cells on cytologic examination. A Southwest Oncology Group[5] analysis of outcome of patients with SCLC demonstrated that the survival of patients with isolated pleural effusions and no other evidence of systemic metastases was nearly identical to patients with LD. Further, the same group[6] had reported previously that the prognosis was not altered significantly even when the pleural effusion contained malignant cells.

In 1989, the IASLC published a consensus report that arose out of a workshop on staging for SCLC.[7] They recommended that LD should include patients with hilar, ipsilateral, and contralateral mediastinal and ipsilateral and contralateral supraclavicular lymph nodes as well as patients with ipsilateral pleural effusions both cytologically positive and negative. They based these conclusions on the observation that the prognosis of patients with contralateral adenopathy and ipsilateral pleural effusions is superior to patients with distant metastatic disease and more closely parallels that of patients with LD.

A new TNM staging system for lung cancer has recently been introduced based on data from a recent publication by Mountain.[8] (See also Chapter 32) Both the old and the more up-to-date TNM staging system have not generally been applied to patients with SCLC, which is not likely to change in the near future. Although this is true, several groups have shown that TNM stage is prognostically important for the small subgroup of patients with SCLC who are able to undergo surgical resection.[9,10] In two large surgical series, Shepherd and colleagues[9] and Karrer and associates[10] reported five-year survivals of 68% and 62%, respectively, for patients with pathologically confirmed stage I tumors (T1-2, N0) treated by surgery and chemotherapy. In both these series, the survival of SCLC patients was similar to that of the same TNM subgroups of NSCLC patients. In an attempt to assess the impact of T and N staging on prognosis, the Toronto Group[11] undertook a retrospective study of 180 LD patients and identified a subgroup called *very limited disease* who had a more favorable prognosis. For these patients, who had no evidence of mediastinal or supraclavicular node involvement, obstructing tumors, or pleural effusions, the projected five-year survival was 25%. This unusually good prognostic group may be particularly important in the interpretation of clinical trials of new therapy.

In most series, about one-half to two-thirds of patients are found to have ED. This wide range is the result of variability in both the number of staging procedures undertaken and the sensitivity of the imaging modalities employed. With the introduction of more sensitive diagnostic techniques, more patients will be found to have ED. The removal of these "previously occult" ED patients from the LD group will result in an improvement in survival for both groups of patients (LD and ED), although the overall survival of the two groups will not change. This phenomenon of stage migration, or the Will Rogers phenomenon, in which increased sensitivity of staging

techniques makes all stages of cancer patients appear to live longer, was first reported by Feinstein and colleagues. [12] Dearing and associates[13] analyzed the effect of changes in staging procedures on prognostic factors over a 14-year period. They reported that brain involvement was associated with significantly shorter survival in patients treated before 1979 but not in patients treated thereafter. Brain metastases were diagnosed by radionuclide scanning before 1979 and by computed tomography (CT) after 1979. In contrast, the introduction of CT scanning of the abdomen led to a reduction in the proportion of patients who underwent routine liver biopsy. The scan was less sensitive than blind biopsies, and this led to a poorer prognosis for patients with liver metastases identified by scan than for those identified by histologic examination of biopsy material.

Staging Procedures

The subject of staging of SCLC has recently been reviewed [13] and the author's recommendations go along with our approach to this subject. Table 34.1 lists the staging procedures that are most appropriate for patients who are undergoing standard therapy and for those who are on clinical trials. All patients should have a complete history and physical examination, a chest radiograph, simple blood tests, including hematology with white blood cell differential and platelet counts, and biochemistry, including electrolytes, liver function tests, and alkaline phosphatase and lactate dehydrogenase (LDH) levels. For patients who are not in a clinical trial, some level of further investigation is required to determine whether they have LD or ED because patients with localized tumors are potential candidates for combined modality treatment programs that incorporate thoracic irradiation. Because the determination of all sites of metastatic involvement does not influence the choice of therapy, it may not be necessary to undertake all scans for all patients. The most common sites of extrathoracic involvement are the bone, liver, bone marrow, and central nervous system. If abnormalities are detected on the baseline history, physical examination, or laboratory screening tests, the initial staging tests should be directed by those abnormalities. Once a staging test is positive and ED has been confirmed, it is not necessary to proceed with the rest of the staging investigations unless required for a clinical trial. [14],[15]

TABLE 34.1. RECOMMENDED STAGING PROCEDURES FOR PATIENTS WITH SMALL CELL LUNG CANCER

As diagnostic procedures have become more sophisticated, the costs incurred to investigate patients with SCLC have also increased. In the absence of a specific therapeutic intervention that contributes significantly to long-term survival, these costly diagnostic procedures potentially only add to the cost of therapy without offering a significant benefit in terms of outcome. In this era of increased competition for healthcare funds, greater fiscal responsibility on the part of the physician is essential, and it becomes increasingly necessary to limit diagnostic and therapeutic procedures to those that have significant impact on treatment decisions or treatment outcome. Richardson and colleagues[15] from the Navy Medical Oncology Branch of the National Cancer Institute developed an algorithm for staging SCLC patients. They recommend that patients should be staged using a sequence of procedures, rather than a standard battery of staging tests for all patients. They reported that approximately 20% of their patients were found to have ED on their initial history, physical examination, and routine biochemical screen. Those patients did not undergo any further scans. The patients who had no evidence of ED on their initial diagnostic evaluation underwent investigation of the bony skeleton first, followed by abdominal and then cranial CT. At each step, further testing was discontinued once a positive result was obtained. This series of staging procedures resulted in an overall cost saving of $1,418.00 per patient. The major factor in reducing costs was the concept of stopping subsequent staging procedures once a single site of distant metastatic disease had been identified.

Intrathoracic Staging

The plain posteroanterior and lateral chest radiograph is one of the most important diagnostic tests for patients with SCLC. [16] Its sensitivity, ease of performance, and low cost make this option the investigation of choice for repeated assessment of response during therapy. It is well recognized, though, that plain chest radiographs may underestimate the degree of chest wall invasion or involvement in the mediastinum either by direct extension of the tumor or by mediastinal lymph node metastases.

Computed Tomography

With the introduction of CT in the late 1970s, a giant step was taken in the ability to diagnose and stage lung cancer employing noninvasive imaging techniques. CT imaging confirms abnormalities seen on plain chest radiograph and can often detect lesions that cannot be resolved on chest radiograph. It also has played an important role in staging lung cancer, especially spread to areas of the mediastinum undetected on plain films, although perhaps it is more important for patients with NSCLC. There is a general agreement that normal mediastinal lymph nodes are less than 1 cm in transverse diameter. Any lymph node larger than this suggests lymphadenopathy and should be investigated further by more invasive techniques. [17],[18]

CT also can suggest possible areas of local invasion of the primary tumor to chest wall, vertebrae, or mediastinal structures. Small pleural effusions or pleural nodules, often undetected on plain films and evident on CT, are of uncertain significance. [19],[20]

An added advantage of CT scanning is the ability to detect abnormalities below the diaphragm, especially metastases to the liver and adrenal glands. CT for the investigation of lung cancer should include upper abdominal scanning to the level of the kidneys to include imaging of the liver and adrenal glands. With respect to determining metastatic spread to mediastinal lymph nodes, a large prospective study comparing the results of CT with pathologic staging of the mediastinum showed a sensitivity on a per-patient basis of 64% and a specificity of 62%. Although the likelihood of metastatic involvement increases with increasing size of lymph nodes, 15% of nodes less than 10 mm in size may contain tumor, and conversely, as many as one-third of lymph nodes measuring 2 to 4 cm in diameter may not contain tumor.[21],[22] and [23] Although CT scans provide superior visualization of the soft tissues of the hila and mediastinum, confirmation of hilar or mediastinal lymph node involvement is not likely to alter treatment for most patients with SCLC. For that reason, CT scanning does not always play a critical role in the management of patients with this tumor, and the major uses of this diagnostic technique should be to plan radiotherapy for those patients found to have LD and to exclude patients with disease that cannot be encompassed in a tolerable radiotherapy port. In view of this, Richardson and colleagues [15] recommend delaying CT scanning until all other investigations have ruled out extrathoracic metastatic spread. This procedure could potentially reduce the number of CT scans needed by more than 60%. Unfortunately, however, many patients have already had a thoracic CT scan by the time they are referred to a medical oncologist. There is general agreement that magnetic resonance imaging (MRI) does not add significantly to plain chest radiograph or CT scanning for patients with SCLC. [24],[25]

Although positron emission tomography (PET) is being explored extensively in NSCLC for staging purposes, very little information is presently available on its value in staging SCLC. Because of both the lack of data and the lack of PET scanners worldwide, its use for the staging of this malignancy must presently be considered experimental. Invasive staging procedures to define the extent of intrathoracic tumor are seldom necessary for patients with SCLC. Fiberoptic bronchoscopy need not be undertaken, unless it is necessary to make a diagnosis. However, if bronchoscopic confirmation of complete response is required for patients participating in a research protocol, a pretreatment bronchoscopy is essential to compare results. [26] Similarly, mediastinoscopy is almost never required for patients with SCLC with the possible exception of the very small subgroup of patients with T1-2, N0 tumor who may be considered for surgical resection. [11]

Central Nervous System Metastases

Brain metastases are present at the time of initial diagnosis in approximately 10% of patients with SCLC [14],[15] but may be present at autopsy in up to 65% of patients.

Although MRI is probably superior to CT in the detection of brain and spinal cord metastases, CT scanning remains the most common staging investigation for the central nervous system. Because CT scanning is more sensitive than radionuclide scanning of the brain, it can identify considerably smaller tumor deposits. This method has the potential to significantly alter the prognostic implications of detecting metastatic disease in the brain. As shown by Dearing and colleagues [13] in their review of 411 patients with SCLC, brain involvement diagnosed by radionuclide scanning before December 1979 was associated with shorter survival, but this was not the case for patients treated thereafter who had their brain metastases documented by CT scanning. For the 19 patients in this series who presented with brain involvement as the only site of ED, survival was only slightly less than that of the LD patients. Other investigators have also reported that patients who have asymptomatic brain metastases diagnosed incidentally through staging procedures have a survival similar to that of LD patients. [27]

Leptomeningeal involvement and carcinomatous meningitis are infrequent at the time of initial diagnosis of SCLC. Therefore, lumbar puncture and cytologic analysis of the cerebral spinal fluid should not be considered a routine staging procedure and should be undertaken only if indicated by clinical symptoms. Several lumbar punctures may be required to confirm the meningeal involvement. MRI may contribute significantly to the diagnosis of carcinomatous meningitis and may be more helpful than myelography, which will not demonstrate the tumor unless nodular lesions are present along the nerve root sleeves or the spinal cord.

Abdominal Staging

The liver and adrenal glands are common sites of metastatic involvement in SCLC. [14,15,28] Radionuclide scanning of the liver has virtually been abandoned in favor of ultrasound and CT scanning, which have the potential to detect not only liver metastases but also adrenal and other abdominal metastases. Hirsch and colleagues [28,29] compared ultrasound and CT in a prospective study of seventy-seven patients undergoing staging for SCLC. For liver metastases, the diagnostic sensitivity, specificity, and negative predictive value were not statistically different, although the positive predictive value was slightly lower for CT than for ultrasound (0.67 versus 0.86). Conversely, extrahepatic abdominal metastases were diagnosed more often by CT than by ultrasound, and in 14% of patients, extrahepatic metastases were diagnosed exclusively by CT. The median survival was 458 days for the 36 patients classified as having LD after both CT and ultrasound, compared to 242 days for the patients with ED. The median survival for the 10 patients with stage migration from LD to ED based on CT alone was intermediate at 242 days. In the subgroup of 22 good performance status patients with normal serum LDH and alkaline phosphatase levels, the two-year survival was 31%. Five of these patients were downgraded from limited to ED by CT scanning. When these five patients were removed from the good prognostic group, the two-year survival rose to 41%.

Some investigators[30] have also recommended liver biopsies performed either under ultrasound guidance or by peritoneoscopy. In the prospective study discussed earlier, sixty patients underwent peritoneoscopy and biopsy as well as CT and ultrasound. In only one patient was metastatic disease identified by biopsy that had not been previously identified by CT or ultrasound. This result would indicate that invasive biopsy procedures are probably not indicated as a routine staging procedure. Dearing and colleagues[31] assessed the prognostic impact of demonstrating liver metastases by biopsy as opposed to CT scan. They demonstrated that liver metastases were associated with shorter survival when diagnosed by CT scan compared to those identified microscopically by a routine liver biopsy. This finding again demonstrates the important impact that the sensitivity of individual staging procedures may have on the assessment of survival of cancer patients.

Bone Marrow Staging

A bone marrow aspirate and trephine biopsy reveal involvement of the marrow by SCLC in 20% or more of patients at the time of initial diagnosis, [15,32] but in less than 5% of patients is this the only site of extrathoracic spread. Single iliac crest aspirations and biopsies are usually carried out, but some investigators have recommended bilateral biopsies. In contrast, oncologists have been questioning whether the bone marrow needs to be investigated. Campling and associates [33] were the first to report that bone marrow examination changed the stage in less than 5% of patients. Since then, similar results have been reported by other investigators,[34,35] and there appears to be general agreement that bone marrow examination should be performed only when no metastatic sites have been found. In fact, outside the clinical trial setting, bone marrow examination can probably be abandoned completely for patients who have normal peripheral blood counts. This point is emphasized in a review by Shepherd.[36]

When more sensitive techniques are employed, a higher incidence of bone marrow involvement may be detected. Stahel and colleagues [37] used a monoclonal antibody reactive with the surface membrane of SCLC cells, SM1, and tumor cells were detected in 69% of patients examined with this technique, compared to only 16% when the bone marrow was examined only by routine microscopy. Unexpected marrow involvement has also been detected using systemically administered monoclonal antibodies,[35] and SCLC colonies have been grown from apparently normal bone marrow in the tumor stem cell assay.[34] Another method of possibly improving on the diagnosis of bone marrow involvement is the use of monoclonal antibody to MLuC1. In a recently published study, [38] when the bone marrow was incubated with this antibody, positive cells were detected in 38% of 108 samples 60 patients compared to only 13% of the biopsies not incubated with the antibody (p < 0.001), and these patients also had a poorer survival. Although these latter approaches may be useful for the evaluation of patients being assessed for possible autologous bone marrow transplantation, they must be considered research tools at this time and are not part of the routine evaluation of patients with SCLC. Many studies using MRI to evaluate bone marrow involvement by SCLC have been carried out. [35,40,41] This technique does seem to pick up involvement more often than other approaches but does not help to predict prognosis in these patients and, therefore, is still considered experimental in the staging of SCLC.

Biomarkers

Many biomarkers have been identified in patients with SCLC. Although they may correlate to the disease stage and provide some degree of prognostic information, most biomarkers have not proved to be useful independent prognostic indicators. Although rising levels of biomarkers may antedate clinical evidence of tumor relapse by several weeks or months, changes in tumor markers are seldom used to guide therapy.[42] The consensus is that biomarkers are of little value for pretreatment prognosis or as early markers of relapse. They add only to the cost and should at this time be considered as research tools.

The single exception is the serum LDH level. Several investigators have found this simple biochemical test to be an extremely useful prognostic factor. [3,5 and 6,43] Other more recent studies confirm the value of serum LDH levels as a good independent prognostic factor in this disease. It is an independent prognostic variable, and serial measurements often mirror clinical response. Furthermore, Sagman and associates[44] reported that LDH levels were rarely normal in patients with bone marrow involvement. They recommended that patients with normal LDH levels need not be subjected to invasive bone marrow staging procedures. Although still controversial, many European studies suggest that elevated serum levels of neuron specific enolase (NSE) may be a useful marker to predict for a worse prognosis [45,46,47] This marker may be especially important because a high proportion of patients (88% in one study) have an elevated level of this marker at presentation; [45] therefore it may be possible to identify the small group of patients with normal levels who may have a particularly good survival. This marker is still not accepted as a routine to be used in patients with this disease. None of the markers discussed have been found to be better than clinical examination or imaging to detect early recurrence. [48]

Monoclonal Antibodies

Several groups evaluated the usefulness of monoclonal antibodies in the detection of bone marrow metastases in patients with SCLC. Balban and colleagues reported their results with a technetium-99mm–labeled monoclonal antibody (NRLU-10 Fab) administered intravenously, followed by total-body scanning 14 to 17 hours after injection. Fifteen patients were studied, and metastases to the marrow compartment were identified in one patient who had known bone marrow involvement. Unexpected radioactive marrow uptake led to the reassessment of the bone marrow and histologic confirmation of metastatic disease in two patients.

Skov and associates[49] evaluated a panel of monoclonal antibodies using immunohistochemic techniques in the diagnosis of bone marrow infiltration. Although the monoclonal antibodies detected tumor deposits in patients with known involvement, they did not detect metastatic tumor in bone marrow sections from patients who did not have tumor identified by routine histologic examination.

Monoclonal antibody imaging techniques appear to be neither sensitive nor specific enough to replace any of the staging procedures more commonly in use. Nonetheless, monoclonal antibody staging of the bone marrow is potentially beneficial for the small proportion of patients who may be considered for high-dose chemotherapy and autologous bone marrow transplantation, should this type of treatment prove successful in future trials. Anti-Hu antibodies (HuAb) recognize antigens expressed by neurons and SCLC. In a recent study involving 196 patients, the presence of the antibody at diagnosis of patients with SCLC was found to be a strong and independent prognostic factor that predicted for complete response and hence prolonged survival. [50] This interesting data requires confirmation.

Many studies have been conducted to evaluate iii octreotide scans for staging patients with SCLC. [51,52,53 and 54,55] Although some of these studies are encouraging, many do not support its general use at the present time. It rarely detects disease not detected by other imaging techniques.

Other new markers, such as vascular endothelial growth factor, (VEG-F)[56] TPS and CYFRA-21-1,[57] look promising as possible future prognostic factors in patients with SCLC based on the preliminary data from the quoted studies, whereas the presence or absence of anti-*p53* antibodies does not look encouraging in this regard.[58]

Restaging

Plain chest radiographs provide a simple and cost-effective way to follow patients and assess response during treatment for SCLC. However, as reported by Quoix and associates,[59] the ability to reliably assess tumor size on chest radiographs falls considerably after treatment. Nonetheless, it should not be necessary to repeat CT scans routinely unless a radiotherapy decision needs to be made. For patients with LD who have responded to chemotherapy, little is to be gained by routine restaging of extrathoracic sites. In a retrospective study reported by Feld and colleagues [60] for the National Cancer Institute of Canada, posttreatment bronchoscopy revealed residual disease in 9% of patients who had achieved complete clinical response based on radiologic assessment. A small survival benefit was demonstrated for the subgroup of patients who had a negative posttreatment bronchoscopy, but because all patients received radiotherapy, the results of this investigation did not alter treatment strategies for any patient. The investigators suggested, therefore, that posttreatment bronchoscopy should be undertaken only in clinical trials. An economic analysis that was also part of this study supported the concept of not undertaking extrathoracic restaging. In contrast, Stahel [14] still recommends restaging, including repeat bronchoscopy.

New Concepts for Staging

Although the simple LD and ED staging system for SCLC has provided worthwhile prognostic and therapeutic information for several decades, analyses of large patient databases from several cooperative groups have identified subgroups of patients within both the LD and ED categories who have significantly different prognoses. Shepherd and colleagues[11] reported significantly longer survival for patients with LD who had no evidence of mediastinal lymph node involvement, obstructive pneumonia, or pleural effusion. This subgroup of patients had a projected five-year survival of 25%, and because this group of patients represents most of the five-year survivors in this disease, an imbalance of this group in a clinical trial could have major consequences on the interpretation of outcome.

Albain and colleagues[5] for the Southwest Oncology Group, and Sagman and colleagues,[43] for the University of Toronto Group, have analyzed multiple prognostic variables using recursive partitioning and amalgamation techniques to refine the two-stage system.

PROGNOSTIC FACTORS

A general truism of both clinical and biologic aspects of SCLC is its remarkable heterogeneity. Studies of prognostic factors aim directly or indirectly to explain the nature of this heterogeneity. It has therefore become the goal of investigators to identify and assess prognostic factors as predictors of the natural history of the disease. Both practical and theoretic reasons for studying prognostic factors exist, particularly as they relate to SCLC. *A prior*, it should be possible to predict the outcome of patients with disease with a great degree of accuracy. The assessment of prognostic factors also allows for valid comparison in assessing the results of treatment. As such, prognostic factors are used to stratify patients into comparable prognostic groups. In the design of clinical studies, prognostic factors are used to define eligibility criteria or assignment of patients into specific risk groups. Prognostic factors therefore aid in the stratification of patients and aim to minimize confounding factors that may influence the results of treatment. Prognostic factors may also serve as a guide in the selection of alternative treatment for patients both in clinical studies and in the management of individual patients. Finally, prognostic factors may clarify the understanding of the natural history of the disease and hence may provide insight into further studies.

Relation to Staging

The primary role of staging investigations is to assess tumor bulk and its anatomic distribution. The extent of detectable tumor spread, however, has inherent limitations in predicting the natural history of the disease, and in fact measurable extent of disease may not necessarily reflect the aggressivity of the tumor. Staging, therefore, cannot be used in isolation in making accurate prognostication. The influence of other factors that may reflect tumor activity must complement clinical staging. The identification of prognostic attributes that reflect the biologic behavior of tumors have led to the realization that several factors provide separate and additional value in the prediction of disease outcome. In turn, efforts have been mounting to exploit the collective impact and influence of select prognostic factors in addition to disease extent.

Chronology

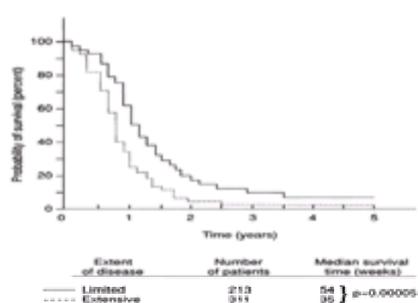
The most consistent prognostic attribute in SCLC in the past was extent of disease as determined by staging investigations. Disease extent partitions patients into those with disease confined to a hemithorax (LD) and those with disease outside those confines (ED). As demonstrated universally and by data from the Toronto group (Figure 34.1), the probability of survival for LD patients is significantly superior relative to that for patients with ED. Further progress in the identification and assessment of prognostic factors in SCLC has evolved along two principal paths. First, it has become apparent that the current staging system lacks stringency and, in fact, may not reflect tumor burden accurately, so that dissection of each stage by further assessment of tumor bulk is essential. As illustrated in   Figure 34.2, evidently, patients with LD can be further divided into those with and without mediastinal involvement, and the number of metastatic sites further segregates patients with ED. Consequently, four distinct prognostic groups are formed. Furthermore, the actual metastatic site bears prognostic significance in patients with ED, as illustrated by the uniformly grave outcome for those with brain involvement and the more favorable prognosis for those with bone metastasis relative to patients with liver spread (Figure 34.3). The amalgamation of patients into either disease category under the current system enshrines prognostic biases that may have deleterious bearing on treatment planning approaches and on the interpretation of response to treatment.


FIGURE 34.1. Overall survival curves from date of first treatment for patients grouped by extent of disease.
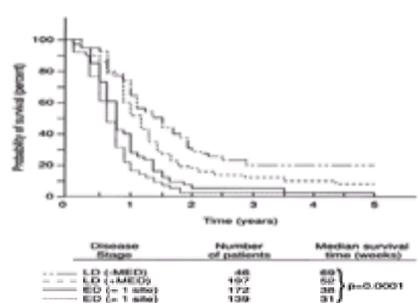

FIGURE 34.2. Overall survival curves from date of first treatment according to mediastinal involvement for patients with limited disease (LD) and according to number

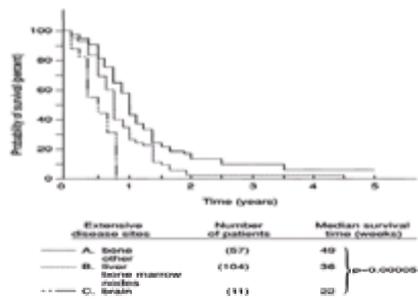
of metastatic sites for patients with extensive disease (ED).


FIGURE 34.3. Overall survival curves from date of first treatment for patients with extensive disease according to specific sites of metastasis.

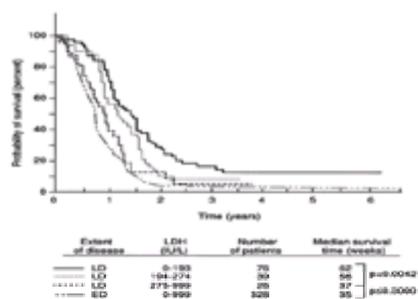
Second, it has become clear that clinical staging is an important prognostic factor but of a different nature from biologic factors. The influence of biologic prognostic factors are to be seen as a measure of tumor aggressivity and must complement clinical staging. As an example, in Figure 34.4, elevated levels of serum LDH in patients with LD predict poorer survival relative to patients with LDH in the normal range. Moreover, the survival of a subset of LD patients, those with markedly elevated levels of LDH, is not significantly different from that of patients with ED.


FIGURE 34.4. Survival curves from date of first treatment for patients grouped by extent of disease and by different ranges of pretreatment serum lactate dehydrogenase (LDH) levels.

Emphasis on the further assessment of tumor bulk and the identification of substances that reflect the biologic behavior of tumors have led to the identification of numerous prognostic factors in SCLC. These factors encompass attributes of clinical determinants, tumor markers, routine laboratory parameters, biologic features, and host factors. Table 34.2 outlines the most important of these prognostic factors. The realization that several factors provide separate and additional value in the prediction of disease outcome forged the basis for analysis of multivariate prognostic models. These models, in turn, seek to exploit the collective impact and importance of select prognostic factors. Multivariate models inherently depend on the methodology used for their development. Traditional and novel methods have been used in the analysis of multivariate models. These methods are described in more detail before a discussion of multivariate prognostic models for SCLC.

TABLE 34.2. SUMMARY OF PROGNOSTIC FACTORS IN SMALL CELL LUNG CANCER

STATISTICAL METHODS FOR PROGNOSTIC STRATIFICATION

Standard methods for forming prognostic strata are the familiar statistical tools used to explore censored survival data, such as the Kaplan-Meier estimator of the survival function,[61] the logrank test statistic for assessing differences in survival between two or more groups,[62] and Cox's proportional hazards regression model.[63] These methods are well known and often used for developing prognostic stratifications. In addition, tree-based methods for exploring survival data have been developed and are particularly useful for forming prognostic groupings of patients.

Tree-Based Methods for Survival Data

Tree-based methods, often called *recursive partitioning methods*, have found applications in many scientific fields, including pattern recognition, artificial intelligence, and medicine. Tree-based methods have several advantages over traditional linear model methods such as linear regression, logistic regression, or the Cox regression models. Probably most important to clinicians, the decision tree representation of the model can yield easier interpretations than linear models, especially for classification and prognostic stratification. Although the tree-based methods have been in existence since the early 1960s,[64] advances in the methodology, as included in the Classification and Regression Tree (CART) algorithm of Breiman, Friedman, Olshen, and Stone,[65] and the availability of software have helped tree-based methods become popular tools for classification.

Tree-based methods as applied to prognostic classification models can be described as follows: A rule splits the initial patient population into two groups according to a splitting rule that maximizes their differences. This splitting rule is applied repeatedly until all the patient population has been split into prognostic groups, each containing only a few observations. The partition is represented as a binary tree. The data within each of the prognostic groups is assumed to be relatively homogenous. Therefore, for survival data, the simple Kaplan-Meier estimate of the survival function can be used to describe prognosis in each group. Typically, a large tree or model that overfits the data is formed to ensure that all possible distinct prognostic groups have been investigated, and the tree is then "pruned" back. This process is analogous to forward stepwise regression and backward stepwise regression methods that are available in many statistical packages. A schematic of

the recursive partitioning approach is depicted in Figure 34.5.

FIGURE 34.5. The first split decision statement (SDS) allocates patients into internal nodes 2 and 3 as stipulated by covariates Xii and Xi, respectively. Recursive splitting of nodes 2 and 3 by SDS_2 and SDS_3 culminates in four terminal nodes dictated by covariates Yi and Yii for nodes 4 and 5, respectively, and Zi and Zii for nodes 7 and 6, respectively. Terminal nodes 4 and 7 are distinctly different with regard to the outcome criteria, and hence by definition are designated as classes A and C, respectively. Terminal nodes 5 and 6, which originate from different internal nodes, are similar with regard to the outcome criteria and hence are amalgamated into a homogeneous class, B. Classes A, B, and C are homogeneous and by definition significantly different from each other. Recursive partitioning steps are outlined by solid lines, and the amalgamation algorithm by broken lines. Note that the root defines the initial patient population.

Tree-based methods for survival data that adopt most aspects of the CART algorithm have been proposed by several authors.[66,67,68,69 and 70] Although differences exist in the algorithms, basic components of the tree-based methods for survival data include general rules. For the sake of brevity, these have been expounded on in the Appendix at the end of this chapter and are outlined under the headings.

Multivariate Models

During the past decade, at least nine groups reported on multivariate assessment of prognostic factors for SCLC. These models used different statistical methodologies, with most employing proportional hazard models (Table 34.3). Some conclusions could be drawn from the tabulation of factors incorporated into these models. The first is that each model uses a different permutation of prognostic factors; that is, no two models used identical factors. Second, most models used factors in addition to those employed in clinical practice, such as disease extent and performance status. For example, mediastinal status in LD and sites of disease in ED, and age and sex as attributes of disease bulk and patient characteristics, respectively, were predominant in most models. These same conclusions are further illustrated with the incorporation of biologic attributes in these same models. These attributes included serum LDH and alkaline phosphatase biochemically; aspartate transaminase, albumin, urate, sodium, and bicarbonate, serologically; and hematologic parameters, such as hemoglobin and total white blood cell count. Here, in fact, some models have not incorporated any of these biologic attributes, whereas others used them exclusively in their models.

TABLE 34.3. MULTIVARIATE ASSESSMENT OF PROGNOSTIC FACTORS IN SMALL CELL LUNG CANCER

Reasons for the analysis of multiple prognostic factors vary. The methods of analysis used may depend heavily on the reasons for doing the analysis. In considering assessment of multiple factors, interactions between prognostic factors are important and, in fact, not explored fully by the proportional hazard models. Therefore, other multivariate methods were evaluated in the analysis of prognostic factors in SCLC.

Tree Classification Approach

As a statistical tool, recursive partition and amalgamation algorithm have been developed in an effort to integrate clustering and amalgamation techniques into a biomedical context. The tree classification methodology and respective computer program have been detailed elsewhere.[67] In its application to data on SCLC, the aim of the analysis is to define homogeneous prognostic strata on the basis of censored survival times. At the University of Toronto Hospitals, we have accrued retrospective data on 614 patients with SCLC entered into four therapeutic studies during a ten-year interval (1976 to 1985). Twenty-one prognostic factors encompassing attributes of both clinical and biologic significance were evaluated by the tree classification method. Figure 34.6 illustrates the tree classification model for the patients with SCLC. Disease extent, the first split decision statement, partitions the initial population into those with LD and ED. Subsequent partitioning of those with LD ensues by knowledge of mediastinal status, white blood cell count, sex, and serum LDH. Patients with ED are further partitioned by the attributes, performance status, serum alkaline phosphatase, sex, and liver involvement. Ultimately, the amalgamation of eight terminal nodes elaborates four prognostic groups. The respective survival curves of the groups are illustrated in Figure 34.7.

FIGURE 34.6. Tree classification model for patients with small cell lung cancer. Classes A, B, C, and D are homogeneous and significantly different from each other. By definition, leftward branchings and increasing class order denote poorer prognosis. LDH, lactate dehydrogenase; LD, limited disease stage; ED, extensive disease.

FIGURE 34.7. Survival curves for the prognostic groups identified in the tree classification model.

Several features are important to emphasize regarding the tree classification model. First, in contrast to multivariate regression models, in which prognostic factors impart global influences, the tree classification model emphasizes interactions among prognostic factors and hence identifies the importance of specific prognostic factors to specific subpopulations of patients. Second, the assignment of patients by the tree classification model into four prognostic groups defies the conventional two-stage classification for SCLC and, hence, infers that the current staging system has inherent limitations. In fact, the intermediate prognostic groups (B and C; see Figure 34.6) are obtained by amalgamating nodes issuing from both the ED and LD categories. Finally, the model clearly shows that patients in each prognostic group are easily identified by a constellation of distinct prognostic attributes. A particular advantage of the tree classification model, then, is that the identification and definition of prognostic groups in clinical terms enable the application of complex prognostic analysis to direct clinical settings.

Consensus Model

As joint consideration of many prognostic factors led to development of diverse prognostic models, a need to establish a consensus model evolved. Ideal methodology to achieve this aim is being sought to enable applications both in clinical trials and in the management of individual patients. Toward this end, efforts have been mounting to develop a new prognostic classification for SCLC through an overview analysis of available collective data.

A working schema for the attainment of a consensus model through an overview analysis has been developed. The analysis was based on an aggregated pool of prognostic data from diverse international centers conducting studies on lung cancer. The tree classification methodology was chosen for the analysis as a vehicle for use both in clinical trials and in the management of individual patients. The variables selected to define the resulting four prognostic groups allocated a pivotal role to serum LDH in addition to extent of disease and performance status.[71] The other prognostic variables chosen to define prognostic groups included age, sex, and the present of brain metastases. The consensus model was tested for each individual center participating in the overview analysis. Similar prognostic groups were obtained for each center.

The consensus model confirms the importance of select prognostic attributes that bear on disease outcome in addition to knowledge of disease extent, which traditionally is assessed by staging procedures. The impact of newer approaches to prognostication and staging in SCLC is yet to be fully realized in patient care. However, as more effective treatments evolve, it is hoped that staging strategies and disease prognostication will bear more extensively on direct patient management, clinical studies, and healthcare costs.

Recent Studies

A group of Danish investigators tried to identify a subset of SCLC patients at increased risk for early death due to treatment.[72] They looked at a population of 937 patients on recent randomized trials by this group. Poor performance status, high serum LDH at presentation, and initial therapy with epipodophyllotoxins (etoposide and tenoposide) and cisplatin during the first course of therapy predicted for a high risk of early toxic death. They produced an algorithm to remove the high-risk patients from clinical trials to minimize early deaths. The Medical Research Council in Great Britain also posed a similar question.[73] This kind of data could be very useful if it is confirmed by others.

A 408-patient study evaluated the prognostic significance of the presence or absence of superior vena cava syndrome as part of the initial presentation of SCLC patients.[74] They were surprised to find that the syndrome was not a negative prognostic factor. Rapid treatment with present-day active combination chemotherapy along with the high response rate usually makes this syndrome nonissue, but this data confirms our clinical impression and allows us to reassure patients regarding this common and somewhat terrible syndrome.

An English group looked at the value of other prognostic models in this disease and developed a prognostic index that included initial serum LDH, hypoalbuminemia, neutrophilia, disease extent, and performance status.[75] The index defined three different risk groups with quite different survivals, but this data was not very different from other published studies on this subject.

A Danish cooperative group published an important study looking at the characteristics of long-term survivors (5 and 10+ years) treated for SCLC.[76] Seventeen hundred and fourteen consecutive patients were included in the study. The characteristics of the patient's surviving 5 to 18+ years were analyzed. The five-year survival was 3.5% and the ten-year survival was 1.8%. Late relapses occurred in 15% of patients surviving longer than five years and secondary malignancies (including lung) occurred in 20% of these long-term survivors. Extensive disease, performance status more than 2, liver and bone metastases, and elevated serum LDH at presentation were all had prognostic factors. The authors concluded that long-term survivos were at high risk for continued relapses and death because disease but also were at high risk for aerodigestive second malignancies (mostly smoking associated). This high risk of second malignancies has been seen worldwide, particularly associated with continued smoking.[77,78]

A Swiss cooperative group looked at something a little different.[76] They used quality of life as an endpoint rather than survival in a group of patients treated for SCLC on a clinical trial. Patients with poor prognostic factors especially poor performance status, extensive disease, and significant weight loss reported a worse quality of life at baseline but improved on treatment. More data of this kind may be helpful in the care of these patients.

Staging and prognostic factor analysis evolved since the first edition of this book, and the changes and new data have been reviewed. Staging has changed the least, but many new potential prognostic factors have been identified. More models and indexes, are also available to consider for use in clinical trials. These new factors require more study, and then models need to be developed that select out which of the factors are truly independently significant and which ones can be substituted for by older and more well-established factors. This study required a worldwide effort perhaps best facilitated by IASLC. Our prime aim for the future is to develop a simple prognostic index that can be easily applied by clinicians all over the world to give their patients the best information on their prognosis and to help select appropriate patients for specific clinical trials.

APPENDIX

Growing a Tree-based Model

Tree-based methods for survival data split the covariate space on a rule that maximizes some measure of improvement. The simplest and most interpretable class of splits are those on a single covariate; they can be described by the following rules:

1. Each split depends on the value of one predictor X_j.
2. If X_j is an ordered variable, splits induced by questions of the form, "is $X_j < c$?" are allowed; for example, "is sodium < 136?" Note that if a variable has K distinct values, up to K - 1 different splits are possible.
3. If X_j is nominal, with values in B = {b_1, b_2, .., b'}, then splits induced by any question of the form, "is X_j in S," where S is a subset of B, is allowed; for example "is

smoking in (never, infrequently)."

Partitioning a node, h, involves finding the split, s, among all variables and values of the variables that maximize some measurement of improvement, G(s, h). In our case, G(s, h) is usually a standardized two-sample logrank test statistic between the resulting two groups of observations; however, G(s, h) could also be the reduction in the model deviance:

$$G(s, h) = R(h) - [R(l(h)) + R(r(h))],$$
(1)

where R(h) is the deviance for node h being split, and R(l(h)) and R (r(h)) are the deviances for the left and right daughter nodes l(h) and r(h).

The split, s, that corresponds to the variable and value that maximizes G(s, h) is chosen to partition the data. The procedure is then repeated on each of the resulting groups of data until a large tree that overfits the data is constructed.

It is important to determine if splits in the tree represent real structure in the survival times or if they are just caused by chance. This determination is not easily made because of the large number of possible splits that are evaluated before choosing a split. Simple calculations for approximate p-values that do not account for the multiple-comparison problem are not valid; therefore, better ways of helping to determine the tree size are needed.

Pruning and Selecting Tree Size

After growing a large tree, informal methods of removing branches (or terms) can be used to select a set of more parsimonious tree-based models. For instance, one could start removing the splits lowest in the tree that correspond to the smallest improvements G(s, h), or the smallest logrank test statistics or reductions in deviance. A more formal method of obtaining good trees can also be used. In the CART algorithm, the cost–complexity measure of tree performance is:

$$R_a (T) = \sum R(h) + a \text{ \# of terminal nodes in } T,$$
(2)

where a is a penalty per terminal node, R(h) is within-node goodness-of-fit, and T are the terminal nodes in the tree.

Some authors have proposed using exponential model deviance for R(h), a full likelihood deviance based on the proportional hazards model or other measurements of goodness-of-fit. The parameter, a, controls the tradeoff between how well a tree fits the data and the simplicity of the tree. The advantage of using such a penalty is that a simple and efficient algorithm exists for finding the best pruned subtree (a tree obtained by removing splits or branches) for any parameter, a. This issue is important because a tree with only 32 terminal nodes can have almost 500,000 different pruned subtrees.

A measure of tree performance analogous to the cost complexity of the CART algorithm can also be defined for recursive partitions based on two sample logrank tests statistics, when within node error is not used to grow or prune the tree. Let $S = T - \tilde{T}$ denote the set of internal nodes of T. Again, define $a \geq O$ as the complexity parameter, and define split complexity G_a(T) as

$$G_a(T) = G(T) - a \text{ \# of splits in } T,$$
(3)

where G(T) is the sum over the standardized splitting statistics, $G(h)$, in the tree T:

$$G(T) = \sum_{h \in S} G(h).$$
(4)

Just as with the cost–complexity measure, there is an efficient way to find the best pruned subtree for any complexity parameter, a.

Pruning algorithms based on the complexity measures described gives the best trees for various values of parameter a. Alternative, less formal methods can also be used to obtain a smaller number of potential tree-based models.

Finally, an important difficulty is picking the best tree objectively. The expected deviance or prediction error can be estimated by K-fold cross-validation. [47] Boot-strapping methods or permutation techniques can be used to select tree sizes for methods that only use two sample test statistics. [52]

Combining Nonadjacent Nodes and Missing Data

Until this point, we have only pruned the tree-based models or equivalently recombined adjacent nodes in the tree. However, only a few prognostic strata with widely different survival may be required, and some nonadjacent nodes in the tree may have similar prognoses. Therefore, methods have been developed for recombining nodes with the most similar prognoses. [49,52]

Tree-based methods can efficiently use data with missing values on some covariates. For some tree-based methods, if an observation is missing on a variable chosen for a split, then the observation stops at that branch of the tree. However, if an observation is not missing on the variable used in the split (but it can be missing values for other variables), then it can be used farther down in that branch. Note that this is different than for other regression methods, which require that all observations have complete data.

For example, consider a tree grown for SCLC. Suppose that a split is on LDH but that many of the observations are missing LDH, so those observations could not be used in branches below an LDH split. However, observations missing on another covariate, such as sodium, could still be used farther down the tree for modeling.

Other methods, such as CART, even use observations that are missing on the variable corresponding to the split by using surrogate variables (correlated to the missing variables with the missing values) to send those observations down the tree.

SURGICAL STAGING OF THE MEDIASTINUM

AMIR ABOLHODA
STEVEN M. KELLER

MEDIASTINOSCOPY

Historical Perspectives

The first formal diagnostic technique for pathologic evaluation of mediastinal lymph nodes was described by Daniels in 1949 [1] and consisted of digital exploration of the superior mediastinum following a scalene fat pad biopsy. In 1954, Harken [2] introduced a Jackson laryngoscope to visualize and explore paratracheal mediastinal lymph nodes via bilateral cervical incisions. He was the first to associate poor survival following surgical resection with the presence of tumor in mediastinal lymph nodes. Radner, in 1955, reported the value of a single suprasternal notch incision to provide bilateral access to the paratracheal nodes. [3] Carlens introduced the use of a cervical mediastinoscope under general anesthesia and named the procedure *mediastinoscopy*.[4] Although mediastinoscopy rapidly became popular in Europe, it was not until the mid 1960s that Pearson and colleagues in Toronto began performing mediastinoscopy routinely in the prethoracotomy staging of non–small cell lung cancer (NSCLC). They established systematic mediastinal lymph node evaluation as a reliable procedure for the appraisal of the regional extent of metastatic disease in NSCLC.[5,6]

Indications

Mediastinoscopy is utilized to demonstrate the presence or absence of metastatic disease in the ipsilateral or contralateral mediastinal lymph nodes. Similar to any test, it should be performed only if the results will alter the patient's future therapy. Biopsy of bulky, unresectable, mediastinal lymph nodes in a patient with a lung mass provides both a diagnosis and staging information. Biopsy of enlarged but potentially resectable lymph nodes may document evidence of metastatic disease in multiple levels, a finding that places the patient in a cohort with an extremely poor prognosis. Similarly, patients with T3 or T4 tumors should undergo mediastinoscopy regardless of lymph node size because these patients do not appear to benefit from pulmonary resection in the presence of mediastinal lymph node metastases.

Patients with synchronous bilateral pulmonary lesions may have either two primary lung cancers or a single tumor with a solitary metastases. By convention, if tumor is not present in the mediastinal lymph nodes, then the tumors are treated as independent neoplasms. Therefore, a mediastinoscopy is indicated to determine if the patient should be treated for two early-stage lung cancers or stage IV disease. Mediastinal lymph node biopsy may also be required to determine patient eligibility for participation in neoadjuvant therapy trials. Finally, the rare patient with documented small cell lung cancer (SCLC) that has presented as a solitary pulmonary mass should undergo mediastinoscopy prior to pulmonary resection.

The role of mediastinoscopy remains controversial in the absence of enlarged mediastinal lymph nodes. If the attending physicians believe that the presence of any tumor within the mediastinal lymph nodes, no matter how minute, renders the patient inoperable (at least initially), then mediastinoscopy should be performed routinely. If, however, the consensus is to recommend removal of completely resectable N2 disease (usually disease in a single nodal level), then mediastinoscopy is unnecessary. This approach is satisfactory for patients with right lung cancers in whom all the ipsilateral mediastinal lymph nodes are easily resected during a right thoracotomy. However, because of the aortic arch, the left paratracheal region is not readily accessible during a left thoracotomy; therefore, some surgeons believe that all patients with resectable tumors of the left upper lobe should undergo mediastinoscopy. [7]

Relative Contraindications

Few anatomic conditions preclude safe cervical mediastinoscopy. These include severe cervical arthritis (preventing adequate extension of the neck and physical insertion of the scope), the presence of a large cervical goiter, extensive calcification or aneurysmal dilatation of the aortic arch or innominate artery, and the presence of a tracheostomy. Repeat mediastinoscopy can be safely accomplished in most patients despite the peritracheal fibrosis and obliteration of cervical mediastinal fascial planes caused by prior mediastinoscopy.

STANDARD CERVICAL MEDIASTINOSCOPY

Mediastinoscopic examination of the mediastinum via the standard cervical approach allows assessment of the highest mediastinal and upper and lower paratracheal mediastinal lymph nodes (levels 1, 2R, 2L, 4R, and 4L) as well as anterior subcarinal lymph nodes (level 7). Standard cervical mediastinoscopy has a sensitivity of 85% to 90%, a specificity of 100%, and a negative predictive value of greater than 90%. Cervical mediastinoscopy remains the most accurate modality for preresectional mediastinal staging of patients with NSCLC [8] (Table 35.1).

	CXR	CT	MRI	Mediastinoscopy
Sensitivity (%)	80	82	71	87
Specificity (%)	43	76	84	100
Accuracy (%)	57	81	83	95
Positive Predictive Value (%)	45	74	81	100
Negative Predictive Value (%)	79	91	84	93

CXR: chest roentgenography; CT: computed tomography; MRI: magnetic resonance imaging. (From Patterson GA, Ginsberg RJ, Poon PY, et al. A prospective evaluation of magnetic resonance imaging, computed tomography, and mediastinoscopy in the preoperative assessment of mediastinal node status in bronchogenic carcinoma. *J Thorac Cardiovasc Surg* 1987;94:679, with permission.)

TABLE 35.1. CORRELATION OF PREOPERATIVE STAGING MODALITY WITH PATHOLOGIC NODAL STAGING

Operative Technique

General endotracheal anesthesia is established, and the patient is placed supine with the occiput at the edge of the operating table. A right radial artery catheter and/or a digital pulse oximeter are utilized to monitor not only blood pressure and oxygen saturation, but also the duration and extent of inadvertent innominate artery compression that occurs during the procedure. A roll is placed beneath the shoulders, and the neck is hyperextended to draw the trachea upward from the mediastinum and to facilitate insertion of the mediastinoscope. The endotracheal tube is positioned in the mouth contralateral to the side from which the surgeon utilizes the dissecting instrument. The anterior chest is prepped and draped to the level of the xiphoid and a 3- to 4-cm transverse skin incision is made approximately 1 to 2 cm above and parallel to the sternal notch. The incision is carried through the platysma, the strap muscles are retracted laterally, and a longitudinal dissection plane is developed down to the pretracheal fascia.

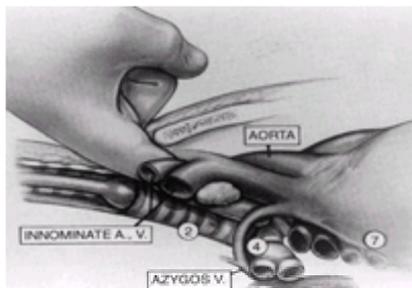
The pretracheal fascia is incised and elevated by insertion of the index finger into the pretracheal space (Figure 35.1). This important maneuver permits blunt digital dissection of the pretracheal space to the level of the carina and often allows palpation of abnormal lymph nodes. The mediastinoscope is introduced into the predissected tunnel and is gently advanced under direct vision (Figure 35.2). A blunt dissecting instrument equipped with suction and cautery is utilized to identify both the constant nonlymphatic structures and the mediastinal lymph nodes. The carina, proximal mainstem bronchi, innominate artery, main pulmonary artery, and azygous vein are commonly visualized. In order to avoid injury to the left recurrent laryngeal nerve, dissection in the left paratracheal region should be performed cautiously and the cautery used sparingly. After adequate hemostasis, the wound is closed in layers. A video-mediastinoscope is useful for demonstrating the operative technique.


FIGURE 35.1. The innominate artery is palpable anteriorly. A gentle sweeping motion clears soft tissue from the anterior tracheal surface. (Reproduced with permission of WB Saunders from *Seminars in oncology,* 1993, Sugarbaker D and Strauss G.)
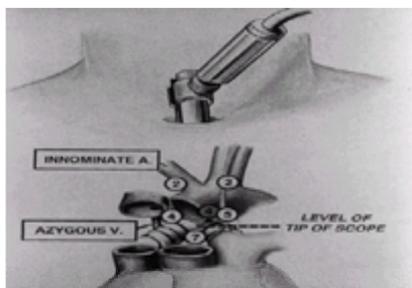

FIGURE 35.2. A small-gauge needle may be used to aspirate the "lymph node" prior to biopsy in order to avoid injury to vascular structures. No attempt is made to excise the entire lymph node. A twisting motion, rather than a direct pull, is used to remove the biopsy specimen. (Reproduced with permission of WB Saunders from *Seminars in oncology,* 1993, Sugarbaker D and Strauss G.)

Complications

Minor hemorrhage, most commonly related to the bronchial arterial supply to the mediastinal lymph nodes (particularly the subcarinal nodes), is the most common complication. This is usually controlled with electrocautery or gauze packing. Massive hemorrhage from injury to a major blood vessel is potentially life-threatening and requires prompt recognition, tamponade, and repair. Bleeding from the azygos vein can sometimes be controlled by packing the mediastinum. However, a right thoracotomy may be necessary to achieve hemostasis. Injury to the innominate artery, aortic arch, or pulmonary artery generally requires a sternotomy for repair. Another rare complication of mediastinoscopy potentially requiring thoracotomy is tracheobronchial tear.

Other structures at risk of injury during standard cervical mediastinoscopy are the left recurrent laryngeal nerve (vulnerable at the left tracheobronchial angle), the mediastinal pleura (right greater than left), and the esophagus (vulnerable in the posterior subcarinal region). Recurrent nerve palsy and pneumothoraces are generally treated observantly. Esophageal perforation is rare and may elude diagnosis until signs and symptoms of mediastinal sepsis develop.

Despite the potential complications, cervical mediastinoscopy is a safe procedure and is commonly performed in the ambulatory setting. Pearson reported minor complications in 1.6% of 432 patients who underwent mediastinoscopy (2 pneumothoraces, 3 recurrent nerve palsies, and 2 hemorrhages). [6] No patient required thoracotomy and no patient died following the procedure. Coughlin [9] documented 1,259 consecutive preresectional mediastinoscopies performed in patients with proven and operable lung cancer; no deaths occurred. Right pneumothorax was the most common complication, occurring in eight patients, and in every instance was the result of transmediastinal pleural biopsy of the lung. Seven patients had left recurrent nerve injury, three of whom recovered with normal voice. Three patients (0.2%) required thoracotomy for a pulmonary artery branch avulsion, an esophageal tear, or a cautery burn of the right main bronchus. Complications occurred in 1.7% of patients. Luke reported [10] 1,000 cervical mediastinoscopies. Three patients (0.3%) sustained major complications that required thoracotomy two for hemorrhage, one for tracheal tear), and twenty patients (2%) sustained minor complications for a collective morbidity of 2.3%; no operative mortality occurred.

SCALENE LYMPH NODE BIOPSY WITH THE MEDIASTINOSCOPE

Scalene lymph nodes are no longer routinely biopsied as part of the preoperative evaluation of patients with NSCLC. However, investigators have reported that occult metastases may be found in nonpalpable lymph nodes[11,12,13 and 14] in 4% to 24% of patients with potentially resectable cancers. The presence of tumor in the supraclavicular lymph nodes (N3) drastically alters the prognosis and treatment recommendations. Therefore, evaluation of this region is appropriate.

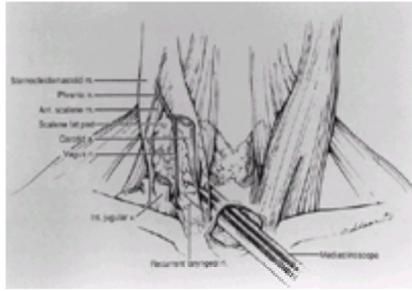
Lee and Ginsburg[1] have described a modification of standard cervical mediastinoscopy that permits biopsy of the supraclavicular lymph nodes. Following completion of the mediastinal biopsies, the mediastinoscope is rotated behind the carotid sheath and into the supraclavicular fossa (Figure 35.3).


FIGURE 35.3. The medial aspect of the scalene fat pat is dissected and lymph nodes biopsied or removed. (Reproduced with permission of Elsevier Science LTD from *Annals of thoracic surgery,* 1996;62:338, Lee D and Ginsberg R.)

Results

The authors have reported their experience with a select group of 81 patients in whom N2 or N3 disease was suspected. Twenty-nine patients were proven N0 by standard mediastinoscopy, and none had supraclavicular lymph node metastases. However, of the 39 patients found to have metastases to the N2 lymph nodes, 15% also had tumor in the supraclavicular lymph nodes. Finally, 13 of 19 (68%) patients with contralateral N3 disease also had metastases to the supraclavicular lymph nodes. All of the tumor-containing supraclavicular lymph nodes were found in patients whose tumors were central (visible by fiberoptic bronchoscopy) and of nonsquamous histology.

EXTENDED CERVICAL MEDIASTINOSCOPY

Extended cervical mediastinoscopy (ECM), a procedure originally described by Kirchner in 1971, [16] has been popularized by Ginsberg and colleagues [17] as a single staging procedure for preoperative assessment of bronchogenic carcinomas of the left upper lobe. Considered as an alternative technique to circumvent the limitations and potential complications of anterior mediastinotomy, ECM has been designed to provide full invasive staging of the paratracheal and para-aortic mediastinal lymph nodes in patients with left upper lobe tumors. Indications are similar to those previously cited for mediastinoscopy.

Operative Technique

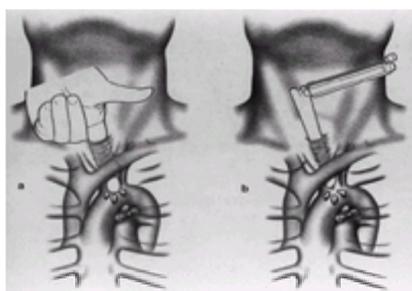
Following completion of a standard cervical mediastinoscopy, the mediastinoscope is withdrawn from the cervical incision. The fascia investing the aorto-innominate junction is opened with an index finger, and the innominate triangle along the anterolateral surface of the aortic arch posterior to the innominate vein is entered (Figure 35.4). The mediastinoscope is gently advanced through the previously created tunnel into the para-aortic mediastinal compartment. Utilizing blunt dissection, the loose fatty tissue encompassing the lymph nodes is cleared and node biopsies are obtained. Care is taken not to transgress the mediastinal pleura. After ensuring absence of significant bleeding, the mediastinoscope is withdrawn and the cervical incision is closed in the usual fashion.


FIGURE 35.4. A: Finger dissection between the innominate artery and left carotid arteries. **B:** The mediastinoscope in place for anterior mediastinal and aortopulmonary node biopsy. (Reproduced with permission of Lippincott-Raven from *Mastery of cardiothoracic surgery,* pg. 23, Kaiser, ed.)

Complications and Results

ECM has a steep learning curve and should be employed with caution. The first attempts with this technique should be performed with an anterior mediastinostomy counter-incision to allow bimanual palpation and to facilitate atraumatic advancement of the mediastinoscope into the innominate triangle. [17] Ginsberg and associates from Toronto reported the results of their first 100 consecutive patients with left upper lobe tumors who underwent ECM. [18] Twenty patients were found to have nodal spread to the superior or anterior mediastinum or both, with seven patients having sole involvement of the superior mediastinum. A total of 75 thoracotomies were performed, and 74 patients were able to have complete resection of their tumors. Eight false-negative ECM procedures were reported. In each, microscopic N2 disease in the level 5 or 6 lymph nodes was identified only following a final histologic examination. In all eight patients the tumors were completely resectable. In this series, the only reported complication was a superficial cervical wound infection.

Lopez and associates reported the use of ECM in 50 patients with bronchogenic carcinoma of the left upper (38) and left lower (12) lobes. [19] Mediastinoscopy was positive in nine patients, five via the extended approach. Resectability in the remaining 41 patients was 97.6%. This study identified a negative predictive value of 97.5% and a diagnostic accuracy of 97.8%.

A case report of a cerebrovascular accident following an ECM by Urschel et al. has questioned the safety of this staging procedure. [20] Indeed, presence of aortic arch calcification on CT scan or palpation of atheromatous plaques in the great vessels should constitute an absolute contraindication to ECM. However, with careful patient selection, the incidence of major complications including neurologic sequella should remain negligible.

ANTERIOR MEDIASTINOTOMY (CHAMBERLAIN PROCEDURE)

Left anterior parasternal mediastinostomy was introduced by McNeil and Chamberlain in 1966[21] as a method for establishing the diagnosis and resectability of tumors of the left upper lobe. Chamberlain believed that the procedure would enable the thoracic surgeon to not only biopsy the left hilar and aortopulmonary window lymph nodes, but also assess the degree of fixation of the left upper lobe tumor to the mediastinal structures and, therefore, would avoid unnecessary thoracotomy in patients with locally advanced unresectable bronchogenic carcinoma. Currently, the Chamberlain procedure is utilized as a staging technique for assessment of the mediastinal nodal levels inaccessible by standard cervical mediastinoscopy: aortopulmonary window and para-aortic (levels 5 and 6, respectively).[22] Indications are similar to those of mediastinoscopy.

In 1983, Deneffe[23] reported a series of 45 anterior mediastinotomies in patients with a presumed left lung cancer and a clinically negative mediastinum. Of the biopsies, 28.9% (13) demonstrated N2 metastatic disease, none of which were associated with lower lobe tumors. In this pre–computed tomography (CT) scan era report, the authors concluded that anterior mediastinostomy should be performed in patients with left upper lobe tumors to improve operability. Jolly[24] demonstrated that a negative anterior mediastinostomy in patients with primary tumors of the left lung predicted resectability in 25 of 26 (96%) cases.

More recently, Barendregt and colleagues[25] reported the results of parasternal mediastinotomy and mediastinoscopy in 37 clinically N0 patients with proven left upper lobe tumors. In conjunction with manual palpation, the mediastinoscope was inserted into the mediastinotomy incision. Lymph node tissue was identified in 16 patients, but only one patient was found to have N2 disease. The authors concluded that anterior medistinoscopy is not necessary in the absence of clinical N2 disease.

Surgical Technique

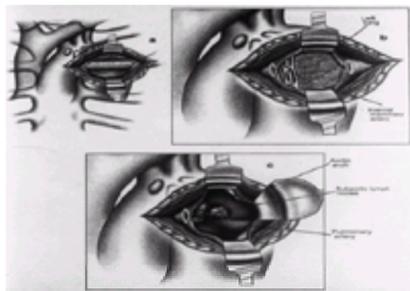
The patient is positioned supine under general anesthesia and is intubated with a single-lumen endotracheal tube. A 5- to 6-cm transverse skin incision is made lateral to the sternum, overlying the second or third costal cartilage and deepened through the pectoralis muscle. The perichondrium is incised and the costal cartilage is removed in a subperichondrial plane (Figure 35.5). Alternatively, the incision is placed over the intercostal space without removing the cartilage. The internal mammary artery and vein are within the operative field and should be retracted or ligated and divided. The mediastinal pleural reflection is bluntly separated from the posterior table of the sternum and reflected laterally to expose the para-aortic and aortopulmonary mediastinal space. Enlarged lymph nodes are sampled under direct vision by excision or biopsy. The mediastinoscope can be introduced via the incision to facilitate exploration of the mediastinum.


FIGURE 35.5. A: Incision over the second costal cartilage, **B:** After resection of the costal cartilage. **C:** View of enlarged subaortic nodes. (Reproduced with permission of Lippincott-Raven from *Mastery of cardiothoracic surgery,* pg. 24, Kaiser, ed.)

Anatomic definition and access may be improved by opening the pleura. If the pleural space is entered, then a chest tube is not required provided the lung is not injured. Evacuation of air is accomplished by positioning a catheter in the pleural space prior to closure of the incision and placing the opposite end under 2 cm of water. After hemostasis is ascertained, the wound is closed in layers and the catheter is withdrawn as the anesthesiologist fully inflates the lungs.

Complications and Results

Anterior mediastinostomy is associated with little morbidity and mortality and can be performed safely in an ambulatory setting. The main disadvantages of this procedure are the local pain and potential wound healing problems that follow resection of the second costal cartilage, particularly if adjuvant radiation therapy is administered.[22] The major structures at risk for injury during the operation are the aorta, the internal mammary artery, the pulmonary artery, the superior pulmonary vein, the phrenic nerve, and the left recurrent laryngeal nerve. However, damage to these structures, aside from the internal mammary artery, are rare. The most commonly reported complications are superficial wound infections and pneumothoraces.

VIDEO-ASSISTED THORACOSCOPIC MEDIASTINAL LYMPH NODE SAMPLING

Video-assisted thoracoscopic mediastinal exploration and lymph node sampling has emerged as yet another invasive staging modality in the preresectional evaluation of patients with NSCLC. Video-assisted thoracoscopy (VATS) not only permits sampling of the mediastinal lymph node stations accessible by the standard cervical mediastinoscopy, but also allows evaluation of mediastinal adenopathy in those N2 stations inaccessible by the traditional mediastinoscopic techniques (nodal levels 3, 5, 6, posterior subcarinal 7, 8, and 9). In addition, VATS may provide additional staging information by demonstrating unsuspected malignant pleural effusions or pleural carcinomatosis.

Operative Technique

Following intubation with a double-lumen endotracheal tube, the thoracoscope is inserted via an 11-mm trocar through the sixth intercostal space in the midaxillary line. Additional access sites for insertion of endoscopic dissecting instruments and clip appliers are created under direct thoracoscopic vision. A lung-retracting instrument is often useful to allow unimpeded thoracoscopic view of the periazygous region and aortopulmonary window. The pleura is opened and the appropriate nodal levels biopsied. Care is taken to avoid injury to the phrenic and vagus nerve trunks. A chest tube is place under direct vision and may be removed in the immediate perioperative period if no air leak and little drainage occur.

Results

Gossot et al.[26] reported the results of a prospective nonrandomized study of cervical mediastinoscopy versus VATS for assessment of mediastinal masses and lymph nodes. The diagnostic yield of VATS was 91.9% (versus 94.3% for the mediastinoscopy group). Four of the five failures in the VATS group were the result of insufficient mediastinal exposure because of the inability to completely collapse the ipsilateral lung. There were three complications in the VATS group: one injury to the internal thoracic artery, one small tear of the trachea during biopsy of a paratracheal lymph node, and one prolonged air leak. In addition, the mean length of hospital stay was 3.2 days in the VATS group and 1.1 days for the mediastinoscopy group. The authors noted that although thoracoscopy has a comparable diagnostic yield to conventional mediastinoscopy, the complication rate and duration of hospital stay of patients who underwent diagnostic VATS was greater than that of patients who had standard mediastinoscopy. They concluded that VATS should be reserved for those clinical situations in which the mediastinal lesions are not within the reach of the mediastinoscope or when prior biopsy and fibrosis make repeat mediastinoscopy difficult or unsafe.

Landreneau and colleagues reported their experience with thoracoscopic mediastinal exploration in 40 patients with NSCLC, in whom VATS was utilized as an adjunct to cervical mediastinoscopy.[27] All patients had CT scan evidence of enlarged (>1.5 cm) aortopulmonary window (n = 30) or right peri/subazygous or subcarinal (n = 10) lymph nodes. Thirty-four patients had undergone a prior negative cervical mediastinoscopy. In 18 patients, thoracoscopic sampling of the mediastinal adenopathy detected malignant tissue. Fourteen of these patients had mediastinal lymph node metastases from a lung primary. In this study, adjunctive thoracoscopic nodal sampling was 100% sensitive and 100% specific in diagnosing the nature of the mediastinal adenopathy. The sole postoperative complication was a chylous leak,

which spontaneously resolved. The mean length of stay for the patients undergoing VATS without subsequent thoracotomy was 3 days.

Mediastinal lymph node dissection can be accomplished during a VATS lobectomy comparable to that achieved during thoracotomy. Kaseda[26] performed 36 VATS lobectomies and reported that all lymph node levels were accessible. The number of lymph nodes removed was comparable to that obtained with an open procedure. Similar results were documented by Iwasaki,[29] who performed 25 VATS lobectomies for stage I NSCLC.

INTRAOPERATIVE MEDIASTINAL LYMPH NODE DISSECTION

Mediastinal staging is an integral part of the surgical treatment of lung cancer. Just as a pulmonary resection involves transecting and ligating the appropriate pulmonary arterial branches, pulmonary venous branches, and bronchi, so too must the intrathoracic extent of the malignancy be determined. Histologic staging completely depends on the material submitted during the operative procedure, and hence the surgeon must *accurately identify* and *properly label* the requisite specimens.

The T category of the primary tumor is readily apparent to both surgeon and pathologist. However, the presence or absence of tumor within the intrathoracic lymph nodes is often not at all obvious. Indeed, the lymph nodes may not be apparent and must be diligently sought. Microscopic assessment is required to accurately determine the N status.

Appreciation for the rationale of lymph node dissection is gained through knowledge of the patterns of lung cancer metastases. The definitions of lymph node levels and the techniques of lymph node dissection are best understood in their anatomic and historic perspectives. Finally, the benefits of a mediastinal lymph node dissection can only be fully comprehended through a review of the attendant risks and benefits.

Purpose of Lymph Node Dissection

Accurate and thorough lymph node dissection is crucial for appropriate staging of lung cancer. Without precise staging, the comparison of results from different institutions is impossible, as is the conduct of multi-institutional trials. Most authors do not believe that even the most aggressive lymph node dissections have therapeutic value. However, some investigators (principally from Japan) believe that complete removal of all intrathoracic and supraclavicular lymph nodes in the likely drainage pathway results in improved survival. [30,31,32 and 33]

Critical assessment of the published literature relating survival to pathologic stage in patients with NSCLC requires knowledge of the intrathoracic staging technique. In general, *sampling* means that only those lymph nodes that were obviously abnormal were removed. *Systematic sampling* refers to routine biopsy of lymph nodes at levels specified by the author. *Complete mediastinal lymph node dissection* indicates that all lymph node–containing tissue was routinely removed at those levels indicated by the investigators.

Only one English-language publication directly compares intraoperative visual evaluation of lymph nodes with pathologic examination. Gaer and Goldstraw [34] reported on a series of 95 consecutive patients with NSCLC who underwent pulmonary resection and mediastinal lymph node dissection. Based on inspection and palpation of the lymph nodes after their dissection, the surgeon recorded his impression regarding the tumor status of the lymph nodes. Two hundred and eighty-seven nodal levels were removed; results appear in Table 35.2. Sensitivity was 1%, and the positive predictive value was 64%. These values would presumably have been even lower if only a tactile inspection of the nodal levels was made through unopened mediastinal pleura.

Assessment	No. of Node Stations	No. of Patients
True negative	238	88
True positive	25	16
False positive	14	11
False negative	10	9
Total number of resection	95	

Accuracy, 91.6%; predictive value: positive, 25:(25 + 14) = 64.1%; negative, 238:(238 + 10) = 96.0%.

TABLE 35.2. INTRAOPERATIVE ASSESSMENT OF LYMPH NODES

The need for some type of routine intraoperative systematic lymph node sampling was further demonstrated by Graham and colleagues, [35] who reported the results of systematic sampling of right levels 2–4 and 7–10 or left levels 4–10 in 240 patients with clinical T1-3N0 NSCLC. All patients had undergone mediastinoscopy prior to thoracotomy if the CT scan demonstrated mediastinoscope-accessible lymph nodes greater than 1.5 cm. No patient with known N2 disease underwent attempted resection. Mediastinal lymph node metastases were demonstrated in 20% of patients, the majority of whom had T1 or T2 tumors.

Haiderer and colleagues[36] reported on 83 patients who underwent routine mediastinal lymph node dissection as part of their operation for NSCLC. Enlarged mediastinal lymph nodes were found in 34 patients (41%); however, only 19 (56%) contained metastatic disease. Of the 49 patients with normal-appearing mediastinal lymph nodes, 2 were documented to have micrometastatic disease (4.1%). Supporting data are contained in a publication by Bollen and colleagues, [37] who found that the discovery ratio (calculated in a fashion similar to the more familiar relative risk ratio) of N2 disease in patients with NSCLC who underwent mediastinal lymph node dissection was 1.9 (confidence interval, 0.9–4) when compared to patients whose lymph nodes were removed only if they appeared or felt abnormal.

The extent of mediastinal biopsy necessary to obtain accurate staging information has been evaluated by several investigators. In a retrospective review, Bollen [37] found that systematic sampling of mediastinal lymph nodes was as successful as mediastinal lymph node dissection in identifying N2 disease (discovery ratio 2.7; confidence interval 1.04–4.2). Izbicki[38] compared systematic lymph node sampling to mediastinal lymph node dissection in a randomized prospective trial containing 182 patients. Although the percentage of patients found to have N1 or N2 disease was not significantly different between the two study arms, the number of N2 positive levels was greater in the patients who had full lymph node dissections. Sugi [39] conducted a similar study in 115 patients with clinical T1N0 tumors that were less than 2 cm in diameter. Mediastinal metastases were found in 13% of each study group. Thus it appears that systematic lymph node sampling is as efficient as mediastinal lymph node dissection for staging NSCLC. The survival advantage of mediastinal lymph node dissection, if any, has not been proven.

Identification of the sentinel lymph node has been proposed as a selective method for directing mediastinal lymph node biopsy. Following thoracotomy, Little [40] injected each quadrant of lung tissue surrounding the tumors of 36 clinically N0 patients with isosulfan blue dye. Systematic mediastinal lymph node sampling was performed following pulmonary resection. A sentinel lymph node was identified in 17 patients, 5 in the mediastinum and 12 within the pleural reflection. All of the former contained tumor, whereas only three of the latter harbored metastatic cancer. Among the 19 patients in whom no sentinel lymph node could be found, 5 patients proved to have N1 disease and 1 patient had N2 disease. Additional data are necessary to determine the role of this technique in intraoperative lung cancer staging.

N Category

The N of the TNM system is the stumbling block of accurate lung cancer staging because of competing definitions for a number of the N levels (levels 2 through 4) as well as disagreement about the stage to which they should be assigned (level 10).

The definitions of the N category grew from the realization that clinical outcome varied with the location of the tumor-containing lymph node. Although prosectors provided a detailed description of lymph nodes found within the thorax, the input of the clinicians was required to correlate the anatomic findings with treatment

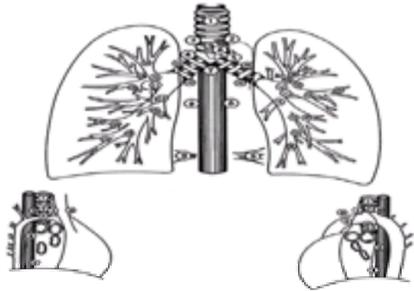
outcome. The lymph node mapping schema proposed by Naruke and colleagues[41] and accepted by the American Joint Committee for Cancer Staging and End Results Reporting (AJCC) achieved universal acceptance after publication in 1978 (Figure 35.6). Numbers were assigned to regional locations where lymph nodes were commonly found. However, the lack of precise anatomic definitions allowed wide interinstitutional as well as intrainstitutional interpretation of lymph node levels. For example, level 10 was given the vague term *hilar.* Were these lymph nodes within the pleural reflection, or were they located in the mediastinum? If they were located outside the pleural reflection, why were they included in the N1 category, and how could they be differentiated from the contiguous level 4 lymph nodes? The exact limits of the *superior mediastinal lymph nodes* (levels 1 through 4) and *aortic lymph nodes* (levels 5 and 6) were similarly imprecise, allowing some investigators to report multilevel metastases, whereas others reported only single-level involvement.


FIGURE 35.6. Lymph node map originally proposed by Naruke. *1,* Superior mediastinal or highest mediastinal; *2,* paratracheal; *3,* pretracheal, retrotracheal, or posterior mediastinal (3p), and anterior mediastinal (3a); *4,* tracheobronchial; *5,* subaortic or Botallo; *6,* para-aortic (ascending aorta); *7,* subcarinal; *8,* paraesophageal (below carina); *9,* pulmonary ligament; *10,* hilar; *11,* interlobar; *12,* lobar (upper lobe, middle lobe, and lower lobe); *13,* segmental; *14,* subsegmental. (From Naruke T, Suemasu K, Ishikawa S. Lymph node mapping and curability at various levels of metastasis in resected lung cancer. *J Thorac Cardiovasc Surg* 1978;76:832, with permission.)

The resultant confusion led the American Thoracic Society (ATS) to form a Committee on Lung Cancer, one of whose charges was to: "Develop a map of regional pulmonary lymph nodes that would be acceptable to all physicians who care for the patient with lung cancer."[42] This committee recommended that the vague terms "hilar" and "mediastinal" be discarded in favor of nodal level definitions based on constant anatomic structures. For instance, right level 4 lymph nodes were defined as those lymph nodes found ". . . to the right of the midline of the trachea between the cephalic border of the azygous vein and the intersection of the caudal margin of the brachiocephalic artery with the right side of the trachea." This committee recognized the difficulty in deciding whether level 10 lymph nodes belonged in the N1 or N2 category and recommended that this determination be made after examination of survival data of patients who had accurate and thorough intraoperative lymph node dissections. The ATS nodal definitions have become widely used, although they were not officially accepted by the AJCC.

The former Lung Cancer Study Group initially used the AJCC lymph node definitions in their numerous prospective randomized trials but later adopted and modified the ATS definitions.[43,44] They firmly placed the level 10 lymph nodes in the N2 category. A revised international staging system for lung cancer was adopted by the AJCC and the Union Internationale Contre Cancer in 1986 [45] and utilized by most investigators during the ensuing decade.

The staging system and lymph node level definitions were again significantly modified in 1997 [46,47] and are discussed in detail in Chapter 32. The new mediastinal lymph node level definitions are based on constant anatomic structures that are readily identified by CT scans (Fig. 35.7 and Fig. 35.8, Table 35.3). This was done to enable accurate and reproducible preoperative clinical staging. Unfortunately, the revised definitions render the intraoperative identification of some of the lymph node levels more difficult (right levels 2 and 4) because they utilize structures that are difficult to accurately identify during surgery. The uncertainty surrounding level 10 lymph nodes was eliminated by defining them as N1 lymph nodes found along the anterior surface of the mainstem bronchus distal to the pleural reflection. The importance of identifying the nodal and stage definitions used by different authors when interpreting and comparing their results has been emphasized by Mountain and colleagues.[48] Studies presently being conducted under the aegis of the various American national cooperative oncology groups utilize the new revised staging system.

TABLE 35.3. AMERICAN THORACIC LYMPH NODE LEVEL DEFINITIONS

Anatomy and Patterns of Metastatic Spread

The development of the pulmonary lymphatics within the human embryo has been documented by Harvey.[49] The definitive description of the locations of the extrapulmonary intrathoracic adult human lymph nodes was written by Rouviere.[50] Excellent summaries of the common intrapulmonary lymphatic anatomy and its interconnecting network were made by Borrie[51] and Weinberg.[52]

Borrie[51] investigated the patterns of lung cancer dissemination within the intrapulmonary lymphatics of resected specimens. Because a thorough mediastinal lymph node sampling or dissection was not routinely performed, the patterns of mediastinal spread were not as reliably determined. Borrie found that right upper lobe tumors spread to the lymph nodes surrounding the right upper lobe bronchus and to those lymph nodes "in the angle between the upper and middle lobe bronchus and also along the medial surface of the right main bronchus."[61] The latter region became known as the *lymphatic sump of Borrie.* Tumor from the right upper lobe did not spread below the level of the middle lobe bronchus.

Right middle lobe tumors spread to the lymph nodes surrounding the middle lobe bronchus and proximally to the previously described bronchial sump. Tumors within the right lower lobe metastasized not only to the peribronchial lymphatics but also to the lymph nodes contained within the inferior pulmonary ligament and sump of Borrie. The presence of endobronchial tumor in the middle or lower lobe orifices has been found to correlate with metastases to the lymphatic sump. [53]

Left upper lobe cancers metastasized to lymph nodes surrounding the left upper lobe bronchus and to those surrounding the apical and basilar segmental bronchi of the left lower lobe. Sites of lymphatic metastases of left lower lobe tumors included nodes surrounding the left lower lobe bronchus, the inferior pulmonary ligament, and the left upper lobe bronchus.

Nohl-Oser[54,55] confirmed these observations and extended them to include the patterns of mediastinal spread. He examined the locations of nodal specimens from 749 patients who underwent mediastinoscopy or scalene node biopsy. If patients underwent surgery, then the mediastinal lymph nodes removed during operation were included in the analysis. Histology was not stated. A summary of the results are presented in Table 35.4. Right upper lobe tumors spread rarely to the subcarinal region (1%) or to the contralateral scalene nodes or mediastinum (3%), but they commonly spread to the ipsilateral mediastinum (50%). Sufficient numbers of right middle lobe tumors were not present to allow analysis. Similarly, tumors within the right lower lobe metastasized to the contralateral scalene nodes or mediastinum infrequently (4%), but more commonly spread to the subcarinal region (13%) and ipsilateral mediastinum (29%).

Lymph Node Location	Right Upper Lobe (N = 230)	Right Lower Lobe (N = 108)	Left Upper Lobe (N = 262)	Left Lower Lobe (N = 68)
Ipsilateral				
Scalene	27	10	13	5
Levels 2-4	78	21	4	0
Level 10	36	9	46	15
Level 7	2	13	9	5
Contralateral				
Scalene	6	3	10	6
Levels 2-4	1	1	10	6
Level 10	0	0	3	5

TABLE 35.4. PATTERN OF MEDIASTINAL METASTASES

Tumors originating in the left upper lobe metastasized to the subcarinal region (5%) and contralateral mediastinum (7%) more often. Tumors within the left lower lobe did metastasize to the subcarinal region (3%) and the contralateral mediastinum. Nohl-Oser[56] cites clinical data from Greschuchna obtained in a similar fashion that differed from his results. The latter documented a much higher prevalence of subcarinal lymph node metastases from upper lobe tumors and a greater occurrence of paratracheal disease from lower lobe neoplasms.

Watanabe and colleagues[57] reported the intrathoracic metastatic patterns of 124 patients with N2 NSCLC who underwent pulmonary resection and mediastinal lymph node dissection. In contradistinction to Nohl-Oser, he reported frequent metastases from right upper lobe tumors to the subcarinal lymph nodes (36%). He also demonstrated that tumors originating in the right middle and lower lobes commonly (28%) spread to the ipsilateral paratracheal region (level 4). Metastases were commonly found in the subcarinal lymph nodes from tumors of the left upper (20%) and left lower (38%) lobes.

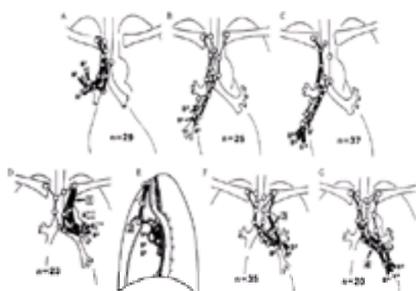
Hata and colleagues[31] provided experimental support for these results. They performed 192 lymphoscintigraphies in 179 patients without evidence of lymph node involvement by injection of antimony sulfide or rhenium colloid labeled with technetium-99m into the submucosa of each segmental bronchus using the flexible bronchoscope. Hourly anterior and lateral scanning with a gamma camera for up to 6 hours demonstrated patterns of lymphatic drainage that recapitulated the clinical findings of Greschuchna (cited in Nohl-Oser [56]) and Watanabe and colleagues [67] (Fig. 35.9).


FIGURE 35.9. The width of each arrow corresponds to the relative frequency of lymphatic drainage. **A:** Apical and dorsal segments of the right upper lobe. **B:** Middle lobe and superior segment of the lower lobe. **C:** Basal segments of the lower lobe. **D–G:** Four routes of drainage were identified from the left lung: **(D)** through the subaortic lymph nodes and then divides to run proximally along either the vagus nerve to the scalene nodes or along the recurrent laryngeal nerve to the mediastinal

nodes; **(E)** by way of the phrenic nerve to the scalene nodes; **(F)** along the mainstem bronchus to the paratracheal nodes; **(G)** under the mainstem bronchus to the subcarinal lymph nodes. (From Hata E, Hayakawa K, Miyamoto H, et al. Rationale for extended lymphadenectomy for lung cancer. *Theor Surg* 1990;5:19, with permission.)

Techniques of Lymph Node Sampling and Dissection

The earliest detailed description of a thorough intrathoracic lymph node dissection as part of an operation for lung cancer was given in 1951 by Cahan and colleagues,[58] although Brock[59] indicated that it was a routine part of his operative procedure for lung cancer several years earlier. Great emphasis was placed on the need for *en bloc* removal of the lymphatics and lung. Other authors[60,61,62,63,64 and 65] soon published their techniques, which were variations on the same theme. The lymph node locations were described only in general anatomic terms. Weinberg[60] was the first to assign numbers to the lymph node regions.

A more recent description was given by Martini,[66] who detailed their dissection of three mediastinal lymph node compartments: (a) the right paratracheal, (b) the subcarinal, and (c) the aorticopulmonary window. During a right thoracotomy, the right paratracheal and subcarinal regions were routinely cleared of all lymphatic tissue, whereas during a left thoracotomy, the subcarinal and aorticopulmonary window lymph nodes were removed in their entirely. Lymph nodes were not resected in continuity with the pulmonary specimen. Level numbers were assigned according to Naruke and colleagues.[41]

Those surgeons who believe that removal of regional lymphatics offers a survival advantage have devised more extensive lymphadenectomies. These have included contralateral mediastinal lymph nodes and, in some cases, supraclavicular lymph nodes. During a right thoracotomy, Watanabe and colleagues[30] transect the azygos vein to gain access to the upper mediastinal lymph nodes (Naruke levels 1 through 4). Nodes anterior to the superior vena cava with associated thymic tissue are also removed. In addition, left levels 2 through 4 have been resected by continuing the dissection to the contralateral aspect of the trachea. The subcarinal region is cleared of all lymph node–containing tissue. During this aspect of the procedure, both ipsilateral and contralateral levels 8 and 10 lymph nodes are removed.

An equally aggressive lymph node dissection is performed in the left hemithorax for patients with left lung cancers. However, because of the aortic arch, such an approach is of necessity more complicated. Watanabe's attempt at left mediastinal lymph node dissection involved mobilizing the arch of the aorta and a portion of the descending aorta. This was accomplished by transecting several intercostal arteries. In this fashion, left levels 3 and 4 as well as portions of level 2 could be resected.[30]

This group have modified their operative procedure to permit more thorough dissection of all left mediastinal lymph nodes. After completion of pulmonary resection by means of a standard posterolateral thoracotomy, a mediansternotomy is performed. This allows complete dissection of all left levels 1 through 4 as well as access to contralateral levels 1 through 4 and 10. This approach has been investigated by Mitsuoka and colleagues.[67]

Nakahara and colleagues[32] described a similar approach to right lung cancer. A mediansternotomy was not employed for left lung cancer. Rather, the ligamentum arteriosum was severed and the aorta encircled with a catheter. Traction was applied caudally, and the pleura between the left common carotid and subclavian arteries was opened to expose the trachea and left mainstem bronchus.

Hata and colleagues[31,33] have pursued an even more aggressive approach, extending the right lymphadenectomy performed during posterolateral thoracotomy to include ipsilateral scalene lymph nodes if the most cephalad right paratracheal lymph nodes (Naruke levels 1, 2, and 4) contain metastatic cancer. This group advocates broadening the supraclavicular dissection to include the left scalene lymph nodes if anterior mediastinal lymph node (Naruke level 3) involvement is suspected.

Their procedure for left lymphadenectomy was determined by tumor histology and stage. The mediastinal lymph nodes of patients with stage I squamous cell cancers were removed by means of a left posterolateral thoracotomy. Although the details of this approach are not specifically stated, they appear to include division of the ligamentum arteriosum and mobilization of the aortic arch. Patients with other stages and histologies undergo mediansternotomy followed by anterior and bilateral paratracheal lymphadenectomy (levels 1 through 4). Exposure is obtained by retracting the ascending aorta to the left and the superior vena cava to the right. Access to the subcarinal nodes is obtained by caudal retraction of the right main pulmonary artery. The left lobe of the thymus is resected to uncover the aortopulmonary window lymph nodes. These are removed to the ligamentum arteriosum. Left upper lobectomy and pneumonectomy are performed by means of the sternotomy. Should a left lower lobectomy be necessary, an anteroaxillary thoracotomy is added.

Cervical dissection is performed if metastatic disease is found in the highest mediastinal, supraclavicular, or scalene lymph nodes. This procedure is accomplished using a cervical collar incision. The sternocleidomastoid muscles are retracted laterally and the strap muscles divided. The fascia over the internal jugular vein is opened and the vein is skeletonized. The cervical paraesophageal lymph nodes are removed while the recurrent laryngeal nerve is gently retracted forward.

COMPLETE DISSECTION

Right Hemithorax

Entry into the chest through the fifth interspace provides ready access to the mediastinal lymph nodes. A posterolateral thoracotomy or vertical muscle-sparing skin incision may be used with equal success. The authors usually perform the lymph node dissection at the completion of the pulmonary resection. However, if the presence of tumor within the lymph nodes changes the operative procedure, then the lymph node resection may be performed before lung removal. The mediastinal lymph node dissection is most easily accomplished if the lung is collapsed with either a double-lumen endotracheal tube or a bronchial blocker.

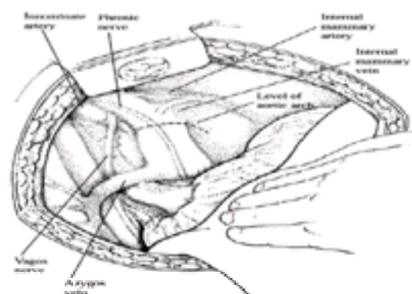
The lung is retracted anteriorly and inferiorly, exposing the superior mediastinum, which is bounded by the trachea, superior vena cava, and azygos vein (Figure 35.10). The phrenic nerve is visible, coursing over the superior vena cava. The vagus nerve traverses the superior mediastinum and is usually visible through the unopened mediastinal pleura. The mediastinal pleura is grasped with a forceps just cephalad to the azygos vein and opened with cautery between the trachea and superior vena cava. A right angle clamp is inserted, and the pleura is incised to the level of the innominate artery. The pleural edge over the trachea is grasped, and the mediastinal fat pad is dissected off the tracheal surface from the azygos vein to the innominate artery (Figure 35.11). A peanut sponge rolled tightly on a clamp is satisfactory for this portion of the operation. The pleural edge over the superior vena cava is similarly grasped, and the mediastinal fat pad is gently dissected from the junction of the superior vena cava and azygos vein to the level of the innominate artery. Not infrequently, a small vein drains from the mediastinal fat pad directly into the superior vena cava. If present, it must be identified and properly ligated to prevent unnecessary blood loss.


FIGURE 35.10. Exposure of right superior mediastinum with mediastinal pleura intact.
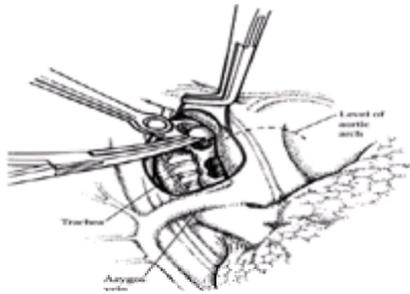

FIGURE 35.11. The internal mammary vein drains into the approximate juncture between the right and left innominate veins as they combine to form the superior vena cava and is a reliable structure with which to differentiate the division between *level 2* and *level 4* lymph nodes. The dashed line represents the aortic arch.

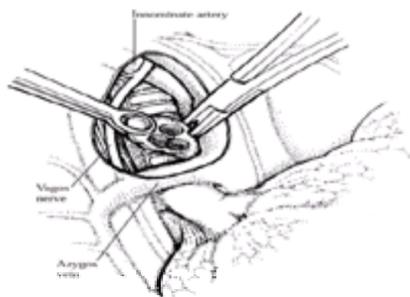
The mediastinal fat pad is grasped with an empty ring clamp and is removed from the superior vena cava anteriorly to the trachea posteriorly, and from the cephalic border of the azygos vein inferiorly to the cephalic border of the left innominate vein superiorly. Nonmagnetic clips (to avoid artifacts on future CT scans) are used liberally. Those lymph nodes between the cephalic border of the aortic arch and the cephalic border of the innominate vein are labeled *right level 2* (Figure 35.11). The lymph nodes distal to the aortic arch and proximal to the azygos vein are labeled *right level 4 superior* (Figure 35.12).


FIGURE 35.12. The lymphadenectomy may be extended to the contralateral lymph node levels. Care must be taken not to injure the left recurrent laryngeal nerve, which is found in the tracheoesophageal groove.

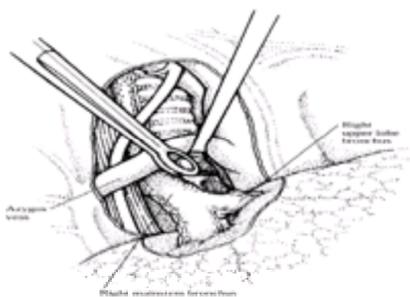
The azygos vein is elevated with a vein retractor, and all lymph nodes between its cephalad border and the origin of the right upper lobe bronchus are removed with sharp and blunt dissection (Figure 35.13). Care must be taken not to injure the pulmonary artery during dissection of these *level 4 inferior* lymph nodes.


FIGURE 35.13. Division of the azygos vein is rarely necessary.

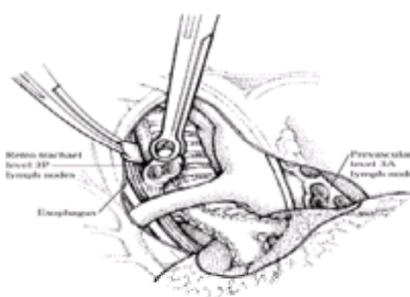
Extension of the dissection behind the trachea reveals *level 3 posterior* nodes located between the esophagus and membranous portion of the trachea (Figure 35.14). Additional lymph nodes, *level 3 anterior,* are found anterior and medial to the superior vena cava at the insertion of the azygos vein.


FIGURE 35.14. The location of the membranous portion of the trachea and the phrenic nerve must be determined prior to application of clips.

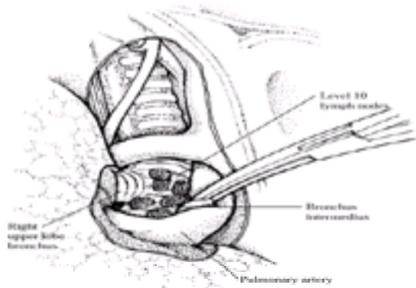
Right level 10 lymph nodes are located along the anterior border of the bronchus intermedius distal to the pleural reflection (Figure 35.15). The interlobar, *level 11,* lymph nodes located in the sump of Borrie are dissected with the lung retracted anteriorly. The pulmonary artery is located anteriorly, and therefore clips must be placed under direct vision. *Level 12* nodes are adjacent to the distal lobar bronchus and are removed with the specimen (Figure 35.16).


FIGURE 35.15. Exposure of the *level 10* lymph nodes is accomplished by retracting the pulmonary artery anteriorly.
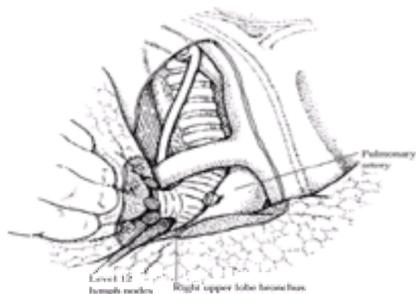

FIGURE 35.16. d include them with the specimen. Cautery is employed to transect soft tissue because a clip may interfere with application of a stapling device.

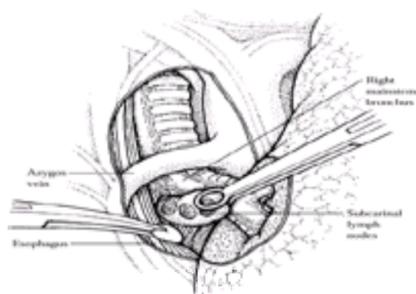
Exposure of the *level 7* subcarinal region is obtained by retracting the lung directly anteriorly (Figure 35.17). The mediastinal pleura is opened, and the edge overlying the esophagus is grasped with a right-angle clamp. The esophagus is retracted posteriorly, and the subcarinal lymph node packet is swept anteriorly. Small vessels are coagulated or tied as necessary. The fat pad is grasped with a ring clamp and elevated off the pericardium. Attachments to the right and left mainstem bronchi are clipped before transection. The blood supply to this lymph node packet includes vessels that course along the anterior border of the trachea to enter the lymph nodes from the carina. Particular care must be taken to identify and control these vessels before they are transected because once they retract beneath the carina, they may be difficult to locate.


FIGURE 35.17. The esophagus and membranous portion of the bronchus must not be injured when applying clips.

Level 9 lymph nodes are located within the inferior pulmonary ligament and are easily visualized. They can be grasped with a ring forceps and removed with cautery or clips. *Level 8,* paraesophageal lymph nodes, are not always present.

Left Hemithorax

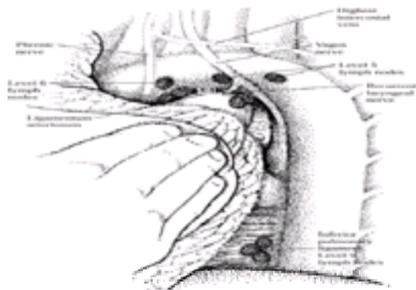
Thoracotomy through the fifth interspace provides excellent exposure for dissection of the aortopulmonary (*levels 5* and *6*) and subcarinal (*level 7*) lymph nodes (Figure 35.18). The lung is racted inferiorly, and the pleura is incised in a cephalad direction midway between and parallel to the vagus and phrenic nerves, beginning at the level of the aortopulmonary window and extending above the aortic arch. The ligamentum arteriosum is readily palpated but less easily visualized. The *level 6* lymph nodes are exposed by grasping the pleural edge closest to the phrenic nerve and dissecting away the lymph node–containing fat pad. This step is best accomplished with blunt dissection. Vessels should be controlled with clips or ties to avoid electrical injury to the nearby nerves. The location of the phrenic nerve must be constantly known to avoid iatrogenic diaphragm paralysis. *Level 5* lymph nodes are exposed by grasping the posterior pleural edge and bluntly dissecting the fat pad posterior to the ligamentum arteriosum. The recurrent laryngeal nerve and the proximal vagus nerve must be zealously protected because vocal cord paralysis is a potential complication.


FIGURE 35.18. The left superior mediastinum before opening the mediastinal pleura. Exposure of *level 2* or *4* lymph nodes would require mobilization of the aortic arch.

The subcarinal lymph nodes, *level 7,* are approached with the lung retracted anteriorly (Figure 35.19). The pleura is opened anterior and parallel to the aorta at the level of the left mainstem bronchus. The lymph nodes are grasped with a ring clamp, and clips are liberally applied before excision of the nodal packet. An arterial

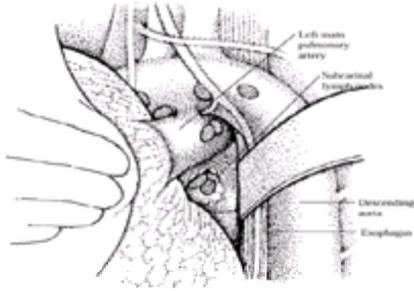
vessel usually enters the lymph nodes at the carina. It must be identified and clipped to avoid postoperative hemorrhage.


FIGURE 35.19. The subcarinal lymph nodes are more difficult to expose in the left hemithorax than in the right hemithorax. A malleable retractor is used to retract the aorta and esophagus posteriorly.

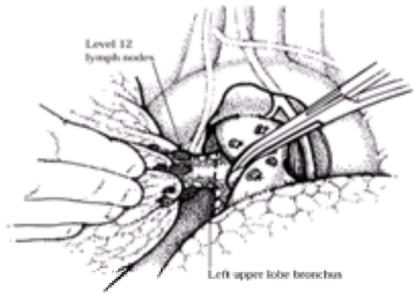
Level 11 interlobar nodes are best approached with the lung retracted anteriorly. The pulmonary artery is immediately anterior and must be protected if clips are applied or cautery utilized. *Level 12* lymph nodes are located along the distal bronchus near its junction with the mainstem bronchus (Figure 35.20). The *level 9,* pulmonary ligament lymph nodes are identified within this structure and removed with cautery or clips. Esophageal injury must be avoided.


FIGURE 35.20. As the soft tissue is cleared to permit application of the stapling device, the nodes are pushed distally with a peanut sponge.

Even the most detailed lymph node dissection provides little information if the resected specimens are not correctly labeled. Many surgeons have not adopted the habit of routinely performing a lymph node dissection, and many pathologists do not report their histologic findings by individual lymph node level. To ensure that each level is reported separately and that levels are not lumped together as "mediastinal lymph nodes," they must be sent from the operating room as discrete specimens.

COMPLICATIONS OF MEDIASTINAL LYMPHADENECTOMY

Some surgeons are hesitant to perform a complete mediastinal lymph node dissection for fear of complications that might arise from either interrupting the blood supply to the bronchial stump or removing a large portion of the intrathoracic lymphatics. Bollen and colleagues [37] compared the postoperative complications of 155 patients with NSCLC who underwent no mediastinal lymph node dissection or sampling (n = 70), complete mediastinal lymph node dissection (n = 65), or systematic mediastinal lymph node sampling (n = 20). No significant difference among the groups was noted for intraoperative blood loss or the need for transfusion. Unintentional left recurrent laryngeal nerve injury occurred in three patients (5%) who underwent complete nodal dissection. Two additional patients developed chylothoraces. One patient who underwent node dissection required reoperation for bleeding not related to the lymphadenectomy. The two patients who developed bronchopleural fistulas had not undergone node dissection. Hata and colleagues [31] reported two left recurrent laryngeal nerve injuries and one phrenic nerve paralysis in 50 patients who underwent extensive mediastinal dissection. Reoperation or bronchopleural fistulas were not reported.

Izbicki and colleagues[68] compared the morbidity and mortality associated with systematic mediastinal sampling and mediastinal lymph node dissection in a randomized prospective study (n = 182). They found that although mediastinal lymph node dissection added approximately 20 minutes to the operative procedure, there was no increase in blood loss, mortality, or need for reoperation. One chylothorax occurred in each group. Recurrent laryngeal nerve injury was reported in six patients who underwent systematic sampling and in five patients who underwent mediastinal lymph node dissection. The duration of chest tube drainage and hospitalization were similar in both groups.

RESULTS OF LYMPH NODE SAMPLING AND DISSECTION

Five-year survival of patients with N2 disease after pulmonary resection and mediastinal lymph node dissection performed in a fashion similar to that described earlier is reported from 9% to 29%.[66,69,70,71,72,73 and 74] Most investigators make no therapeutic claim for nodal dissection but rather emphasize the benefits of accurate staging. The proponents of the more extensive nodal dissections, however, purport to demonstrate improved survival.

Hata and colleagues[30] reported five-year survival of 66% in 15 patients with N2 disease and 35% in 13 patients with N3 (contralateral mediastinal) disease who underwent bilateral mediastinal lymph node dissection by means of sternotomy. The five-year survival of 12 patients with scalene or supraclavicular N3 disease who underwent sternotomy and cervical dissection was 33%. Nakahara and colleagues [32] documented a three-year median survival for 13 patients with N2 disease who also underwent bilateral mediastinal lymph node dissection. No patient found to have N3 disease survived more than 14 months (n = 4). Watanabe and colleagues [30] claimed significantly improved survival of patients with left upper lobe tumors who underwent bilateral lymph node dissections when compared to patients who had only suspicious lymph nodes removed. These studies should be interpreted carefully because they contain small numbers of patients whose improved survival may result from factors unrelated to the extensive lymph node dissection. Indeed, Mitsuoka and colleagues [67] found no significant survival advantage for patients with pathologic stage IIIa left lung cancers who underwent sternotomy and nodal dissection when compared to patients who had thoracotomy only. In addition, no patients with N3 disease survived 3 years.

MEDICAL EVALUATION AND MANAGEMENT OF THE LUNG CANCER PATIENT PRIOR TO SURGERY, RADIATION, OR CHEMOTHERAPY

FERNANDO J. MARTINEZ
MARK IANNETTONI
ROBERT PAINE, II

For the patient with non–small cell carcinoma of the lung (NSCLC), lung resection remains the best potentially curative therapy. Therefore, it behooves physicians who manage lung cancer to approach such patients as though surgery is possible and to tailor their evaluation with this goal in mind. However, surgery cannot benefit the patient if it results in early postoperative death or intractable respiratory failure. The determination that a given patient should undergo resectional surgery hinges on four factors: a resectable tumor (decided after a staging evaluation, which is described elsewhere in this text); adequate respiratory reserve to allow sufficient lung resection for cure; the absence of a major medical contraindication to surgery; and an agreeable patient. In those patients in whom surgery is not feasible because one or more of these requirements cannot be met, radiation therapy and/or chemotherapy are often utilized. We will describe our approach, based on available literature, to the patient to whom surgery, radiation therapy, and chemotherapy are offered to treat bronchogenic cancer. The goal of this evaluation is to identify patients at inordinate risk for posttreatment respiratory insufficiency and major perioperative morbidity. [1] Much of the earlier literature describes an approach to standard thoracic resection, while the later literature emphasizes improved methods of postoperative pain management and lung-conserving procedures. [2,3,4 and 5] These techniques are revolutionizing the preoperative evaluation of patients with suspected thoracic malignancies. We will also describe perioperative management strategies which can be used to decrease such complications.

CONSIDERATIONS FOR SURGICAL THERAPY

Physiology of Thoracotomy

The surgical invasion of the thorax to remove a portion of the lung is a major attack on the respiratory system. In addition to the resection of significant portions of functioning lung, there are major physiologic consequences of thoracotomy that are independent of actual lung resection. The major effects of entering the thorax appear to relate to a change in chest wall compliance and an increase in the work of breathing, due both to the direct influences of the surgical wound on the chest wall, including any chest wall resection, and to postoperative pain. Peters and colleagues [6] examined total chest compliance and work of breathing in 16 patients prior to, as well as one, three, and seven days after one of three different thoracic surgical procedures (thoracotomy only; thoracotomy with lung resection; or midline thoracotomy with open-heart surgery). Thoracotomy with or without lung resection decreased chest compliance to 47% of control values on postoperative day three. There were significant increases in work of breathing in the thoracotomy and thoracotomy plus resection groups (143% of control values on postoperative day three). Interestingly, these effects were much less prominent with "midline thoracotomy" (see below).

In part as a consequence of these changes in compliance, thoracotomy results in dramatic falls in the vital capacity that are sustained over the first three postoperative days. [7] This decrease in ventilatory capacity often results in alveolar hypoventilation with respiratory acidosis in the early postoperative period. [7] A drop in oxygen saturation is most marked two to three days postoperatively. [8] Cough is also frequently impaired after thoracotomy. Byrd and Burns [9] studied 24 adult patients undergoing thoracotomy. Cough pressures (measured using pleural pressures from intraesophageal catheters) dropped to 29% of preoperative values in the immediate postoperative period and had increased to only 50% of control one week after surgery. Since many patients with bronchogenic cancer are older and have underlying COPD, it is not surprising that thoracotomy and its resulting physiologic defects may be associated with significant postoperative cardiopulmonary complications.

Median sternotomy as described by Peters and colleagues [6] has been shown to preserve postoperative lung function better. Cooper and associates [10] examined the changes seen in pulmonary function after median sternotomy (n = 14 for coronary artery bypass surgery) and lateral thoracotomy (n = 14, left lateral thoracotomy for repair of hiatal hernia). Both groups showed a 50% reduction in peak expiratory flow rate and vital capacity by the second hospital day. Subsequent to that, however, the sternotomy group showed progressive improvements in pulmonary function. One week postoperatively, vital capacity had increased to 71% of control in the sternotomy group but only to 58% of control in the lateral thoracotomy group. As such, in marginal cases, this operative approach may be associated with better preservation of postoperative pulmonary function. There are limitations to this operative approach, however. In general, pulmonary anatomy may be more difficult to expose via sternotomy, particularly the left lower lobe. [7]

PREOPERATIVE PULMONARY EVALUATION

Overview of Physiologic Assessment of Operability

The benefit of surgical resection of a bronchogenic tumor can be manifest only if the patient survives the surgery and avoids chronic respiratory insufficiency due to the loss of resected pulmonary parenchyma. The normal adult has an enormous respiratory reserve that would allow removal of an entire lung with relatively little compromise. However, the vast majority of patients with lung cancer have smoked cigarettes and thus are at risk for chronic obstructive pulmonary disease (COPD). In some series, up to 90% of lung cancer patients have had signs and symptoms of COPD, and at least 20% of these patients have had severe respiratory dysfunction at initial evaluation. [11] A major goal of the preoperative evaluation of the patient with potentially resectable lung cancer is to predict the likelihood of severe postoperative respiratory insufficiency, based upon the patient's preoperative characteristics. It would be relatively easy to define criteria that would be sensitive predictors of postoperative respiratory difficulties (for example, prior cigarette use). However, this approach would lead to exclusion from potentially curative surgery of a significant number of patients. Ideally, it would be possible to exclude from surgery all patients who develop postoperative respiratory failure, while at the same time allowing surgery in the maximum number of individuals who could survive surgery without respiratory compromise. Thus over the last 45 years an extensive literature has been devoted to efforts to define preoperative characteristics that are both sensitive and specific predictors of postoperative respiratory insufficiency due to lost of resected lung. In addition, in some instances these studies also have provided opportunities to predict overall perioperative complications based upon preoperative characteristics.

The history of efforts to define with ever-greater precision the subset of patients with potentially resectable carcinoma of the lung in whom surgery is feasible on

physiologic grounds provides an instructive overview of our evolving understanding of the pathophysiology of chronic respiratory insufficiency. Investigators have attempted to define the limits of safe resection based upon traditional ventilatory parameters, measurements of gas transfer, techniques aimed at determining the contributions of specific portions of the lung to the patient's respiratory function, studies of pulmonary vascular reserve, and cardiopulmonary exercise testing (Table 36.1, Table 36.2). While simple measures may suffice for patients with relatively well-preserved lung function, the use of multiple parameters is often necessary for patients with more significant impairment. The historical perspective presented in the discussion that follows is helpful for understanding the complimentary roles of the different parameters for the determination of operative risk. Recent series describe postoperative mortality that ranges from 0.9% to as high as 11.6% depending on the type of resection (higher for pneumonectomy).[12],[13],[14] and [15] Operative morbidity ranges from the teens to higher than 40%.[16] However, in comparing figures for morbidity and mortality from different surgical series, it is critical to recognize not only the differences in the patient characteristics but also differences in the accepted limits of operability in each study.

TABLE 36.1. PUBLISHED CRITERIA OF PULMONARY FUNCTION FOR PREDICTING HIGH RISK FOR LUNG RESECTION

TABLE 36.2. STUDIES EXAMINING MEASURE OF AEROBIC CAPACITY IN THE PREOPERATIVE EVALUATION OF LUNG CANCER PATIENTS

Spirometry/Lung Volumes

A spirometric study is one of the most widely used measures of ventilatory function. Well-accepted standards for measurement [17] and interpretation are available.[18] With a spirometer one can measure expired volumes such as the FVC, and the time components including the FEV_1. These studies are particularly valuable in assessing airflow obstruction.[18] Maximum breathing capacity (MBC), now named the maximum voluntary ventilation (MVV), can be measured as the total volume of air which can be rapidly inhaled and exhaled repetitively for up to 12 seconds. Using such measures (timed FVC and MBC), Gaensler and associates [19] studied 460 patients treated surgically for pulmonary tuberculosis. Those patients with an MBC of less than 50% predicted and a FVC of less than 70% predicted suffered a 40% postoperative mortality due to respiratory insufficiency.

Mittman[20] retrospectively reviewed various pulmonary function parameters in 196 patients undergoing thoracic surgical procedures (103 for thoracic malignancy). The best parameter in separating those with postoperative mortality was a MBC of less than 50% predicted. The addition of an elevated RV/TLC ratio (suggesting hyperinflation from underlying COPD) and an ECG with "nonspecific abnormalities" strengthened the ability to identify patients at high risk for thoracic surgery.

Boushy and colleagues[21] studied 142 patients with bronchogenic carcinoma using various pulmonary function studies, and followed for up to three years postoperatively. Those patients (n = 12) with severe postoperative respiratory difficulty including death had a lower FEV_1. These authors felt that an FEV_1 of less than 2 L and an FEV_1/FVC of less than 50% were poor prognostic signs in patients over the age of 60 undergoing pulmonary resection. These criteria have been widely accepted and often quoted.

Lockwood[22] measured multiple pulmonary function studies in 243 patients evaluated for thoracotomy for lung carcinoma. This author advocated using multiple parameters in identifying high-risk patients.[23] He found the following parameters to identify these high-risk patients: VC less than 1.85L, FVC less than 1.7L, RV more than 3.3L, TLC more than 7.9L, RV per TLC more than 47%, FEV_1 less than 1.2L, FEV_1/FVC less than 35% or MVV less than 28 L per minute. Note that these parameters were not indexed to a patient's age, sex, race, or weight, and as such their widespread applicability to all patients is limited.

Boysen and associates[24] prospectively studied 72 patients considered for thoracotomy. Postoperative respiratory complications (mainly pulmonary) were seen in 40 patients. FEV_1, FVC, and MVV were lower in these patients compared to those without postoperative complications. Miller, [25] using preoperative pulmonary function testing, split perfusion lung scans (see below), and Reichel exercise tests (see below) reported surgical results in 2,340 patients who underwent pulmonary resection over a 16-year period. Using the criteria shown in Table 36.1 (based in large part on predicted postoperative pulmonary function testing described later), the author reported an operative mortality, confined to the 30-day hospital period, of less than 1%. The authors reported that 39 patients were denied the operation on the basis of preoperative pulmonary function.

These data suggest that simple pulmonary function testing has a role in identifying patients at particularly high risk for resection. Nevertheless, there is not uniform agreement in the literature. Larsen and Cliffton [26] retrospectively examined the results of 533 patients who underwent thoracic surgery at Memorial Sloan-Kettering Cancer Center from 1949 to 1960. Seventy-three of these patients did not tolerate surgery (died in hospital or developed severe respiratory failure). No difference was seen in VC or MBC between these patients and those who "tolerated" surgery. Of interest, is that "chronic lung disease" was present in only 33.7% of all patients but was more likely to be seen in those with respiratory insufficiency after surgery than in those without respiratory insufficiency. Furthermore, FEV_1 was not examined, nor were spirometric measures performed in a standard fashion throughout the course of the study period. Keagy and colleagues [27] studied 90 patients undergoing pneumonectomy for lung cancer with spirometry. The authors found no correlation between morbidity or mortality after surgery and preoperative spirometry. The authors, however, did not report the number of patients during the study period that had been evaluated for surgery but rejected on the basis of pulmonary function testing. This selection bias limits the conclusions reached by the authors. Kearney and colleagues prospectively studied 331 patients undergoing thoracic resections over a two-year period.[15] An FEV_1 below 1 L was not predictive of postoperative complications.

In summary, spirometry serves as a simple, cheap, and reproducible test of respiratory function that is a sensitive but not specific predictor of postoperative difficulty. Most studies have shown that parameters such as FEV_1, FVC, and FEV_1/FVC can identify patients who are likely to experience perioperative complications and/or postoperative respiratory insufficiency. However, as surgery is the only good curative alternative in patients with NSCLC, we must be sure to minimize the number of patients who are inappropriately denied surgery based on simple spirometric results. Therefore, we use spirometry to identify the highest-risk patients and exclude only those patients with severely abnormal pulmonary function (see Table 36.1) unresponsive to aggressive efforts to improve airflow obstruction (as will be described

later) or unsuitable for lung sparing surgical resection. Further studies are usually required to define better the clinical situation.

Diffusion Capacity (DLCO)

The DLCO has been widely available for over 30 years.[28] The test measures the available alveolar-capillary surface area for gas diffusion, the alveolar membrane integrity, and the pulmonary capillary blood volume. It is thus a particularly sensitive, albeit nonspecific, test for pulmonary disease. [29] In patients with COPD, the DLCO is closely correlated with the extent of anatomic emphysema.[30;31] Limited study has been devoted to this test as a predictor of postthoracotomy outcome. Ferguson and colleagues[32] retrospectively studied the results of lung resection in 237 patients (lung cancer in 199). The DLCO (as a percent of predicted) was the most important predictor of mortality and the sole predictor of postoperative pulmonary complications. The same group confirmed these findings in a prospective study of 40 patients undergoing lung resection. [33] Those patients with a postoperative complication had a lower DLCO (65.3% of predicted) than those not experiencing such a complication (90.1% of predicted). In an excellent study, Markos and associates [34] prospectively studied 55 consecutive patients with suspected lung cancer. Patients were studied with spirometry, DLCO (expressed as a percent of predicted), pulmonary scintigraphy (described below), and exercise testing (discussed below). Among their findings, the DLCO was the best predictor of overall complications. In a retrospective study of 62 resections in 61 patients at high risk (FEV$_1$ less than 60% predicted or DLCO less than 50% predicted), a low DLCO identified patients at higher risk of respiratory complications and long-term respiratory morbidity. [35] In a prospective study of resection in 54 patients, Pierce and colleagues confirmed that preoperative DLCO as a percent of predicted was an excellent predictor of surgical complications, although not of cardiovascular or respiratory complications. [36] It is plausible that the DLCO, because of its sensitivity in identifying pulmonary parenchymal or vascular abnormality, may be particularly sensitive in identifying gas exchange difficulty after thoracotomy. [11]

Measure of DLCO may serve as an additional parameter which aids in identifying patients at high risk for perioperative complications and/or postoperative respiratory failure. The data are limited, however, and, as such, elimination of patients from curative resection solely on the basis of a decreased DLCO may not be appropriate. We use the DLCO to identify patients needing further testing and more intensive preoperative "tuning," as will be discussed later. In addition, DLCO data are used to strengthen our initial suspicion of unresectability as suggested by spirometric data.

Split Lung Function Studies

As we approach the question of resection of a portion of lung for treatment of carcinoma, it seems intuitively obvious to take into account that all portions of the lung may not contribute equally to the patient's ventilatory reserve. It is likely that a patient who is not experiencing respiratory compromise despite complete atelectasis of one lung will survive resection of that lung without postoperative respiratory insufficiency. Since the time of the height of the tuberculosis epidemic, investigators have attempted to estimate unilateral lung function in an effort to predict loss of function after aggressive surgical therapy in the individual case. More recently, additional efforts have focused on the ability to predict precisely postoperative lung function after lobectomy.

Bronchospirometry

Neuhaus and Cherniack[37] used the technique of bronchospirometry to predict postoperative VC and MBC. This technique involved the placement of a double-lumen endotracheal tube under local anesthesia, which allowed the isolation of each lung. In this way, during quiet breathing and maximal ventilation, the VC of each lung could be estimated. Furthermore, the oxygen uptake (VO$_2$) of each lung could be measured. These investigators [37] studied 80 patients who underwent pneumonectomy for tuberculosis and had undergone bronchospirometry preoperatively. They were able to predict postoperative VC and MBC with correlation coefficients between predicted and actual postoperative values of 0.86 and 0.67, respectively. An earlier study using bronchospirometry in 45 patients undergoing pneumonectomy and 97 patients after thoracoplasty allowed Snider and Shaw[38] to construct regression equations to predict the loss of VC and MVV resulting from surgery. The authors noted that the bronchospirometrically determined function of lung resected had little effect on postoperative lung function unless the preoperative pulmonary function was low. These data, in conjunction with the difficulty in performing the studies as well as the discomfort associated with the placement of the double-lumen endotracheal tube, have markedly limited the use of this study. The equipment to perform this test is now rarely available. We describe these studies to emphasize their historical role as the first accurate way to predict unilateral lung function. [11]

Lateral Position Test (LPT)

This study was first developed by Bergan in the late 1950s[39] and consists of a period of tidal breathing from an oxygen-filled spirometer containing a CO$_2$ absorber. A baseline VO$_2$ is obtained with the patient breathing supine from functional residual capacity (FRC). The patient is then asked to lie in a right or left lateral decubitus position while still breathing from the spirometer. After lying supine again to reestablish a baseline, the patient lies with the other lung superior. The difference in FRC owing to hyperinflation of the uppermost part of the superior lung as a percentage of the total volume change allows the unilateral lung function to be estimated. [11]

Marion and colleagues[40] and Walkup and colleagues [41] noted good correlations between predicted and actual pulmonary function (particularly FEV$_1$ and FVC; DLCO and lung volume estimates were less accurate) using LPT to predict postsurgical function. The limitations of the LPT quickly became evident however. Walkup and colleagues[41] correctly pointed out that lobar function could not be estimated using this technique. Furthermore, an earlier study [42] compared LPT, radionuclide studies, and bronchospirometry to determine unilateral lung function. There was an excellent correlation between values estimated using radionuclide studies and bronchospirometry (for FVC, r = 0.95). Values estimated by LPT were "statistically inferior" (for FVC, r = 0.87). A subsequent study by Jay and colleagues [43] revealed the major limitation of this study when they examined the variability of values obtained using this technique. In ten normal subjects, tests were performed in triplicate for five consecutive days. The variability of same-observer and different-observer measurements was minimal. However, there was significant variability in tests conducted in the same subject on the same day and in day-to-day measurements in any given subject. Finally, Schoonover and associates [44] examined the variability of the LPT in patients with COPD (24 patients with an FEV$_1$ of less than 2 L). A good correlation was found between estimated postpneumonectomy FEV$_1$ predicted from radionuclide scan and LPT (r = 0.72). There was however a more than 10% difference between these results in 59% of the patients. Furthermore, a subgroup of patients performed multiple LPTs. The variation was 14 times greater than in normal subjects, suggesting that as many as 37 tracings would be needed on each patient to obtain a value with an acceptably low measurement error. Because of these limitations, the LPT appears to have a limited applicability in the preoperative evaluation of patients being considered for lung resection. It is rarely used now and usually in centers without access to radionuclide studies.

Radionuclide Studies

Over the past 20 years, radionuclide techniques have become widely accepted for estimating postoperative function after lung resection. These techniques have been used predominantly to minimize postoperative respiratory failure by identifying particularly high-risk patients. The techniques available have recently been reviewed. [45] Kristersson and associates[46] first estimated unilateral lung function by measuring ^{133}Xe (^{133}Xe-ventilation radiospirometry). The estimated postpneumonectomy values for spirometry were compared with actual values measured one month to one year postsurgery. The correlations between these values were reasonably for FEV$_1$ (r = 0.63) and FVC (r = 0.73). The authors suggested that a postoperative FEV$_1$ of less than 1 L was the lower limit of operability.

Subsequently, Olsen et al[47] modified the technique by estimating unilateral lung *perfusion* by injecting ^{99m}technetium ferric hydroxide macroaggregates intravenously. This approach is designed to identify the extent of alveolar-capillary membrane that would remain following resection. The radioactivity emanating from each hemithorax was quantified and the predicted postoperative pulmonary function estimated using the formula:

Postsurgery PFT = (Preoperative PFT) × (% of total function contributed by the lung remaining).

In this way PFT parameters were compared to values measured three months following pneumonectomy. Thirteen patients in the study had moderately severe COPD preoperatively. The correlations between predicted and actual postpneumonectomy values were significant for FEV$_1$ (r = 0.72), FVC (r = 0.71), MVV (r = 0.75), and DLCO (r = 0.62). A significant error was present in the majority of cases. However, the predicted values were generally lower giving a "margin of safety." The authors suggested a postoperative FEV$_1$ of less than 0.8 L as being particularly high risk, although no specific evaluation of this cutoff was provided. Furthermore, pulmonary function was not corrected for age, sex, and height, particularly as the patients in this study were from an elderly, male, veteran population.

Ali and associates[48] prospectively studied 27 patients undergoing pneumonectomy for lung cancer using ^{133}Xe to study regional ventilation and perfusion. The correlation of percentage loss in FEV$_1$ and FVC as compared to predicted loss using estimated single lung function was in a range similar to prior studies (r = 0.63). These authors expressed postoperative function as a percent of predicted values, thereby normalizing function across all patients. The authors showed that seven of

eight patients with an FEV$_1$ of less than 40% predicted had died, while ten of seventeen with an FEV$_1$ of more than 40% predicted remained alive. The causes of death were not provided, however. These same authors[49] in a subsequent study investigated the ability of ^{133}Xe radiospirometry to predict postoperative function after pneumonectomy (n = 97) or lobectomy (n = 44). They noted a good correlation between predicted FVC and FEV$_1$ and measured postoperative values for resections involving *more* than three segments (r = 0.83). Resections involving less than three segments (generally right upper lobectomies) were associated with less reliable predictions. Furthermore, the authors noted relatively stable function after pneumonectomy but a disproportionate early loss after lobectomy, which improved over time. This is quite significant, as patients with marginal pulmonary function may have very little reserve in the early postoperative period, leading to a greater likelihood of respiratory failure. More recently the same group[50] reported that a postoperative FEV$_1$ (ppoFEV$_1$) of less than 40% predicted was associated with a greater short-term mortality, but that long-term mortality was more closely related to tumor stage. Highest-risk individuals were noted to have estimated ppoFEV$_1$ values of less than 33% predicted with evidence of severe generalized airway obstruction (FEV$_1$/FVC less than 50%) and abnormal distribution of regional ventilation or perfusion within the non–tumor bearing lung. The importance of a predicted postoperative FEV$_1$ of more than 40% predicted is evident.

Boysen and colleagues[51] studied 33 patients felt to be at high risk for pneumonectomy on the basis of prior PFT criteria (similar to those shown in Table 36.1). Quantitative perfusion lung scans were used to predict postoperative FEV$_1$ (ppoFEV$_1$) as described earlier. If the ppoFEV$_1$ was more than 0.8 L, surgery was offered to the patient. Perioperative mortality before 30 days after surgery) was found to be an "acceptable" 15% (particularly given the high-risk nature of the patients). A subsequent study by the same group[52] of high-risk individuals (mean preoperative FEV$_1$ of 1.68 L prior to pneumonectomy) was published in 1981. These authors followed patients for a minimum of one year after surgery. A low incidence of deaths due to respiratory failure (17%) was noted, which was felt by the authors to related to the estimation of an adequate postoperative pulmonary reserve (FEV$_1$ of more than 0.8 L). The majority of deaths occurred from metastatic disease (69% of the deaths).

Wernly et al.[53] used a similar radionuclide technique (^{133}Xe ventilation and ^{99m}Te-macroaggregated albumin perfusion scans) prospectively in 85 patients (45 pneumonectomies, 40 lobectomies). Correlation of predicted postpneumonectomy pulmonary function was similar to the results of other investigators described earlier, whether ventilation or perfusion scans were used to estimate postsurgical lung function. The authors provided novel information in predicting ppoFEV$_1$ after lobectomy. They noted an excellent correlation (mean percent error less than 10%) using perfusion scans to estimate unilateral lung function and the following equation to estimate postlobectomy FEV$_1$:

$$\text{Expected loss of function} = \text{Preoperative FEV}_1$$
$$\times \;(\%\text{ function to affected lung})$$
$$\times \;\frac{(\text{number of segments in lobe to be resected})}{(\text{total number of segments in that lung})}$$

Similar correlations occurred if expected loss of function was estimated by regional function of the lobe to be resected (estimated from the perfusion scan) or by simply subtracting the number of segments to be removed as a fraction of all segments in both lungs. Using a ppoFEV$_1$ of over 1 L as the lower limit of operability the authors noted no postoperative deaths from respiratory failure in 22 patients with a preoperative FEV$_1$ of less than 2 L who underwent pneumonectomy. Forty patients with an FEV$_1$ of less than 1.5 L underwent lobectomy (again assuming a ppoFEV$_1$ of over 1.0 L) with no deaths or cases of postoperative respiratory insufficiency. A similar study by Egeblad and colleagues[54] estimated the loss of lung function expected by estimating the number of lung segments to be resected. No unilateral measure of lung function was performed; the authors estimated at the time of bronchoscopy the number of patent and nonventilated segments (occlusion defined as over 75% luminal narrowing) and estimated ppoFEV$_1$ using the following equation:

$$\text{ppoFEV}_1 = \text{Preoperative FEV}_1$$
$$\times \;\frac{\text{number of segments remaining postresection}}{20 - \text{number of nonventilated segments preresection.}}$$

In studying 96 patients undergoing lung surgery, they found a correlation coefficient between ppoFEV$_1$ and actual FEV$_1$ six months postoperatively of r = 0.83; the correlation coefficient was r = 0.85 for FVC. The obvious limitations to this technique include the failure to account for differences in ventilation/perfusion ratios of the varying pulmonary regions (particularly in patients with COPD) and the failure to consider the differences in size between the two lungs. An overestimation in predicting functional loss has been measured at approximately 250 mL after lobectomy and 500 mL after pneumonectomy.[55] Furthermore, patients with severe atelectasis, endobronchial tumor involvement, and/or hilar disease may not have equal ventilation to each segment.[15] Nakahara and associates accounted for this in a nonscintigraphic estimate of postoperative pulmonary function which made a distinction between obstructed and nonobstructed airways.[56] Using this technique, ppoFEV$_1$ was predictive of postoperative complications. If a physician has no access to radionuclide studies, this crude method may be able to provide a rough estimate of ppoFEV$_1$.

Radionuclide scanning has also been reported to accurately predict postoperative exercise function. Corris et al[57] used ^{133}Xe ventilatory and ^{99}Te perfusion scans in 28 patients before pneumonectomy. Estimates of ppoFEV$_1$ showed good correlation with measured values postsurgery. Fourteen patients performed exercise tests with measures of maximum ventilation (maxVE) and maximum oxygen uptake (maxVC$_2$) before and four months after pneumonectomy. A significant correlation was found between the change in maxVE and maxVO$_2$ after surgery and the percentage perfusion to the resected lung. Estimation of postoperative maxVE and maxVO$_2$ on the basis of ^{99m}Te perfusion scans showed good agreement with observed values. Similarly, Bolliger and colleagues were able to accurately estimate postsurgical aerobic capacity in 22 patients after thoracic resection.[58] These data suggest that estimates of unilateral lung function may serve to estimate exercise capacity after pneumonectomy.

Not all data have been consistently supportive of radionuclide scanning, however. Ladurie and Ranson-Bitker[59] recently reviewed their experience with 159 patients who had undergone pneumonectomy (131 for lung cancer). Unilateral functional determination was done with bronchospirometry in 47 patients and with radionuclide scanning in 112. The difference between the ppoFEV$_1$ and the actual postoperative FEV$_1$ was greater than one standard deviation in 37 patients (mean difference 415 mL). Overestimation of ppoFEV$_1$ was seen in 20 patients, while underestimation was seen in 17. In addition, Holden and colleagues found neither the ppoDLCO nor ppoFFEV$_1$ predictive of complications in a small study of 16 patients.[60]

Markos and associates[34] published an excellent prospective study of 55 consecutive patients with suspected lung cancer which places many of these issues into practical perspective. The patients were studied preoperatively with spirometry, lung volume measurements, DLCO measurements, radionuclide studies to predict postoperative function, and an exercise test (discussed later). Eighteen patients underwent pneumonectomy, while 29 underwent lobectomy. Predicted pulmonary function correlated well with measured postoperative values. The lower correlations seen with pneumonectomy in this study were felt to reflect the effects of postoperative radiation therapy. PpoFEV$_1$ was less than 0.8 L in 12 of 29 patients treated with lobectomy. However, expressing data as a percent of predicted allowed the authors to show that ppoFEV$_1$ of over 40% predicted was associated with no mortality, while ppoFEV$_1$ of less than 40% predicted was associated with a 50% mortality. Furthermore, predicted postoperative DLCO (ppoDLCO) of less than 40% predicted was also associated with a high mortality and morbidity. PpoFEV$_1$ and ppoDLCO were the best predictors of postoperative death and postoperative respiratory failure, respectively. It should be noted however, that 47% of the patients studied had a preoperative FEV$_1$ of over 2 L with only 6% having a preoperative FEV$_1$ of less than 50% predicted. These patients were thus generally "healthier" than those reported in most previous studies. Nevertheless, this study showed the value of predicting postoperative function in estimating not only postoperative mortality but complications as well. Furthermore, expressing data as a percent of normal predicted for a given patient had a clear, practical value.

Recent data have expanded the role of postsurgical prediction of lung function. Pierce and colleagues prospectively examined 54 patients undergoing thoracic resection.[36] Postoperative pulmonary function was estimated using quantitative perfusion scanning in those patients with a presurgical FEV$_1$ of over 55% predicted and by estimating the proportional loss of pulmonary segments in those patients with a presurgical FEV$_1$ of less than 55% predicted. They confirmed the value of ppoFEV$_1$ and ppoDLCO in predicting surgical mortality, while ppoDLCO predicted surgical complications. A composite score generated by multiplying ppoFEV$_1$ and ppoDLCO, the PPP, or predicted postoperative product, was highly predictive of complications and the best single predictor of surgical mortality in contrast to baseline pulmonary function studies. A PPP over 1850 was seen in seven of eight patients dying but in only five of 44 survivors. Similarly, Ribas and colleagues prospectively

examined 65 patients scheduled for thoracotomy by estimating postoperative pulmonary function.[61] They confirmed that ppoFEV$_1$ was the only value that differed between those patients experiencing postoperative respiratory complications and those that did not experience such complications. Filaire and associates prospectively defined predictive factors of postoperative hypoxemia and mechanical ventilation in 48 patients undergoing lung resection. [62] In lobectomy but not pneumonectomy the best predictor was ppoFEV$_1$. Similarly, Wang and colleagues retrospectively examined 410 patients undergoing lung resection over a 17-year period at the University of Chicago.[63] A low ppoDLCO was predictive of operative death but of long-term survival.

Wu and colleagues estimated postoperative pulmonary function using quantitative computed tomography (CT). [64] Excellent correlations were noted between CT estimates and actual measurements of postoperative FEV$_1$ (r = 0.93). As most patients with suspected bronchogenic cancer undergo preoperative CT scanning, this technique could prove particularly useful if prospective validation is provided in comparison to standard scintigraphic techniques.

Measurement of predicted pulmonary function after lobectomy or pneumonectomy is easily done with the use of radionuclide imaging (either perfusion or ventilation). Using a ppoFEV$_1$ of over 40% predicted likely minimizes postoperative respiratory failure and may identify those patients with lower perioperative complications. If radionuclide scanning is not available, then estimates of the number of segments to be resected can be made at the time of bronchoscopy. The data supporting this technique are limited, however. In most patients it is not necessary to estimate postoperative function. This approach is reserved for those patients in whom initial spirometric or DLCO measurements suggest a higher risk of postoperative respiratory insufficiency, as defined in Table 36.1. If one is unsure of the extent of resection, then estimates of ppoFEV$_1$ should be made for both limited and extensive resection (including pneumonectomy). In this way the surgeon carries all necessary information into the operating room, where the final decision will be made.

Vascular Studies

The role of pulmonary hypertension and cor pulmonale in respiratory disability became evident during the tuberculosis epidemics. In 1958, Harrison and colleagues [65] noted significant rises in pulmonary artery pressure with exercise in 28 patients after pneumonectomy. The authors also found a correlation between the degree of disability and abnormal pulmonary hemodynamics, confirming the importance of abnormal pulmonary vasculature in the postoperative morbidity after pulmonary resection. Subsequently, measures of preoperative pulmonary vascular function were felt to be useful in minimizing postoperative respiratory failure.

Temporary unilateral pulmonary artery occlusion (TUPAO) was felt to aid in assessing the pulmonary vascular response to planned pulmonary resection. TUPAO was first described with the use of a cardiac catheter with a large distal rubber cuff by Carlens and associates. [66] When passed into the pulmonary artery of the lung to be removed, inflation of the catheter occluded the blood flow to this lung. This occlusion was felt to result in a "physiologic pneumonectomy." [11] Measurement of pulmonary artery pressures and arterial hypoxemia was felt to identify patients at high risk for postoperative hemodynamics instability. Uggla [67] examined the role of TUPAO in 1956 in 109 patients with varying bilateral benign disease. The patients were separated into three groups, based on follow-up: "dead," "cardiorespiratory cripples," and "fit for work." There was a progressively larger VC and MBC across these groups although the differences were not striking. Resting pulmonary artery pressures were somewhat higher in the patients who had died, with a resting pressure of 22 mm Hg carrying a "very grave prognosis." With TUPAO, the pulmonary artery pressure in all patients rose approximately 50%. This was accentuated with activity. The authors reported that a pulmonary artery pressure of over 35 mm Hg and a systemic arterial oxygen level of less than 45 mm Hg during TUPAO was frequently associated with death.

Rams et al[68] incorporated intraoperative TUPAO as part of the routine evaluation of patients undergoing pneumonectomy. The authors reported results in 61 patients studied in such a fashion. The duration of pulmonary artery occlusion was not reported. The patients who survived the immediate 30-day postoperative period (n = 45) were compared to those who died within this 30-day period (n = 16). The former patients showed a resting pulmonary artery pressure of 22 increasing to 26 with TUPAO, while the latter group showed a resting pulmonary artery pressure of 26 mm Hg which rose to 30 with TUPAO. The authors could not define absolute criteria but felt that a patient with a resting pulmonary artery pressure of over 25 mm Hg with a further rise on TUPAO as well as low preoperative VC and MBC was at particularly high risk. Similar data were provided by Van Nostrand and associates, [69] who felt that a rise in pulmonary artery pressure to over 40 mm Hg with TUPAO during exercise may be a reasonable cutoff for operability, although this rarely happened in their patients.

Laros and Swierenga[70] studied 142 patients with TUPAO prior to lung cancer surgery. TUPAO was performed for ten minutes at rest and with 20 to 25 leg raises. No correlation was found between preoperative findings and early postoperative mortality. In three patients right ventricular rupture complicated the procedure, with death resulting in two. In an often quoted study, Olsen and colleagues [71] prospectively studied 56 patients with abnormal screening pulmonary function studies using TUPAO and split lung function measured with radionuclide scanning. Surgery was offered to those patients with a ppoFEV $_1$ of over 0.8 L, pulmonary artery pressure with occlusion (at rest or exercise) of less than 35 mm Hg, and systemic paO$_2$ with TUPAO during exercise of over 45 mm Hg. Using these criteria, 42 patients underwent surgical exploration (resulting in 17 pneumonectomies and 13 lobectomies). The cardiopulmonary mortality was 17.6% for pneumonectomy and 7.7% for lobectomy, which the authors felt was acceptable particularly given the high-risk nature of the patients. Of interest is that TUPAO was not technically possible in 26% of the patients. Given the technical difficulties and risk of TUPAO, it is now rarely used and likely has a very limited role in the preoperative evaluation of a candidate for pulmonary resection.

More recently Lewis and colleagues performed detailed hemodynamic monitoring at rest and after pulmonary artery clamping in 20 patients with moderately severe COPD (FEV$_1$ of 66% predicted) undergoing pneumonectomy.[72] No relation was noted between any pulmonary function test or derived hemodynamic variable and length of hospital stay or the development of in-hospital complications. Late cardiopulmonary disability was more likely in those patients with a right ventricular ejection fraction less than 35%, pulmonary vascular resistance greater than or equal to 200 dyne-sec-cm $^{-5}$, and a pulmonary vascular resistance/right ventricular ejection fraction ratio greater than or equal to 5.0 after pulmonary artery clamping.

Given the technical difficulties and poorly defined thresholds for resection, pulmonary vascular measurements are rarely made. We reserve this for the rare patient in whom the studies described earlier (spirometry, DLCO, radionuclide testing) are contradictory but resection is felt feasible.

Exercise Testing

Exercise tests have become widely accepted in the evaluation of cardiovascular disease, dyspnea, and disability, and for the determination of exercise prescriptions. As they provide an objective assessment of a subject's exercise capacity, much interest has been devoted to examining their role in the evaluation of the lung resection candidate. The majority of studies use exercise capacity to predict postoperative morbidity. This has been elegantly reviewed by Olsen [73] and Bolliger and Perrucoud.[1] Olsen separated exercise tests in this setting into three categories: simple tests of exercise tolerance, tests of pulmonary vascular response to exercise, and tests of aerobic capacity utilizing expired gas analysis. We will discuss each of these in turn.

Simple Exercise Tolerance Tests

Tests of exercise tolerance were among the first used to assess "operability" in patients being considered for lung surgery for tuberculosis. Gaensler [19] in 1955 measured ventilation during walking 180 feet within one minute in a large group of patients undergoing surgical treatment of tuberculosis. There was no prognostic value to this measurement. Olsen[73] estimated this degree of exercise to translate to a VO$_2$ (see below) of approximately 12 mL per kg per minute in a 70 kg male, a moderate workload at best. Bagg[74] used a similar simple test of ambulation. Thirty patients with lung cancer walked for 12 minutes with a measure of the total distance walked (12-minute walk test). There was no significant ability of this 12-minute walking distance or the level of dyspnea experienced to discriminate the seven patients who suffered postoperative ventilatory complications. This level of stress was likely inadequate.

Van Nostrand and colleagues, [69] as part of their preoperative evaluation, assessed the ability of patients to climb one flight of stairs (19 steps) without severe dyspnea. The authors pointed to the death of two of the four patients who could not walk one flight of stairs without severe dyspnea. Only seven of 63 patients who were able to climb two flights with little dyspnea failed to survive pneumonectomy. The authors recommended rejection for pneumonectomy if: (a) patients were unable to climb one flight without severe dyspnea; (b) estimated postoperative FEV $_1$ was less than 0.7 L; or (c) pulmonary artery pressure rose to more than 40 mm Hg with intraoperative pulmonary artery clamping (see above). The importance of a single flight of stairs climbed without dyspnea is still widely used despite limited supporting data.

Recently stair climbing has received more rigorous investigation. Bolton and associates [75] related pulmonary function to a stair climb (performed at subject's own pace as far as possible to a maximum of 127 steps, five flights) in 70 male patients. There was a correlation between the number of steps climbed and FVC (r = 0.59), FEV $_1$ (r = 0.65), FEV$_1$/FVC (r = 0.56), and MVV (r = 0.55). The authors further noted that patients who climbed all five flights had an FEV $_1$ of over 1.75 L, while of those who

climbed less than three flights the majority had an FEV_1 of less than 1.7 L.

A subsequent study by these same investigators[76] examined the ability of such a stair climb to serve as a preoperative study prior to thoracotomy. The ability to climb three flights was associated with a decreased complication rate, shorter mechanical ventilation time, and shorter hospital stay. Unfortunately, due to the small number of fatal complications, mortality could not be accurately predicted. The retrospective nature of data collection and inconsistent collection of data were obvious limitations to this study. Nevertheless, it suggested that this simple test of exercise endurance could serve as a predictor of outcome after thoracotomy.

In a recent prospective study of 16 patients with lung cancer, Holden and colleagues [60] studied all patients with spirometry, DLCO, cycle ergometry (with gas exchange measurements as described below), radionuclide scanning with prediction of ppoFEV $_1$, walking distance, and a symptom-limited stair climb (at the patient's own pace). Those patients who died within 90 days of surgery (n = 5) had a shorter six-minute walk distance and lower stair climb than those who had minor or no postoperative complications (n = 11). A six-minute walk distance greater than 1000 feet and stair climb greater than 44 steps (four flights) were predictive of a successful surgical outcome. This level of work is clearly greater than that of Gaensler and colleagues [19] and Van Nostrand and colleagues. [69]

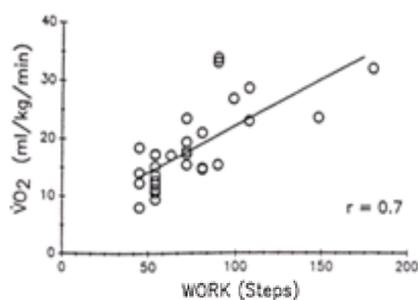
Pollock and colleagues[77] studied 31 men with moderate COPD (mean FEV_1 52% predicted; range 21% to 89% predicted). All underwent cycle ergometry with gas exchange measures and a symptom-limited stair climb. During the latter, expired gases were collected and VO_2 and VE calculated during each of the last three flights. The VO_2, VE, and heart rate were greater during stair climbing than prediction of cycle ergometry, suggesting a greater metabolic load to the former. The number of steps climbed correlated well with VO_2 (see Figure 36.1). This study allows a reasonable estimation of aerobic capacity (VO_2) using a readily accessible method of testing exercise capacity (stair climbing). It also suggests that to achieve a significant metabolic load, a patient may need to climb more than one or two flights. In a recent, prospective study, Pate and colleagues compared spirometric and radionuclide techniques, stair climbing, and formal cardiopulmonary exercise testing in 12 patients at high risk based on routine spirometric criteria (FEV_1 over 2 L).[78] All patients underwent thoracic resection, with two experiencing major complications (one death) and five minor complications. Ten of the 12 patients were able to climb more than three flights, which the authors felt was an appropriate threshold for considering thoracic resection.


FIGURE 36.1. The peak VO_2 achieved is linearly related to the number of steps climbed by 31 men with moderately severe chronic airflow obstruction (FEV_1 52% predicted). (From Pollock M, Roa J, Benditt J et al. Estimation of ventilatory reserve by stair climbing. A study in patients with chronic airflow obstruction. *Chest* 1993;104:1378, with permission.)

Rao and colleagues reported a retrospective review of 396 consecutive patients of whom 299 underwent both preoperative spirometry and oximetry during a standard 150 meter walk.[79] Abnormal oxygen saturation during this limited exercise test was defined as an oxygen saturation below 90%, with subgroups experiencing a greater than 4% or 5% absolute drop in oxygen saturation. Compared with spirometric indices, abnormal oximetry more reliably predicted home oxygen requirements, the need for intensive care unit admission, prolonged hospital stay, and respiratory failure. Prospective validation in comparison with postoperative prediction of pulmonary function is required, however.

Several investigators have explored more formal exercise endurance tests in the preoperative assessment of patients prior to thoracotomy. Reichel [80] reported a retrospective study of 75 patients undergoing pneumonectomy. Thirty-one of these patients performed an incremental treadmill exercise test (performed in six stages of increasing grade, speed, and cumulative time). No patient who performed all six stages of the protocol experienced postoperative complications. Fifty-seven percent of those who did not complete the test experienced significant postoperative complications. Of the four unable to walk through stage 1, two died and one survived with severe complications. Apparently, other measures of pulmonary function could not predict mortality or morbidity in this study. Others have utilized this exercise protocol. Miller[25] reported a less than 1% operative mortality using a preoperative evaluation including the Reichel exercise test (performed in 217 of 2,340 patients). Of the 160 patients who passed the test, 84 underwent pneumonectomy (four died); 67 patients failed the test, with seven undergoing pneumonectomy and two dying.

Berggren and associates[81] reported the results of bicycle ergometry in 82 elderly patients performed as part of a preoperative evaluation prior to lung cancer surgery. Exercise was performed at 50 watts for six minutes, and the workload was increased at 10-watt increments to a maximal cardiac frequency of less than 170 beats per minute. The results for lobectomy (44 patients) were presented in detail. Postoperative mortality was 7.7% in those who completed more than 83 watts in six minutes, while it was 22% for those completing less than this. Mortality was also higher with lower pulmonary function (FEV_1 of less than 2.4 L, FVC below 3.7 L, FEV_1/FVC less than 68%).

Gerson and associates[82] reported the results of bicycle ergometer in predicting cardiac and pulmonary complication in 177 elderly patients (age over 65 years) undergoing abdominal or noncardiac thoracic surgery. Exercise was on a supine bicycle ergometer with an initial workload of 25 watts; load was increased by 12.5 watts per minute until limiting dyspnea, chest pain, or fatigue. "Inability to complete exercise" was defined as the inability to raise heart rate above 99 beats per minute for two minutes. The result of exercise testing was the best predictor of perioperative pulmonary, cardiac, or combined complications. In the 108 patients who were able to "complete the exercise" ten patients (9.8%) suffered a complication (with one death); in the 69 patients who were unable to complete the exercise protocol (as defined earlier) 29 suffered complications (with five deaths). As such, simple measures of exercise endurance (treadmill, bicycle ergometer, or stair climbing) may be appropriate in selected patients to aid in predicting postoperative mortality and morbidity. We do not use these routinely, but reserve them for those patients in whom preoperative screening studies suggest a higher risk (Table 36.1).

Vascular Response to Exercise

As described earlier, pulmonary hypertension was noted as a complication of thoracic resection in the tuberculosis era. The importance of assessing the pulmonary vascular bed was thereby recognized.[65,83] Such early studies of pulmonary vascular response were described above with use of TUPAO at rest and during exercise.[67,70,71,83] As noted earlier, the results of these studies were inconclusive.

Recently the pulmonary vascular response during exercise has again come under scrutiny as a predictor of postoperative complications in patients undergoing lung resection. Fee and associates[84] reported results of resting pulmonary function testing and pulmonary vascular resistance (PVR) measurements at rest and with exercise. Forty-five patients were separated on the basis of resting pulmonary function. Group A (n = 27) had a room air paO $_2$ of over 50 mm Hg and FEV_1 and FVC more than 50% predicted; Group B (n = 18) had paO$_2$ of less than 50 mm Hg and FEV_1 or FVC less than 50% predicted. All patients underwent right heart catheterization while sitting on a treadmill, allowing measurement of pulmonary artery pressure (PAP). Exercise was begun at a low level (two miles per hour and 4% grade) and PAP, cardiac output, and pulmonary capillary wedge pressure were measured. After a 45-minute rest period, patients exercised at four miles per hour and 4% grade with repeat measurement of pulmonary vascular response and cardiac output. Patients were separated on the basis of PVR: Group A had maximum exercise PVR of less than 190 dynes-sec-cm^{-5} and Group B had PVR of over 190 dynes-sec-cm.$^{-5}$ Thirty of the patients underwent lung resection. Five patients died (all with exercise PVR over 190 dynes-sec-cm^{-5}). Four of these were in the Group A, with better pulmonary function. The authors concluded that a PVR with exercise over 190 dynes-sec-cm^{-5} were at high risk for lung surgery. However, seven of the 25 *surviving* patients also had an exercise PVR over 190 dynes-sec-cm^{-5} and would have been denied surgery. This study confirms the limitation of simple measures of pulmonary function in predicting postthoracotomy outcome and suggests a possible role for the assessment of the pulmonary vasculature during exercise. An absolute criterion for rejecting a patient from lung resection remains unsettled.

Olsen and colleagues[85] studied 52 elderly men with COPD and a lung mass. Pulmonary function tests at rest and radionuclide scanning were performed and a high risk for lung resection confirmed (FEV_1 of under 2 L, MVV less than 50% predicted). All underwent exercise seated on a bicycle ergometer with a pulmonary artery catheter in place. Exercise was performed at 25 watts for two to four minutes while data (cardiac function, pulmonary vascular resistance and pressures, VO_2 and oxygen delivery) were collected. After a rest period, exercise was repeated at 40 watts, with similar data collected. Patients were approved for pneumonectomy or lobectomy if $ppoFEV_1$ was over 0.8 L and PVR at the highest workload was less than 190 dynes-sec-cm^{-5}. Twenty-nine patients underwent surgery (eight pneumonectomies, 13 lobectomies, seven wedge resections and one bronchoscopy), with seven dying within 60 days or needing prolonged (over 30 days) mechanical ventilation ("intolerant of surgery"). The parameters found to be predictive of "intolerance" included: low cardiac index, low oxygen delivery, and low VO_2 (see below). The study suggested that a deficit in oxygen transport may be predictive of surgical complications. Clearly, the invasiveness of this protocol limits widespread applicability of the technique. As with other cumbersome modalities, it may have a role in particularly difficult cases.

On the other hand, Bolliger and colleagues examined five patients with severe COPD using both maximal exercise testing (see below) and rest and exercise pulmonary hemodynamic measurements.[86] Using traditional exclusions based on hemodynamic measurements would have excluded four patients from surgery, although all patients were able to tolerate resection with little postoperative difficulty. Similarly, Ribas and colleagues were unable to find clinically useful hemodynamic measurements at rest or during exercise which predicted postoperative outcome in a group of 46 patients undergoing thoracotomy. [61]

Tests of Aerobic Capacity

The most recent exercise measurement to achieve some degree of popularity is the measure of aerobic capacity. The analysis of expired gases allows the calculation of aerobic capacity as defined by maximum achieved VO_2 (VO_{2max}). This is a sensitive parameter which can reflect limitation in any component involved in the response to exercise (cardiac, pulmonary, vascular, and peripheral muscles). Conflicting data have been published regarding the value of VO_{2max} measurements in the preoperative assessment of the lung resection candidate (Table 36.2).

Eugene and associates[87] reported the results of VO_{2max} measurement in 19 patients prior to pulmonary resection (six pneumonectomies, 12 lobectomies, one segmentectomy). Three patients died from cardiopulmonary failure. Pulmonary function studies did not identify this group preoperatively. Of patients who achieved a VO_{2max} of less than 1 L per minute, three died, while none who achieved a VO_{2max} of over 1 L per minute died (p = 0.004). Smith and colleagues [88] supported the use of VO_{2max} measurements in a study of 23 patients scheduled for thoracotomy who were prospectively evaluated with incremental exercise testing. Pulmonary function tests and radionuclide scanning were performed in all. Eleven of the patients had no cardiopulmonary complications postoperatively. The only preoperative value separating the 11 patients who suffered complications postoperatively from those who did not was VO_{2max} (22.4 mL per kg per minute in those without complications versus 14.9 mL per kg per minute in those with complications). Only one of ten with a VO_{2max} greater than 20 mL per kg per minute had a complication compared to all six with a VO_{2max} of less than 15 mL per kg per minute.

A similar study was published by Bechard and Wetstein in 1987 [89] of 50 consecutive patients studied with pulmonary function testing and incremental exercise testing. A criterion for FEV_1 as shown in Table 36.1 was used to determine suitability for resection. There were ten pneumonectomies, 28 lobectomies, and 12 wedge resections. Seven patients suffered cardiopulmonary complications within 30 days of surgery. Pulmonary function tests did not separate these seven patients from the 43 who did not suffer cardiopulmonary complications. A significant difference was seen in VO_{2max} (17 mL per kg per minute for those without complications versus 9.95 mL per kg per minute for those with complications). This difference extended across all types of pulmonary resection. The authors reported no complications in those with a VO_{2max} of over 20 mL per kg per minute. There was a 71% complication rate in those with a VO_{2max} of less 10 mL per kg per minute. Those with a VO_{2max} between 10 and 20 mL per kg per minute had a complication rate of 10.3%. The study by Holden and colleagues [60] supports this conclusion. Both patients with a VO_{2max} under 10 mL per kg per minute died postoperatively, while only one of eight with a VO_{2max} over 10 mL per kg per minute died (this patient died of lung metastases after hospital discharge and not as a result of postoperative complications).

Miyoshi and colleagues[90] studied 33 lung cancer patients with spirometry, DLCO measurement, and an incremental exercise test. Cycle ergometry workload was increased at three-minute increments with arterial lactate level measured during the last 30 seconds of each workload. Complications occurred in 45% of the patients. FEV_1 corrected for body surface area (BSA), FEV_1/FVC, DLCO, and MVV/BSA were different between those with complications and those without. No difference was seen in those parameters between those surviving and those who died (n = 4). When VO_2/BSA was examined at a submaximal lactate level of 20 mg per dL, this parameter did differ between surviving and deceased patients. A follow-up study by the same group [91] of 31 lung cancer patients supported parameters during exercise testing as the best predictors of fatal versus nonfatal complications. Data relating to oxygen delivery (O_2D = blood O_2 content times cardiac output) per BSA showed that an O_2D per BSA of under 500 mL per minute per m^2 at a lactate of 20 mg per dL was seen in all patients who died, and greater than this value in all who survived. The authors suggested that: (a) an exercise test be considered in all those patients with borderline "performance status"; (b) if VO_2 per BSA$_{lac20}$ is over 400 mL per minute per m^2, thoracotomy should be safe; and (c) if VO_2 per BSA$_{lac20}$ is below this level, then O_2D per BSA$_{lac20}$ should be measured and if it is over 560 mL per minute per m^2, thoracotomy should be safe. These results support the earlier data of Olsen and colleagues. [85] Confirmation of these data is required in a larger prospective study. Due to the expense and cumbersome nature of the testing, it would likely find applicability in a small, select group of patients felt to be at high risk for postoperative respiratory failure or perioperative morbidity on the basis of screening studies.

Morice and associates[92] reported results in 37 patients at high risk for resection due to an FEV_1 of less than or equal to 40% predicted, a $ppoFEV_1$ of less than or equal to 33% predicted or a $paCO_2$ of over or equal to 45 mm Hg. All underwent incremental exercise testing and surgery was offered if VO_{2max} was greater than 15 mL per kg per minute. Eight patients underwent resection (three lobectomy, one bilobectomy and four wedge resections). Six of these eight had an uncomplicated postoperative course. Two had complications but did not die as a result of surgery or postoperative complications. This small study suggests that VO_2 measurements may indeed have a role in the evaluation of those patients felt unresectable by standard pulmonary function criteria. This same group reported similar results in a prospective series of 66 patients felt to be at high risk for pulmonary complications. [93] Twenty patients achieved a maximal VO_2 of over 15 mL per kg per minute and underwent surgical resection with no mortality and a complication rate of 40%. Five patients with a maximal VO_2 of under 15 mL per kg per minute underwent resection, with one death. Thirty-four patients with a low maximal VO_2 and seven who declined surgery were treated with chemotherapy or radiation therapy. The median duration of survival was 48 months in the surgically treated patients and 17 months in the nonsurgical patients. The authors concluded that surgical resection is feasible in patients with severe pulmonary function abnormality, and that survival is improved with surgical therapy in this group. In a small series of five patients at high risk for resection, a VO_{2max} of over 69% predicted allowed a safe lobectomy. [86]

Bolliger and colleagues described a consecutive series of 80 patients undergoing preoperative exercise testing. [94] These investigators confirmed that the VO_{2max} was the best predictor of postoperative complications. Furthermore, receiver operating characteristic analysis suggested that the percent predicted VO_{2max} was significantly more sensitive than absolute values in mL per kg per minute. The probability of suffering no postoperative complication was 90% if the VO_{2max} was greater than 75% predicted, and was 10% if the VO_{2max} was less than 43% predicted. A value of less than 60% predicted proved to be prohibitive in resections of more than one lobe. In a subsequent study by the same group, a 100% mortality was noted in those patients with a scintigraphically estimated $ppoVO_{2max}$ under 10 mL per kg per minute.[58] Pate and colleagues noted a threshold of over 10 mL per kg per minute as the best predictor of successful outcome in their prospective study of 12 patients at high risk for thoracic resection. [76] Torchio and associates examined maximal exercise testing in 54 patients with mild to moderate COPD before lung resection. [95] Only one patient with a maximal VO_2 of over 20 mL per kg per minute suffered severe complications, while 11 of 26 patients with a maximal VO_2 under 20 mL per kg per minute suffered such complications. Interestingly, all 11 of these latter patients had an anaerobic threshold of less than or equal to 14.5 mL per kg per minute. Further data are required to confirm the value of the anaerobic threshold as a predictor of postoperative complications.

Not all studies support these concepts, however. In 1982, Colman and colleagues[96] studied 59 consecutive patients with suspected lung cancer. All underwent pulmonary function testing, two-flight stair climb, and progressive, symptom-limited bicycle ergometry with measurement of VO_{2max}. A logistic regression model was used to test whether VO_{2max} could predict postoperative complications (*all* complications, including technical ones such as blood loss or wound infection). FEV_1 and FVC were weakly predictive, whereas VO_{2max} was not. It is unclear if physiologic assessment should be used to predict technical postoperative complications, however. As such, this negative conclusion should be interpreted with caution. Similarly the study by Markos and colleagues [34] described earlier showed no difference in VO_{2max} between those patients suffering and those not suffering postoperative complications. Boysen and associates [97] studied 17 patients preoperatively with incremental exercise testing. No significant difference was seen in exercise parameters between patients with and without cardiopulmonary complications after lung

resection. The study was limited by only two patients experiencing such complications, however. Pierce and associates were unable to identify a clear threshold value of VO_{2max}, which predicted postsurgical complications.[36] Most recently, Wang and colleagues examined preoperative pulmonary function testing and maximal exercise testing in 40 patients undergoing lung resection.[33] No difference was seen in maximal VO_2 between those patients experiencing postoperative complications (16.3 mL per kg per minute) and those not experiencing such complications (17.8 mL per kg per minute). The differences in the results of these studies include different patient groups, and widely varying definitions of post surgical complications and exercise formats.

A study by Epstein and colleagues[98] adds an interesting twist. These investigators analyzed the findings in 42 patients considered for lung resection. All subjects had detailed analysis of cardiac risk factors (adapted from Goldman and colleagues[99]) as well as pulmonary factors (obesity, productive cough, wheezing, tobacco use, ratio of FEV_1/FVC of under 70%, $paCO_2$ over 45 mm Hg). A cardiopulmonary risk index (CPRI) was generated, ranging from 1 to 10 points. All subjects had pulmonary function testing, radionuclide scanning when appropriate, DLCO measurement, and a symptom-limited exercise test with expired gas analysis. Fourteen patients suffered at least one postoperative cardiopulmonary complication. When stratified by VO_{2max} of over 15 mL per kg per minute, no significant difference was seen between those suffering complications and those not suffering a complication. When corrected for BSA (VO_2 per BSA), a VO_{2max} per BSA of under 500 mL per m^2 was predictive of pulmonary and total complications. Patients with a CPRI of more than or equal to 4 were 22 times more likely to develop a complication. This level of CPRI was also associated with a lower VO_{2max}. With multiple logistic regression analysis, VO_{2max} was *not* an independent predictor of postoperative complications. Although the study supports the value of VO_{2max} measurement, *clinical* assessment with generation of a CPRI was able to predict high-risk patients. In a subsequent study from the same group, the value of the CPRI was confirmed, although the inability to perform bicycle ergometry also predicted postoperative complications.[100]

A unique variation of this exercise format was described by Pierce and colleagues[101] in 1986. In six high-risk patients (based on parameters shown in Table 36.1) incremental exercise on a bicycle ergometer was performed with expired gas analysis. A subsequent steady-state exercise study was performed with bronchoscopic occlusion (during exercise) of the segments felt involved by tumor and likely needing resection. If the patient was able to tolerate exercise while the appropriate bronchus was occluded, he underwent pulmonary resection. Five of the six patients tolerated resection well, with the sixth suffering an early postoperative death (this patient had the lowest VO_{2max}, 13 mL per kg per minute). The format of this exercise study is creative but obviously limited by the level of complexity required.

SIMULTANEOUS LUNG VOLUME REDUCTION SURGERY AND CANCER RESECTION

The resurgence of lung volume reduction surgery (LVRS) has provided a potentially valuable surgical approach to improving short-term lung function and exercise capacity in selected patients with advanced emphysema after unilateral[102] and bilateral[103] reduction procedures. Although controversial, patients with severe airflow obstruction, hyperinflation, and heterogeneous emphysema with surgical target areas appear to be better candidates for surgical volume reduction.[104] Several groups have reported short-term results of combined LVRS and resection of suspected lung cancer, as reviewed in Table 36.3.

Reference	Sample Size (patients with nodules) of patients undergoing LVRS)	Preoperative FEV₁ (mean, % predicted)	Resections Performed	Pathologic Findings	Length of Stay (days)	Operative Mortality (%)
McKenna, et al.⁴	51/535	21	Lobectomy 4 Wedge 47	Benign 42 Malignant 11	11.1	3.9?
Pigula, et al.¹⁰⁵	10/128	25	Wedge 10	Malignant 10	8.4	0
Ojo, et al.⁵	11/75	26	Wedge 11	Benign 8 Malignant 3	7.6	0
Hazelrigg, et al.¹⁰⁶	111/281	28?	Wedge 78	Benign 63 Malignant 12	8.4	1?
DeRose, et al.¹⁰⁷	14/66	24	Lobectomy 3 Wedge 11	Benign 6 Malignant 8	14.4	7
DeMeester, et al.¹⁰⁸	5/42	30	Lobectomy 5	Malignant 5	14	0

TABLE 36.3. REPORTS OF COMBINED LUNG VOLUME REDUCTION SURGERY (LVRS) AND RESECTION OF A PULMONARY NODULE

McKenna and colleagues have reported the largest series, with 51 patients undergoing resection of 53 lung masses (11 NSCLC, and 42 benign lung masses).[4] Of the 11 lung cancers, three were specifically referred to this group for combined LVRS and cancer resection, while seven were found during evaluation for LVRS, and in one it represented an incidental pathologic finding. The mean preoperative FEV_1 was 21% of predicted, with all patients considered inoperable by all criteria described earlier. No operative deaths were reported despite lobectomy in four patients, while short-term improvement in lung function was reported in most patients.

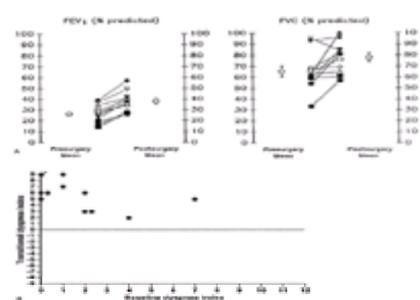
Pigula and colleagues described ten patients undergoing simultaneous LVRS and wedge resections of malignant nodules.[105] As enumerated in Table 36.3, the mean FEV_1 of 25% predicted would have resulted in denial of standard thoracic resection procedures. Data from our center confirms these findings, as we have recently described successful combined LVRS and nodule resection in a group of 11 patients with severe emphysema (preoperative FEV_1 26% of predicted).[5] All underwent successful wedge resection, with a mean length of stay (7.55 days) similar to a matched control group undergoing lobectomy (8.81 days). Minor postoperative complications occurred in two COPD patients and three control patients. Figure 36.2A illustrates the improvement noted in spirometry before and after surgery, while Figure 36.2B demonstrates significant baseline dyspnea in most patients, and improvements after surgery.


FIGURE 36.2. A: A comparison of FEV_1 and FVC as percent of predicted values before and after simultaneous lung volume reduction surgery (LVRS) and nodule resection in 11 patients with severe emphysema. **B:** Dyspnea at baseline (BDI) versus transitional dyspnea index (TDI) after simultaneous LVRS and nodule resection in 11 patients with severe emphysema. In most patients baseline dyspnea was severe and significant improvement occurred after surgery. (From Ojo TC, Martinez FJ, Paine III R et al. Lung volume reduction surgery alters management of pulmonary nodes in patients with severe COPD. *Chest* 1997;112:1494, with permission.)

The importance of these findings is highlighted by the report of Hazelrigg and associates, who described the finding of at least on lung nodule in 39.5% of 281 patients prospectively evaluated for LVRS.[106] Of these 111 patients with nodules, 52 were felt to have benign lesions by radiographic imaging. Of the remaining nodules, 78 were resected, with 17 being cancerous lesions. Interestingly, of the neoplastic lesions, three were identified by CT only, five by both chest radiograph and CT, four in the operating room (not seen radiographically), and five incidentally by the pathologist. The overall incidence of cancer was 6.4%.

DeRose and colleagues confirmed these findings in 14 patients successfully undergoing combined LVRS and resection of solitary pulmonary nodules.[107] DeMeester and associates[108] extended these findings by performing an anatomic lobectomy in a small group (n = 5) of patients with severe emphysema (mean FEV_1 30% of predicted). Importantly, all patients demonstrated short-term physiologic and functional improvement. As such, in some patients with otherwise prohibitive pulmonary

function, consideration of simultaneous LVRS may be appropriate.

CONSIDERATIONS FOR SURGICAL THERAPY: A RATIONAL APPROACH

Since our approach to the patient with NSCLC emphasizes surgical therapy, much of the preoperative evaluation is aimed at identifying those patients in whom the risk of postoperative respiratory failure is excessive. The possibility of perioperative morbidity is considered as secondary. This is particularly so as most of the above studies did not incorporate recent advancements in postoperative care. For example, extrapleural intercostal blocks in a recent study [109] led to a marked improvement in immediate postoperative FEV_1 (an average of 40% higher) than with saline injection (as a placebo). Similarly, Richardson and colleagues noted improved pain relief and preservation of postoperative pulmonary function in a group treated with preincisional prophylaxis and postoperative, continuous, extrapleural, intercostal nerve block and nonsteroidal anti-inflammatory agents.[110] These approaches, among other recent innovations described by Boysen, [111] may allow a much more rapid improvement in pulmonary function and secretion clearance in the early postoperative period, which is the highest-risk period for cardiopulmonary complications. [11] As such, current and future studies should show a lower cardiopulmonary complication rate. Nevertheless some patients will always have an increased risk from thoracotomy due to markedly abnormal pulmonary function. It is in identifying these patients that pulmonary function studies will retain a prominent role in the preoperative assessment of the lung resection candidate.

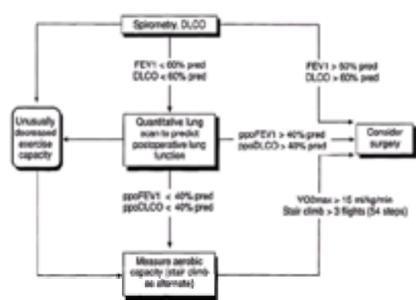
An algorithmic approach has recently been suggested by Marshall and Olsen [11] for an approach to the thoracic resection candidate. We have adapted these in our center, as illustrated in Figure 36.3. It is evident that all patients should have measures of FEV_1, FVC, and DLCO. Those with values greater than 60% predicted should tolerate resection, although if functional status is particularly low (as in unusually decreased exercise capacity) there may be an increased risk of complications and further testing, including exercise testing, may be required. [91] In those patients with screening studies showing function below 60%, predicted radionuclide studies are used to estimate postoperative spirometric function and DLCO. Predicted postoperative function over 40% of predicted generally indicates acceptable risk with a similar caution as mentioned above. Predicted postoperative values below 40% of predicted certainly suggest a greater risk and warrant further evaluation. Exercise testing should be quite useful in this setting. A VO_{2max} greater than 15 mL per kg per minute is felt to reflect a lower risk, with VO_{2max} greater than 20 mL per kg per minute reflecting the lowest risk. If expired gas analysis is not available, then the data of Pollock and colleagues [77] suggests that a stair climb of over three flights (18 steps per flight) approximates this degree of metabolic load in patients with COPD. A cardiopulmonary exercise test provides more information than simple stair climbing, as it examines the ventilatory response (including gas exchange) and the cardiac response during exercise, and should be utilized first if available. Patients who cannot meet these criteria may still be candidates for resection but will require more complex study (exercise with bronchial occlusion or measurement of pulmonary vascular function with exercise). As further prospective information becomes available, the CPRI of Epstein and colleagues [96] may become more widely used during the initial evaluation of a lung cancer patient. Given the poor long-term prognosis in NSCLC without surgery, all patients should be considered for surgical treatment if at all possible. This should include consideration of simultaneous lung volume reduction surgery and cancer resection.


FIGURE 36.3. Algorithm of the physiologic assessment of the lung volume resection candidate. DLCO, diffusing capacity for carbon monoxide; FEV_1, forced expiratory volume in one second; ppo, predicted postoperative VO_2; pred, predicted; VO_{2max}, maximal oxygen uptake. (From Marshall MC, Olsen CN. The physiologic evaluation of the lung resection candidate. *Clin Chest Med* 1993;14:305, with permission.)

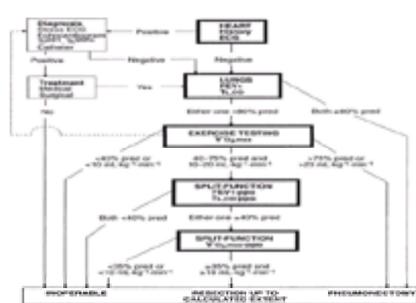
Bolliger and Perrucoud have proposed an alternate, although similar, algorithm which highlights the importance of cardiopulmonary exercise testing in the preoperative evaluation of patients considered for thoracic resection (see Figure 36.4). This group recently presented prospective application of this algorithm in 137 consecutive patients with clinically resectable lesions. [1] Five patients were deemed inoperable, while 132 underwent resection. The postoperative complication rate was reduced from 20% in a previous publication [94] to 11%, while the mortality decreased from 3.8% to 1.5%. Interestingly, the two patients who died achieved a maximal VO_2 of under 10 mL per kg per minute. As such, the authors suggested modifying the algorithm demonstrated in Figure 36.4 by excluding patients with a VO_{2max} under 10 mL per kg per minute regardless of the percent of predicted. These authors noted that an exercise test was easier to obtain and substantially cheaper than radionuclide imaging at their institution. Prospective comparison is required to define better the cost-effectiveness of routine exercise testing versus (or in addition to) estimation of postoperative pulmonary function. These algorithms will, it is hoped, minimize the risk of this approach and will continue to be modified as further data are published and simultaneous LVRS is incorporated into routine surgical practice.


FIGURE 36.4. Alternate proposed algorithm for the assessment of cardiorespiratory reserve in patients evaluated for lung resection. (From Bolliger CT, Perrucoud AP. Functional evaluation of the lung resection candidate. *Eur Respir J* 1998;11:198, with permission.)

GENERAL MEDICAL EVALUATION AND PREOPERATIVE RISK ASSESSMENT

There is considerable information available regarding the risk of medical morbidity and mortality after major surgical procedures. [112,113 and 114] Much of this literature has focused on the preoperative evaluation of patients prior to general surgical procedures such as laparotomy. However, it appears that much of this information is applicable to the patient undergoing pulmonary resection.

Obese patient have been felt to have an incidence of general, postoperative pulmonary complications ranging from 3.9% to 95%. [113] The increase in incidence of postoperative mortality is best established for abdominal surgery in morbidly obese patients (height to weight ratio in inches to pounds of less than or equal to 10.4). Data regarding risk in thoracotomy are scarce. Nevertheless, given the difficulties expected in intubating and mobilizing morbidly obese patients during operation, [115] it is intuitive that obesity should have a detrimental role on the postoperative course after thoracotomy.

Smoking clearly has an effect on postthoracotomy course, as it relates to underlying lung disease and will be discussed in great detail later. There are extensive data

in coronary artery bypass grafting (CABG) that active smoking increases postoperative risk. Warner and colleagues [116] retrospectively reviewed the records of 500 CABG patients at the Mayo Clinic over a two-year period. The amount, duration, and most recent extent of cigarette smoking were recorded, as were details of the postoperative course. Those patients with an over 20-pack-year history of smoking had an increased risk of postoperative complications compared with nonsmokers. The authors also noted that a statistically significant decrement in postoperative complications occurred only in patients who had stopped smoking over eight weeks prior to surgery (see below). Similar findings were reported by Bluman and associates, who noted an odds ratio for developing postoperative pulmonary complications of 5.5 compared to never-smokers.[117] Reduction in smoking within one month of general surgery was not associated with a reduction in the risk of postoperative pulmonary complications. Although the data in these studies were not collected in patients undergoing pulmonary resection, it seems obvious that the results should be more impressive in this patient population, as the extent of postoperative physiologic abnormality is greater with lateral thoracotomy than other incisions.

Preexisting disease can certainly influence the postoperative course after any surgical procedure. Prior cardiac disease, in particular, has been investigated extensively. The screening for cardiac risk in the preoperative setting has been reviewed by Gerson. [118] Goldman and colleagues[95] prospectively evaluated 1,001 patients over the age of 40 undergoing noncardiac surgery (including 31 intrathoracic procedures). Using multivariate, discriminant analysis, they identified nine significant correlates of life-threatening or fatal cardiac complications. These included preoperative third heart sound or jugular venous distention; myocardial infarction within the six months prior to surgery; cardiac rhythm other than sinus or premature atrial complexes on the preoperative electrocardiogram; greater than five premature ventricular contractions at any time preoperatively; intraperitoneal, *intrathoracic,* or aortic operation; age of over 70 years; important aortic stenosis; emergency operation; or poor general medical condition. Using these criteria, a cardiac risk index was calculated which separated the patients into four risk classes. Ten of 19 postoperative cardiac deaths occurred in the 18 patients in the highest-risk group. This study has served as a foundation for many published subsequently. Of interest is that Mittman[20] identified an inordinate risk for patients with an "abnormal" electrocardiogram prior to thoracic surgery, suggesting that these criteria should be applicable to those patients being considered for lung resection.

Gerson[118] uses these criteria to separate patients by degree of cardiac risk. Those felt to be at highest risk should have objective documentation of cardiac function and aggressive preoperative and perioperative management. Those in the low-risk group should have little added cardiac risk. Those in the moderate-risk category (which includes all elderly patients undergoing thoracotomy) should be subjected to an exercise study, if possible (the format used by these authors will be described subsequently), or a dipyridamole thallium scan to assess functional coronary reserve. Although this approach has not been rigorously subjected to prospective evaluation in the lung resection candidate, it seems quite reasonable.

The American College of Cardiology has published an exhaustive guideline for perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery.[119] This recommendation is based on an algorithmic approach to establishing cardiac risk, the need for preoperative cardiac evaluation, and modification of risk. [120] The initial steps determine the urgency of the proposed surgical procedure and the history of previous coronary revascularization or coronary evaluation. In those patients undergoing nonurgent surgery with no recent cardiac evaluation, risk is initially established on the basis of clinical predictors. Major clinical predictors include unstable coronary syndromes, decompensated congestive heart failure (CHF), significant arrhythmias, or severe valvular disease. These patients require specific management of these clinical predictors. Intermediate clinical predictors include mild angina pectoris, prior myocardial infarction, compensated or prior CHF, or diabetes mellitus. Further stratification in this group is based on exercise capacity and the surgical risk, with intrathoracic operations invoking an intermediate risk. Minor clinical predictors include advanced age, an abnormal EKG, a cardiac rhythm other than sinus, low functional capacity, history of stroke, or uncontrolled systemic hypertension. Further evaluation in these individuals is based on functional capacity and surgical risk, as in the previous group. Validation of this algorithm in thoracic resection is not available, although the principles are remarkably similar to the functional evaluation suggested in the previous section.

Although age has been noted by some to be an independent risk factor for cardiopulmonary complications (as by Goldman and colleagues [95]) it is more controversial when examined in the thoracic surgery population. [115] Boushy and associates,[21] for example, found a high mortality in patients over the age of 60 and impaired pulmonary function after lung resection. Berggren and colleagues [81] found an increased mortality in 82 patients over the age of 70 subjected to thoracotomy for bronchogenic carcinoma. They also felt that an aggressive preoperative assessment for cardiopulmonary risk could minimize this risk, however. Djokovic and Hedley-Whyte[121] noted that 57% of elderly (over 80 years) patients undergoing thoracic surgery required controlled endotracheal ventilation for more than 24 hours postoperatively, compared with 2% of those undergoing surgery that did not enter the pleura or peritoneum. Contrary to these data, several authors have not found age to be an independent risk factor [121,122 and 124] and suggest that age should not be used in the absence of other contraindications to reject a patient from possible curative lung resection. With aggressive preoperative and perioperative management we do not routinely use age in excluding patients from surgical treatment.

Unfortunately, further data specifically addressing risk factors for thoracotomy are scant. Nagasaki and associates [126] reviewed the experience at the Memorial Sloan-Kettering Cancer Center from 1973 to 1980 (961 patients undergoing thoracotomy). They studied the effect of various preoperative factors including age, sex, cardiopulmonary status, and factors relating to the tumor and extent of surgery. They identified high risk factors as age (over 70 years), decreased cardiopulmonary function, and the need for more extensive pulmonary resection (pneumonectomy). In a similar review of 476 thoracotomies, Kohman and colleagues [127] examined 37 factors (including age, weight, pulmonary factors, cardiac factors, and characteristics of the tumor and the extent of lung resection) in predicting postoperative mortality. They noted that the risk of postoperative death could not be predicted from the patient's preoperative status. Most recently, Epstein and colleagues [98] formulated a cardiopulmonary risk index (CPRI) using the principles described by Goldman and associates. [95] In this fashion patients were assigned not only a cardiovascular risk index but also an index based on pulmonary risk factors (including obesity, smoking use, productive cough, wheezing, spirometric values, and an increase in $paCO_2$). By combining both these indices into a CPRI (scores ranging from 1 to 10), they noted that a combined score above 4 was associated with a 22-fold increase in the likelihood of pulmonary complications.

One can see that thoracotomy is associated with distinct physiologic changes in the postoperative pulmonary status. Cardiopulmonary complications can be commonly seen, particularly as many patients have underlying cardiac and/or pulmonary disease. Nevertheless, as surgery is the optimal treatment for NSCLCs, the physician should make every effort to consider a patient as resectable. In this context, a thorough preoperative medical evaluation may identify particular risk factors that can be modified (such as active smoking or heart disease). As most postoperative complications are pulmonary, detailed evaluation of pulmonary function is likely the most important aspect of the preoperative evaluation.

PERIOPERATIVE RESPIRATORY MANAGEMENT

Having determined that the patient with NSCLC is a candidate for potentially curative resectional surgery, based on a staging evaluation and a physiologic evaluation, the goal of pre- and postoperative respiratory management is to prevent postoperative respiratory morbidity. While these patients may succumb to a very wide variety of complications, many of these are independent of or only loosely related to the respiratory system. Wound dehiscence, perioperative myocardial infarction, and acute tubular necrosis are important sources of morbidity and mortality but are not respiratory complications that may be amenable to prevention by the application of appropriate pulmonary management. The focus of the current discussion is on the preventable respiratory complications that are common features of the postoperative course of patients who have undergone lung resection. These include clinically significant atelectasis, acute bronchitis, pneumonia, bronchospasm, respiratory failure, and pulmonary thromboemboli (Table 36.4).

Atelectasis

Bronchitis

Bronchospasm

Pneumonia

Pulmonary thromboemboli

Respiratory failure (hypoxemic or hypercapnic)

TABLE 36.4. POSTOPERATIVE PULMONARY COMPLICATIONS

Because long-term cigarette use is the most important risk factor for carcinoma of the lung and for chronic obstructive pulmonary disease (COPD), it would be anticipated that chronic airflow obstruction is the most common pulmonary physiologic abnormality in patients with lung cancer. In fact several series found that the vast majority of patients presenting for resection of lung cancer had preoperative airflow obstruction.[11,128,129] Thus the focus of the discussion of respiratory management of patients undergoing pulmonary resection for carcinoma of the lung is on the patient with underlying COPD.

There is a strong physiologic relationship between COPD and most of the postoperative complications listed in Table 36.4. Individuals with chronic bronchitis produce increased quantities of respiratory secretions that are often colonized with pathogenic bacteria.[130] Diminished flow rates in patients with obstructive lung disease result in a less effective cough and impaired ability to expel secretions obstructing the airway lumen. These factors place the patient at risk for atelectasis with retained secretions, acute bronchitis, and pneumonia. Many individuals with COPD have nonspecific airway hyperactivity and may develop bronchospasm as a consequence of airways inflammation,[131,132] further worsening their ability to clear secretions in addition to direct effects on gas exchange. To reduce these risks of pulmonary complications in patients with underlying COPD, the interventions described in the discussion that follows largely are aimed specifically at (a) reversing or minimizing airflow obstruction, and (b) minimizing retained secretions.

Smoking Cessation

In the face of both carcinoma of the lung and COPD, many patients who present for resectional surgery still are smoking cigarettes at the time of initial assessment. It has long been recognized that current smoking increases the risk of postoperative complications for many different surgical procedures.[133] There is a tendency to assume that smoking cessation preoperatively is a significant benefit in reducing the risk of postoperative pulmonary complications. In fact, many thoracic surgeons view smoking cessation as a requirement before patients can be allowed to undergo resectional surgery for lung carcinoma. There are reasons for this view. Cigarette smoke is a constant irritant and may promote inflammatory changes in the airways and contribute to excess mucous secretion, chronic bronchitis, and airways hyperactivity.[134] At a cellular level, Chalon and associates found that cigarette smoking was correlated with airway epithelial injury and with increased risk of postoperative pulmonary complications.[135] Current cigarette smokers also maintain significantly elevated levels of carboxyhemoglobin as high as 10%, thereby reducing oxygen transport and increasing the risk of ischemic cardiovascular or cerebrovascular insults during surgery.[136] Finally, smoking cessation may serve as an important indicator of the patient's willingness to be responsible for and participate in his or her own health care.

However, despite these observations, there is surprisingly little data that directly support this assumption. Warner and colleagues compared the time since last cigarette to the risk of significant pulmonary complications.[116,137] As anticipated, current smokers were at significantly increased risk compared to lifelong nonsmokers or to individuals who had stopped smoking more than eight weeks prior to surgery. Unfortunately, the rate of complications was actually slightly higher for those who had stopped smoking less than four weeks prior to surgery than for current smokers. This was recently confirmed by Bluman and associates.[117] The apparent benefit of eight weeks without smoking prior to surgery may be a reflection of continued inflammatory changes in the airways or of the period required to repair the chronically injured airway epithelium. The degree to which these observations can be extended to patients undergoing pulmonary resection is not clear.

We routinely insist that patients stop smoking prior to surgery for the theoretical reasons described above. Physicians in general do a rather poor job of counseling patients to stop smoking. In some series, as few as 25% of smokers reported having discussed smoking cessation with their primary care physician.[138] Emphasizing to the patient that the use of cigarettes is a major source of morbidity and mortality is the first step in helping the patient to stop this habit. However, it is clear that encouragement by the physician often is not sufficient to induce even a temporary respite, much less long-term abstinence. Additional aids, including patient-directed literature, videotapes, support groups, and pharmacological interventions such as nicotine transdermal patches and gums are available and potentially very helpful in reducing or stopping the patient's use of tobacco.[139,140] The balance between the time required for a patient to stop smoking and the potential benefit of a longer cigarette-free period prior to surgery, on the one hand, and the potential progression of the patient's tumor, on the other, must be determined in each individual case.

Pharmacological Therapy for COPD

While it had long been assumed that individuals with COPD have fixed abnormalities in airway resistance leading to irreversible airflow obstruction, there is considerable evidence that many of these patients do have a component of reversible airflow obstruction over and above their underlying, fixed abnormality.[131,141] There are several pharmacological interventions that may potentially improve airflow obstruction by alleviating this reversible abnormality in patients undergoing pulmonary resection for bronchogenic carcinoma. While a detailed discussion of the pharmacology of each of these agents is beyond the scope of the present work, it will be useful to consider certain features related to the selection and use of agents in this group of patients.

Inhalation Therapy

Many of the drugs that are most useful for the treatment of airflow obstruction may be administered by the inhalation route. There are important advantages in taking this approach in contrast to systemic administration.[142] Specifically, there is excellent availability of the drug within the airways, with greatly decreased or no systemic side effects. Unfortunately, unless the drug is administered with proper technique, large amounts may be deposited in the oropharynx and upper airways, with a significant loss of therapeutic effect.[143] The most common means of delivering aerosolized drugs to the lungs is with a metered dose inhaler. With each activation, these canisters deliver a preset dose of drug as a stream of particles of uniform size optimal for deposition in the peripheral airways. For best effect, the patient must synchronize the activation of the canister with the initiation of a slow inspiration from functional residual capacity to total lung capacity, followed by a breath hold of up to ten seconds. Many authorities suggest that the metered dose inhaler be held several inches from the open mouth to decrease deposition in the oropharynx. This maneuver requires careful teaching with demonstrations to maximize patient compliance. There are a number of points at which many individuals, particularly those who are older or more dyspneic, may have difficulties. For this reason, devices such as tube spaces or chambers into which the cloud of drug is released prior to inhalation have been developed. These devices can significantly improve drug delivery and are of benefit for any individuals who have difficulty mastering the basic technique.[143] Furthermore, several alternative preparations of b-agonists have recently been developed that place less stringent requirements on patient coordination. These include breath actuated inhalers (Maxair Autohaler)[144] and finely powdered preparations of drug that are inhaled directly from a holder and require no actuation (Ventolin rotohaler).[145] Finally, it is possible to give both b-agonists and anticholinergic agents using updraft nebulizers powered by an external compressed gas source. Due to a larger particle size that results in considerable upper airway deposition and the delivery of drug during expiration as well as inspiration, the use of nebulizers is a relatively inefficient approach to inhalation therapy.[143] However, in patients who are unable to use metered dose inhalers due to difficulties with coordination or severe dyspnea, they provide an important modality.

Beta-Adrenergic Agonists

b-agonists have long been the first line drug for the treatment of reversible airflow obstruction in asthma (Table 36.5). They also have proven to be effective agents for many patients with increased airways resistance due to COPD.[142,146] Binding to b2 selective adrenergic receptors in the small airways, these agents raise intracellular cAMP levels within airway smooth muscle cells and induce relaxation with reduced airflow obstruction.[147] When administered by inhalation, they have an excellent therapeutic index. At standard doses, modern agents such as albuterol and pirbuterol induce limited increases in cardiac rate and with rare instances of cardiac arrhythmias, even in older individuals with underlying cardiac disease.[142,148]

Albuterol	Levalbuterol
Bitolterol	Metaproterenol
Epinephrine	Pirbuterol
Isoethane	Salmeterol
Isoproterenol	Terbutaline

TABLE 36.5. COMMERCIALLY AVAILABLEb-AGONISTS

In patients who demonstrate airflow obstruction by spirometry or who have had episodes of acute bronchitis with symptoms suggesting airflow obstruction, we institute therapy with a b2 selective agonist prior to pulmonary resectional surgery, even if the patient has not been using the drug previously. Therapy is then continued throughout the perioperative period. In selected individuals we then reassess the benefit of the b-agonist after the patient has recovered from surgery and returned home. We prefer to use metered dose inhalers (often with spacer devices) rather than updraft nebulizers for reasons of cost and convenience, even in the postoperative period, so long as the patient can manage to use the device with a technique adequate to insure delivery of the drug to the airways.

Anticholinergic agents

Anticholinergic drugs cause bronchodilation by blocking the bronchoconstricting effects of stimulation of parasympathetic nerves that are most abundant in the central and larger airways.[149] Thus it is likely that these agents influence bronchomotor tone at a more proximal anatomic site than do b-adrenergic agonists. Anticholinergic agents are generally less potent than b-agonists in individuals with asthma, but are of particular benefit in patients with chronic bronchitis. [150],[151] Ipratropium bromide is a quaternary derivative of atropine that is a potent anticholinergic agent. It is very poorly absorbed into the circulation from the airways, and thus has very few systemic effects when administered via inhalation.[150],[152] Recent data have confirmed that the combination of ipratropium and a b-agonist results in greater clinical and physiologic improvement than the b-agonist alone. [153] Furthermore, the addition of ipratropium to a regimen of b-agonists has been demonstrated to result in fewer exacerbations and an improved treatment cost and cost-effectiveness.[154] Although no data specific to the postoperative state exist, we encourage the use of ipratropium bromide at relatively high doses (such as three to four puffs four times daily) as well as a b-agonist beginning as soon as possible preoperatively in patients who have chronic airflow obstruction and are undergoing pulmonary resection. As with the b-agonists, the drug should be continued throughout the perioperative period, with emphasis on proper use of the metered dose inhaler. The potential benefits of long-term administration of ipratropium are then assessed after the patient has left the hospital, during outpatient follow-up. The recent development of long-acting b-agonists has improved the ability to provide bronchodilation in patients with COPD. Salmeterol xinafoate has demonstrated prolonged bronchodilation and improved breathlessness in patients with COPD. [155] The relative safety and simplicity of administration may make this class of agents the optimal b-agonists for this patient population.

Anti-Inflammatory Agents

Many individuals with airflow obstruction due to chronic bronchitis and emphysema have chronic inflammation of the bronchial wall. [156] This inflammatory process can result in superimposed bronchoconstriction, exacerbating the fixed abnormality of the underlying process. Inhaled corticosteroids can be effective agents for the reduction of mucosal inflammation in patients with asthma and in selected individuals with COPD. [142],[157] When administered by inhalation, these drugs have very few side effects. They can induce coughing, a problem that can be largely alleviated by administering a b-agonist prior to the anti-inflammatory drug. Inhaled steroids can cause oral thrust and modest changes in phonation.[158],[159] Recent data suggest that inhaled fluticasone may improve pulmonary function and clinical symptoms and decrease the incidence of exacerbations in patients with COPD. [160] Similar results have been suggested with long-term use of this agent,[161] although inhaled budesonide does not appear to provide the same benefit. [162] This may reflect differences in the patient groups studied, however. [161] On the basis of these data, we opt to begin therapy preoperatively in selected individuals based on their clinical history and results of spirometry. In particular, individuals who have coughing or wheezing in response to specific allergens, cold air, or exercise may well benefit from the addition of inhaled steroids to their bronchodilator regimen. Similarly, patients with significant variability in their spirometry, especially those with over 10% improvement in FEV_1 after the administration of an inhaled b-agonist, are good candidates for a trial of inhaled corticosteroids or cromolyn. [163] For maximum benefit, inhaled steroids should be used at relatively high doses initially and tapered to lower maintenance doses after several weeks. We continue these agents in the postoperative period after the patient no longer requires mechanical ventilation, and we assess the potential benefit of continued therapy as an outpatient.

Approximately 10% of stable patients with airflow obstruction due to COPD will have a statistically significant improvement in spirometry after a course of systemic corticosteroids.[164] Patients who have evidence of significant reversible obstruction, as indicated by improvement in spirometry after the use of an inhaled b-agonist, may be more likely to show physiologic benefit from a trial of steroids than are patients whose spirometric abnormality appears to be fixed. [165] However, the chronic inflammatory changes that have developed over months to years may improve only over a more extended period, with little initial response to a single dose of a bronchodilator. Therefore, in patients with marginal pulmonary function or in individuals with very labile pulmonary function despite aggressive therapy with bronchodilators and inhaled corticosteroids, we will often give a trial of prednisone therapy, 40 mg daily for up to two weeks, and then repeat spirometry. If this trial results in clinically significant improvement in FEV_1, the prednisone then is tapered, while inhaled corticosteroids are continued at high doses. The benefits of any improvement in pulmonary function must be weighed against the important risks of difficulties with wound healing and postoperative infection. In general, we hope to have patients on at most low-dose prednisone (approximately 10 mg per day) at the time of surgery. Occasional patients who develop acute exacerbation of bronchitis without pneumonia postoperatively may require short courses of systemic steroids as well.

Methylxanthines

While theophylline preparations were previously considered first-line agents for patients with airflow obstruction of all sorts, these drugs have largely fallen out of favor in recent years. They are less potent bronchodilators than inhaled b-agonists and have a very low therapeutic index. [142],[147] Potentially life-threatening side effects, including cardiac arrhythmias and seizures, can occur at serum levels only modestly higher than the traditional therapeutic range. [166] This problem is worsened by the highly variable hepatic metabolism of theophylline, which can result in wide fluctuations in serum levels despite a constant daily dose. However, there are arguments to suggest that theophylline may yet have a role in selected patients. [166],[167] In addition to the fact that occasional patients have impressive symptomatic improvement with the drug, especially those troubled by nocturnal awakenings due to dyspnea, theophylline has been shown to enhance both strength and endurance of diaphragmatic muscle.[168],[169] If theophylline is used in the perioperative period for the patient undergoing pulmonary resection for lung carcinoma, serum levels must be monitored closely. The target level should be 10 mg per dL, and levels of greater than 15 mg per dL are to be carefully avoided. The physician must be aware of and adjust the dose accordingly in patients in whom hepatic metabolism of theophylline will be reduced, including those with hepatic dysfunction or congestive heart failure, and patients receiving drugs such as erythromycin, ciprofloxacin, or cimetidine that inhibit the hepatic P450 system. [147]

Antibiotics

All patients who are being assessed for thoracic surgery should be questioned regarding cough and sputum. Of particular importance are the volume and characteristics of the sputum.[169] Individuals who are producing sputum with any purulence should be treated with a seven to ten day course of oral antibiotics prior to surgery. In this circumstance, the therapy is generally empiric; there is no evidence to suggest that there is benefit from routine sputum culture to determine bacterial species and antibiotic resistance. Amoxicillin or ampicillin (250 mg three times daily or four times daily, respectively), trimethoprim/sulfamethoxazole (one double-strength tablet twice daily), or doxycycline have all been considered appropriate choices. These antibiotics cover the most common bacterial flora in patients with chronic bronchitis (*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*)[130],[170] and are well tolerated and inexpensive.[171]

Recent data have suggested different bacterial flora in patients with more severe disease, however. In a prospective study of 211 patients admitted to the hospital with an exacerbation, Eller and colleagues performed detailed studies to identify pathogens [172] and characterized the patients by performing spirometry at the time of discharge. Those patients with more severe airflow obstruction (FEV_1 under 50% of predicted) were more likely to have infections caused by enteric gram-negative rods. In addition, in a prospective study of 471 patients with chronic obstructive pulmonary disease, Ball and associates examined the features which predicted a high likelihood of failure to recover during the treatment of an exacerbation. [173] The only factors predicting failure to recover from an exacerbation included coexisting cardiopulmonary disease and the number of chest infections during the preceding 12 months. As such, recent recommendations suggest treating younger individuals with less severe disease and infrequent exacerbations with first-line antibiotics (amoxicillin, trimethoprim/sulfa-methoxazole, or doxycycline), while older patients with more severe disease or frequent exacerbations should be treated with a second-line agent (newer macrolide or fluoroquinolone). [174] Recent data support the above concepts as cost-effective. Grossman and colleagues randomized a total of 240 adult patients with a type I or II exacerbation and history of frequent exacerbations over the previous year.[175] Patients received the fluoroquinolone ciprofloxacin or non-fluoroquinolone antibiotics. Assessments included symptoms, all medications used, adverse events, hospitalizations, outpatient health care utilization, and health-related quality of life. Cost-effectiveness of ciprofloxacin use was demonstrated in older patients (age over 56), those with more severe or long-standing disease (over ten years), more frequent exacerbations (more than four per year) or more

comorbid conditions (over three comorbidities). As such, the choice of antibiotic should be individualized to the patient.

Respiratory Physiotherapy

Following the induction of general anesthesia for a surgical procedure, there is a rapid decrease in functional residual capacity. [176] Even in individuals whose preoperative lung is normal, this decrement in lung volume results in atelectasis in dependent zones. These atelectatic regions can be detected on CT scans through the thorax performed within minutes after the induction of anesthesia, and result in significant increase in intrapulmonary shunting. [177,178] In the postoperative period, functional residual capacity is assaulted by many different factors, including pain that causes splinting and diminished inspiratory effort, diaphragmatic dysfunction, prolonged supine position, and clouded sensorium due to narcotics. In addition to these general considerations, patients who have undergone a thoracic surgical procedure may have an incision through accessory muscles of respiration, pain with respiration due to irritation of the pleura, and more severe atelectasis of portions of the dependent lung if a lateral incision has been used. [111] Together, these factors greatly diminish pulmonary compliance and promote atelectasis. [6,177] Atelectasis in turn places the patient at risk for bronchitis, pneumonia, or respiratory failure. A major goal in the perioperative management of patients undergoing pulmonary resection for bronchogenic carcinoma is the reversal of these physiologic derangements and the attendant reduction in the risk of postoperative respiratory complications.

Several different physiologic and mechanical techniques have been used in an attempt to prevent or correct alveolar collapse after surgery. Early approaches often emphasized forced expiratory maneuvers with the use of "blow bottles" or balloons. These devices encouraged the patient to make repeated and sustained forced expiratory efforts. In retrospect, it is clear that Valsalva maneuvers can cause compression of airways due to increased intrathoracic pressure and in fact may be counterproductive in the postoperative period. [179]

The recognition that general anesthesia and surgery consistently cause a reduction in functional residual capacity led to the use of methods that focused not on expiration, but on inspiration, in hopes of returning lung volumes towards normal. Available measures include supervised cough and deep-breathing exercises (CDB), incentive spirometry, intermittent positive pressure breathing (IPPB), and constant positive airway pressure (CPAP) delivered by face mask. In CDB and incentive spirometry the immediate goal is to encourage repeated and sustained maximal inspiratory efforts and thereby prevent alveolar collapse and recruit atelectatic lung units. [179,180 and 181] They thus require active participation on the part of the patient. IPPB and CPAP devices use positive airway pressure to increase functional residual capacity. [182,183 and 184] The patient may play a more passive role when using these devices than with CDB or incentive spirometry.

The benefits of these different approaches to lung expansion have not been assessed in trials using patients who have undergone pulmonary resection. However, several prospective studies have evaluated these measures in patients who have undergone upper abdominal surgery. Morran and colleagues evaluated the efficacy of routine postoperative chest physiotherapy compared to no prophylactic physiotherapy in 102 patients undergoing upper abdominal surgery. [185] In this randomized trial, the incidence of postoperative pulmonary infections was reduced significantly in the group that received prophylactic physiotherapy, compared to the control group (seven of 51 versus 19 of 51). Celli and colleagues [182] prospectively randomized 172 patients undergoing upper abdominal surgery into four treatment groups: CDB, incentive spirometry, IPPB, and control patients who received no specific prophylactic therapy. Pulmonary complications were significantly reduced for patients receiving any of the three prophylactic treatment regimens, compared to the controls. Of note was that the rate of complications was virtually identical for all three treatment groups. There was also a trend towards decreased length of stay in the prophylactically treated groups, although this achieved statistical significance only for the patients treated with incentive spirometry. These randomized studies support the widely held belief, shared by surgeons, anesthesiologists, and pulmonologists, that postoperative respiratory measures to promote lung expansion can reduce the risk of pulmonary complications.

Several studies have compared the relative benefits of specific approaches to prophylactic respiratory care. Celli and colleagues [182] found that IPPB was associated with increased patient discomfort and, as noted above, found no benefit of IPPB compared to either CDB or incentive spirometry. Similarly, Oikkonen and associates found no advantage to IPPB compared to incentive spirometry in a study involving 52 patients undergoing coronary artery bypass grafting. [186] In an early direct comparison of incentive spirometry with routine chest physiotherapy in 70 patients undergoing upper abdominal surgery, Craven and colleagues [187] found that use of the incentive spirometer was associated with a reduced rate of pulmonary complications and increased number of patients with no postoperative abnormality. However, in this study the intensity of treatment in the incentive spirometer group was considerably greater than for the chest physiotherapy group. More recently, Hall and associates [188] used a large prospective trial of 876 patients undergoing laparotomy to compare the prophylactic benefit of incentive spirometry to that of routine chest physiotherapy. The rate of overall pulmonary complications, of specific complications, and the length of stay were not different between the groups.

Both incentive spirometry and CDB techniques are very dependent upon patient cooperation for maximum benefit. Because CPAP has been used to increase functional residual capacity and improve gas exchange in patients with reduced pulmonary compliance due to lung injury, [189] it has been suggested that the application of this intervention prophylactically in the postoperative period might reduce pulmonary complications with diminished dependence on patient effort. When applied for 12 hours after extubation in patients who had undergone aortocoronary bypass surgery, nasal CPAP improved gas exchange but did not affect the incidence of pulmonary complications, including atelectasis, throughout the postoperative course. [190] Stock and colleagues [184] directly compared CPAP, incentive spirometry, and CDB in a prospective, randomized study involving 65 patients undergoing upper abdominal surgery. CPAP was delivered by face mask at 7.5 cm H_2O for 15 minutes every two hours. Functional residual capacity decreased in all three groups postoperatively, compared to baseline values. The rate of recovery of functional residual capacity was faster in the CPAP group than with incentive spirometry or CDB; however, this difference was apparent only if values were normalized to the postoperative nadir, not the preoperative baseline. Furthermore, the rate of postoperative pulmonary complications was low in all three groups, with no differences between modalities. Based on this information, these authors concluded that CPAP may be of equal benefit to incentive spirometry or CDB. However, until more extensive controlled trials are performed to assess adequately the impact of CPAP on the rate of clinically significant complications, it is difficult to assess its proper role in the prevention of postoperative pulmonary complications. [191]

Bilevel positive airway pressure (BiPAP) is a recently developed technique that shows great promise in the treatment of acute respiratory failure during exacerbations of COPD. The BiPAP machine delivers gas at a set pressure throughout inspiration (providing an inspiratory assist), with a lower level of pressure during the expiratory phase of the ventilatory cycle. Unlike IPPB, the patient determines the flow rates, the duration of the respiratory cycle, and the tidal volume. BiPAP may be delivered by a variety of nasal masks or by a full face mask. In the patient with COPD who has significant respiratory muscle fatigue in the setting of an exacerbation of his or her underlying lung disease (but who does not emergently require intubation and mechanical ventilation), periods of BiPAP ventilation may reduce the work of breathing, improve gas exchange, and prevent the progression to more severe respiratory failure. [192] In a randomized study of 85 patients with acute exacerbations of COPD, patients treated with BiPAP had a lower rate of intubation (26% versus 74%) and lower in-hospital mortality (9% versus 29%) compared to patients who received standard therapy only. Patients who required emergent intubation in the emergency department were excluded from the study. This study suggests that elective BiPAP ventilation may improve respiratory muscle function and gas exchange in patients experiencing an acute exacerbation of COPD. [193] Patients with marginal respiratory reserve who undergo lobectomy for the treatment of lung carcinoma may have a disproportionate decline in pulmonary function during the early postoperative period, with increased work of breathing and limitation of ventilatory capacity. In selected patients, the early application of BiPAP therapy may avoid progression to respiratory failure and provide a temporary support to allow time for improvement in pulmonary mechanics.

Several important conclusions can be drawn regarding the use of respiratory therapy in the perioperative period. There are few data from randomized studies involving patients undergoing thoracotomy for pulmonary resection; however, physiologic considerations suggest that information derived from studies of patients undergoing upper abdominal surgery or coronary artery bypass grafting are quite likely to be applicable to patients undergoing pulmonary resection as well. It is clear that the use of some form of respiratory therapy is of benefit in reducing the incidence of postoperative pulmonary complications and, potentially, length of hospital stay. This principle is now almost universally accepted. [194] It also is likely that maximum benefit can be achieved if patient education is begun and respiratory care is initiated prior to surgery, before incisional pain and an impaired sensorium due to narcotics interfere with patient participation in the therapy. [195] As long ago as 1954, Thorens [195] presented information suggesting that therapy initiated prior to surgery was more effective in reducing pulmonary complications than therapy begun postoperatively.

There is little information to suggest that one particular modality is clearly superior to others in terms of the risk of postoperative complications. The critical factor appears to be the use of some form of therapy. Because IPPB is cumbersome, expensive, and has no advantages over simpler interventions, it has largely fallen out of favor. The choice between CDB and incentive spirometry is best made based upon a number of considerations, including local resource availability and costs, and the ability of the individual patient to participate with either modality. We initially use incentive spirometry in virtually all patients because, once taught, the patient can perform the therapy with little or no supervision multiple times throughout the day. In individuals who have difficulty using the incentive spirometer, who are having problems with postoperative atelectasis or hypoxemia, or who have remained in the intensive care setting, it is reasonable to use CDB under the supervision of a trained nurse or respiratory therapist. In selected patients with large volumes of sputum, postural drainage and chest percussion may play an adjunct role, although this intervention can cause transient deterioration in gas exchange and increase chest wall discomfort in individuals whose respiratory reserve may be already quite

limited.[197] On physiologic grounds there is intuitive appeal to the use of CPAP to increase functional residual capacity in the postoperative period. However, further studies are required to define both the benefits and the relative costs of this more complex intervention.

Pain Control

Many of the adverse effects of thoracic surgery on pulmonary function are independent of pain. [110] However, the control of postoperative pain remains an issue of particularly great importance for the patient who has undergone pulmonary resection for bronchogenic carcinoma. The majority of patients will have lateral incisions that involve injury to respiratory muscles. Pain at the surgical wound may be a problem with each breath. Furthermore, many of these patients have significant underlying chronic obstructive pulmonary disease, rendering them susceptible to the hypoventilatory effects of injudiciously administered narcotics.

Traditionally, postoperative pain has been controlled with periodically administered narcotics. This approach gives significant variation in narcotic levels, with often inadequate pain control when the level is at a nadir and unacceptable effects on sensorium and respiratory drive when the level is at a peak. [111,198] Several recent innovations offer the promise of considerably improved the therapy of postoperative pain while lessening adverse side effects. Patient controlled analgesia (PCA) and epidural analgesia are approaches that may be of benefit following any surgical procedure in which postoperative pain is a major consideration. [199] Both methods can give improved analgesia with relatively easily controlled side effects. In PCA, the patient receives a low-dose continuous infusion of intravenous narcotic that he or she can supplement on demand with a controlled bolus of drug. This approach has been well accepted by patients, with improved patient comfort and perhaps fewer effects of peak narcotic levels on sensorium. If the limits on bolus doses are adjusted appropriately, there is little risk of significant overdose. [111]

Epidural analgesia is now an accepted method of pain control in this patient population. Narcotics are delivered in bolus fashion, controlled either by the patient or the nursing staff, via an epidural catheter for up to 24 hours after surgery. Pain control and patient acceptance are generally excellent. [200,201] Pruritis and urinary retention are problems that are easily treated with an antihistamine or short-term urinary catheterization, respectively. In general there are few problems with significant respiratory depression.[111] Of note is that, in a prospective study in which oxygen saturation was monitored continuously for 24 hours after lower abdominal surgery, Wheatley and colleagues[202] found more frequent episodes of mild arterial oxygen desaturation (over 94% for less than six minutes per hour) in patients receiving epidural analgesia than in groups receiving PCA or traditional intramuscular narcotics. These episodes occurred almost exclusively during sleep at night and were not predicted by decreases in respiratory rate. To prevent this complication, some authors have advocated concomitant therapy with an opiate antagonist given intravenously.[203]

An innovative approach to pain control after thoracotomy involves regional anesthesia with a long-acting local anesthetic agent such as bupivacaine used for extrapleural intercostal nerve block[109] or instilled into the pleural space at the end of the surgical procedure. [204,205] With either repeated administration or a continuous infusion of drug, there is excellent local control of thoracic pain with no evidence of respiratory depression or other major side effects. In theory, these uses of regional analgesia may significantly improve patient comfort, decrease the requirement for systemic narcotics, and improve pulmonary function in the postoperative period. For example, Berrisford and colleagues[109] showed that extrapleural intercostal nerve block with bupivacaine led to an immediate postoperative FEV_1 which was 40% higher than with saline placebo.

CONSIDERATIONS FOR RADIATION THERAPY

For those patients for whom surgery is not a therapeutic option, radiation therapy often serves as a good alternative. Similarly, for those patients with extensive local disease at the time of thoracotomy, postoperative radiation therapy is often employed. The clinical indications and techniques employed in this form of therapy will be discussed elsewhere in this volume. Pulmonary changes have been known to occur after pulmonary radiation for almost 100 years. [206] Recent work has clearly described two major clinical phases of lung injury from pulmonary radiation: an acute pneumonitis and a later-appearing fibrosis. [207,208 and 209] Because many patients with lung cancer have underlying lung disease, it would be expected that an additional effect of radiation-induced lung injury will occur. Furthermore, the effect of radiation injury would be expected to be different from the effect of surgical resection on lung function. The extent of functional loss should not be as well defined after radiation therapy, and the time course of functional loss will be different (immediate for resection versus delayed for radiation injury). [210] The risk of an early radiation pneumonitis seems to be strongly influenced by the dosage delivered and the field size. [211,212] The late effect may be quite important, as severe or fatal pulmonary complications were seen in 3% of patients receiving 4,000 cGy in four weeks through a Radiation Oncology Group (RTOG) study [213] and in 5% of patients receiving 6,960 cGy in another RTOG study.[214]

Brady and colleagues[206] monitored spirometry, lung volumes, MBC, DLCO, dynamic lung compliance, and arterial blood gases prior to and four weeks after thoracic radiation therapy in lung cancer patients. Little change was seen during this brief period of follow-up in most parameters. A decrease in DLCO was highly significant and appeared to correlate with the volume dosage delivered to the thorax. Mattson and colleagues [215] studied 34 patients treated with split-course radiation therapy for lung cancer in addition to chemotherapy. At regular intervals after radiation, pulmonary function was measured, as was regional pulmonary perfusion using ^{133}Xe (as described earlier for thoracic resection). Only decreases in DLCO were significant and seen six and nine months after finishing radiation. In a large prospective study, Choi and colleagues[216] measured pulmonary function (spirometry, lung volumes, MBC, and arterial blood gases) prior to initiation of postoperative (lobectomy in 49 and pneumonectomy in 22 patients) radiation and one year after finishing radiation (and every year thereafter). They noted very little change in pulmonary function regardless of the surgical procedure. In four of 137 patients there was symptomatic pulmonary toxicity.

Two groups have utilized similar techniques of split perfusion scans to estimate postradiation therapy pulmonary function as was described earlier for lung resection. Rubenstein and associates[217] prospectively examined 22 patients (six treated postoperatively and 16 treated with primary radiation therapy) using quantitative perfusion lung scanning. Careful estimates were made of the volume of lung exposed to radiation. Assuming this lung would no longer contribute to the patient's FEV_1, the authors predicted postradiation therapy pulmonary function by using the following equation:

Postradiation FEV_1 = Preradiation FEV_1 × (1-fraction of total lung perfusion in radiated portal)

After sequential follow-up, the authors noted that a latent period in FEV_1 was followed by a decline in FEV_1. Nevertheless in only two patients was postradiation FEV_1 below the predicted postradiation pulmonary function.

In a more ambitious study, Choi and coworkers[210,218,219] prospectively studied patients with unresectable lung cancer treated with radiation therapy. Using quantitative radionuclide lung scans to measure regional lung function, the authors estimated postradiation therapy FEV_1 using an equation similar to that of Rubenstein and colleagues.[217] The authors noted that the change in pulmonary function after radiation therapy depended on pretreatment lung function, the extent of bronchial or pulmonary vascular obstruction by tumor, and the location of treatment. In this way, group A patients, with preradiation-therapy FEV_1 of less than 50% predicted (and over 10% shift in ventilation or perfusion to the uninvolved side of the lung), showed the greatest decrement in lung function. In these patients, FEV_1, FVC, MBC, and PEFR decreased by 15% to 25%, TLC decreased by 12%, and DLCO by 6%. In group B patients, with preradiation FEV_1 of over 50% predicted (and over 10% shift in ventilation or perfusion to the uninvolved side of the lung), there was a small *increase* in pulmonary function 12 months after radiation therapy. The predictability of loss in pulmonary function was greater in group A patients (69% correlation between measured and predicted postradiation therapy pulmonary function). Only 10% of group B patients showed the decrease predicted (50% showed a small increase in pulmonary function, with 40% showing a small decrease). Choi suggested in an editorial[210] that the functional loss in pulmonary function after radiation therapy depends on the balance between direct tissue injury due to the radiation and possible improvement in pulmonary function by improved traction of adjacent lung caused by radiation. Axford and associates [220] suggested that radiation may actually relieve breathlessness in emphysema patients via a similar process. As such, in patients with relatively normal preradiation pulmonary function, there is likely to occur a predictable loss in pulmonary function with radiation therapy. Patients with markedly reduced pulmonary function may have some improvement. The extent of airway or vascular obstruction by tumor may also have an impact. Fazio and colleagues [221] noted an early improvement in ventilation (in 83% of patients) and perfusion (in 86% of patients) after radiation therapy for unresectable lung cancer. Of interest was that subsequent decrease in pulmonary function was seen and was felt to be due to delayed radiation fibrosis.

The value of pulmonary function testing and accurate estimation of dose-volume calculation was highlighted by Marks and colleagues, who prospectively studied 100 patients (67 with lung cancer) during the course of radiation therapy. [222] They utilized three-dimensional, CT-based estimates of dosage and pretherapy pulmonary function studies to predict the development of symptoms (which occurred in 21 of 100 patients) and decrements in pulmonary function. The authors noted that the extent of alteration in whole-lung function, as defined by symptoms or pulmonary function change, was best related to dose-volume and pretherapy pulmonary function. As such, most patients with pulmonary symptoms had either a high dose-volume parameter or low pretherapy pulmonary function. Interestingly, there was no

quantitative relation between dose-volume parameters and the percent reduction in pulmonary function. Further data are required to develop more accurate predictive models.

In conclusion, radiation therapy results in clear-cut injury to normal lung. In most patients this should not prohibit treatment. In some patients prediction of postradiation therapy pulmonary function may be useful, particularly if one uses similar criteria established for postresection lung function. This is particularly true because the measured posttreatment pulmonary function is rarely lower than predicted function. This should provide a "cushion of error" which may quite clinically useful. In patients with severe pulmonary dysfunction, the resulting late decrement in pulmonary function with high-dose radiation must be taken into account when weighing therapeutic options.

CONSIDERATIONS FOR CHEMOTHERAPY

As with surgical treatment and radiation therapy, chemotherapeutic agents used to treat bronchogenic carcinoma have been shown adversely to affect pulmonary function. A comprehensive review of this topic is outside the range of this chapter. The reader is referred to several excellent reviews. [223],[224],[225],[226] and [227] In this discussion we will primarily address issues of pretreatment assessment in an effort to minimize toxicity, and we will concentrate on agents commonly used to treat lung cancer.[228],[229]

The incidence and major risk factors associated with these chemotherapeutic agents are summarized in Table 36.6. Bleomycin is included because it is considered by many to be the prototypical agent of drug-induced lung damage.[226] Furthermore this agent has been the most extensively studied, with two major clinical scenarios described: a chronic, progressive fibrosis, and an acute hypersensitivity reaction. [223] The risk factors described in Table 36.6 are the best-defined in the literature. Mitomycin C has been shown to result in pulmonary toxicity 3% to 36% of the time.[226] Toxicity can occur after a single dose or several months after stopping therapy; clinical scenarios include pulmonary pneumonitis/fibrosis, hemolytic-uremic syndrome, and bronchospasm. [225] Risk factors for lung toxicity with this drug are less well defined; the major ones are shown in Table 36.6. Cyclophosphamide is the most common agent used in the treatment of lung cancer. Toxicity has been reported after a single dose or up to 13 years after discontinuing therapy. [223],[226] The reports of cyclophosphamide toxicity are difficult to interpret as this drug has been usually administered with other agents. Fortunately, the incidence of lung toxicity is less than 1%. [223] Risk factors for development of pulmonary toxicity are also poorly defined. Vinca alkaloids administered alone rarely cause significant pulmonary toxicity but can when administered in conjunction with mitomycin. Several studies [230],[231] and [232] have noted this association, with the unusual syndrome of acute bronchospasm described by some. [231],[232]

TABLE 36.6. INCIDENCE AND RISK FACTORS FOR CHEMOTHERAPY-ASSOCIATED PULMONARY TOXICITY

Data have been published reporting an increased risk of pulmonary toxicity in the face of combined therapy with chemotherapeutic agents and thoracic radiation. [233] This relation is best established for bleomycin,[234],[235] and [236] cyclophosphamide,[225],[237],[238] doxorubicin,[239],[240],[241] and [242] dactinomycin,[243] irinotecan,[244] and possibly vindesine.[245] This should be taken into account, as combined therapy is often considered for lung cancer patients, particularly if administered concurrently. [244],[246] A review of series published before 1994 that used combined modality therapy suggested that, in multivariate analysis, radiation pneumonitis was most commonly seen in the setting of high dose per fraction. [247] These authors suggested the use of twice-daily radiation in this setting to minimize risks of pulmonary toxicity.

The role of pulmonary function testing in this setting remains unclear. Most data have been published regarding bleomycin. Many authors feel that DLCO is the most useful test to monitor for potential toxicity,[248],[249] while others do not concur.[250],[251] and [252] Most recently Wolkowicz and colleagues [253] prospectively studied 59 patients undergoing treatment for testicular cancer. DLCO dropped significantly with bleomycin but failed to differentiate patients with pneumonitis. The TLC was found to be a more specific indicator of significant pneumonitis. Van Barneveld and associates [254] studied 39 patients treated for testicular cancer by combining various parameters in a discriminant analysis to predict pulmonary toxicity. The combination of a low normal creatinine clearance, decrease in VC, and decrease in alveolar volume with no decrease in pulmonary capillary blood volume predicted an increased risk of pulmonary toxicity. Unfortunately, similar data are not available for other chemotherapeutic regimens. Limited information has been published during treatment for small cell cancer. Sorensen and colleagues [255] prospectively studied 30 patients treated with aggressive chemotherapy (six achieved a complete response and ten a partial response). In both of these groups VC, FEV_1, TLC, and PEFR increased three months after initiation of treatment. This improvement paralleled the roentgenographic improvement. As described earlier for radiation therapy, the treatment of lung cancer may lead to an initial improvement in pulmonary function as tumor bulk decreases along with associated airway involvement. In a preliminary communication, Valdivieso and associates [256] reported an increased incidence of pulmonary toxicity in patients with a lower FEF_{25-75} who were treated for lung cancer with mitomycin, etoposide, platinum, and radiation therapy.

It is likely that the role of pulmonary function testing is limited in those patients undergoing chemotherapy for lung cancer. In those with multiple risk factors (Table 36.6), pretreatment spirometry, lung volume, and DLCO measurement as well as close monitoring during treatment are appropriate. Isolated abnormalities in pretreatment pulmonary function should not preclude chemotherapy. On the other hand, decreases in lung volumes or DLCO during therapy should lead one to reassess the benefits of further chemotherapy. In this fashion pulmonary toxicity should be minimized.

CONCLUSIONS

The treatment of bronchogenic cancer includes surgical resection, radiation therapy and chemotherapy; frequently combinations of these are used. Unfortunately, all of these modalities have associated deleterious effects on pulmonary function. In this chapter we have summarized the role of pretreatment evaluation in these patients. With aggressive testing and appropriate treatment the majority of patients should be able to undergo treatment while minimizing pulmonary side effects.

SURGICAL THERAPY OF STAGE I AND NON-T3N0 STAGE II NON-SMALL CELL LUNG CANCER

ROBERT J. GINSBERG
JEFFREY L. PORT

In North America, less than 25% of patients will present with stage I or II disease. Unfortunately, this early stage of disease is where potential for cure is greatest and where surgical resection is undoubtedly the treatment of choice.

In this chapter, we discuss the indications for surgery, principles of surgical oncologic therapy, and results of such treatment of patients deemed to have stage I or II (N1) lung cancer. The role of adjuvant and neoadjuvant therapies is discussed in Chapter 42, Chapter 43 and Chapter 44.

HISTORICAL BACKGROUND

Surgery for lung cancer dates back to the mid-nineteenth century with multiple reports of nonanatomic partial resections for lung cancer. Davies in 1912 was first to describe a dissection lobectomy for lung carcinoma.[1] "The various structures at the pedicle of the lower lobe were ligated separately, and the lobe containing the growth was removed. The patient's condition was quite good for the first 6 days; he then developed an empyema and died on the eight day." The author concluded that lung carcinomas in their earliest forms were amenable to surgical resection and complete removal. He prophetically stated that it was incumbent upon the clinician to perform early radiologic diagnosis prior to tumor extension beyond the boundaries of potential resection.

The modern era of thoracic surgery was ushered in with the advent of underwater pleural drainage and improved x-ray technology, which could detect smaller, more resectable lesions. Brunn described a one-stage lobectomy in 1929, followed by Allan and Smith who described a two-stage lobectomy in which adhesions were first created by pleural abrasion followed by lobectomy 12 days later.[2,3] By 1931 there were only six reported cases of patients successfully treated for lung carcinomas by surgical resection. In 1933 Graham and Singer reported on the historic, successful removal of a lung carcinoma via left pneumonectomy.[4] This was the first one-stage pneumonectomy. They proposed that pneumonectomy for lung carcinoma was not only technically feasible but also offered the patient the greatest chance for complete cure. Radical pneumonectomy with *en bloc* removal of mediastinal nodes was proposed by Allison in 1946.[5] For the next 10 years, pneumonectomy became the standard of care for non–small cell lung cancer (NSCLC).

Over the ensuing several decades, the concept that the more radical a cancer resection the better was challenged. Several factors set the stage for a transition from radical pneumonectomy to less extensive operations. Surgical techniques improved and hilar dissection with lobectomy became practical. Improved x-ray technology allowed for earlier detection of smaller and more peripheral lesions. In addition, it became apparent that many of the surgical candidates suffered from chronic obstructive lung disease and would not tolerate a pneumonectomy. Lobectomy was no longer considered a compromise operation but rather the new standard of care for early-stage lung cancer. More recently, surgeons have questioned the need for lobectomy in early-stage disease. Jensik reported on the results of segmentectomy as an alternative to lobectomy for the treatment of lung cancer in 1973.[6] The technique was not widely adopted because of the increased technical difficulty. However, the more recent, widespread use of surgical stapling devices and thoracoscopy has rekindled the controversy over performing more limited resections, especially in T1N0 tumors.

This chapter discusses the management of those patients with relatively early-stage disease where, following clinical evaluation, a complete resection is anticipated. Although clinical staging underestimates final pathologic staging in at least 25% of cases, those patients with clinical stage I and II disease are usually offered surgical resection as the initial therapy.

DIAGNOSIS AND STAGING

The methods of diagnosing and staging lung cancer are well reviewed in Chapter 29, Chapter 30, Chapter 31, Chapter 32, Chapter 33, Chapter 34 and Chapter 35. Many are asymptomatic and include patients who are smokers screened by their family physician, or who had a routine chest x-ray for employment medical clearance or preadmission testing prior to nonthoracic surgery. Surgical resection remains the mainstay of treatment for these patients, provided a complete resection can be performed and is warranted by a patient's functional status. Five-year survival following a complete resection of this early asymptomatic stage of disease (usually stage I) can approach 70%.[7,8,9,10,11,12 and 13]

The chest radiograph remains the most common and most inexpensive imaging modality to detect the pulmonary abnormalities related to early-stage disease. It must be remembered that early-stage lung cancers can often cause atelectasis or postobstructive pneumonias and may be mistaken for benign processes. One must be compulsive with follow-up before dismissing new x-ray abnormalities as benign processes, especially in smokers. The plain chest x-ray delineates the primary tumor and may also suggest mediastinal node involvement or direct tumor extension into the chest wall or mediastinum. A computed tomography (CT) scan of the chest remains the standard of care for further evaluation of a suspected lung cancer. This should include the entire chest and upper abdomen through the kidneys. We routinely use IV contrast to better delineate mediastinal structures. The diagnosis can be established by sputum cytology or bronchoscopy for more central lesions and percutaneous needle biopsy or thoracoscopy for peripheral abnormalities. Positron emission tomography (PET) scans have proven useful with an accuracy of up to 90%.

Whenever possible, we believe that a preoperative histologic or cytologic diagnosis of malignancy is worthwhile. If a diagnosis has not been reached prior to surgical resection, it is our practice to perform a wedge excision or intraoperative needle aspiration biopsy to obtain a diagnosis prior to the formal resection. Unfortunately, errors can occur with frozen section histology, usually the pathologist mistaking a malignant process for a more benign one. When the clinical suspicion of malignancy is great, and a frozen section analysis is unavailable, a formal resection (segmentectomy or lobectomy) is indicated for diagnosis and treatment. However, a pneumonectomy should never be performed without a preresection diagnosis of malignancy.

The minimum staging requirements include a complete history and physical examination, chest x-ray, and, whenever available, a CT scan of the chest and upper abdomen. Whether a search for distant metastases by other imaging techniques is warranted in these early stages of disease, is a moot point. The cost-effectiveness of this investigation, beyond a complete history and physical examination as well as screening blood chemistries, has never been substantiated. In our own practice, those patients with clinical stage Ib or II are usually screened for occult brain and bone metastases. With increasing frequency, we are employing PET scanning

together with CT scanning as one-stop shopping. [14]

The role of invasive staging is even more debatable. Except for tiny peripheral tumors, occult mediastinal lymph node disease occurs in 10% to 25% of patients with stage I disease and an even greater percentage in clinical stage II disease. For this reason, we have employed mediastinoscopy liberally in our preoperative assessment. However, the standard of care in North America suggests that if mediastinal lymph nodes are clinically negative (<1 cm in transverse diameter), then mediastinoscopy is not required before offering surgical resection. In our own practice, if mediastinal lymph nodes are negative on CT scan but a patient has a 2 cm or greater peripheral nodule or has clinical evidence of stage Ib or II disease, we perform mediastinoscopy just before the formal thoracotomy, cautioning the patient that surgical resection will not proceed if the mediastinal lymph nodes prove to have N2 disease, believing that, in this group of patients, surgery alone is insufficient. With this approach, the likelihood of unresectability at the time of thoracotomy is lessened and, for patients harboring mediastinal lymph node involvement, the opportunity to be treated by multimodality therapy, including preoperative chemotherapy, is still available.

PREOPERATIVE ASSESSMENT

Although the preoperative assessment of the surgical patient has been discussed in Chapter 36, we believe that this assessment must be performed by the thoracic surgeon in every instance prior to surgical therapy and is useful to highlight again.

The thoracic surgeon must be compulsive in his or her initial assessment of the patient. Because the majority of postoperative complications and deaths are related to cardiopulmonary events, risk factors for these complications should be identified preoperatively. The surgeon must also ensure that the anticipated resection will leave the patient with a reasonable quality of life without chronic respiratory failure. A multitude of risk factors have been analyzed as predictors of postoperative morbidity and mortality.[15,16,17,18,19,20,21,22 and 23] The extent of resection, stage of disease, co-morbid medical disease, weight loss more than 10% and age over 70 appear to be most significant. Interestingly, a patient's attitude toward his or her disease has been confirmed in a prospective analysis as an important predictor of outcome.[24]

The history and physical examination are the most important tools in physiologically evaluating patients with lung cancer. Most patients with lung cancer are current or former smokers, which increases their risk for vascular, cardiac, and obstructive pulmonary disease. The history should focus on the patients' cardiopulmonary reserve, smoking status, and current sputum production. It is extremely important to also assess the patient's ability to cough. Marked preoperative improvement can occur by smoking cessation (minimum of 2 weeks preoperatively), antibiotics, bronchodilators, steroids, pulmonary rehabilitation, and patient education on how to cough effectively.[16,25]

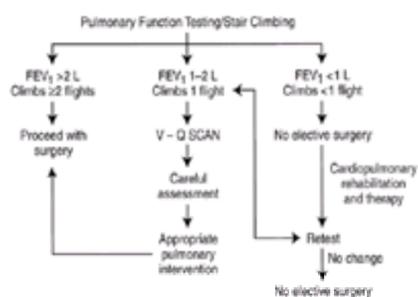
Pulmonary function testing runs the gamut from simple physical examination with stair-climbing to sophisticated exercise testing. Stair-climbing with pulse oximetry has been well documented to accurately predict function.[26,27] However, the standard of practice requires preoperative spirometry with carbon monoxide diffusion capacity (DLCO) and an arterial blood gas in patients prior to resection.[28] Ventilation–perfusion scanning is usually reserved for patients requiring pneumonectomy or for those who have severely compromised function on spirometry. Although guidelines for predicting high risk for resection are not absolute, a predicted FEV_1 of less than .8 after any resection, an MVO_2 less than 10, hypercarbia, or cor pulmonale make surgery risky and pneumonectomy prohibitive (Figure 37.1). However, prior to denying any patient a potentially curative resection, aggressive pulmonary rehabilitation programs can be instituted for up to 2 months. Many patients subsequently show significant improvements and often qualify for resection. More recently, lung volume reduction surgery has been used in conjunction with pulmonary resection to improve lung function for patients with COPD.[29,30 and 31]


FIGURE 37.1. The usual algorithm for assessing people with regard to suitability of pulmonary resection. The recent evidence suggests that even severely compromised patients can undergo thoracotomy and lobectomy. There is no absolute FEV1 value that contraindicates any surgical approach in selected patients.

An accurate cardiac assessment is crucial in the thoracic patient. Hypertension, coronary artery disease, valvular disease, and arrhythmias are predictors of increased risk. A routine electrocardiogram is part of the preoperative assessment. More often, exercise stress testing and thallium imaging are being routinely utilized in patients over age 60 or with other risk factors to identify correctable defects.

STAGE I DISEASE (T1-2N0)

The Solitary Pulmonary Nodule

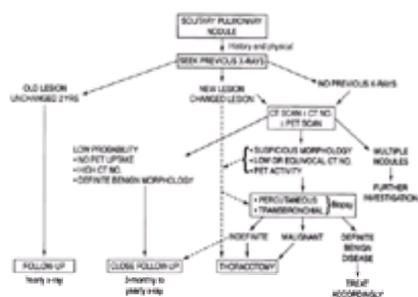
The solitary pulmonary nodule (SPN) deserves special attention because it often poses a diagnostic and therapeutic dilemma (Figure 37.2). More refined imaging and minimally invasive techniques have reduced the need for open thoracotomy for diagnosis. The SPN is defined as a round, 1 to 4 cm, well-circumscribed lesion surrounded by lung and without evidence of bronchial obstruction. Most often, these lesions present on routine chest x-ray as an unexpected finding in an asymptomatic patient. A thorough history, including questions regarding smoking history and previous malignancy, as well as a thorough physical examination may direct the clinician toward a diagnosis. A search for previous x-rays for comparison is imperative. If a lesion has not changed over 2 years, then one can ascribe a benign diagnosis with confidence.


FIGURE 37.2. Algorithm for investigating a solitary pulmonary nodule. Not seen in this algorithm is the insertion of PET scanning. A high SUV number (greater than 7) would indicate malignancy. However, significant errors are seen with bronchoalveolar carcinomas.

If old x-rays are unavailable, initial attempts should be directed at characterizing the lesion. Features such as dense, central, "popcorn," or lamellar calcification

suggest a benign lesion. CT scans have proven invaluable. High CT Hounsfield units indicating a dense lesion point toward a benign diagnosis. If doubt remains following these investigations, fluoroscopic or CT-guided percutaneous needle biopsy or transbronchial biopsy utilizing fluoroscopy can be performed. Recently, PET scans have been used to differentiate benign from malignant nodules with high accuracy. [32] This method appears highly accurate, approaching 95%. However, it has been shown that bronchoalveolar tumors are not well-suited for assessment by PET scanning (See also Chapter 30).

Several patients will remain whose lesions continue to elude tissue diagnosis. In these situations, tissue must be obtained either by open or video-assisted techniques, through which intraoperative aspiration cytology, core needle biopsy, wedge or segmental resection, and occasionally lobectomy can be performed for diagnosis.

Occult Lung Cancer

Patients with occult lung cancer (positive cytology, no lesion identified on x-ray) account for less than 1% of all lung cancer patients. [33,34 and 35] These patients usually include individuals who have participated in early lung cancer screening programs or who have developed hemoptysis without x-ray findings and have a positive sputum cytology documenting squamous cell cancer. Prior to any treatment, a thorough aerodigestive exam is required. One-third of these patients will actually have a head and neck cancer. [34] Following head and neck exam, bronchoscopy must be performed under local anesthesia to accurately examine the proximal and distal airway. A lesion that is easily visualized can be biopsied. When no endobronchial lesion is seen, brushings and washings from segmental bronchi must be obtained. Most recently, newer techniques have been established to assist in the detection of occult disease (see also chapter 22 and chapter 24). These techniques include detection of early dysplasia and carcinoma with autofluorescence endoscopy (LIFE). [36] This technique has been reported to allow for almost 50% better detection of early carcinomas compared to ordinary flexible bronchoscopy.

Except for *in situ* carcinoma, or tiny superficially invasive tumors (less than 1 cm [2]), the treatment of choice for even these early occult lesions is surgical resection. In such instances, lung-sparing operations are often indicated using bronchoplastic techniques because tumors often occur in major airways. The long-term survival following surgical resection for radiologically occult disease is excellent, approaching 100%. Although recurrences are rare, 45% of patients will develop new primary carcinomas of the aerodigestive tract. It is therefore imperative that surveillance endoscopy continue to be carried out.

SURGICAL ONCOLOGIC PRINCIPLES

Surgical resection remains the mainstay of treatment for early-stage lung carcinoma. However, an incomplete resection rarely benefits a patient. Several basic, yet important oncologic guidelines should be followed to provide an optimal and complete resection and complete the final TNM staging.

1. The tumor and its draining intrapulmonary lymphatic tributaries should be resected in their entirety whenever possible.
2. The tumor should be completely excised without spilling or traversing it.
3. The surgeon should resect *en bloc* any structure invaded by tumor in order to achieve negative margins.
4. A complete ipsilateral mediastinal lymph node dissection or sampling should be performed in all patients.

Lobectomy Versus Pneumonectomy

It has been clearly established that incomplete resections rarely lead to cure. Intraoperatively, the surgeon must determine if a lobectomy will suffice to provide a complete resection. All resection margins must be confirmed as negative by frozen section. In addition, lymph nodes lying on the pulmonary artery and straddling adjacent lobes must be examined by frozen section. If these nodes are positive, then a larger resection may be required to effect a complete resection (e.g., bilobectomy, sleeve resection, or pneumonectomy). Lymph node involvement of the airway or vessels proximal to the upper lobe takeoff involving the mainstem bronchus or the main pulmonary artery may necessitate a sleeve resection of the main bronchus or pneumonectomy.

Lymph Node Sampling Versus Mediastinal Lymph Node Dissection

During the conduct of surgical resection for lung cancer, surgeons must perform adequate nodal staging (see also Chapter 35). This process requires sampling of lymph nodes at the hilum and at all available mediastinal lymph node stations. If a mediastinoscopy has been done prior to the surgical resection, then those areas already sampled at mediastinoscopy need not be sampled again. If any sampled lymph nodes contain metastatic disease, then it is recommended that a complete ipsilateral mediastinal lymph node dissection be performed. Whether this latter procedure is required as routine (versus sampling) in all pulmonary resections for cancer is a debatable point. Advocates point out that in at least 10% of cases, occult mediastinal lymph node involvement occurs and may be missed unless an ipsilateral node dissection is carried out. On the other hand, the only randomized trial available to date suggests that although surgical staging is improved with regard to the number of mediastinal lymph node stations involved, the overall incidence of N2 disease discovered at the time of sampling is not improved with mediastinal lymph node dissection and, in this small randomized trial, no improvement in survival was demonstrated with the use of ipsilateral node dissection. [37] A North American trial was begun in 1999, comparing these two approaches in early-stage lung cancer.

Limited Resection Versus Lobectomy

The standard treatment for stage I disease is a complete removal of the primary tumor, usually lobectomy, and at minimum lymph node sampling of all available hilar and mediastinal nodes.

Advocates of limited (wedge or segmental) resections have argued that small peripheral T1N0 tumors can be removed safely by wedge resection with minimal risk of local residual lymphatic involvement. However, Ishida and colleagues reported that only for very small tumors (less than 1 cm in diameter) is the incidence of lymphatic permeation and nodal involvement near zero. [38,39] Tumors of 1.1 to 2 cm had intrapulmonary lymphatic spread in up to 17% of cases. Tumors greater than 2 cm had lymph channel or nodal spread in 38% of cases. This data suggests that to achieve complete resection in tumors greater than 1 cm in diameter, removal of local and regional nodes by standard lobectomy should be performed. Because less than 5% of lung cancers are discovered as peripheral tumors smaller than 1 cm, extensive data on these very small tumors is limited.

In a multivariate analysis of completely resected T1, N0, M0 tumors, Macchiarini and colleagues were unable to find a statistical correlation between tumor size and survival. [40] In their study, blood vessel invasion and mitotic index were more important factors in predicting survival. In a similar study by Ichinose and colleagues, tumor size alone was not a significant prognostic factor, and in multivariate analysis, only grade of differentiation and DNA ploidy patterns significantly impacted on survival in stage I disease. [41] Thus even very small peripheral tumors have the potential for local, regional, and systemic spread.

Types of Limited Resection

Limited resection can be defined as removal of a pulmonary tumor and surrounding lung by a technique designed to preserve lung parenchyma encompassing less than a lobectomy.

Segmentectomy

Segmental resection of the lung was originally described for the treatment of bronchiectasis by Churchill and Belsey. [42] The lymphatic drainage of each segment usually but not always follows the segmental anatomy without crossing into the adjacent segment. Segmentectomy has the theoretic advantage over other parenchyma-conserving operations of encompassing all or most of the local lymphatic drainage. Thus this operation can be considered the most reasonable compromise to lobectomy in the treatment of lung cancer.

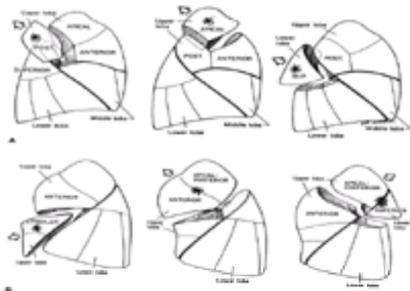
The classic operation includes isolation and division of the segmental artery and bronchus centrally. The segment is manually stripped from surrounding segments along the plane delineated by the intersegmental veins. With the advent of stapling devices and the risk of entering tumor during the stripping procedure, in cancer surgery, stapling rather than stripping is often employed. Those segments abutting a single other segment, such as the lingula or superior segment, are the most appropriate for segmentectomy by virtue of technical simplicity (Figure 37.3).


FIGURE 37.3. Various types of segmentectomies. **A:** Right lung. **B:** Left lung.

Wedge Resection

Small peripheral tumors can be totally removed by a wedge excision. Complete local resection of the primary tumor is the goal of the operation, and no attempt is made to encompass the draining lymphatics. It is not known how much normal surrounding tissue should be resected as an adequate margin.

Precision-Cautery Dissection

When tumors cannot be excised by wedge excision and segmentectomy is not an option, precision-cautery dissection has been proven to be extremely useful. [43] This technique is done on the expanded lung and, using electrocautery or laser-cautery, the tumor and at least 2 cm of surrounding lung are dissected as deeply as necessary, usually ending up at the origin of a subsegmental bronchus and artery. This technique provides good hemostasis and, surprisingly, minimal air-leakage.

Video-Assisted Thoracoscopic Limited Resection

Video-assisted thoracoscopic (VAT) pulmonary resection has progressed substantially over the last several years. [44,45,46,47,48,49,50,51 and 52] Initial thoracoscopic reports were aimed primarily at determining the technical feasibility and safety (mortality 0% to 3%) of thoracoscopic wedge resection. Shannib et al. recently studied the role of VAT wedge resection in 30 patients with T1 tumors and severe pulmonary compromise and found only a 3% mortality rate. [47] Further assessment of this technique combined with postoperative radiation therapy is the focus of an ongoing intergroup study.

Multiple reports have now emerged documenting the technical feasibility of thoracoscopic lobectomy and lymph node dissection. [45,49] To date, no long-term data has demonstrated equivalent survival in NSCLC patients resected by VAT compared to conventional open lobectomy. Despite the claims of improved cosmesis, acute and chronic postoperative pain relief, and reduced hospital stays, randomized studies to date have failed to demonstrate any advantages of video-assisted surgery other than improved cosmesis. As the role of thoracoscopy in lung cancer becomes better defined, surgeons must hold thoracoscopic procedures to the basic principles of cancer surgery and not compromise the resection for the sake of convenience.

Results of Limited Resection for Early-Stage Lung Cancer

Segmentectomy

The results of segmentectomy were the first and most widely reported limited resections for lung cancer. Two broad categories have been reported: (a) compromise operations when pulmonary function would not permit standard lobectomy, and (b) intentional segmentectomies for T1-2 NO lung cancers when the surgeon considered this to be an adequate resection. [53,54,55,56,57 and 58] In pulmonary compromise situations, patients with both N1 and N2 disease were often included in studies, thus five-year survival ranges from 15% to 30%. Although local recurrence rates were not reported, limited data suggested they were high (Table 37.1).[6,59,60,61,62 and 63]

Investigators	No. of Patients	Type of Resection	Local Recurrence (%)	5-Year Survival (%)
Bennett & Smith, 1978	44	Segmental	40	36
McCormack et al., 1980	51	Wedge segmentectomy	19.3	35
Errett et al., 1985	100	Wedge	45	69
Jensik, 1986	119	Segmental	165	55 (est.)
Miller & Hatcher, 1987*	32	Wedge segmental + radiotherapy	6.25	31.5 (p)
Terveck et al., 1992	61	Wedge	6.4	29 (est.)
Read et al., 1990**	107	Segmentectomy	4.4	76
Warren et al., 1991	164	Wedge segmentectomy	5	<59
Ginsberg & Rubinstein, 1994	123	Segmentectomy	17.5	76
Warren & Faber, 1993	74	Segmentectomy	21.6	56

* A wedge resection was utilized; postoperative radiotherapy appeared to improve survival and approached that of segmentectomy.
** Stage T1, NO; NS cancer.
NS, not significant; est., estimated

TABLE 37.1. RESULTS OF REPORTED SERIES OF LIMITED RESECTIONS FOR EARLY-STAGE LUNG CANCER IN PAST 20 YEARS*

In the few series that reported on patients resected with curative intent, the five-year survival rate ranged from 50% to 70% for T1, NO tumors, which is comparable to the results of lobectomy. Local recurrence rates in these series ranged from 5% to 17.5%, higher than the 5% seen after lobectomy (Table 37.1).[55,64,65 and 66]

The Rush-Presbyterian group has continued to report their extensive retrospective experience with segmentectomy as a curative treatment option for early lung cancer.[6,67] Most recently, they reported on 169 patients who underwent either a standard lobectomy (n=103) or a segmental resection (n=66) for pathologic stage I (T1, NO; T2NO) primary NSCLC. Patients in the segmentectomy group fared worse in terms of local recurrence, which was 22.7% compared to 4.9% after lobectomy. Five-year survival in the segmentectomy group was 45%, compared to 63% in the lobectomy group (p£0.035).

The North American Lung Cancer Study Group (LCSG) confirmed previous retrospective studies with a prospective, randomized trial. [41] Patients with T1, NO NSCLC were randomized to lobectomy (n=125) or limited resection (n=122: seg.=82, wedge=40). In this prospective study, the locoregional recurrence rate for lobectomy was 5%. There was a 2.4-fold increase in locoregional recurrence with limited resection (17%). There was a 30% increase in the overall death rate and a 50% increase in death with cancer for the limited resection group. There was no late functional advantage or decrease in perioperative morbidity for the limited resection group.

Wedge Resection

The reported series of wedge resections in the management of NSCLC have primarily involved compromise resections in patients with limited pulmonary reserve. However, there have been recent reports of intentional limited resections for small peripheral tumors after open and thoracoscopic procedures. [66] Little data exist to support the widespread use of wedge resection even for small peripheral tumors, except in the setting of pulmonary compromise. In the previously mentioned study of limited resection reported by the LCSG, 40 patients underwent wedge resection as a curative procedure. Even worse than segmentectomy, the locoregional recurrence rate was four-fold higher than the lobectomy group. No data on the results of precision-cautery dissection is available.

In summary, based on the available data, lobectomy and adequate nodal sampling or dissection should remain the mainstay of treatment for early-stage lung cancer.

In compromise situations, limited resection can be performed, but with an expected increase in locoregional recurrence and decreased five-year survival. Only rarely is a bilobectomy or pneumonectomy required for stage I tumors. Occasionally, proximal T1N0 or large T2N0 lesions require this enlarged resection to effect complete removal.

STAGE II (N1) DISEASE

When intrapulmonary lymph nodes either within the lung or at the hilum are involved with metastases, the overall survival following surgical resection for lung cancer decreases considerably. Also, to effect a complete resection, pneumonectomy is required with increasing frequency. In our experience, approximately 25% of stage II lung cancers require pneumonectomy for complete tumor extirpation by virtue of the size or portion of the primary tumor or involvement of hilar lymph nodes. [69]

In this group of patients, lung-preserving procedures may indeed allow less than a pneumonectomy to be performed. When lymph nodes involve the main bronchus or invade the adjacent pulmonary artery, sleeve resection of the bronchus with or without a vascular sleeve resection of the pulmonary artery can be employed to preserve lung function, allowing a lobectomy to occur. Although no randomized trial has ever been performed to assess the value of this vis-à-vis complete pneumonectomy, most studies do indicate that the survival rate, stage for stage, of a sleeve lobectomy or combined vascular sleeve resection is identical to that seen with pneumonectomy.[70] With right lower lobe tumors, involved lymph nodes at the origin of the lower lobe bronchus or near the middle lobe take-off necessitate that a bilobectomy be performed. Similarly, upper or lower lobe tumors invading the middle lobe often require bilobectomy for complete excision.

In this stage of disease, especially with hilar lymph node involvement, we believe that concomitant mediastinal lymph node dissection (versus sampling) should be carried out because the incidence of occult mediastinal lymph node involvement in presumed stage II disease is much greater than with presumed stage I and approaches 25% of all cases.

POSTOPERATIVE COMPLICATIONS

Major complications occur in 10% of patients operated on with stage I and II disease. [71,72,73 and 74] (See also Chapter 41.) In a review of 961 patients who underwent major pulmonary resection, there was a 2% mortality and a 17% morbidity: 9% had major complications, which included pneumonia, pulmonary embolus, bronchopleural fistula, empyema, arrhythmia, and respiratory failure, and 8% had minor complications. The morbidity and mortality following resection for stage I and II tumors is less than that seen in stage III disease.

In a 1983 LCSG study, 2,220 patients undergoing resection for lung cancer were analyzed. Eighty-one postoperative deaths occurred (3.7%). The mortality was 6.2% for pneumonectomy and 2.9% for lobectomy. Most recently, morbidity and mortality were prospectively analyzed in 783 patients. [75] This study may reflect current trends toward aggressive neoadjuvant chemotherapy. Mortality was 3.9%, and the major complication rate was a startling 27%. Complications occurred more often in men, in patients greater than 60 years of age, and in patients with a Karnofsky index of less than 9. The high incidence of morbidity in surgically resected lung cancer patients makes careful preoperative assessment and meticulous perioperative care mandatory. In our own center, postoperative mortality in stage I lung cancer resection approaches zero (1 death in the most recent 300 cases).

SURVIVAL

In the literature, survival following surgical treatment of stage I and II NSCLC varies considerably. [76,9,10,11,12 and 13,76,77,78,79,80,81,82,83,84 and 85] These differences may be related to the heterogeneity of the patient population, criteria for surgical resection, the proportion of patients in a subset (i.e., T1N0 versus T2N0), the extent of the staging process (mediastinoscopy versus mediastinal lymph node dissection versus sampling), and length of follow-up. Significant differences in survival exist even among patients with early-stage lung cancer. The best predictor of survival within each stage is in the comparison of the TNM subsets.

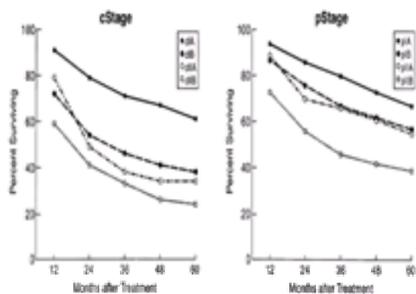
The overall survival for pathologic stage I and stage II disease was recently analyzed (Figure 37.4).[77] These results confirm that nodal involvement has the strongest adverse influence on survival, and results also demonstrate that a significant number of patients are clinically understaged. In our experience, overall survival for stage II is not only affected by the presence of N1 disease but also by the number of involved N1 nodes. [86] Furthermore, improved survival has also been noted in stage II patients with tumors less than 5 cm in size. [8] Several studies have also shown that histology may impact on survival. The LCSG reported an improved survival for squamous carcinomas versus nonsquamous lesions.[83,87] However, this difference has not been borne out in all series. It is important to note that within a given TNM category, it is impossible to predict which patients will experience a relapse of their disease.


FIGURE 37.4. Survival following clinical staging versus pathologic staging. (From Mountain CF. Revisions in the international system for staging lung cancer. *Chest* 1997;111:1710, with permission.)

Other prognostic factors, including gender, age, performance status, weight loss, and tumor location, have been analyzed. [15,17,18,36,41,86,88,89,90 and 91] None of these factors to date has clearly been proven to impact on survival. Numerous molecular and biologic markers are currently being investigated as predictors of survival in patients with NSCLC. They include tumor-associated antigens, aberrantly expressed genes, enzymes, hormones, or other biologic markers. The recognition and development of molecular markers has given new insight into our understanding of the biology of NSCLC. These markers may soon provide a more accurate method for predicting patient survival (See also Chapter 33).

PATTERNS OF FAILURE AND RECURRENCE

The majority of patients who are resected for stage I NSCLC will enjoy long-term, disease-free survival. [8,12,13,80,81,82 and 83,92,93] However, approximately one-third of resected patients will relapse. The majority of these relapses will be distant metastases, with the risk of a local recurrence after complete resection being less than 10%. The brain is the most common site of metastatic recurrence, followed closely by bone, ipsilateral and contralateral lung, liver, and adrenal. More than 80% of recurrences occur within 2 years.

The rate of recurrence for patients with stage II disease is high despite surgical treatment. More than 50% of resected stage II patients can be expected to relapse. Similar to all stages of lung cancer, most recurrences are distant and suggest a need for effective systemic therapy once nodal metastases have occurred. However, the role of induction and/or adjuvant chemotherapy with or without radiotherapy has not been well defined. The patterns of recurrence may differ by histology with more local recurrences seen for patients with squamous carcinoma and more distant metastases seen in patients with adenocarcinoma.

ADJUVANT THERAPIES

Although discussed elsewhere (see Chapter 42, Chapter 43, Chapter 44), adjuvant therapies following complete resection of stage I and stage II lung cancer have failed to make a significant impact. Neither chemotherapy, radiotherapy nor both modalities used in an adjuvant setting have improved survival significantly following

complete resection. This has been borne out in two recent metaanalyses of adjuvant chemotherapy and adjuvant radiotherapy. Also, a recent North American trial comparing postoperative adjuvant radiotherapy to adjuvant chemoradiotherapy in stage II and III lung cancer has failed to demonstrate an impact of the combined treatment.[94]

Because of the failures of adjuvant treatments and the apparent success of induction therapies in more advanced disease, studies are now being conducted to assess the value of induction chemotherapy followed by surgery in patients with clinically staged Ib and II disease. [95,96]

FOLLOW-UP

Resected NSCLC patients must be followed closely, not only for recurrences but also for new lung as well as nonthoracic primary malignancies. Patients with early-stage lung cancer were followed in a study by the LCSG for more than 5 years and were found to develop a significant number of new lung, breast, prostate, and colon cancers. In a recent analysis of 598 patients resected with stage I disease followed at Memorial Sloan-Kettering Cancer Center, 206 patients or 34% developed second cancers. One-third of these new primaries were lung cancers. This finding underscores the need to follow lung cancer patients closely postoperatively. We recommend that surgeons see their patients every 3 months for the first postoperative year, followed by every 6 months for 2 years, and then annually. Follow-up visits should include repeat chest x-rays and thorough physical examinations monitoring weight loss and respiratory and performance status. Screening blood work plays no role in routine follow-up of the postoperative patient. The value of CT scanning in follow-up is currently being investigated. The recommendations for close follow-up in general have recently been questioned in regards to cost-effectiveness. [97] In a small percentage of patients, disease relapse is confined to one local site without distant spread. These patients should be extensively reinvestigated. If no metastatic or mediastinal disease is discovered, such patients should be considered for re-resection and possible completion pneumonectomy. A recent analysis of patients undergoing completion pneumonectomy demonstrated a slightly higher mortality (10%) than patients undergoing pneumonectomy as their initial operation (6.2%), but a considerable number of patients were salvaged by this approach. [45]

FUTURE DIRECTIONS

Future directions in the surgical treatment of early-stage lung cancer await a variety of ongoing clinical trials. Currently, studies are evaluating the role of PET scanning in preoperative staging, whether complete ipsilateral mediastinal lymphadenectomy improves cure rates over lymph node sampling in stage I and II disease, and the role of genetic markers, immunohistochemical staining, bone marrow evaluation, PET scan activity (SUV), and pleural lavage as prognostic indicators. Also ongoing are trials analyzing the efficacy of 13- *cis*-retinoic acid as a chemoprevention agent for second primaries and the role of thoracoscopic wedge resection followed by radiation therapy for patients with severely compromised pulmonary function.

Although adjuvant and neoadjuvant therapies have yet to prove valuable following complete resection in these early stages of disease, trials are continuing to explore these treatments.

CONCLUSIONS

Surgical resection remains the gold standard for treatment of patients with stage I and II NSCLC who have potentially completely resectable lesions and adequate pulmonary reserve. Lobectomy and pneumonectomy afford the greatest chance for complete resection with the lowest recurrence rates and longest durable survival. Limited resections, either conventional or via video-assisted thoracoscopy have been advocated by some as an alternative to standard resections for patients with limited disease. These lesser resections have demonstrated alarmingly high local recurrence rates and shorter survival and should be considered compromise operations for patients who might not tolerate larger resections or who have synchronous disease necessitating more than one resection.

There is an increasing need for more accurate preoperative staging techniques for NSCLC. The current TNM staging system provides a method of standardization, improves our ability to determine ultimate prognosis, and allows us to identify groups that might benefit from trials of neoadjuvant and adjuvant therapy. As we push the treatment envelope further with investigational preoperative therapy, meticulous preoperative assessment becomes even more important if we are to reduce perioperative morbidity and mortality.

EXTENDED RESECTIONS FOR LOCALLY ADVANCED NON-SMALL CELL LUNG CANCER

WILLIAM H. WARREN
L. PENFIELD FABER

For half a century, complete surgical resection has been recognized as the cornerstone of curative management of carcinoma of the lung. Despite advances in chemotherapy and radiotherapy, a complete surgical resection, whenever possible, continues to be the best therapeutic option for most patients with locally advanced primary pulmonary carcinoma, either alone or in conjunction with adjuvant therapy.

The first complete, one-stage resection for a primary pulmonary carcinoma was performed more than 60 years ago.[1] The success of this operation and the long-term survival of the patient encouraged thoracic surgeons to further develop the field of pulmonary surgery. In the years that followed, it became evident that long-term survival for pulmonary carcinoma could be achieved, but only in the setting of complete surgical resection.[2]

This perspective emboldened thoracic surgeons to develop surgical techniques to resect tumors considered initially to be unresectable on the basis of local invasion of chest wall, mediastinal structures, or the diaphragm. In 1959, Chamberlain[3] proposed the term *extended resections* to distinguish these aggressive procedures from the *standard resections* of extrapericardial pneumonectomy and lobectomy. Analysis of the surgical experience that followed is, at best, problematic. Incomplete, "palliative" resections were sometimes combined with those that were "curative" (i.e., tumor completely resected). Results from resecting various mediastinal structures were often grouped together. Adjuvant radiotherapy, when given, was used sporadically. Even among complete resections, however, it is clear that initial perioperative morbidity was high, and long-term survival was poor.[4]

At least three factors contributed to these disappointing early results. First, there was only limited understanding of intraoperative and postoperative pathophysiology. The development of newer anesthesia techniques and agents, the availability of better monitoring, and improved surgical techniques have minimized perioperative complications. Second, much of this early experience with extended resections was performed before a clinicopathologic staging system was accepted. The adoption of an international staging classification for lung carcinoma and the development of sophisticated scanning techniques to detect extrathoracic metastases and to assess intrathoracic structures before operation have enabled surgeons to select cases more appropriately for these aggressive surgical resections. Third, we have come to recognize that the biologic behavior of certain tumors, such as poorly differentiated neuroendocrine carcinomas, precludes surgical cure even in the face of an apparently complete resection. In a retrospective histologic reevaluation of neoplasms resected as "small cell carcinoma," it was found that, among patients who survived beyond 3 years, in most cases the tumors would now be reclassified as *well-differentiated neuroendocrine carcinomas*.[5] Most believe that patients with poorly differentiated neuroendocrine carcinomas should not be considered for these extended surgical resections, despite the development of adjuvant chemotherapy and radiotherapy protocols. The exclusion of these latter cases has no doubt led to overall improved results.

During the past three decades, adjuvant radiotherapy protocols (see also Chapter 43) have been devised to improve the resectability rate and to reduce the incidence of postoperative locoregional recurrence. The results of these clinical trials suggest that, although the resectability rate may be improved, the five-year survival is not affected, with the exception of that for superior sulcus tumors[6,7,8,9 and 10] and possibly a subset of patients with N2 nodal involvement.[11,12 and 13] Because most patients with locally advanced disease die from distant metastases, the role of adjuvant multiagent concurrent chemotherapy and radiotherapy is being assessed (see also Chapter 44).

Despite these developments, some of these extended resections have not been widely accepted. In some cases, clinical experience has been limited, and many reports simply describe surgical technique without long-term follow-up. The purpose of this chapter is to review the development of these extended surgical operations, to present the technical aspects of these resections, and, when possible, to discuss their applicability in the modern surgery.

INTRAPERICARDIAL PNEUMONECTOMY

Radical pneumonectomy was first described by Allison[14] as an approach to performing *en bloc* complete mediastinal node dissection with intrapericardial ligation of the pulmonary vessels. Some surgeons adopted intrapericardial dissection as the approach of choice in performing a pneumonectomy,[15,16] although the advantages and logic of this approach were challenged by many.[17,18,19 and 20] Although few now use an intrapericardial approach as a matter of routine, it remains a useful technique when the tumor has directly involved the pericardium, foreshortened the pulmonary veins, or invaded the left atrium. The intrapericardial approach also provides access to the proximal pulmonary artery and the superior vena cava (SVC) when the tumor involves the pericardium over the hilum.

Preoperative computed tomographic (CT) scans and magnetic resonance imaging (MRI) are of limited value in distinguishing involvement of the pericardium and intrapericardial pulmonary veins from involvement of the left atrium.[21,22,23,24 and 25] Two-dimensional echocardiography, transesophageal ultrasound endoscopy, and intraoperative ultrasonography may be more valuable in this regard.[26,27]

Technical Considerations

An incision is made in the pericardium anterior to the superior pulmonary vein but sparing, if possible, the phrenic nerve, which is often drawn up into the field of dissection. After entering the pericardium, the incision is carried superiorly and inferiorly to identify the pulmonary artery and to identify the inferior pulmonary vein. The intrapericardial extent of tumor must be carefully assessed. If the intrapericardial length of vein is free, then it can be stapled or divided and oversewn.

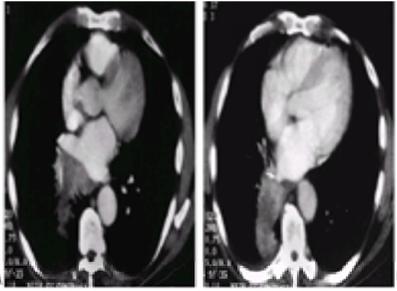
On occasion, a tumor directly invades the wall of the left atrium. Under these circumstances, a vascular clamp can be placed on the left atrium (Figure 38.1), taking care not to compromise the pulmonary venous drainage from the contralateral lung. The left atrium should be closed in a running double layer of 3-0 monofilament nonabsorbable suture. Bailey and colleagues[28] described three patients who underwent cardiopulmonary bypass to resect larger portions of the left atrial wall with reconstruction using a pericardial patch to avoid a restrictive left atrium.


FIGURE 38.1. A: CT scan demonstrating right lower lobetumor abutting the posterior pericardium and the superior pulmonary vein. **B:** Same patient as **(A)** with tumor obstructing inferior pulmonary vein but not invading left atrium.

The intrapericardial approach also allows proximal dissection of the pulmonary artery. On the right side, the pericardium is opened anterior to the phrenic nerve, and the pulmonary artery can be dissected out at the bifurcation. The pulmonary artery can be secured either by stapling or by clamping and oversewing. Simple or double ligation is not sufficient.

Care must be taken to assess whether the tumor directly involves the posterior wall of the SVC. If the SVC is involved, resection and reconstruction can be performed (see also Chapter 62 and later in this chapter).

On the left side, the division of the ligamentum arteriosum provides optimal exposure to the proximal left pulmonary artery, which can be managed in a fashion similar to the right. Ricci and colleagues[29] reported on three cases of resection and reconstruction of the proximal left main pulmonary artery in conjunction with a left pneumonectomy under cardiopulmonary bypass using a median sternotomy.

Results

Although thoracic surgeons are familiar with intrapericardial dissection, it is associated with an increased incidence of supraventricular arrhythmia, and few occasions exist when it is necessary. However, when tumors directly invade the pericardium or foreshorten the pulmonary vessels, intrapericardial dissection is successfully performed with acceptable perioperative morbidity and mortality.

One of the most dramatic complications of intrapericardial dissection is cardiac torsion, whereby the heart herniates through the defect, resulting in diminished cardiac return.[30,31,32,33,34,35 and 36] This complication almost always occurs within the first three days of surgery and is often precipitated by a change in position or forceful coughing. With right-sided herniation, kinking of the SVC, inferior vena cava, and pulmonary artery causes sudden hypotension, tachycardia, cyanosis, and venous congestion. Therefore, a right-sided pericardium defect must be closed, either primarily or with a patch. Parietal pleura, fascia lata, pedicle flap of diaphragm, and prosthetic material (e.g., Gore-Tex, Dacron, Vicryl mesh) have all been used. [35,36 and 37]

On the left side, similar attempts must be made to close the defect primarily whenever possible. Herniation of the heart through a restricting left-sided defect can present as myocardial ischemia from compression of the coronary arteries at the edge of the defect. [35,38] There have also been reports of tearing of the inferior vena cava, right ventricle, or coronary vessels. [35,39] Therefore, when a moderate-size defect persists on the left side, the pericardium should either be widely resected (to allow free mobility of the heart out of the pericardial sac into the pleural space) or closed with a patch, as on the right side. Even when the defect is patched, there has been a report of the patch tearing free, resulting in cardiac herniation. [36] There have also been isolated reports of this complication occurring 14 weeks after a left upper lobectomy with intrapericardial dissection [40] and after a pericardiotomy for trauma without pulmonary resection.[36] Therefore, the surgeon must be alert to this complication whenever the pericardium has been opened.

Because intrapericardial dissection is usually performed in conjunction with the resection of mediastinal structures (including pericardium, phrenic nerve, SVC, left atrium, carina, and aorta) and for tumors with and without mediastinal node involvement, interpretation of the results of this approach is problematic. According to Pitz and associates, tumors found to involve the mainstem bronchus but sparing surrounding mediastinal structures (especially T3 N0) have a better prognosis than tumors with invasion of mediastinal pleura, pericardium, and/or phrenic nerve. [41] Predictably, the best results have been reported when invasion is limited to the pericardium and in the absence of mediastinal nodal metastases.

Patients have survived longer than 5 years when this approach was used to dissect out pulmonary veins. [42,43] In contrast, when the tumor involves the wall of the left atrium, the results are much more discouraging. Of 29 patients undergoing complete resection by pneumonectomy or lobectomy with resection of a portion of the left atrium, the longest survivor is 36 months. [28,44,45,46,47,48,49 and 50] None of the three patients who underwent *en bloc* resection of left atrial wall in the Rush-Presbyterian-St. Luke's (RPSL) experience survived beyond 2 years, despite the use of adjuvant chemotherapy and radiotherapy. Clearly, tumors that invade the wall of the atrium have a worse prognosis than tumors limited to the pulmonary veins or the pericardium. Preoperatively and even intraoperatively, however, such a distinction may be difficult. Two-dimensional echocardiography may be valuable in this regard. [26]

Levett and colleagues[51] reported their experience resecting eight patients with intrapericardial left pneumonectomies with bulky disease in the aortopulmonary window; no patients survived beyond 2 years despite adjuvant chemotherapy. Ricci and colleagues[29] reported their experience with three patients who underwent left pneumonectomy with *en bloc* resection of the origin of the left main pulmonary artery on cardiopulmonary bypass; one patient survived beyond 2 years.

Survival beyond 5 years has been reported when intrapericardial dissections were performed for major pulmonary resections with *en bloc* resection of the carina, a portion of the SVC, and the muscular wall of the esophagus (see following).

SLEEVE PNEUMONECTOMY

Carinal involvement by tumor occurs either primarily from spread through the mucosa or submucosa, or from peribronchial tissues, or secondarily from tumor invasion from metastatic nodes at the tracheobronchial angle or subcarinal space.

Tumor involvement of the carina was initially considered to be a contraindication for complete resection; however, endeavors to resect at least portions of the carina can be traced as far back as 1950.[52] Such early attempts were limited by anesthetic techniques and were limited to resection of the tracheobronchial angle using an atrial clamp. This technique not only provided only a minimal resection margin but also tended to narrow the left mainstem bronchus. The first successful carinal resection for carcinoma, with reconstruction using an end-to-end anastomosis, was reported by Mathey and colleagues in 1966. [53] Other reports ensued as surgical and anesthetic techniques evolved. [54,55,56,57,58,59,60,61 and 62] Although cardiopulmonary bypass has been used successfully to accomplish complicated tracheal and carinal resections, it has been surpassed by the use of small endotracheal tubes and the jet ventilation catheter, which provides better exposure and safer control of the airway. Intraoperatively, transesophageal ultrasonic endoscopy and intraoperative ultrasonography have both been used with superior results. [27]

Sleeve pneumonectomy should be considered for patients with large, central carcinomas that are otherwise resectable, with limited involvement of the carina as assessed by bronchoscopy or CT findings. At bronchoscopy, thickening and corrugation of the mucosa at the tracheobronchial angle indicates submucosal infiltration of tumor. Narrowing of the orifice of the proximal mainstem bronchus also should alert the surgeon that the patient may require a more extended resection than a standard pneumonectomy. Involvement of the trachea should be limited to less than 3 cm in length because resections of the trachea and left mainstem bronchus of 4 cm or longer tend to put excessive tension on the anastomosis.[63]

Mediastinal nodes assessed to be larger than 1 cm by CT should undergo biopsy by mediastinoscopy. The presence of positive mediastinal nodes above the tracheobronchial angle indicates a poor prognosis and has led some [63,64] to consider these cases to be inoperable. However, others [61] believe that if metastatic

disease is confined to the ipsilateral tracheobronchial angle or subcarinal nodes, the patient should be considered for preoperative adjuvant chemotherapy and radiotherapy, and the surgeon should proceed with the appropriate resection (Figure 38.2, Figure 38.3, Figure 38.4 and Figure 38.5).

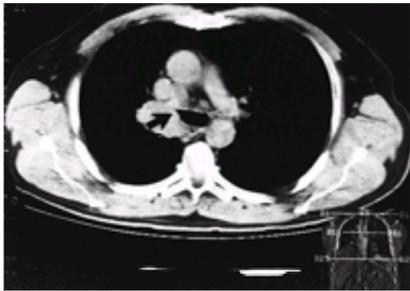

FIGURE 38.3. CT scan showing extensive involvement of the right tracheobronchial angle in the same case as in Figure 38.2. Note the compression of the right mainstem bronchus (*arrow*).
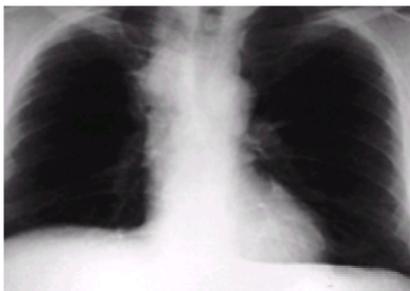

FIGURE 38.4. Posteroanterior radiograph of same patient as in Figure 38.2 after four cycles of preoperative combined chemotherapy and radiotherapy. Note that the mass is significantly smaller and that the right lung is fully reinflated.

FIGURE 38.5. CT scan of same patient as in Figure 38.2 after four cycles of preoperative combined chemotherapy and radiotherapy. Involvement of the right tracheobronchial angle is still evident but more limited.

Patients older than 65 years are not good candidates for sleeve pneumonectomy because they tolerate this procedure poorly, and their long-term survival is lower than in younger patients. Each patient, however, must be considered individually. A careful physiologic assessment is mandatory, including complete pulmonary function tests and quantitative ventilation–perfusion lung scans if the FEV $_1$ is less than 1.8 L or less than 50% of predicted.

Technical Considerations

Careful anesthetic planning is mandatory when sleeve resection is contemplated. The anesthesiologist must be prepared to ventilate the remaining lung for 30 to 45 minutes through an open trachea while the anastomosis is being performed. High-frequency ventilation can be achieved through a 2-mm catheter passed through an 8-mm standard endotracheal tube. The advantages of this technique are that it allows for adequate ventilation and oxygenation and provides excellent exposure during the anastomosis. Intraoperative bronchoscopy is performed as indicated.

Alternative techniques include the use of an uncut single-lumen endotracheal tube, which can be intermittently passed down the left mainstem bronchus, or a sterile second endotracheal tube, intermittently passed over the surgical field and down the distal bronchus during the anastomosis. Double-lumen tubes offer no advantage over these techniques and make the exposure for the anastomosis considerably more difficult. Limited experience with cardiopulmonary bypass for complex carinal resections has been fraught with complication of parenchymal hemorrhage into the remaining lung and should be avoided at all costs. [64]

The technique of sleeve pneumonectomy has been well described elsewhere. [56,60,61] The preferred approach at RPSL for a right sleeve pneumonectomy is a posterolateral thoracotomy through the fourth intercostal space. The patient is not positioned to allow for a laryngeal release, but could be repositioned for an anterior cervical approach if this became necessary. The azygos vein is ligated and divided, and resectability is assessed. If necessary, portions of the SVC or the muscular wall of the esophagus can be resected (see also Chapter 62. Care is taken to preserve blood supply of the distal trachea and the left mainstem bronchus. Dissection

is begun along the anterior and posterior aspects of the trachea, preserving the lateral blood supply above and below the levels of transection; mediastinal lymphadenectomy is performed, with care taken not to injure the small arterial branches. During this part of the procedure, the endotracheal tube can be advanced down the left mainstem bronchus to optimize exposure. If any question exists about carinal involvement, a pneumonectomy can be performed and a frozen section obtained of the bronchial resection margin.

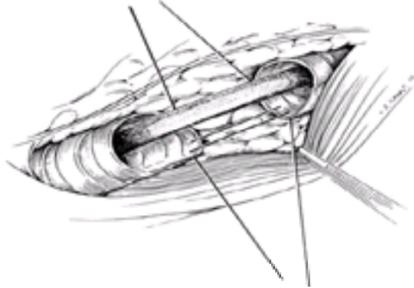
Once the need for carinal resection is confirmed, the distal trachea and left mainstem bronchus are dissected out. The left recurrent laryngeal nerve is sometimes seen at the left tracheobronchial angle. If necessary, it may be divided because the right laryngeal nerve should be out of the field of dissection. The thoracic duct or one of its branches is sometimes injured at this point, and a chylous leak should be carefully sought. Major lymphatic channels should be oversewn; metal clips should be avoided because they tend to sever the walls of these fragile vessels. The trachea is then transected 1 to 3 cm above the carina, and the left mainstem bronchus is transected as close to the carina as possible. No attempt is made to compensate for lumen disparity. The jet ventilation catheter is advanced down the left mainstem bronchus under direct control (Figure 38.6).


FIGURE 38.6. Operative view of the anastomosis of the left mainstem bronchus to the distal trachea. Note the use of a jet ventilation catheter to facilitate placement of the sutures while maintaining ventilation to the left lung.

Frozen sections of the proximal and distal tracheobronchial resection margins are obtained. A positive resection margin is an indication for additional resection, if this action will not place undue tension on the anastomosis. The anastomosis is performed using interrupted 3-0 polyglycolic sutures. Traction sutures of 2-0 polyglycolic acid are placed at the lateral resection margins of the trachea and the mainstem bronchus to relieve tension while the anastomotic sutures are being tied. If necessary, the traction sutures can be tied for additional support. The anastomosis should be covered with viable tissue to seal minute leaks and to minimize complications of a small anastomotic separation. A mediastinal fat pad obtained from the anterior mediastinum draping over the pericardium, a pleural flap, or an intercostal muscle bundle can be used.

Although there has been some experience performing a left sleeve pneumonectomy through a left posterolateral thoracotomy with mobilization of the aortic arch,[57,65] in most cases, this was performed for low-grade tumors with little or no extension into the peribronchial tissues. In bulky, central tumors, a left posterolateral thoracotomy usually does not provide adequate exposure for a carinal resection and reconstruction. If a positive bronchial resection margin is encountered in the course of a left pneumonectomy (such that a carinal resection is necessary), then the bronchus should be closed despite a positive resection margin, deferring the carinal resection through a right thoracotomy for 4 weeks, as described by Gilbert and colleagues.[66] The obvious morbidity and mortality of these two major procedures must be weighed against the technical difficulties of approaching the dissection and the anastomosis of the right mainstem bronchus through the aortopulmonary window. An alternative approach to left sleeve pneumonectomies is to perform a right thoracotomy first, resecting the carina and performing the anastomosis of the right mainstem bronchus to the trachea, stapling the left mainstem bronchus, and dividing the left pulmonary artery to minimize shunting. A left thoracotomy is subsequently performed to complete the resection.[63]

Experience using a median sternotomy to perform a left sleeve pneumonectomy has been limited to low-grade tumors (such as adenoid cystic carcinoma) and is unlikely to provide adequate exposure in the case of a central bronchopulmonary carcinoma. Another approach that has been used is the clamshell incision through the fourth intercostal space; however, this procedure comes at great physiologic cost to the patient, according to Mitchell. [64]

Results

According to the surgical literature, most sleeve pneumonectomies are performed for squamous carcinoma. Most patients are male, with an average age of 55 years. Most of these resections are performed for central carcinomas of the right lung.

Anastomotic complications are frequent. Stenosis of the anastomosis can occur, leading to retained secretions and respiratory failure. Dilation and placement of endobronchial stents have been successfully used in this setting. In cases with exuberant granulation tissue, YAG laser photoablation should be considered.

Adult respiratory distress syndrome complicating sleeve pneumonectomy continues to be a major problem and has been reported in all series.[56,58,59,63,65] Restriction of intraoperative and postoperative fluid intake, prompt clearance of retained secretions, and institution of broadspectrum antibiotics at the first sign of a pulmonary infiltrate are important measures to minimize this risk.

The operative mortality, even in this select group of patients, is significant, ranging from 11% to 25%[64,65,67,68,69]; the RPSL overall operative mortality is 23% (10/43) for sleeve pneumonectomy, 20.5% (8/39) for right sleeve pneumonectomy.[61] Candidates for this procedure should therefore be carefully chosen, and surgeons should know the many aspects of the postoperative care and management of complications as well as the technique of the procedure.

In the largest published series, Dartevelle and colleagues[69] reported a 23% (6/55) five-year survival. In their series, there was a difference in survival in patients with involved subcarinal nodes (mean survival, 33 months) compared to those with involved paratracheal nodes (mean survival, 11 months). In the RPSL series of 43 sleeve pneumonectomies (including patients with positive mediastinal nodes), the five-year survival was 19%. [60,61]

The largest experience with left sleeve pneumonectomy for carcinomas was reported by Gilbert and colleagues. [66] Of the five cases reported, three patients had staged thoracotomies and an additional two had a local recurrence in the left mainstem bronchial stump. There were no operative deaths; three patients lived for at least 2 years; and one patient lived for at least 4 $^1/_2$ years.

Local recurrence is a well-recognized late complication if adjuvant radiotherapy has not been used. Some have advocated postoperative radiotherapy. The most common cause of death is systemic recurrence. To minimize the risk of local recurrence, the risk of distant metastases, and the incidence of incomplete resections, preoperative chemotherapy and radiotherapy should be used in these T4 carcinomas. [60] Preliminary experience in the RPSL protocol indicates that, in most cases, significant tumor shrinkage occurs with little or no deleterious effect on anastomotic healing. These resections, however, require considerable clinical judgment and should only be performed by experienced thoracic surgeons who are able to recognize and manage the various intraoperative and postoperative complications.

RESECTION OF PORTIONS OF THE SUPERIOR VENA CAVA (SEE ALSO CHAPTER 62)

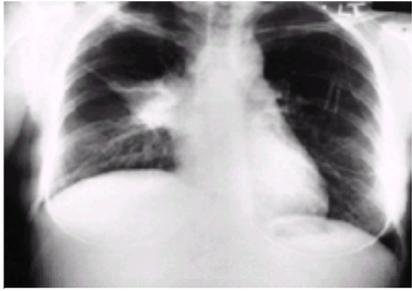
The SVC may be invaded directly by a carcinoma arising in the anterior segment of the right upper lobe or secondarily by tumor metastatic to the right paratracheal or right tracheobronchial angle nodes (Figure 38.7). Traditionally, involvement of the SVC has been a criterion of unresectability. Early attempts to resect a portion of the SVC involved clamping and direct repair and provided discouraging results, in part attributed to cerebral venous congestion and hypoxic injury. [70] Therefore, both external bypass and internal shunts have been devised to maintain cerebral drainage while resection and reconstruction is being performed. [71,72 and 73]


FIGURE 38.7. Posteroanterior radiograph demonstrating a large, central adenocarcinoma with associated mediastinal adenopathy involving the superior vena cava. Note the volume loss of the right lung.

During the past 15 years, there has been considerable experience using these techniques for the resection of bulky mediastinal tumors and selected primary lung carcinomas, particularly in patients who underwent adjuvant therapy. Accumulating laboratory and clinical evidence suggests that simple clamping of the SVC can be tolerated in most patients for periods longer than 30 minutes without neurologic deficiency,[73,74,75,76 and 77,79,80] provided no associated hypotension is present. Nakahara and colleagues[74] advocated selecting patients for shunting on the basis of subclavian venous pressure greater than 40 cm H_2O. Based on its experience, however, RPSL continues to advocate an SVC bypass whenever technically possible to minimize the risk of cerebral venous congestion. [78,81]

The indication for resection and reconstruction of the SVC is restricted to tumors confined to the thorax otherwise considered to be resectable, with involvement of the SVC that is technically resectable. In most cases, resection of a portion of the SVC wall is all that is necessary, and this can be reconstructed with a patch. When the tumor encases the SVC, complete resection and reconstruction with a tube graft of 18 or 20 mm polytetrafluoroethylene (PTFE) is necessary. [76,77] The superior anastomosis is performed first, and the graft is flushed of air prior to completing the anastomosis at the cardiac end of the graft. When the SVC is obstructed from mediastinal involvement of carcinoma of the lung, however, most agree that resection is contraindicated.

Technical Considerations

Whenever involvement of the SVC is suspected, central venous catheters should be avoided because this compromises venous control. Through a posterolateral thoracotomy, the involvement of the SVC is assessed before committing to a major pulmonary resection. The azygos vein is routinely divided. Umbilical tapes are passed around the innominate veins or the SVC above the tumor. The pericardium is opened close to the hilum, sparing the phrenic nerve if possible. The surgeon must then assess the intrapericardial extent of the tumor, including the proximal right pulmonary artery and involvement of the carina. A Rumel tourniquet should be placed proximal to the atriocaval junction to avoid potential injury of the sinoatrial node.

The pulmonary resection is performed first. Although an *en bloc* resection is ideal, if the tumor is bulky, the specimen may be transected, leaving tumor on the SVC. With the pulmonary specimen out of the surgical field, the resection of the SVC is greatly facilitated.

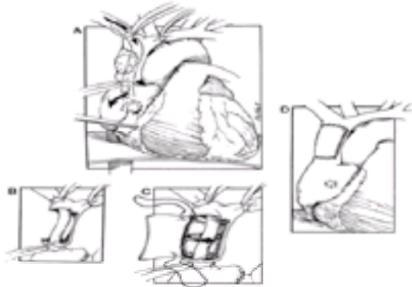
If the planned resection is limited to a portion of the SVC wall, a 20F thoracostomy tube is prepared to serve as an internal venous shunt (Figure 38.8). The distal end of the tube must be trimmed so that only two or three side holes remain and are beyond the proximal innominate tourniquet. The tube is then measured against the length of the SVC and the right atrium. A proximal side hole is then cut in the tube to allow the shunted venous blood to drain into the atrium.


FIGURE 38.8. Operative views of **(A)** placement of an internal shunt and isolation of the superior vena cava (SVC) with tumor invasion of the wall; **(B)** resection of the wall of the SVC, leaving the uninvolved medial wall intact; **(C)** closure of the defect with a patch of pericardium; and **(D)** removal of the shunt with distension of the SVC without narrowing.

The patient is then anticoagulated with 5000 U sodium heparin, and a pursestring suture is placed in the side wall of the right atrium. A small incision is made in the right atrium, and the clamped chest tube is advanced through the right atrium and up the SVC. Once the tourniquets are at the atriocaval junction and the innominate veins are tightened, the SVC should be effectively isolated and can be opened. The affected portion of the SVC can then be safely resected, in most cases, retaining a portion of the medial wall to allow a patch closure (Figure 38.9). Although some surgeons have experience using prosthetic material,[74,75 and 76,80,81,82 and 83] others prefer using autologous pericardium, primarily because of the decreased thrombogenicity (Figure 38.10). Bypass of the SVC for SVC syndrome is covered in detail in Chapter 43.

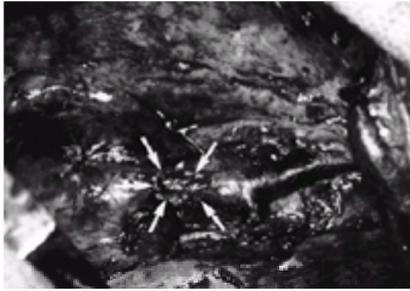
FIGURE 38.9. Operative photograph showing wall of superior vena cava resected and tourniquets in place. Note the placement of the shunt through the right atrium at the left of the photograph, with tourniquet in place (*arrow*).


FIGURE 38.10. Operative photograph in same patient as in Figure 38.9 after placement of pericardial patch (*arrows*) and removal of shunt.

Results

On reviewing the surgical literature, fewer than 50 cases of SVC resection for pulmonary carcinoma have been reported, many with limited follow-up.

Long-term patency of the SVC after reconstruction has been documented by venography[79] and clinical follow-up, including autopsy.[75] However, thrombosis is a recognized complication of spiral vein grafts when used in benign disease to shunt the SVC [82,84] and in SVC reconstruction for bulky mediastinal malignancies.[76] On the basis of this experience, most surgeons choose to anticoagulate patients with sodium warfarin (Coumadin) for at least 3 months.

Analysis of the survival of patients undergoing resection of the SVC is, at best, limited. The largest series consist of six or fewer cases. In many cases, the SVC resection was part of a larger procedure. In two of three patients in Nakahara's series, [74] one of six patients in Dartevelle's series, [75,76] and one of six in the RPSL series,[78,81] the SVC resection was combined with a right sleeve pneumonectomy.

The prognosis for these patients is guarded. In the experience of the Memorial Sloan-Kettering Cancer Center, [46] no five-year survivors were among 18 patients undergoing *en bloc* resections of the SVC. In the experience of Dartevelle and colleagues, [75] three of six patients survived beyond 1 year, and the 3-year survival was 33% (2/6). In the RPSL series,[78,81] three of nine patients presently with lung carcinoma are alive and free of disease more than 5 1/2 years after resection; Inoue and colleagues[79] and Dartevelle and colleagues[75,76,85] have each reported five-year, disease-free survivors after SVC resection. Most of these five-year survivors had adjuvant chemotherapy and radiotherapy.[78,79,81]

Although SVC resection and reconstruction are technically possible in patients presenting with SVC occlusion, Dartevelle and colleagues [75,76] believe that the presence of extensive thrombosis and collateral venous drainage are contraindications to reconstruction. Mori and colleagues [83] reported on two patients with primary pulmonary tumors presenting as SVC obstruction who underwent resection and reconstruction with ringed PTFE grafts. Neither patient developed recurrence of the SVC obstruction; one was alive at 7 months, and the other died 22 months after resection from massive hemoptysis. Certainly, the presence of an SVC syndrome carries a poor prognosis, and SVC resection and reconstruction should be performed in only select cases.

Most of these patients die from distant metastases. According to Dartevelle and colleagues, [75] neither of the two patients who presented with N2 nodal metastases survived beyond 8 months. One of three patients reported on by Nakahara and colleagues [74] presented with N2 nodal involvement and died 5 months later with systemic metastases. Yoshimura and colleagues[3] reported on one patient with N2 nodal metastases who died with a cerebral metastasis 3 months later. The survival is better for patients with N1 or N0 disease. For these reasons, adjuvant chemotherapy and radiotherapy should be instituted preoperatively in these T4 carcinomas, [86] and every attempt should be made to exclude distant metastases before resection.

EXTENDED RESECTIONS FOR SUPERIOR SULCUS TUMORS

Since the early 1960s, the role of surgical resection of superior sulcus tumors has been established (see also Chapter 39). Contraindications to surgery have been the presence of distant metastases, extensive involvement of the brachial plexus, and extensive involvement of the paraspinal extension, including involvement of the intervertebral foramina or the bodies or laminae of the thoracic vertebrae. Likewise, the involvement of the subclavian artery or vein, while distinctly uncommon among these tumors, has been traditionally regarded as a criterion of unresectability. Resections "extended" beyond those classically performed for superior sulcus tumor have included carcinomas involving the transverse process, or up to one-fourth of the vertebral body, and anterior tumors involving the subclavian vessels. Although experience with these resections is still limited, the techniques involved and the preliminary results merit review.

Similar to all other extended surgical procedures, careful preoperative planning is of the utmost importance. Involvement of the head of the rib, the transverse process, and the vertebral body should be assessed by CT scan or MRI. Extension into the spinal canal, with or without cord compression, is a sign of unresectability. If the tumor extensively destroys the body, then it is considered inoperable, but a tumor that simply abuts the vertebral body should be considered for resection. Extension into the intervertebral foramen must be anticipated to avoid excessive traction on the nerve root or bleeding in this region.

Anteriorly, tumor metastatic to the scalene node is a criterion of inoperability. Extensive involvement of the brachial plexus is a relative contraindication to surgical resection. Although some consider the involvement of N2 nodes to be a contraindication to surgery, others believe that these cases should be entered in a trial of preoperative combination chemotherapy and radiotherapy, and restaged before resection. [86]

Technical Considerations

Extended Posterior Resections

The operative approach in patients with extensive posterior disease is through a high posterolateral thoracotomy, dividing the trapezius and rhomboid muscles as well as the latissimus dorsi and the serratus anterior to provide optimal exposure. The pleural space is entered early in the procedure to assess the pulmonary component of the tumor. The chest wall resection is performed before the pulmonary resection because exposure of the hilum is limited. The superior and posterior components of the dissection are determined by the extent of the tumor mass. The scalenus anterior and medius are divided either at the insertion onto the first rib or higher if necessary. The affected ribs, intercostal muscles, and vessels are divided anterior to the tumor mass, and the first rib is pulled inferiorly to expose the superior extent of the tumor. The subclavian vessels are identified and dissected off the first rib. Dissection of the subclavian artery off the tumor mass may be tedious but can usually be accomplished through an adventitial plane. Occasionally, branches of the subclavian artery have to be sacrificed, including, on occasion, the vertebral artery. [87] The lower trunk of the brachial plexus must then be identified and examined for tumor involvement. If any question exists about the ability to save the T1 or C8 nerve root, division may be deferred until further dissection of the posterior elements.

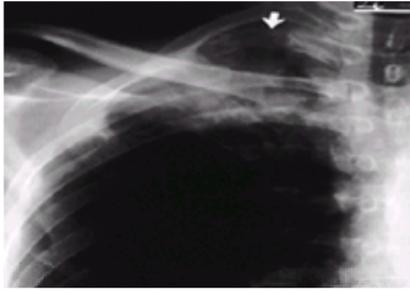
Division of the posterior elements begins inferiorly by rotating the chest wall anteriorly and retracting the erector spini complex posteriorly. If the transverse process is not involved in the tumor mass, then the costotransverse junction is opened using a periosteal elevator, and the rib is rotated anteriorly. The intercostal nerves and vessels are then ligated and divided. Bipolar cautery should be used near the intervertebral foramina. The tumor is then elevated off the thoracic spine. The transverse process can be resected using rib shears. If the transverse process or the vertebral body is involved, an osteotome is used to complete the resection, approaching the body tangentially from the posterolateral aspect (Figure 38.11 and Figure 38.12). Up to 25% of the vertebral body can be removed without compromising spinal support. Walsh, et al. reported four cases of Pancoast tumor with extensive involvement of the thoracic spine, necessitating resection up to one-half of the vertebral body at several levels. [86] The spine was reconstructed for stability. In the Walsh experience, complete resection was accomplished; however, patients had poor outcome secondary to ventilator dependence and radiation pneumonitis. Dartevelle has resected seven such patients with spinal reconstruction, and six are alive without recurrence with a median follow-up of 1 year. [69]


FIGURE 38.11. Posteroanterior radiograph illustrating a squamous carcinoma with extensive involvement of the posterior chest wall. Note destruction of the posterior aspect of the second rib (*arrow*).
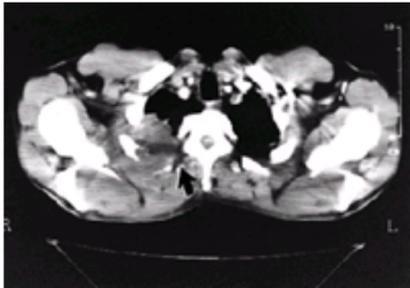

FIGURE 38.12. CT scan of same patient as in Figure 38.11 demonstrating destruction of the rib and the transverse process (*arrow*), but without involvement of the vertebral body.

The sympathetic chain is divided. As the head of the first rib is approached, the serratus posterior is divided, and the status of the C8 and the T1 nerve roots can be further assessed. If one or both are involved, they should be divided at this point. Division of the C8 nerve root causes some loss of sensation over the inner aspect of the arm to involve the fifth finger and part of the fourth finger.

Extended Anterior Resections

If, clinically or radiologically, the carcinoma is assessed to involve the subclavian vessels extensively and predominantly, an anterior approach is indicated. The anterior approach should be reserved for those cases in which the posterior chest wall is largely spared.

The patient is placed in the supine position, with the neck extended and the head turned to the uninvolved side. An L-shaped incision is made, with the vertical limb over the anterior border of the sternocleidomastoid muscle and the horizontal limb over the inferior aspect of the medial end of the clavicle. The sternocleidomastoid is dissected off the clavicle. The scalene fat pad is dissected out and examined microscopically to assess for metastatic disease. If the tumor is deemed resectable and the scalene node is free of metastasis, then the medial third of the clavicle is resected to provide excellent exposure of the subclavian vessels, according to the Dartevelle technique. Nazari et al. and Spaggiari have performed this resection by disarticulating the clavicle, dividing and reconstructing the clavicle at the completion of the case or dividing the manubrium [89,90 and 91] (Figure 38.13). On the left side, dissection of the subclavian vein is begun with ligation of the thoracic duct. Ligation and division of the internal jugular vein affords excellent exposure of the innominate and the distal subclavian veins. Direct tumor invasion of the subclavian vein does not preclude resection; a segment of the subclavian vein can be resected *en bloc* with the specimen after proximal and distal control is achieved. Reconstruction of the vein is not necessary.

FIGURE 38.13. PA radiograph after anterior and posterior approaches to a Pancoast tumor with reconstruction of the left clavicle.

Attention is then turned to the subclavian artery and its branches. After proximal and distal control is achieved, branches, including the internal thoracic artery, the thyrocervical trunk, and, if necessary, the vertebral artery, can be ligated and divided. Often, the subclavian artery can be dissected off the tumor mass using a subadventitial plane. If the tumor mass invades the wall of the subclavian artery, then a segment of the artery can be resected with the specimen; revascularization is usually accomplished by end-to-end anastomosis without prosthetic material, but in some cases, an arterial graft is necessary. Most experience has been with PTFE.[87]

The scalenus medius is divided remote from the tumor mass. The branches of the brachial plexus are then dissected from the distal branches back to the spinal foramina, depending on the level of tumor involvement. The sympathetic chain, the heads of the ribs, and the vertebral bodies are then exposed; the first and second ribs can often be divided behind the mass.

Improved exposure to the posterior aspect of the tumor can be achieved if the incision is extended into the deltopectoral groove, according to Dartevelle and colleagues.[87] If both anterior and posterior exposure is necessary, then the anterior dissection is performed first, and the resection is completed using a posterolateral thoracotomy.

Results

Reported surgical experience with these extended posterior surgical resections has been limited. According to Shaw and colleagues, [6] DeMeester and associates,[92] Wright and colleagues, [93] and Paulson and coworkers,[94] minimal additional operative morbidity or mortality occurred in patients who underwent extended posterior resections (including resections of the transverse process or a portion of the vertebral body) when compared to the more traditional resections.

Despite the extent of disease, according to DeMeester and colleagues, [91] only 3 of 12 patients with tumor adherent to the vertebral column developed local recurrence, and the overall five-year survival was 42%.

Most patients die from distant metastatic disease. According to Paulson and colleagues, [94] few patients survive beyond 2 years with an extended posterior resection. This view is shared by Santori and colleagues, [95] who reported that none of eight patients with vertebral body erosion survived beyond 1 year. According to Wright and associates,[93] vertebral body involvement does not preclude long-term survival, but none of their five patients demonstrated bony destruction by CT scan preoperatively. In that series, one of five patients was alive 36 months after resection of a portion of the vertebral body. DeMeester and colleagues [92] reported experience with 12 patients with tumors abutting the spine. The resected specimens were decalcified and assessed regarding the level of invasion; neither of the two patients who had cortical bone destruction survived beyond 3 months, whereas of six patients with tumor confined to the vertebral periosteum, two patients survived beyond 5 years, and two others were alive 1 to 5 years after resection. Accordingly, the most favorable results are seen in tumors without obvious destruction of the vertebral body. Although CT scans are sometimes helpful in identifying bony destruction, they are not entirely reliable in ruling it out. MRI may be marginally superior to CT in demonstrating bony destruction.[96]

Combined radiotherapy and surgery provides better palliation of pain in these patients than irradiation alone. Moreover, these survival statistics are a vast improvement over the results of radiotherapy alone with a local recurrence rate of more than 50% among which there are no two-year survivals. [97,98]

The largest experience with extended anterior transcervical–thoracic resections has been reported by Dartevelle and colleagues. [87] These authors reported no significant operative morbidity and no mortality in 29 patients, 20 of whom also underwent a posterolateral thoracotomy to complete the posterior part of the resection. Twelve of the 29 patients had involvement of the subclavian artery or its branches, and nine of these patients required reconstruction. The branches of the subclavian artery, including the vertebral artery, have been successfully ligated without cerebrovascular insufficiency, provided the patient has good collateral flow. [87] Revascularization of the subclavian artery, however, is imperative because radiotherapy and division of the upper intercostal vessels compromise collateral flow to the arm. Without vascular reconstruction, there have been several reports of ischemic gangrene of the forearm. [93,94] Dartevelle and associates[87] reported on one of nine patients reconstructed with an unringed PTFE graft who developed a late graft occlusion, and therefore they recommend using a 6- or 8-mm externally supported PTFE graft when an end-to-end anastomosis cannot be safely performed.

Similar to the experience of extended posterior resections, long-term pain control is better after an extended anterior resection (with or without a posterolateral thoracotomy) than with irradiation alone. The incidence of local recurrence was reported by Dartevelle and associates [87] to be 7% (2/29), and the survival ranged from 4 to 137 months.

The two- and five-year survival statistics were 50% and 31%, respectively, as reported by Dartevelle and colleagues. [87] According to Wright and colleagues, [93] one of four patients with documented invasion of the subclavian artery was alive 29 months after complete resection and reconstruction. The most common cause of death is metastatic disease, the most common site being the brain.

Most believe that 3,000 to 4,500 cGy radiation delivered preoperatively shrinks the tumor, providing a wider margin of resection and decreasing the number of imcomplete resections. Several authors have emphasized the prognostic significance of achieving a complete resection. Shahian has examined the value of providing additional postoperative radiation therapy in patients who were found to have incomplete resections and/or positive mediastinal nodes. Hilaris et al. have examined the value of providing brachytherapy at the time of surgery to improve local regional control. [99] More recently, Ginsberg et al. were unable to show any improvement in five-year survival by providing brachytherapy in patients undergoing incomplete resection. [100]

In the absence of mediastinal adenopathy, some[6,90,94,97] believe that 3,000 to 4,500 cGy preoperative radiotherapy shrinks the tumor and provides a wider resection margin; Shahian and colleagues[101] suggested that there may be an advantage to giving additional postoperative radiotherapy if the resection is incomplete, or if positive mediastinal nodes are discovered at the time of resection. Trials of combined preoperative chemotherapy and radiotherapy are being conducted to improve the incidence of local control, distant recurrence, and five-year survival in these T3 and T4 tumors.

Most consider the presence of mediastinal lymph node metastases as a contraindication for these extended resections. RPSLMC advocates treating these patients with preoperative adjuvant chemotherapy and radiotherapy. Preliminary results using this combined modality are encouraging. [86]

Miscellaneous Extended Pulmonary Resections

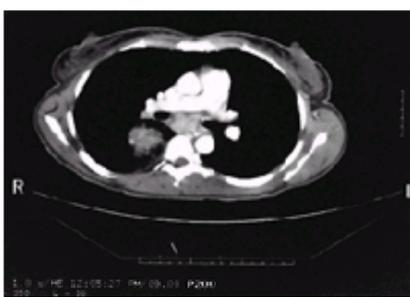
Although the early literature alludes to the practicality of extending pulmonary resections to include portions of the muscular wall of the esophagus, the diaphragm, and the aorta, no operative mortality and long-term survival statistics could be provided. [3,19,20] During the years that followed, occasional cases involving resections of the muscular wall of the esophagus appeared without a long-term survivor [45,102,103] (Figure 38.14 and Figure 38.15). Burt and colleagues[47] reported the only five-year survival in a patient with pulmonary carcinoma involving the esophageal wall.


FIGURE 38.14. CT scan illustrating an adenocarcinoma of the right lower lobe with extensive subcarinal adenopathy.

FIGURE 38.15. Operative photograph of same patient as in Figure 38.14 demonstrating *en bloc* resection of the muscular wall of the esophagus with the subcarinal mass after preoperative chemotherapy and radiotherapy. White arrows identify the edge of the muscular wall; black arrow indicates bronchial stump.

Experience with tumors fixed to the aorta has been more limited but equally discouraging. The two largest series [47,50,51] reported on a combined experience with 27 patients who underwent *en bloc* resection of the aorta; no patient survived beyond 2 years. Nakahara and colleagues [74] reported that one of three patients who underwent *en bloc* resection of the aortic arch survived disease-free for 17 months. If such resections are to be undertaken, the surgeon must be prepared to perform cardiopulmonary bypass in order to resect and graft the aorta because resections limited to the subadventitial plane are often found to be incomplete. [50,74,104,105] Clearly, such aggressive resections should be reserved for exceptional cases.

In contrast to the incidence of chest wall involvement, pulmonary tumors rarely directly invade the diaphragm. Although the option to resect portions of the diaphragm was acknowledged as far back as 1959,[3] only a few case reports have appeared[44,45,103] (Figure 38.16, Figure 38.17 and Figure 38.18). Others[106,107,108,109 and 110] have explored the option of extrapleural pneumonectomy and hemidiaphragmectomy in the presence of an associated malignant pleural effusion, with predictably poor results.

BRONCHIAL SLEEVE LOBECTOMY

A sleeve resection of the bronchus is indicated when tumor approximates or involves the lobar orifice so that a standard lobectomy leaves a positive bronchial resection margin.

Bronchoscopy is often the first examination that alerts the surgeon that the tumor may not be completely resected using a standard lobectomy. Pertinent findings include mucosal changes of corrugation, erythema, and dilated submucosal vessels at the lobar orifice, which are all indications of submucosal infiltration of tumor. More obvious findings include gross extension of polypoid endobronchial tumor to or beyond the lobar orifice and thickening of the lobar spur. Compression or distortion of the bronchial orifice indicates extrinsic disease. The thoracic surgeon is obliged to perform a repeat bronchoscopy, possibly at the time of thoracotomy, if the same surgeon did not perform the initial bronchoscopy. This is especially true in patients with compromised cardiopulmonary reserve, who require a lung-sparing operation.

Patients with central tumors should have a CT scan, which often alerts the surgeon to the need for a resection beyond a standard lobectomy. The tumor mass may be seen extending to the mainstem bronchus or obliterating the normal tissue plane of the main pulmonary artery. Correlating the bronchoscopic and CT or MRI findings is important in planning the resection. [111]

In addition, mediastinal nodes greater than 1.5 cm indicate the need for mediastinoscopy. Involved contralateral mediastinal nodes and extension of tumor beyond the capsule of superior mediastinal nodes contraindicate resection. If the tumor is limited to ipsilateral or subcarinal nodes, the patient should be considered for a program of adjuvant chemotherapy and radiotherapy.

Patients older than 65 years and those with compromised cardiopulmonary reserve are ideal candidates for sleeve lobectomies. The elderly do not tolerate a pneumonectomy well, and every attempt should be made to perform a lesser resection whenever technically possible. A predicted postoperative FEV$_1$ of less than 1 L is a good predictor of complications after a pneumonectomy, and preservation of lung tissue in this setting is of paramount importance. Preoperative pulmonary function studies, quantitative ventilation–perfusion lung scans, and a full cardiac evaluation are necessary in the compromised patient.

Despite the preoperative assessment, the patient and the family must be made aware that, for technical or anatomic reasons, a pneumonectomy may become necessary, with its attendant increased morbidity and mortality. There are too many instances in which a sleeve lobectomy is planned when a pneumonectomy is

required.

Technical Considerations

The performance of a bronchoplastic procedure requires one-lung ventilation. The surgeon should be able to perform preoperative or intraoperative bronchoscopy, and the choice of endotracheal tube should be discussed with the anesthesiologist. An uncut, single-lumen endotracheal tube can be advanced down the contralateral mainstem bronchus. For left thoracotomies, the tube is easily passed down the right mainstem bronchus. Under bronchoscopic control, the side hole is positioned at the right upper lobe to ensure that the entire right lung is ventilated. For procedures on the right side, the endotracheal tube is advanced down the left mainstem bronchus intraoperatively. This technique allows the surgeon to use a standard flexible bronchoscope, with excellent optics to visualize the anastomosis, and a 2.2-mm instrument channel to aspirate blood and secretions from the distal airway. Increased minute ventilation minimizes hypercarbia, and oxygenation is well maintained despite shunting through the nonventilated lung. Occlusion of the pulmonary artery is not required. High-frequency ventilation is usually not necessary.

A double-lumen endotracheal tube also permits satisfactory one-lung anesthesia and is preferred by many. The anesthesiologist must be experienced in placing these tubes, and it is necessary to have a pediatric bronchoscope available to confirm proper positioning. Although this instrument can be used to inspect the anastomosis, secretions and clots cannot be easily aspirated. Furthermore, patients who need continued ventilation in the recovery room require replacement of the double-lumen tube with a standard single-lumen tube.

The Univent tube is often unsatisfactory for a right-sided sleeve resection because the blocker is positioned too close to the upper lobe orifice. Furthermore, the blocker has a tendency to migrate proximally and can act as a ball valve at the tip of the endotracheal tube.

Through a posterolateral or a muscle-sparing lateral thoracotomy, the hilum is explored. Operative dissection of the bronchus is performed with careful attention to the bronchial arteries. The thoracic surgeon must be aware of the normal and variant locations of the bronchial arterial supply of the right and left mainstem bronchi. To safeguard this blood supply, the bronchus must not be denuded or skeletonized. When dissecting level 5 and 6 lymph nodes, it is important not to injure the left bronchial artery, which arises under the transverse aortic arch. Careful dissection of the subcarinal nodes is required because branches of the bronchial arteries are always located in this area. When dissecting out level 7 nodes on the right side, care must be taken not to injure a branch of the bronchial artery that passes through the subcarinal area posterior and lateral to the right mainstem bronchus.

The branches of the pulmonary artery are isolated with care. The primary tumor or hilar nodes often abut the lobar arterial branches. On occasion, however, tumor may invade or encase the artery, which may require arterioplasty or a pneumonectomy (see later). If difficulty is encountered in this part of the dissection, it is wise to obtain proximal control of the artery. Some have advocated reconstruction of the bronchial defect using a bronchial flap to avoid complete transsection of the bronchus. However, an unacceptably high incidence of kinking and distortion of the bronchus has occurred using this method. [112],[113]

Once one-lung ventilation is obtained, the bronchus is transected using a #15 blade to ensure a clean, straight margin. No attempt is made to bevel the distal bronchus to accommodate the larger mainstem bronchial orifice. Immediately after removal of the specimen, frozen sections of the proximal and distal bronchial margins are obtained. If a positive resection margin is discovered, the surgeon must decide whether an additional bronchial margin can be safely obtained or whether a pneumonectomy is necessary. The resection of additional bronchus may put undue tension on the anastomosis. Care must be taken that resection of additional distal margin does not compromise a segmental bronchus of the remaining lung. Under these circumstances, it may be prudent to perform the pneumonectomy rather than risk anastomotic complications.

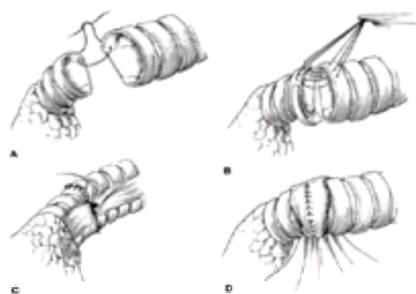
The bronchial anastomosis is performed using simple sutures of 3-0 or 4-0 polyglycolic acid. The anastomosis is started by placing two or three simple sutures at the medial junction of the cartilaginous and membranous portions of the bronchus. These sutures are tied, placing the knots on the outside of the bronchus and bringing the cartilaginous rings together. These sutures are placed to minimize tension and to allow accurate placement of the remaining sutures. The remaining sutures are then serially tied as they are placed to approximate the cartilaginous rings. Luminal disparity is addressed when closing the membranous bronchus, as illustrated in Figure 38.19. No attempt should be made to compensate for lumen disparity by oblique placement of the sutures because this causes bronchial distortion and risks tearing of the tissue from uneven tension. Not infrequently, the distal bronchus "telescopes" into the proximal bronchus, causing some compromise of the lumen size, but this technique may provide additional security of the anastomosis.


FIGURE 38.19. Operative drawings illustrating the technique of bronchial anastomosis. **A:** The first suture is placed at the corner of the bronchus to provide orientation. **B:** The cartilaginous rings are approximated using simple sutures and avoiding telescoping. **C:** Discrepancy in the lumen size is addressed when closing the membranous bronchus. **D:** A pleural wrap is performed to seal the anastomosis and cover the knots, protecting the adjacent pulmonary artery.

The practice at RPSL is to encircle the bronchial anastomosis with a broad-based pleural flap or with a pedicled anterior mediastinal fat pad. This tissue protects the pulmonary artery from erosion by the knots of the anastomotic sutures and minimizes the complications of a minor anastomotic leak. Others, [112],[113] and [114] however, have provided experimental evidence that a pleural flap actually impedes revascularization of the anastomosis. More recently, Kutlu and Goldstraw have reported their series of 100 patients undergoing a bronchial anastomosis using a continuous suture technique with an acceptable incidence of airway stenosis. [115]

Results

According to several large series, the mean age of patients undergoing sleeve lobectomies is 60 to 65 years, with a strong male predominance. Approximately 75% of tumors are classified as squamous carcinoma. The most common site is the right upper lobe, followed in frequency by the left upper lobe and the left lower lobe. Other bronchial sleeve resections have been described, including right upper and middle lobe, right middle and lower lobe, right middle lobe and superior segment, and even right upper, middle, and superior segment resections, anastomosing the basal segments to the mainstem bronchus. [116]

Postoperative complications are mainly related to the anastomosis. Accumulations of clot and secretions at the anastomosis may lead to atelectasis. For this reason, blood and secretions should be routinely aspirated from the distal airway in the operating room, and the anastomosis should be inspected. If the distal airway is compromised (especially the superior segment of the lower lobe or the middle lobe bronchus), part or all of the anastomosis is refashioned. [117] Tedder and associates[118] reported the incidence of postoperative atelectasis to be 5.2%. Retained, inspissated secretions may be managed with a minitracheostomy or a daily bronchoscopy.

Persistent air leak for greater than 7 days may be evidence of an anastomotic leak. Under these circumstances, the anastomosis must be carefully inspected with a fiberoptic bronchoscope. Dehiscence appears as an area of pale discoloration of the bronchial margins, and careful inspection may disclose to-and-fro movement of secretions through the bronchial wall. Careful judgment must be used to determine the next course of action. If the leak is small and more than half of the anastomosis is intact, then judicial observation, leaving the chest tubes in place, may be the best option, particularly if the anastomosis was wrapped with a pleural flap. An empyema can usually be avoided. If more than half of the anastomosis is in jeopardy, or if a large leak is evident with an air space around the anastomosis, a completion pneumonectomy should be performed. An abscess at the anastomosis can erode into the pulmonary artery; therefore, proximal control of the pulmonary artery must be achieved early on reoperation. When close attention is paid to the details of the anastomotic closure, including the preservation of the bronchial arterial

supply and wrapping of the bronchial anastomosis, only about 6% of patients require completion pneumonectomy for complications relating to the bronchial anastomosis.[117]

The operative mortality rates vary widely in reported series, in part because of controversy over indications for the procedure. [116,117,118,119,120,121,122,123,124] and [125] The mortality rates are as low as 2%.[117] The mortality rate has been reported to be as low as 2%.[117] The long-term survival is primarily determined by the nodal status. Excellent long-term functional results have been reported by Gaissert et al. and Van Schil et al. [119,120]

PULMONARY ARTERIOPLASTY WITH PULMONARY RESECTION

Some patients considered to be candidates for pulmonary resection are found to have tumor invading or encasing the pulmonary artery or its branches. This finding may be on the basis of direct invasion by the pulmonary tumor, or the artery may be invaded by tumor metastatic to the lobar or mediastinal nodes. Occasionally, involvement of the wall of the pulmonary artery can be suspected on the basis of preoperative pulmonary arteriography or CT scan. [29] In most cases, however, involvement of the artery is first discovered intraoperatively.

When a sufficiently long segment of artery is available, a segment of the artery can be resected along with the lung and reconstructed using a variety of techniques. Such reconstructive operations on the pulmonary artery were first discussed by Allison in 1954. [126] In 1959, Johnston and Jones[127] reported their experience with sleeve resections, including eight resections of the pulmonary artery. Wurning, [128] Pichlmaier and Spelsberg,[129] and Vogt-Moykopf and colleagues[130,131] and [132] further explored the techniques of pulmonary angioplastic reconstruction. Other reports have further popularized pulmonary arterioplasty. [133,134,135,136] and [137]

Because a much longer segment of pulmonary artery is available for reconstruction on the left side, most experience has been with carcinomas arising from the left upper lobe. However, right-sided resections and reconstructions have also been performed. [127,128,129] and [130,133,136,137]

Technical Considerations

When exposing the hilum, the pulmonary artery is explored proximal and distal to the area of suspected involvement. On the left side, an adequate length can usually be obtained by dividing the ligamentum arteriosum. On the right side, the pulmonary artery may have to be dissected out behind the SVC, or using the intrapericardial approach.

The artery is encircled proximally and distally. If only a small portion of the arterial wall is involved, umbilical tapes are passed around the artery distal to the involved segment and secured with a Rumel tourniquet. In this setting, tapes are preferred because they are less likely to traumatize the pulmonary arterial wall. If greater portions of the artery are involved, vascular clamps should be used because they are less likely to distort the artery during reconstruction. Great care must be taken when applying even a soft atraumatic clamp to the proximal pulmonary artery because these vessels are often sclerotic and the intima is easily torn. If sufficient length of pulmonary artery is not available to achieve distal control of the artery, then the lower lobe vein can be secured with a Rumel tourniquet or a vascular clamp. Collateral bronchial flow, however, may still compromise exposure.

Uninvolved upper lobar branches of the pulmonary artery are ligated and divided to facilitate mobilization and exposure. The pulmonary vein draining the involved lobe is dissected out and ligated to minimize back-bleeding. The bronchial dissection is then completed.

Then, 5000 U of heparin is given, and vascular control is achieved. If a bronchial sleeve resection is indicated, then the mainstem bronchus is divided, resecting a portion of the wall of the pulmonary artery. If the artery is more extensively involved, then it may be transected, dividing the distal pulmonary artery tangentially to minimize any discrepancy in the lumen size. The bronchial anastomosis is performed first to avoid placing undue tension on a completed vascular suture line.

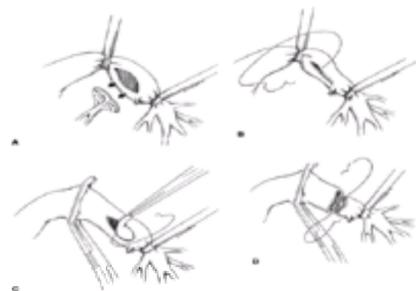
If only a segment of the arterial wall is resected, then care must be taken that simple oversewing does not leave the artery significantly narrowed. If more than one-third circumference of the wall is resected, then the defect should be closed using a patch of pericardium [29,61,136,137] (Figure 38.20 and Figure 38.21).


FIGURE 38.20. Operative drawings depicting several techniques of pulmonary arterioplasty. **A:** Proximal and distal control of the pulmonary artery is achieved, and the wall is resected. **B:** If less than one-third of the wall circumference is resected, then the defect may be closed primarily without stenosis. **C:** If more than one-third of the wall is resected, then the defect may be patched. In this case, proximal control is achieved using a vascular clamp to minimize distortion. **D:** If a short length of pulmonary artery is resected, then an end-to-end anastomosis is performed.
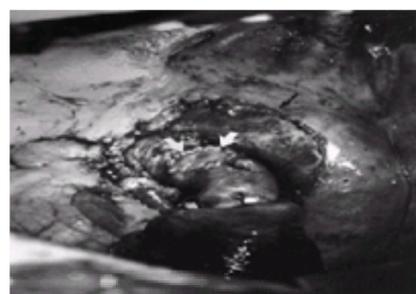

FIGURE 38.21. Operative photograph showing a pericardial patch (*white arrows*) on the proximal left pulmonary artery under the aortic arch (*black arrow*).

If a resection of a short length of artery is indicated, then it should be reconstructed using an end-to-end anastomosis. Care must be taken that the artery is not twisted or kinked at the closure and that no tension exists. Continuous-stitch 4-0 or 5-0 polypropylene suture is used for the arterial closure or anastomosis. A flap of pleura can be used to encircle and separate the bronchial anastomosis from the vascular suture line.

If a length of pulmonary artery is resected so that an end-to-end anastomosis cannot be performed without tension, then an interposition graft may be necessary. Saphenous vein, Dacron, and PTFE grafts have been used successfully. [134,135] Alternatively, a bronchial sleeve can be resected to minimize tension on the vascular anastomosis, as proposed by Vogt-Moykopf.[130,131] and [132]

The tip of the chest tube should be directed away from the field of dissection. The heparin is not reversed at the conclusion of surgery, but the patient is not anticoagulated further.

Results

Although the technique of pulmonary arterioplasty was described more than 40 years ago, clinical experience has been limited to a few centers with a total reported experience of less than 250 patients. Technically, it is much simpler to perform a pneumonectomy, but this procedure carries greater attendant morbidity and mortality and greater pulmonary compromise.

The pulmonary artery remains patent in most cases, as determined by routine postoperative pulmonary angiograms or nuclear perfusion scans.[130,134,136] However, thrombosis of the pulmonary artery has been reported, presenting as pulmonary consolidation and fever without bronchial obstruction. At least four cases have been reported,[127,133,138,139] and in most cases, this is an indication for a completion pneumonectomy. One case, however, was discovered 6 months after surgery in an asymptomatic patient who went on to survive for 11 years.[138]

Vogt-Moykopf and colleagues[130] reported a 5% operative mortality for patients undergoing combined bronchial and vascular sleeve resections. The median survival for 29 patients undergoing bronchial and vascular sleeve resections was 625 days.

Read and colleagues[138] performed six interposition grafts (three saphenous vein, three PTFE) of the left pulmonary artery without thrombosis or infection; four of six patients were alive and disease free an average of 17 months after resection.[134] Rendina et al. have reported a series of 68 patients who have undergone Cisplatin-based induction chemotherapy and underwent bronchial and/or pulmonary artery reconstruction with excellent results.[136,137,140]

SUMMARY

The surgical experience of the last four decades has supported the contention that a complete surgical resection provides the best chance of cure for pulmonary carcinomas, even in most of those cases that are locally advanced by virtue of direct extension to mediastinal structures and the chest wall. Perioperative care has been vastly improved, resulting in lower morbidity and mortality when compared with earlier results.

The best prognostic factors in these cases are the stage of the tumor and the completeness of the resection. Among stage IIIA carcinomas, T3, N0-1 tumors have a better prognosis than T1-2, N2 tumors, according to several reports.[86,141,142] This has also been the experience with sleeve pneumonectomies, for which patients with T4, N0-1 tumors have a more favorable prognosis than patients with N2 metastases. The importance of careful staging in these cases is paramount when it comes to predicting the outcomes.[143] Overall, squamous cell carcinomas and adenocarcinomas appear to have a better prognosis than large cell carcinomas.[144] The risk of local recurrence has been minimized by the use of adjuvant external radiotherapy, administered either preoperatively or postoperatively. Intraoperative or postoperative brachytherapy has also been employed[145,146 and 147] (see also Chapter 43, Chapter 49).

The long-term survival statistics, however, are still disappointing. The most common cause of death continues to be distant metastatic disease. The assumption that microscopic metastases are present at the time of presentation has been the main rationale for including chemotherapy in the adjuvant setting. In addition, some chemotherapeutic agents are known to act as radiosensitizing agents.

CHEST WALL INVOLVEMENT INCLUDING PANCOAST TUMORS

WILLIAM H. WARREN

In 1959, Chamberlain proposed the term "extended resections" to describe operative procedures that were intended to completely resect locally advanced lung cancers, and in so doing, distinguish them from the "standard resections," a term reserved for lobectomies and pneumonectomies.[1] These so-called "extended resections" included the resection of lung cancers involving the chest wall. The physiologic consequences and operative techniques involved in resecting and reconstructing a portion of the chest wall were, at that time, largely unknown, and the therapeutic value of doing so was controversial. Over the last 40 years, the operative techniques of chest wall resection and reconstruction have evolved and become incorporated into the thoracic surgeon's armamentarium. Moreover, the prognosis of patients undergoing a complete extirpation by pulmonary and *en bloc* chest wall resection is so vastly superior to those undergoing nonsurgical therapy or incomplete resection that the value of chest wall resections is no longer controversial.

This chapter is devoted to resections of the lung involving the chest wall, including the conventional approach to resecting superior sulcus tumors. The topic of alternative operative approaches, including anterior approaches to locally advanced superior sulcus tumors and tumors involving the thoracic spine, is discussed in a separate chapter (see also Chapter 38).

PRIMARY LUNG CARCINOMA INVOLVING THE CHEST WALL (EXCLUDING APICAL TUMORS)

Historical Perspective

In 1947, Coleman reported his experience of five patients undergoing pulmonary and *en bloc* chest wall resections with only one mortality.[2] It was subsequently reported that two of these patients survived 8 and 13 years after the procedure.[3,4] This was the first study documenting the feasibility and survival advantage of patients undergoing this type of resection. Over the following years, the techniques of resection and materials available for reconstruction improved to the degree that the resection of lung cancer involving the chest wall is no longer considered to be an "extended" resection.

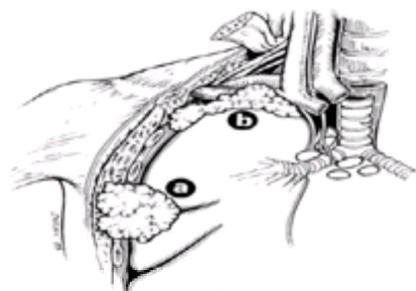
It is estimated that 5% of all primary tumors of the lung have, at the time of presentation, involvement of the chest wall. Most of these tumors are classified as T3, and thus represent at least stage III disease according to the International Staging System.[5] T4 tumors of the chest wall are distinguished by involvement of the vertebral body, involvement of the great vessels (including the aorta, subclavian artery, and vein), or association with a malignant pleural effusion (Figure 39.1, Figure 39.2).


FIGURE 39.1. Schematic of International Staging System definitions for T3 disease involving the chest wall. Diagram shows chest wall invasion in a nonsulcus position **(A)** and with the superior sulcus presentation **(B)**. (From Mountain CF. A new international staging system for lung cancer. *Chest* 1986;89:225S, with permission.)

Preoperative Assessment

Chest wall discomfort ranging from a vague ache to a discrete localized pain is a presenting symptom in 37% to 88% of patients. [6,7,8,9,10,11,12,13,14,15,16,17 and 18] On occasion, the pain may be referred to the shoulder or anterior to the area of involvement, presumably referred from intercostal nerve involvement. Almost invariably, if the patient presents with any chest wall symptom, some degree of chest wall involvement can be anticipated. On the other hand, there are reported cases where a patient can present without any chest wall complaint and be found to have periosteal involvement at the time of surgery.

By definition, these tumors are peripheral. Patients who present with a cough, with or without hemoptysis, predictably have large tumors and/or metastases to mediastinal lymph nodes. However, presenting symptoms have not been demonstrated to have prognostic significance with respect to resectability or long-term survival.

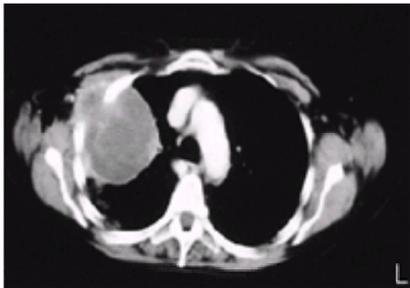
In most patients, a plain posterior-anterior assessment and lateral chest radiograph demonstrates a solitary, peripheral lung mass. In the absence of chest wall symptoms, the computed tomography (CT) scan may provide the first evidence that the tumor may involve the chest wall because this relationship may be difficult to appreciate on plain films, and the physical examination is seldom revealing. Although CT scans are generally poor in distinguishing pulmonary tumors that are simply abutting the chest wall from true chest wall invasion, certain features have been proposed to aid in interpretation. These include contact of tumor against the chest wall over a distance of greater than 3 cm, the ratio of pleural tumor contact/tumor diameter, and obliteration of the extrapleural fat plane [15,20] (Figure 39.3, Figure 39.4). CT with artificial pneumothorax and expiratory dynamic CT have both been used with some success to increase the diagnostic accuracy, but these techniques are rarely justifiable.[21,22 and 23]


FIGURE 39.3. Lung cancer invading chest wall, with invasion through the intercostal bundles into the external chest wall musculature. This patient was completely resected after mediastinoscopy revealed the absence of N2 involvement.
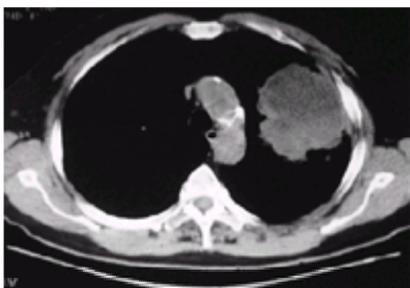

FIGURE 39.4. Lung cancer with abutment of the pleura and partial obliteration of the fat stripe. Patient was found to have chest wall invasion, requiring *en bloc* chest wall resection.

Thoracic ultrasound has been utilized to detect movement of the tumor against the chest wall. [24] Magnetic resonance imaging may demonstrate a disruption in the normal extrapleural fat plane on the T2-weighted images, although distinction between tumor invasion and associated inflammatory changes may be impossible.[25,26,27,28 and 29] In the final analysis, these tests are not able to reliably predict the degree of involvement of the chest wall, and therefore the surgeon must be prepared to make intraoperative decisions about chest wall involvement, and consequently, the best technique of resection.

Ideally, a diagnosis is established prior to embarking on a major chest wall resection. Bronchoscopic examination is usually normal but may reveal extrinsic compression of segmental bronchi, and diagnostic material is occasionally provided using this technique. Postbronchoscopy sputum cytology, transbronchial biopsies, and brushings have all yielded diagnostic material. Many surgeons prefer to perform the bronchoscopy at the time of resection and establish the diagnosis preoperatively by percutaneous fine-needle aspiration.

Percutaneous transthoracic needle aspiration can be performed under fluoroscopic, ultrasound, or CT-directing techniques depending on the size and location of the lesion. With fine-needle (21-gauge) aspiration, a diagnostic accuracy of more than 80% has been reported. [30] Implantation of tumor into the subcutaneous tissue of the chest wall has been documented but is exceedingly rare.[31] Some surgeons have advocated using 14-gauge needle biopsies to establish a histologic diagnosis with lower false-negative and false-positive rates than seen in fine-needle aspiration. [32]

Controversy continues over the issue of performing mediastinoscopy to assess the status of the mediastinal nodes. While some surgeons continue to advocate routine mediastinoscopy,[33,34 and 35] most reserve this study for patients with nodes larger than 1.5 cm, tumors greater than 5 cm, or patients with systemic complaints in the absence of extrathoracic metastases.[36,37,38 and 39] Similarly, controversy exists about the role of nuclear bone scans and serum alkaline phosphatase. According to one study, among patients who were found to have carcinomas with chest wall involvement, only 21% had a positive bone scan and 43% had an elevated serum alkaline phosphatase. [10] The value of a CT brain scan is also controversial. These tests should be performed in patients with tumors greater than 5 cm, with radiologic evidence of mediastinal nodal involvement, complaints consistent with distant metastases, or with a weight loss of greater than 5%.

Preoperative Neoadjuvant Therapy

The role of preoperative radiotherapy has been debated for decades without any clear consensus. Several single-institutional series have been published advocating 3,000–3,700 cGy to the chest wall. However, most of these reports did not randomize patients, instead selecting those patients with large tumors for preoperative therapy in the hopes that a wider margin could be achieved. [15,40]

The leading cause of death in these patients is tumor recurrence at distant sites. Therefore, preoperative adjuvant therapy protocols have been modified to incorporate chemotherapy in an attempt to improve the long-term survival. [41,42] The preliminary results have been encouraging, especially in cases without mediastinal nodal involvement. However, the results of preoperative chemo- and radiotherapy in cases of T3N2 carcinomas have been predictably disappointing. [42] Controlled, prospective, and randomized trials are underway to further explore the role of neoadjuvant therapy.

Operative Strategies

The goal of surgery is complete resection of the carcinoma with resection of the involved chest wall and regional nodes with reconstruction, when necessary, to minimally compromise respiration.

Most tumors are approached through a standard posterolateral thoracotomy. Occasionally, when the sternum or apex of the chest is involved (superior sulcus tumors), the incision has to be modified. The chest wall must be opened so that the surgeon can assess the tumor involvement without compromising the resection. Usually, this means entering the chest one interspace below the lowest rib assessed radiologically to be involved by the carcinoma. Once the pleural space has been opened, a finger is inserted to confirm the location of the tumor. The muscles of the appropriate intercostal space are then divided. With greater exposure of the mass, the degree of chest wall invasion can be assessed. Inflammatory adhesions are usually thin and friable, whereas malignant adhesions are usually broad and firm. If the tumor is adherent to the chest wall by only inflammatory adhesions and is completely mobile, then an extrapleural plane is developed 3 to 4 cm from the tumor mass and mobilization is begun. By gentle blunt dissection, the tumor can often be dissected completely free of the chest wall, avoiding a formal chest wall resection and reconstruction. If resistance is met or if any doubt about the adequacy of the margin exists/then a chest wall resection should be performed. Although the technique of extrapleural dissection is widely practiced and studies have supported its use, [10,11,14] some centers have warned about the overuse or inadequacy of this technique, impacting on both the incidence of local/regional recurrence and the five-year survival. [34,38]

In most cases, the chest wall resection is performed first to allow optimal exposure of the hilar structures. However, when the lung mass is 10 cm or greater, it may be easier to perform the pulmonary resection first. Some surgeons have advocated stapling through the lung remote from the tumor and completing the lobectomy after the specimen is out.[15,43] Others, however, have warned that survival is significantly compromised after discontinuous resection. [19,37]

Controversy also exists regarding the margins of the chest wall resection when a formal chest wall resection is necessary. Some surgeons advocate complete resection of all involved ribs, plus one rib above and below providing at least a 5 cm margin whenever possible. [9,43] Others have shown that complete resection of an involved rib is not necessary, and that a 3 cm margin without resection of adjacent but clearly uninvolved ribs above and below the tumor mass is adequate. [35,36] Excising overlying chest wall muscles or subcutaneous tissue is rarely necessary.

Recent studies have documented that the incidence of local/regional recurrence in the setting of stage I carcinoma is much lower with a lobectomy than a segmental resection.[44] Furthermore, some studies have suggested that the postoperative pulmonary function tests performed 3 months after resection are not significantly different when comparing patients undergoing segmentectomy versus lobectomy. Whether or not these observations apply specifically in the setting of lung carcinomas invading the chest wall has not been addressed, but in most series, lobectomy is preferred in low-risk patients. Pneumonectomy with chest wall resection can be performed with acceptable perioperative morbidity and mortality, but the long-term results have been disappointing chiefly because of the development of distant metastases. [16,33]

A mediastinal lymph node dissection must be performed to properly and completely stage the carcinoma. [5,35] The involvement of mediastinal nodes has been widely recognized as an important prognostic factor. [37,39,40]

Reconstruction of the chest wall defect can be avoided if the defect is smaller than 5 cm in greatest diameter unless the patient has marginal pulmonary reserve. Defects between 5 and 10 cm warrant reconstruction, especially if the defect is anterior, lateral, or posterior below the scapula. Higher posterior defects of this size lie under the scapula and reconstruction can be avoided. Defects larger than 10 cm should be reconstructed but rarely occur in this clinical setting.

Although reconstruction using autogenous tissue, such as rib grafts and fascia lata, has been described, the advent of synthetic material such as Marlex, Prolene, and Gore-Tex has largely relegated these techniques to historical reference only. [43] Marlex has the advantage of tissue ingrowth into the interstices, presumably limiting the potential for long-term infections. In addition, a "Marlex sandwich" technique has been developed, whereby even large defects can be patched using a contoured prosthetic patch. This technique is particularly valuable in reconstructing very large defects after the resection of large primary chest wall tumors but is seldom necessary in this setting. Gore-Tex is waterproof and therefore preferable after pneumonectomy. This material is more pliable than Marlex and handles easily. Sutures should be passed through the folded edge of the Dualmesh (reinforced Gore-Tex) patch to minimize the risk of tearing the material. Intrapleural chest tubes are positioned, and the soft tissues of the chest wall are closed in the usual fashion. Chest wall drains are best avoided.

Postoperative Care

Prior to the widespread use of prosthetic patches, the major postoperative complication was pulmonary insufficiency manifest by either inability to clear secretions, or in some cases, ventilatory insufficiency. Vigorous chest physiotherapy and optimal pain management are the cornerstones of postoperative care. Aspiration bronchoscopy is often necessary to clear secretions but in exceptional circumstances, should postoperative ventilatory support may be necessary.

Seromas often form over the prosthesis, but the temptation to aspirate them to avoid an infection should be avoided. Antibiotic coverage is usually provided for only 48 hours unless a seroma is detected, in which case a 7-day course is indicated. If infection of the prosthesis is established, then management depends on the prosthetic material used and the size of the defect. Marlex mesh infections can be eradicated by antibiotics and drainage, providing time for tissue ingrowth. Prosthetic infections tend to wall off early, protecting the adjacent structures. The temptation to remove an infected prosthesis should be balanced against the potential consequences of a flail defect. If the defect is large and the patient is not toxic, a delay of 6 weeks before the removal of the prosthesis allows a fibrous capsule to form, providing an element of chest wall stability.

Prognosis

The overall five-year survival among patients undergoing a complete resection of a primary lung carcinoma invading the chest wall ranges from 15% to 40%. [7,8 and 9,11,12 and 13] Several reports have appeared about the importance of obtaining a complete resection. Patients undergoing "incomplete" resections rarely survive beyond 5 years despite the use of adjuvant therapy, including brachytherapy. Patients undergoing incomplete resections (including tumors adherent to the aorta or invading the vertebral bodies) should be analyzed separately from those undergoing complete resections.

Among those cases that underwent a complete resection, by far the single most important prognostic factor is the status of the regional and mediastinal nodes. In patients with T3N0 carcinomas, the five-year survival ranges from 22% to 56%. Patients with T3N1 tumors have a five-year survival of 0% to 33%. Predictably, the worst survival is seen in patients with T3N2 carcinomas, with a five-year survival of only 0% to 16%. [9,19,33]

Several other factors have been assessed for their prognostic value. Conflicting data exist regarding the depth of invasion of the chest wall, histology of the tumor, and the extent of the resection without a clear consensus. One study concluded that the depth of invasion into the chest wall had prognostic significance. It is generally recognized that tumors peripheral enough to require a chest wall resection yet involving central structures necessitating a pneumonectomy have a poor prognosis, regardless of their nodal status. Generally speaking, larger tumors have a worse prognosis. Age, gender, presenting symptom, and histologic classification have not been shown to affect survival.

Postoperative Adjuvant Therapy(see also Chapter 43)

In order to decrease the incidence of local recurrence, some surgeons have advocated the use of routine postoperative radiotherapy. [15] Several reports concluded that postoperative radiotherapy did not improve survival in those patients who had a complete resection. [7,16,39] Most centers, however, continue to advocate radiotherapy for patients in whom wide margins of resection are impossible (e.g., tumor abutting the spine), or in whom the margins of resection were microscopically positive.

The value of combination chemoradiotherapy delivered postoperatively is still debated. One large trial found that no apparent survival advantage was achieved by administering postoperative chemoradiotherapy to patients with T3N1 completely resected carcinomas. [33] When patients are found to have mediastinal nodal involvement (N2 nodes), additional therapy is often given, but without evidence that this treatment improves their long-term survival.

PANCOAST TUMORS

Introduction and Historical Perspective

Lung carcinomas that invade the apex of the thoracic cage merit consideration beyond those tumors invading the chest wall but sparing the apex for several reasons. First, the apex of the chest is difficult to assess using conventional chest radiographs, and carcinomas arising in this location are often overlooked. Second, proximity to the brachial plexus, the subclavian vessels, and the vertebral column make complete resection difficult, and wide margins of resection are seldom achieved, presenting certain technical challenges. Finally, because of the proximity of these structures, patients with these locally advanced tumors are almost always candidates for some form of adjuvant therapy.

The earliest reference to tumors invading the apex of the chest was made by Hare in 1838. [46] Although several other authors offered case histories of such an entity, [47,48] this entity gained much wider recognition with the publications of Pancoast, [49,50] wherein seven cases were discussed. The degree of invasion of the chest wall can so overshadow the pulmonary component that this tumor was initially considered to be a new entity, arising from an embryonal epithelial rest—possibly arising from the fifth brachial pouch. In keeping with the belief that this entity was new (and specifically to distinguish it from the more common tumors arising in the lung and the chest wall), Pancoast initially offered the term "superior pulmonary sulcus" tumor. The superior sulcus is not a recognized anatomic feature of the lung or the chest wall. [51] Even though Tobias published data to the effect that these tumors were locally advanced pulmonary carcinomas, as early as 1932, [46] the view that these tumors represented a new entity was held for more than a decade. By 1946, several authors had presented additional data supporting the conclusion that at least some of these cases were lung carcinomas. [52,53] For these reasons, the term "superior sulcus tumor" has been rejected by some authorities. [54]

Until 1950, these tumors were considered to be unresectable for cure and palliated with external-beam radiotherapy. In 1954, Haas and colleagues reported on the experience of radiotherapy on "hopeless" cases with significant palliation of arm and shoulder pain and prolonged survival. [55] The radiosensitivity of these tumors was further documented by five-year survivors with external-beam radiotherapy alone. [56]

In 1950, Chardack and MacCallum performed the first successful resection of a Pancoast tumor, followed by 6,500 Gy of irradiation. The patient survived for more than 5 years, renewing interest in the role of surgical resection. [57] The use of such a combination of radiotherapy and surgery however, was accepted as standard only after the report of Shaw and colleagues in 1961. [58]

Clinical Presentation

Although not all patients with an apical tumor involving the chest wall present with a full-blown Pancoast clinical syndrome, most patients present with some clinical complaints. Detection of small, asymptomatic tumors in this region is hampered by difficulty in visualizing the apices by plain chest radiographs.

The most common presenting symptom is shoulder pain, which is often present for 6 months or more before the diagnosis is suspected. The pain is initially located along the vertebral border of the scapula. Headache is also common. The pain becomes constant and progressive as the T1 and the C8 nerve roots become entrapped. Pain and numbness now extends down the arm in the ulnar distribution affecting the forearm and the fourth and fifth fingers. The progression of the pain and the shift in pain distribution often leads the clinician to obtain the diagnostic chest radiograph.

In time, the patient may develop a Horner's syndrome, with ptosis and miosis. This clinical finding carries a poor prognosis because it usually signifies involvement of the vertebral column. In the latter stages, as the pain progressively worsens, the patient may characteristically support the affected elbow with the opposite arm to minimize traction on the brachial plexus. At this time, atrophy of the hypothenar muscles and weakness of the hand is easily appreciated. Weight loss and insomnia from pain are common findings, but cough and dyspnea are rare. Somewhat surprisingly, hemoptysis is not uncommon. Because of the location of the tumor, the primary tumor is rarely palpable. In latter stages, metastatic spread to a scalene node may render it palpable.

Preoperative Assessment

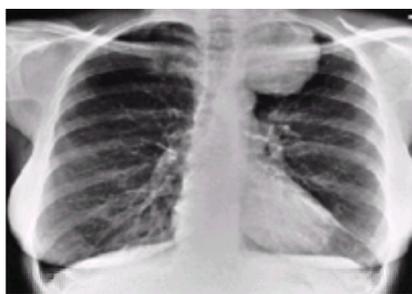
By plain chest radiograph, Pancoast tumors appear as a homogeneous density at the extreme apex of the chest. Apical lordotic views can be helpful, [59] but if clinical symptoms are present, a chest CT scan should be performed. [20,60] Classically, Pancoast tumors are located in the posterior aspect of the apex and usually spare the subclavian vessels until late in their course. However, tumors located more anteriorly have been identified with early involvement of the subclavian vessels. Arteriograms and venograms are occasionally indicated (Figure 39.5, Figure 39.6).


FIGURE 39.5. Chest radiograph revealing tumor in the superior sulcus. Patient presented with arm and shoulder pain.

FIGURE 39.6. CT of the patient whose radiograph is shown in Figure 39.5. Note the absence of transverse process or vertebral body destruction.

In several studies, magnetic resonance imaging (MRI) has been shown to have advantages over CT scan in the assessment of tumor invasion through the apical chest wall, with improved imaging of the subclavian vessels, the brachial plexus, the ribs, and the vertebral bodies. [27,26,60,61 and 62]

The diagnosis should be established before embarking on therapy because several neoplasms and non-neoplastic masses can mimic apical lung carcinoma. [59] Neurogenic tumors of the posterior mediastinum or the brachial plexus, [63] thyroid masses, lymphoma, [64] and an aneurysm of the axillary or subclavian artery all must

be considered in the differential diagnosis. Small cell carcinoma of the lung has been described in this location, [65] but its diagnosis must be accepted with caution because it may be confused with peripheral neuroectodermal tumors of the chest wall (Askin tumor), lymphoma, or plasmacytoma of the first or second ribs. [66,67] Staphylococcus aureus, [68] cryptococcsis, [69,70] aspergillus, [71] and actinomyces [72] apical pulmonary abscesses have all been reported to cause symptoms simulating Pancoast's syndrome.

Because the diagnosis can be established by flexible bronchoscopy in only 10% to 30% of cases, even when fluoroscopy is used, most surgeons have adopted percutaneous needle biopsy as the diagnostic procedure of choice. [73,74,75,76 and 77] Although this procedure can be performed using ultrasonography or biplane fluoroscopy, most lesions are biopsied under CT guidance. [75,78] A posterior approach is most popular, [76] but shallow or small lesions are sometimes approached using a transcervical route.

Similar to all lung cancers, accurate staging has been the cornerstone for rational therapeutic protocols. [79,80,81,82 and 83] Although the distinction between T3 and T4 is not clearly defined in the current classification system, [5] T3 describes tumors where invasion is limited to the parietal pleura, the ribs, and the intercostal muscles. Sensory changes limited to the T1 nerve root alone do not require that these be considered T4 tumors, especially if these symptoms resolve with preoperative radiotherapy and/or the nerve root can be spared at the time of resection. A tumor is classified as T4 by evidence of direct invasion of the vertebral bodies (including the presence of a Horner's syndrome), the presence of any motor dysfunction of the brachial plexus or any of its branches, or involvement of the subclavian vessels. Because most patients who undergo surgical resection undergo some form of preoperative therapy (to which they can respond dramatically), the initial staging is based only on clinical judgement.

Many surgeons advocate nodal staging by routine preoperative mediastinoscopy in cases of superior sulcus lesions, whereas a few surgeons advocate mediastinoscopy only if the nodes are measured to be greater than 1.5 cm as measured by CT scan. CT scans of the chest are routinely performed to visualize the liver and the adrenal glands. A CT scan of the brain and nuclear bone scan are often performed to complete the staging protocol.

The presence of Horner's syndrome has clearly been recognized as a poor prognostic indicator. Nevertheless, long-term survival has been reported with aggressive surgical management. Although surgical resection of neoplasms invading the vertebral bodies or laminae has been described, this procedure is usually performed for palliation, and five-year survivors are rarely reported. Long-term survival has been reported in patients undergoing resections, including division of the T1 nerve root. However, tumors requiring a more extensive sacrifice of the brachial plexus carry a worse prognosis. Extended resections (utilizing an anterior approach) have been described for tumors abutting or with limited involvement of the subclavian vessels, with encouraging early follow-up results. However, encasement of the subclavian vessels or involvement of the subclavian artery at its origin from the aortic arch should still be approached with caution (see also Chapter 38).

Patients with metastatic disease limited to the ipsilateral mediastinal nodes (N2) should be considered for a protocol of preoperative chemo- and radiotherapy. Involvement of the contralateral nodes or supraclavicular nodal disease (N3) or the presence of metastatic disease preclude curative resection.

Role of Preoperative Therapy: Preoperative Radiotherapy versus Neoadjuvant Therapy

The early results of surgical resection alone were sufficiently discouraging that some surgeons believed that Pancoast tumors were categorically unresectable for cure. The natural history of this tumor was limited, with Herbut reporting that none of eight untreated patients survived beyond 8 months from the time of diagnosis. [53] Because all patients eventually become very symptomatic, most patients (even those with limited disease) were submitted for radiotherapy. In 1954, Haas et al. [55] reported significant palliation with occasional prolonged survival with external-beam radiation. Subsequently, five-year survivors were reported with radiotherapy alone. [55,84,85,86 and 87]

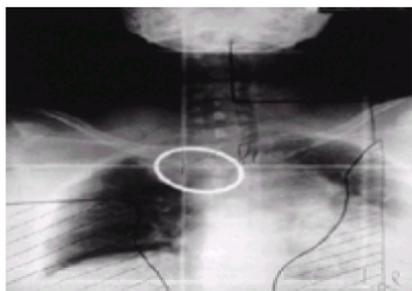
However, the first reported five-year survivor was documented in 1956 by Chardack and MacCallum in a patient who underwent surgical resection followed with 65 Gy irradiation. [57] Subsequently, Shaw et al. reported their results with preoperative radiotherapy, followed by complete surgical resection. [56,88] Their aggressive surgical approach was based, in fact, on the observation that some patients (including those initially considered to have "unresectable" disease), can have a remarkable clinical response and diminution of the tumor mass with limited doses of preoperative radiotherapy. Their initial preoperative radiotherapy protocol was 3,000 cGy given in 10 consecutive days. Most current prorcols give 200 cGy 5 days/week for each of 4 weeks, which is better tolerated. This treatment is followed by a four-week period to allow the patient to recover with respect to their nutritional status, as well as to heal their radiation-induced burn, which can occasionally cause ulceration of the skin (Figure 39.5, Figure 39.6, Figure 39.7, Figure 39.8 and Figure 39.9). Also, additional time may be necessary to allow the erythema to subside prior to surgery.


FIGURE 39.7. Typical radiation portal for a superior sulcus tumor. See text for details.
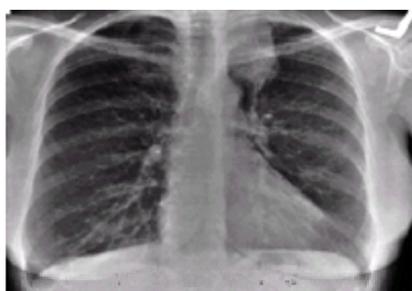

FIGURE 39.8. Chest radiograph before resection in the patient seen in Figure 39.5 and Figure 39.6. Patient received preoperative external-beam radiotherapy.
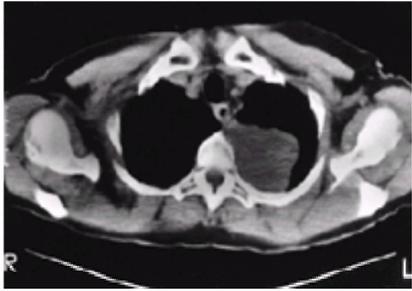

FIGURE 39.9. CT corresponding to the preoperative chest radiograph seen in Figure 39.8.

In a review of the literature on the results of preoperative radiotherapy followed by surgical resection with intent to cure, complete resection was achieved in 70% of cases and was the most important prognostic factor.[89,90,92,94,95,98] Five-year survival ranges from 15% to 50%. The range in results can be attributed to the degree of preoperative selection. The most common cause of death was the development of distant metastatic disease, and the most common site was the brain, with bony metastases being the second most common.[82,8,96,97]

Because distant metastatic disease is an important cause of death in these patients after an apparent complete surgical resection, many surgeons have looked to chemotherapy to control micrometastatic disease, on the assumption that these patients have subclinical metastatic deposits at the time of presentation.[98,99,100,101,102] and [103] Another rationale for the introduction of chemotherapy into the preoperative radiotherapy regime has been the recognition that some chemotherapy drugs are radiosensitizing agents. Most notable on this list are cisplatin and VP-16, on which many protocols are based. Such a neoadjuvant preoperative combination approach has been the basis of current neoadjuvant protocols. The data from these protocols should help to define the role of neoadjuvant therapy.

Technical Considerations

A high posterolateral thoracotomy is performed, providing access to the chest wall by dividing the latissimus dorsi. The posterior aspect of the serratus anterior is also divided. Generally, the chest is opened though the fourth or fifth intercostal space, between the highest ribs not invaded by the tumor as judged by the preoperative chest radiograph and CT scan. The intercostal muscles are divided, and the pleural space is entered to allow for intraoperative assessment of resectability and the extent of resection with respect to the number of ribs and/or involvement of the vertebral bodies and subclavian vessels.

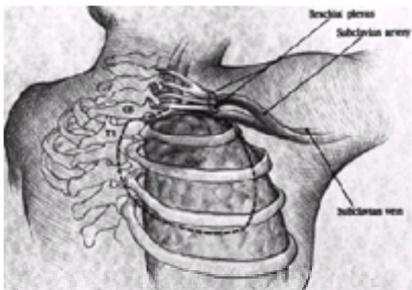
Once resectability has been assured, the skin incision is extended into the parascapular region. Division of the lower portion of the trapezius and rhomboid major and minor provides wider exposure to the upper thoracic spine and the posterior aspect of the upper ribs. The ribs judged to be invaded by the tumor are divided anteriorly. The subclavian vessels are identified and preserved, as are the phrenic and vagus nerves. Posterior dissection is started by dividing the rib where necessary to accomplish a complete resection. Often, the lowest rib can be divided at the costovertebral angle, sparing mobilization of the head of the rib off the vertebral column. The posterior dissection of higher ribs, however, is accomplished by mobilizing the neck of the rib off the transverse process utilizing a periosteal elevator. The head of the rib can then be elevated off the vertebral body (Figure 39.10,Figure 39.11 and Figure 39.12).


FIGURE 39.10. Schematic representation of the surgical approach to the superior sulcus tumor resection. (From McKneally MF. Cardiothoracic techniques. In: Burde PE, ed. *A pictorial review of surgical procedures.* Albany, NY: Learning Technology Incorporated, 1982, with permission.)
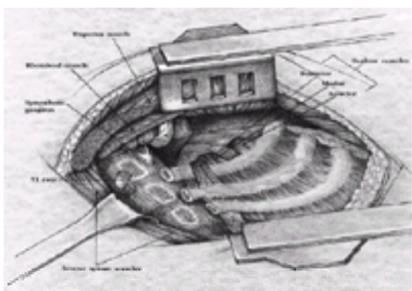

FIGURE 39.11. Schematic representation of *en bloc* resection of superior sulcus tumor. See text for details. (From McKneally MF. Cardiothoracic techniques. In: Burde PE, ed. *A pictorial review of surgical procedures.* Albany, NY: Learning Technology Incorporated, 1982, with permission.)
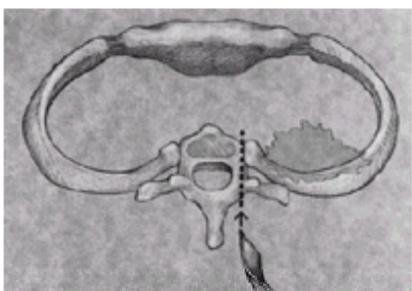

FIGURE 39.12. Use of the osteotome for the posterior margin. (From McKneally MF. Cardiothoracic techniques. In: Burde PE, ed. *A pictorial review of surgical procedures.* Albany, NY: Learning Technology Incorporated, 1982, with permission.)

If tumor is found to invade the vertebral column, then the transverse process (and even a portion of the vertebral body) can be resected at this stage using an osteotome (see also Chapter 38). Sparing the transverse process, and even the neck of the ribs posteriorly (provided it does not compromise the margin of resection), helps to minimize the risk of scoliosis. This is especially true when more than three ribs are resected. Once the posterior aspect of the first rib is divided, the specimen is considerably more mobile. At this point, the T1 nerve root is optimally exposed and spared or divided as necessary to accomplish a complete resection. The C8 nerve root may occasionally also have to be sacrificed. Care must be taken to secure the nerve roots with ligatures at the neural foramina to avoid troublesome leaks of cerebrospinal fluid. If such a leak is caused, it is best managed by patching the neural foramen with a piece of free muscle or erector spinae muscle tacked to the lateral aspect of the vertebral bodies. Opening the neural foramen in an attempt to directly oversew the dural tear is fraught with difficulty and is often unsuccessful. Care must also be taken to identify and ligate branches of the intercostal vessels, especially in the region of the neural foramina to avoid troublesome bleeding. If bleeding is encountered from the neural foramen, it is best controlled with bipolar electrocautery. Occasionally, the neural foramen has to be opened to visualize the vessel. The surgeon must resist the temptation to leave pledgets of Gelfoam in this region because there are case reports of paraplegia resulting from migration into the spinal canal.[104]

The hilar dissection is then performed, resulting in an *en bloc* specimen of lung and chest wall. When the chest wall involvement is bulky, it may occasionally be advantageous to perform the hilar dissection first to facilitate exposure to the posterior aspect of the first and second ribs. If the tumor cannot be dissected off the subclavian vessels, then it may be necessary to complete the resection and/or arterial reconstruction using an anterior approach (see also Chapter 38).

Some controversy exists regarding the optimal pulmonary resection. Some authors believe that limited resections (either wedge or segmental resections) are adequate.[105] In fact, at least two studies suggest that no statistically significant survival advantage is achieved by performing a lobectomy when compared to a more limited pulmonary resection.[44,106] However, Ginsberg et al. found a lower local/regional recurrence rate and a survival advantage in those patients who underwent a lobectomy.[107] All patients undergoing a curative resection should have a mediastinal node dissection.

Because the resulting chest wall defect lies under the scapula, reconstruction is not necessary unless more than three ribs are resected. When a chest wall mesh is used, care must be taken to avoid compromise of the subclavian vessels and the brachial plexus. This goal is best accomplished by avoiding sutures along the superior margin of the patch. The incision is closed in the usual fashion.

Prognostic Factors after Resection with Preoperative Irradiation

Over the last 25 years, many potential prognostic factors have been assessed, including completeness of resection, TNM stage, and histologic evaluation. Overall, approximately 75% of patients in whom a curative operation is intended were found to have a "complete resection," the rest being found to have a microscopically positive margin. This statistic is not surprising given the technical difficulties facing the surgeon. The most common sites for positive margins are the brachial plexus, vertebral bodies, neural foramina, and the subclavian vessels. In this setting, some surgeons have advocated the use of brachytherapy to improve local control.[108,109] However, according to Ginsberg et al., there appears to be little difference in the survival of patients undergoing incomplete resections compared to those patients having no resection even with the use of brachytherapy.[110] Two other studies also report a significantly worse two-year survival in patients undergoing incomplete resections.[96,111] The completeness of the resection is a statistically significant and independent prognostic factor for five-year survival, and every attempt should be made to achieve negative microscopic margins.

Not surprisingly, the stage of the carcinoma has also been found to carry prognostic significance. Factors that determine that the tumor is T4 (i.e., subclavian vessel involvement, Horner's syndrome, and vertebral body involvement) have all been found to negatively impact the five-year survival. Limited involvement of the vertebral bodies (with or without Horner's syndrome) and/or the subclavian vessels does not preclude a complete resection, however, and long-term survivors have been reported.[94,105,112,113 and 114] The size of the tumor and presence or absence of bony destruction of the ribs by the tumor have not been clearly identified to be significant prognostic factors, but one study found that the depth of invasion into the chest wall did correlate with prognosis.[45]

Involvement of the mediastinal nodes has also been identified as a poor prognostic factor.[35,94,95,108,110,112,115] According to Ginsberg et al., the five-year survival in patients undergoing complete resection with N0,N1 disease is 46% compared to 15% in a carefully selected cohort of patients found to have N2,N3 disease and offered combined preoperative radiotherapy followed by complete resection.[110] In other series, patients with N2 or N3 disease either were not offered surgery or underwent resections that were determined to be incomplete. Somewhat ironically, experience at Memorial Sloan-Kettering cancer center suggests that patients with metastatic disease limited to the ipsilateral supraclavicular (N3) node (in the absence of any other nodal metastases) have a better survival than patients found to have mediastinal (N2) nodal metastases.[108,110] Further refinements of the TNM staging classification may be necessary to address this special issue. The mere presence of N2 or N3 nodal disease, however, does not preclude a complete resection, and five-year survivors have been reported.

Survival and Patterns of Recurrence After Curative Resection

The overall five-year survival statistics from various centers reporting over the last 15 years range from 21% to 68%.[82,96,116] In 1987, Shahian et al. reported a 68.6% five-year survival in a highly selected subgroup of patients, who underwent a complete resection of T3N0 tumor and both preoperative and postoperative radiotherapy.[115] Most report a five-year survival, even in the most favorable subset of patients, of 30% to 40%.

Several studies have documented the patterns of recurrence and the survival of patients undergoing curative resections. Local/regional recurrence has been documented to occur in as many as 60% to 70% of cases according to Ginsberg et al.[110] The apical chest wall is often the first site of recurrence. Although this pattern is a reflection of the limitation of the chest wall resection margins, and is an important cause of morbidity, patients are more likely to die from systemic metastases. The most common site of distant metastasis is the brain, accounting for 40% to 80% of systemic recurrences.[83,87,90,96,108,110] According to several authors, bony metastases are the second most common site.[82,90,108]

Alternative Radiotherapy Strategies

In view of the disappointingly high local/regional recurrence rate after preoperative irradiation, alternative radiotherapy strategies have been investigated. Attar et al. reported that increasing the preoperative radiation dose to 55 Gy was associated with wound healing problems (including a 23% incidence of bronchopleural fistula) and a 15% operative mortality.[103] Although Fuller et al. had far fewer complications, higher doses of external-beam irradiation do not seem to improve resectability or survival.[82] Brachytherapy has also been used in an attempt to decrease the incidence of local/regional recurrence after complete resection while minimizing the risk of wound healing problems.[108,109] However, upon reviewing the data, Ginsberg et al. concluded that there was no apparent benefit either with respect to local/regional control or long-term survival after a complete resection.[110] Brachytherapy should be considered, however, if the patient had been explored, anticipating a complete resection, but an incomplete resection had to be performed. If an incomplete resection is inevitable, the patient should not undergo a surgical procedure simply to debulk the tumor and implant brachytherapy sources because this strategy does not provide the patient with better local control or long-term survival when compared to the results of external-beam radiotherapy alone.[110]

Postoperative radiation has been given usually in conjunction with preoperative irradiation.[115,117,118] Interpretation of the results is difficult at best. Most surgeons believe that giving additional postoperative radiotherapy has not been shown to provide better local/regional control or survival advantage after a complete resection. A somewhat atypical but encouraging report was issued by Hagan et al., who gave 14 patients with close or even positive resection margins postoperative radiotherapy. Eleven had no evidence of local/regional recurrence and seven were five-year survivors.[119]

Sundaresean et al. have explored the value of attempting resection prior to radiotherapy in patients with locally advanced tumors, including patients with spinal cord involvement and extensive brachial plexopathy. Although brachytherapy was used, as well as postoperative radiotherapy, predictably poor results were reported because most patients underwent an incomplete palliative resection, in some cases with gross residual and/or metastatic tumor.[118]

Even if the patient is found to have undergone an incomplete resection, with only a microscopically positive margin, the prognosis is not statistically different from those patients who do not undergo a resection, with a two-year survival of 15%. Analysis of this population of patients is poor, but the value of postoperative

radiotherapy and/or brachytherapy is questionable. Few believe that additional radiotherapy after an incomplete resection offers any benefit.

The role of radiotherapy alone in doses of 50 to 70 Gy has been studied by some, with two-year survival reported to be high as 29%. Few consider the results to rival those of combined radiation therapy and surgery. Some surgeons have reported on the results of combining hyperthermia and radiotherapy, in an attempt to improve local control.[120] Others have investigated the role of hyperfractionated radiotherapy, but the results have been inconclusive. [121]

SUMMARY

Management of lung carcinoma invading the chest wall has undergone slow but steady improvement over the last 25 years. This advance has been due, in part, to improved materials available for reconstruction, as well as experience in using them. The treatment of apical carcinomas invading the chest wall presents special technical challenges and remains one of the few clinical scenarios where preoperative irradiation impacted on the resectability and the long-term survival. New techniques have been forged to allow resection of apical carcinomas involving the subclavian vessels, and preliminary long-term survival statistics are encouraging. The current limits of resectability continue to be extensive involvement of the thoracic spine, the subclavian vessels, or the brachial plexus. Current protocols continue to explore the role of adjuvant preoperative chemoradiotherapy.

SURGICAL MANAGEMENT OF SECOND PRIMARY AND METASTATIC LUNG CANCER

JEMI OLAK
MARK K. FERGUSON

Surgical management of lung cancer that has metastasized to other sites has for the most part been confined to selected patients with metastasis to other pulmonary segments or lobes, or to the brain. Patterns of failure for patients with surgically treated lung cancer are changing due to earlier detection, the use of more rigorous staging procedures, and the use of induction and adjuvant therapies. Reports of surgical management of metastatic disease to the liver, pleura, or bone from primary lung cancer are scarce, whereas reports of surgical management of metastatic adrenal disease are increasing. [1,2,3 and 4] This chapter reviews the surgical treatment of multiple primary lung cancer (both synchronous and metachronous) as well as lung cancer which has metastasized to distant sites. The chapter also provides guidelines to the approach and management of these problems.

OTHER PULMONARY LESIONS

Introduction

The incidence of multiple primary lung cancers has been estimated to be between 0.8% and 7.6%. [5,6,7,8,9 and 10] A review of English literature published between 1931 and 1983 identified 382 cases of multiple primary lung cancers from a total of 12,685 patients with lung cancer, an incidence of 1.7%. [10] Subsequent reports have identified 229 additional cases from among 10,791 lung cancer patients, increasing the overall incidence to 2.1% (Table 40.1). An autopsy study of 255 patients who died of bronchogenic carcinoma, however, revealed multiple primary lung cancers in 3.5% using strict criteria and 14% using less strict criteria. [11] The true incidence of multiple primary lung cancers has been hard to estimate because the criteria used to establish this diagnosis have been difficult to agree upon. In addition, the incidence varies depending upon the rigor with which a second primary carcinoma is sought during both the initial clinical staging and the assessment of the pathological specimen. The efficacy of therapy and the length of patient survival also impact on the incidence of multiple primary lung cancer. [5]

TABLE 40.1. INCIDENCE OF MULTIPLE PRIMARY LUNG CANCERS

Synchronous Pulmonary Tumors

The incidence of synchronous primary lung cancer is sufficiently low that the simultaneous discovery of two pulmonary tumors mandates careful consideration of the diagnostic possibilities listed in (Table 40.2). Distinguishing among synchronous primary lung cancers, a primary lung cancer with a metastasis, and two metastases from an extrathoracic carcinoma can be difficult.

i. Synchronous primary carcinomas of lung

ii. One primary carcinoma, one metastasis

iii. Two metastases from an extrathoracic primary

iv. One primary carcinoma, one benign lesion

v. Two benign lesions

TABLE 40.2. SYNCHRONOUS PULMONARY TUMORS—DIAGNOSTIC POSSIBILITIES

Synchronous Primary Carcinomas of Lung

The incidence of synchronous primary carcinomas of the lung is reported to be between 0.26 and 1.33% (Table 40.3). [6,7,9,11,12] The average incidence among 17,567 patients with lung cancer was 0.52%, although slightly different criteria were used to determine the incidence in individual reports. Synchronous carcinomas of the lung (Figure 40.1) are diagnosed less commonly than metachronous carcinomas, the former comprising between 11% and 45% of all cases of multiple bronchogenic carcinomas (Table 40.4). [6,7,9,13,14 and 15]

TABLE 40.4. INCIDENCE OF SYNCHRONOUS AND METACHRONOUS LUNG CANCER IN PATIENTS WITH MULTIPLE PRIMARY TUMORS

In 1889 Billroth suggested that a diagnosis of two primary tumors could be made only if they were anatomically or temporally separate, of different histologic type, and if each produced its own metastasis.[16] Beyreuther reported the first case of synchronous bilateral primary lung cancers in 1924. [17]

Controversy continues to be associated with the definition of synchronous primary lung cancer. Chaudhuri suggested that the tumors needed to be of different cell types.[18] This definition clearly underestimates the true incidence of synchronous primary lung cancer and incorrectly labels some patients as having stage IV disease. Warren and Gates, con the other hand, suggested that synchronous lesions should be bilateral. [19] This definition also underestimates the true incidence of synchronous disease. In an effort to standardize the reporting of synchronous primary lung cancers, Martini and Melamed proposed criteria for their classification in 1975 (Table 40.5).[20] These criteria have been adapted with minor modifications by several authors in publications since that time. [6,7,8 and 9,12]

A. Tumors physically distinct and separate
B. Histology
    1. Different
    2. Same, but in different segment, lobe or lung, and
        a. origin from carcinoma *in situ*
        b. no carcinoma in lymphatics common to both
        c. no extrapulmonary metastases at time of diagnosis

From Martini N and Melamed MR. Multiple primary lung cancers. *J Thorac Cardiovasc Surg* 1975, 20:610, with permission.

TABLE 40.5. CRITERIA FOR THE DIAGNOSIS OF SYNCHRONOUS LUNG CANCER

One Primary Lung Carcinoma and One Metastasis

This category includes patients with a primary lung cancer and a metastasis to a different lobe. According to the 1997 lung cancer staging revision of the American Joint Commission on Cancer (AJCC) and the Union Internationale Contre Cancer (UICC), these patients are considered to have M1 disease. Also included in this category are patients with a primary lung cancer and a satellite nodule(s). The AJCC-UICC considers these patients to have T4 disease. [21]

The diagnosis of a primary lung cancer with an ipsilateral metastasis can often be difficult to make. A retrospective report of 53 patients with lung cancer and another lesion in the same lung revealed that the second lesion was an intrapulmonary metastasis in 16 patients (30%) and a synchronous primary lung cancer in seven (13%).[19] When the cell type, DNA indices, and ploidy studies are identical, an intrapulmonary metastasis is probable. In a second series of 42 patients with intrapulmonary metastasis detected at the time of thoracotomy, the five-year survival was 25.7%. Patients with T1 or N0 status had a better prognosis. [22]

A satellite nodule has been defined as a well-circumscribed accessory focus of carcinoma clearly separate from the main tumor but within the same lobe and with identical histologic characteristics. [23] In 1989, Deslauriers and colleagues reported that the prognosis in 84 resected lung cancer patients found to have satellite nodules was worse at one, three, and five years (61%, 33%, 22%) than in 1,021 resected lung cancer patients without satellite nodules (78%, 54%, 44%). They suggested that patients with a primary carcinoma and a satellite nodule(s) be classified as having stage IIIa disease in view of their relatively poor prognosis. [23] The 1997 revision of the TNM staging system takes into account the poor prognosis of patients with satellite nodule(s) and considers them to be of T4 status and thus at

least stage IIIb.[21]

Lung cancer does not appear to metastasize to the contralateral lung as commonly as to other distant sites. In two necropsy studies of patients who died of bronchogenic carcinoma, a metastasis to the contralateral lung was found in 20% and 22%, respectively. [24,25] Establishing the cell type of a contralateral tumor prior to finalizing the surgical plan, by transbronchial biopsy, CT-guided fine-needle aspiration biopsy (FNAB), or thoracoscopic excision, is recommended.[4]

Two Metastases from an Extrathoracic Primary

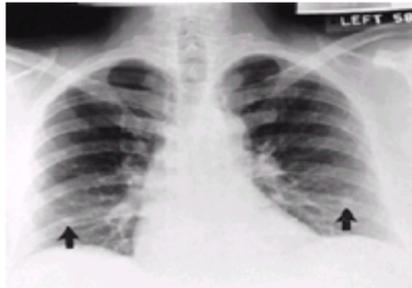
This diagnostic scenario should be considered when any of the following apply: (a) the patient's history and physical suggest an extrathoracic primary site; (b) the radiological characteristics of the tumors are not suggestive of a primary lung cancer (Figure 40.2); or (c) the patient is a nonsmoker without a history of exposure to a known environmental pulmonary carcinogen. When more than two tumors are identified on chest roentgenogram, the suspicion that they represent metastatic disease is heightened. Factors favoring metastatic disease from an extrathoracic primary include a history of extrapulmonary carcinoma, the absence of bronchial wall invasion, a lack of pulmonary or mediastinal lymph node metastases, and histologic features of a nonbronchogenic cell type. [26]


FIGURE 40.2. Two metastatic pulmonary tumors.

One Primary Carcinoma, One Benign Lesion

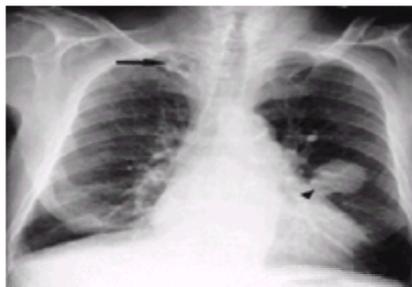
In Kunitoh's study of 53 patients with two ipsilateral lung nodules, one of which was a carcinoma of the lung, the other nodule was found to be benign in 30 cases (56.7%). Foci of pulmonary infarction, inflammation, and fibrosis were found in addition to intrapulmonary lymph nodes, hamartomas, granulomas, and adenomatous hyperplasia (Figure 40.3).[27] In the setting of one known carcinoma of the lung and one indeterminate tumor, a search for evidence of extrathoracic metastases should be conducted. If extrathoracic metastases are found, surgical therapy is not recommended. If no evidence of extrathoracic disease is found, then further evaluation of the second tumor should be left to the discretion of the surgeon. If it is felt to be a granuloma, for example, observation is appropriate, but if there is any question with regard to the diagnosis, further workup is recommended. Ipsilateral lesions can be evaluated and treated at the time of a planned thoracotomy, whereas contralateral lesions might require transbronchial biopsy, transthoracic biopsy, or thoracoscopic resection.


FIGURE 40.3. Primary lung cancer and a benign pulmonary tumor.

Two Benign Lesions

When the history and physical examination are inconsistent with carcinoma of the lung or carcinoma metastatic to the lung, and when confirmation of the nature of pulmonary nodules is indicated, then bronchoscopy with transbronchial biopsy, FNAB, or thoracoscopic excision are possible diagnostic modalities. Because either nodule might represent a primary lung cancer, however, consideration should be given to performing a biopsy on both nodules.

Evaluation

Before the advent of computed tomography, second pulmonary tumors were most often detected either at the time of pulmonary resection or at autopsy. Presently, however, a second pulmonary tumor is most commonly discovered during noninvasive preoperative assessment, less commonly at the time of bronchoscopy, and least commonly at the time of thoracotomy.[28] Deschamps and colleagues reported that 21 of 36 synchronous lesions were first discovered during preoperative evaluation, while the remaining tumors were identified at thoracotomy. [9] Only three of 28 patients were found to have a second lesion during preoperative bronchoscopy in a report by Ferguson [26] and only one of ten was found by this means in a report by Mathisen and associates. [6]

When two pulmonary tumors are discovered on a chest roentgenogram, a computed tomogram of the chest is performed to evaluate the rest of the lung parenchyma for evidence of other lesions. The liver and adrenal glands are imaged in this study to exclude the possibility of metastatic disease to these sites. If multiple nodules are found, either metastatic disease or benign (granulomatous) disease should be suspected, depending upon the clinical scenario. PET scanning in the alveolar is becoming increasingly popular (see also Chapter 30).

Bronchoscopy is performed to be certain that there are no asymptomatic foci of endobronchial disease. McElvaney and colleagues found additional synchronous foci of adenocarcinoma on close examination of the pathological specimens of 12 of 62 patients who underwent resection. These additional foci were identified preoperatively in only two of 12 patients and led the authors to conclude that the incidence of multiple primaries might be even higher than currently estimated, but that they are clinically inapparent due to their slow growth and asymptomatic nature. [29] The role that lung imaged fluorescence endoscopic (LIFE) devices will have in detecting additional foci of carcinoma *in situ* or invasive carcinoma in lung cancer patients is currently being investigated [30] (see also Chapter 24).

Mediastinoscopy is an essential component of the prethoracotomy evaluation for patients with possible synchronous primaries. While some surgeons believe that completely resected mediastinal disease does not preclude a contralateral thoracotomy if the patient is free of recurrence or progressive disease at three months, others do not agree.[28] An algorithm for the evaluation of a patient with synchronous masses on chest roentgenogram is presented in Figure 40.4.[12]

FIGURE 40.4. Algorithm for evaluation of synchronous lung tumors.

Treatment

Patients who are believed to have synchronous tumors are offered surgery if clinical staging indicates that each lesion is stage I. [12] Patients with stage II disease are often treated with surgery, with the knowledge that survival is substantially diminished when N1 lymph nodes are involved. This occurs in part because the status of N1 lymph nodes is often difficult to determine preoperatively. Klingman and DeMeester advise that the intraoperative finding of positive hilar or mediastinal lymph nodes should preclude further surgery in patients with bilateral primaries because of their poor prognosis (median survival 11 months) compared to those with negative lymph nodes (median survival 26 months).[31] Similarly, Deschamps and associates do not recommend additional surgery for patients with bilateral primaries found to have positive mediastinal lymph nodes during initial resection. [9]

When carcinomas are bilateral, resection of the lesion that is felt on clinical grounds to be more advanced is advocated first. [5,8,13,14,31] Further resection is dependent upon (a) the pathological stage of the first tumor, (b) the extent of the second tumor, (c) the anticipated magnitude of the second resection when compared with the first, and (d) the patient's pulmonary reserve.[8,14] Parenchyma-sparing procedures (for example, wedge resection, segmentectomy, sleeve lobectomy) should be considered when a contralateral lesion is present, as long as it does not jeopardize the chance for a curative resection. [13,14] While resection of bilateral carcinomas is approached most often using staged thoracotomies, in selected situations a median sternotomy or bilateral sternothoracotomy is appropriate, the latter made easier by the use of thoracic epidural analgesia.[32]

In patients with ipsilateral lesions confined to one lobe of the lung, a lobectomy is sufficient. When the tumors are ipsilateral and are in different lobes, however, a pneumonectomy is the operation of choice. Conservation of pulmonary tissue is advised (for example, lobectomy and wedge resection or two wedge resections) only when pulmonary function precludes performance of a pneumonectomy.[3] Mediastinal and hilar lymph node sampling are necessary in all cases to complete pathological staging.

Prognosis

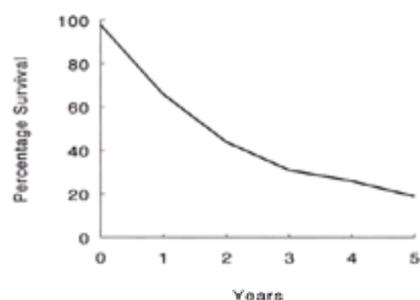
Survival after resection of synchronous primary lung carinomas is worse, stage for stage, than after resection of solitary bronchogenic carcinomas, as illustrated in Figure 40.5. Pairolero and others suggest that these patients should be considered to have stage IV disease. [33] Their poor prognosis might be explained by the more aggressive nature of their disease, by an increased risk of developing cancer, by the fact that the second lesion really was a metastasis all along, or by the fact that both lesions were metastatic from an extrathoracic primary.[9,13] A final possible explanation for the poor prognosis of synchronous tumors is the fact that the second tumor is treated more often by wedge or segmental resection, procedures associated with increased risk of local recurrence. [34,35]


FIGURE 40.5. Actuarial survival following resection of synchronous primary lung cancers. (From Ferguson MK. Synchronous primary lung cancers. *Chest* 1993;103s:399, with permission.)

Metachronous Tumors

In 1975 Martini and Melamed developed criteria for the classification of metachronous tumors (Table 40.6).[20] They proposed a tumor-free interval of at least two years as one of their criteria for the diagnosis of metachronous primary lung cancers. Others have stated that an interval of 30 to 36 months is necessary between tumor occurrences in order to call the second lesion a metachronous primary cancer. At least five series have reported the median interval between treatment of the first and second primary lung cancer to be in excess of 48 months.[6,7,8,15 and 36]Three other series, however, have reported median intervals between 24 and 48 months, [9,37,38] while a fourth reported two peaks at two and five years.[8] There is no consistent evidence that the interval varies among different cell types or for different initial resections.

A. Histology different

B. Histology same if:

   1. free interval between cancers at least two years, or

   2. origin from carcinoma in situ, or

   3. second cancer in different lobe or lung, and

     a. no carcinoma in lymphatics common to both

     b. no extrapulmonary metastases at time of diagnosis

From Martini N and Melamed MR. Multiple primary lung cancers. *J Thorac Cardiovasc Surg* 1975, 20:610, with permission.

TABLE 40.6. CRITERIA FOR THE DIAGNOSIS OF METACHRONOUS LUNG CANCER

Metachronous tumors are estimated to occur in 0.5% of all lung cancer patients overall, in 2% of lung cancer patients who undergo resection, and in 10% to 32% of long-term survivors of lung cancer surgery (Table 40.7).[18,30,32,33]This percentage increases as patient survival improves. The risk of developing a second primary lung cancer is between 0.65% and 5% per year for patients following resection of a lung cancer. [9,14,32,39,40] Shields and associates reported that the incidence of a second primary was 7.6% at 5 years and 10% at ten years in a Veteran's Administration study of 535 patients with resected lung cancer. [36] The Mayo Clinic reported a 10% incidence of second primary lung cancers in their group of 346 patients with resected stage I non–small cell lung cancer (NSCLC). [33] The incidence may be rising in part as a result of its being looked for with increasing vigor. A Lung Cancer Study Group trial reported by Feld and co-workers revealed the contralateral lung to be the site of first relapse in 13% (20 of 158) of 390 patients with resected stage I and II NSCLC, whereas ipsilateral relapse occurred in 26% (41 of 158). Nonsquamous or mixed tumors were twice as likely to recur as squamous cell cancer.[41] DNA flow cytometry and DNA index can help to differentiate between a recurrence and a new primary.

Author (Year)	Resected Lung Cancer Patients	Metachronous Lung Cancer Patients (%)
Abbey-Smith (1976)[15]	1,400	45 (3.2)
Wu (1987)[7]	3,815	20 (0.5)

Total	6,219	90 (1.5)

TABLE 40.7. INCIDENCE OF METACHRONOUS LUNG CANCER IN RESECTED LUNG CANCER PATIENTS

Evaluation

Approximately 80% of patients who develop second primary lung cancers are asymptomatic, and the diagnosis is based upon finding an abnormality on a surveillance chest roentgenogram.[6,8,14,15,20,42] This reinforces the need for continued long-term follow-up of all lung cancer patients. Patients who continue to smoke may be at increased risk for developing a second primary lung cancer.[15] Symptoms, if present, include cough, hemoptysis, and dyspnea.[6,7,8,9,42] The second tumor is evaluated and treated in a manner similar to the initial lesion.[14,41] This includes assessment of the locoregional extent of disease and a search for sites of extrathoracic spread. A positive mediastinoscopy contraindicates a thoracotomy in most cases.

Treatment

It has been stated that it makes no difference whether or not a new lung tumor is a primary or recurrent carcinoma. If the new lesion appears localized and is amenable to surgical excision, then this should be the procedure of choice.[43] There is no doubt that resection offers the best chance of cure and should be attempted in appropriately selected patients.[14] Distinguishing between a stump recurrence or a recurrence at the site of a previous resection might not be critical if the disease is otherwise localized and the patient is a candidate for resection. [6,15,20]

Only one third of patients with a second primary lung cancer are candidates for surgery despite the fact that their second tumor is clinically resectable. [5,14,15,32,38]For example, only 17 of 55 patients in Abbey-Smith's series [15] were surgical candidates, compared to ten of 41 in Shields's series [36] and 12 of 34 in the series by Razzuk and others.[14] Inadequate pulmonary reserve is the reason most commonly given for inoperability. When the metachronous tumor is ipsilateral and in a different lobe from the first tumor, and when the patient's pulmonary reserve is adequate, a completion pneumonectomy is advised. If, however, pulmonary reserve is limited, a segmentectomy or wedge resection with lymph node sampling is appropriate.

When the metachronous tumor is contralateral and the patient has not had a previous pneumonectomy, a lobectomy is the preferred procedure. If, however, the patient underwent pneumonectomy in the first instance, a segmentectomy or wedge resection is performed most often, with lobectomy reserved for highly selected patients with adequate pulmonary reserve.[40,44]

Survival/Prognosis

Morbidity and 30-day mortality after resection of metachronous lung cancer is higher than after initial lung resection. [32] Morbidity in one series was 39%, which is similar to that reported after completion pneumonectomy. Mortality rates range from 4.5% to 9.3%.[6,9,38]

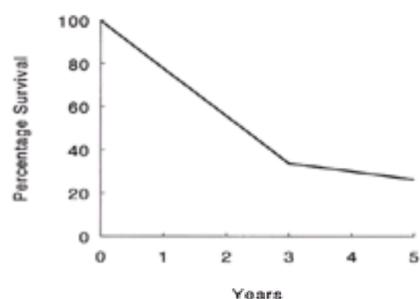
Five- and ten-year survival after resection of metachronous primary lung cancer are 30% and 20%, respectively (Figure 40.6).[6,7,8,9,13,42] The poorest survival is seen in patients who undergo limited resection (segmentectomy, wedge) of their second lung cancer.[42] This might be explained by inadequate margins, underlying pulmonary dysfunction, advanced age at the time of the second resection, misdiagnosis of metastatic disease, and/or increased operative mortality. Sleeve lobectomy is also associated with decreased survival when compared to lobectomy, which might be due to an increase in the rate of local recurrence.[6] The increased risk of local recurrence must be weighed against the benefit of preserving pulmonary parenchyma in anticipation of metachronous disease when advocating conservative resection of lung cancer. Survival is not inferior when the cell type of the second tumor is the same as the first.[12] Verhagen and associates also felt that survival was better if three as opposed to two pulmonary lobes remained after the second resection.[8] Many series report improved survival when the interval between treatment of the lung cancers is greater than two years,[6,8,13] although this has not been a universal finding.[36] This is most likely due to the fact that the longer a patient survives after initial surgery, the more likely a second tumor represents a second primary as opposed to either a metastasis or a missed synchronous tumor.


FIGURE 40.6. cmSurvival after resection of metachronous lung cancer.

All authors conclude that the follow-up of a lung cancer patient should continue indefinitely. It is recommended that patients be followed quarterly for the first two years, biannually for the next three years, and yearly thereafter.[6] This regimen is currently under review by investigators of cost-effective health management

strategies but does not take into account the psychological impact of not having continued follow-up care by their surgeon.

BRAIN METASTASIS

Introduction

Bronchogenic carcinoma is the neoplasm that most commonly metastasizes to brain.[45] It is estimated that in 1998, 170,000 persons were diagnosed with bronchogenic carcinoma and that 51,000 will develop brain metastasis during the course of their disease.[46] Unfortunately a brain metastasis is usually a manifestation of widely disseminated disease. Arbit and Wronski reported that only 38 of 201 patients had brain metastases as the only site of distant disease. Among patients diagnosed with a solitary brain metastasis, 28% to 68% are found to have a primary carcinoma in the lung and between 4% to 20% have no evidence of a primary carcinoma.[45,47,48] An estimated 40% of lung cancer patients develop brain metastases during the course of their disease.[46,50,51,52, and 53] The incidence of brain metastases in lung cancer patients at autopsy is approximately 20% higher owing to their sometimes asymptomatic nature.[54,55, and 56] In one report of 259 patients with inoperable adenocarcinoma of the lung, 24% had or developed clinical evidence of brain metastases during the course of their illness, but brain metastases were found in 44% of the 87 patients autopsied.[57]

In early-stage NSCLC, first recurrences involve distant sites in 50% of patients, and the brain is the site of first recurrence in 20%. The relative risk of recurrence in the brain is higher among patients with T1N1 and T2N0 disease when compared to those with T1N0 tumors. Patients with non–squamous cell or mixed-histology tumors are at an increased risk of developing brain metastasis.[41,58,59]

Without treatment, the median survival after discovery of brain metastases is one month.[60 and 61] Treatment with steroids both palliates symptoms and prolongs median survival to approximately two months.[62,63] Radiation therapy is associated with symptomatic improvement and an increase in the median survival to between three and six months.[64,65] Stereotactic radiosurgery has been applied to lesions under three centimeters, with a median survival of 9.4 months. The exact role of this treatment modality has yet to be defined, and to date no randomized trial data are available for review.[48]

Results of early surgical efforts were not favorable owing to a lack of availability of steroids and modern-day neuroanesthetic and neurosurgical techniques.[66] The availability of steroids, coupled with the development of cortical mapping, laser technology, and the ultrasonic aspirator, has resulted in the development of surgical resection of brain metastasis from bronchogenic carcinoma as an important therapeutic option in selected patients.[47,67,68] The median survival of 583 patients treated by surgical resection at a major cancer center was 9.4 months, and their operative mortality was 5.3%.[48]

Evaluation

The first step in the assessment of a lung cancer patient with a lesion in the brain (Figure 40.7) is to determine whether or not it represents a metastasis.[69] In Patchell's randomized trial of cancer patients with solitary brain lesions, 10% (6 of 59) did not represent metastatic disease, illustrating the importance of establishing the diagnosis before developing a treatment plan.[70] Overall, approximately 3% of NSCLC patients develop an operable solitary brain metastasis during the course of their disease. The goal of the evaluation, therefore, is to select patients most likely to benefit from surgical treatment of their brain metastasis.

FIGURE 40.7. Brain metastasis from carcinoma of the lung.

Neurologic symptoms precede lung cancer symptoms in about 80% of patients found to have synchronous disease.[71,72,73] Headache is the symptom most commonly associated with brain metastasis and occurs in approximately 50% of patients.[74] Focal weakness or hemiparesis occurs in about 40%, and dysphasia, seizure, or visual changes occur less frequently.[51,74] Patients with adenocarcinoma have an increased incidence of asymptomatic brain metastases compared to those with other non–small cell types.[74]

Computed tomography (CT) and magnetic resonance imaging (MRI) are the primary radiographic modalities used to evaluate patients suspected of having brain metastasis.[73,75,76] CTs are more sensitive in detecting small tumors and in assessing the effect of steroids, whereas MRI allows for improved visualization of the brainstem.[74,75] Since it has been estimated that CT of the head may reveal silent brain metastases in only 3% of lung cancer patients at the time of initial staging, it is not cost-effective to include a head CT as part of routine staging in patients who are early-stage by clinical criteria and have no neurologic symptoms.

At presentation, between 30% to 50% of brain metastases are solitary, 20% of patients have two metastases, and 13% have three metastases. Local therapy can thus be offered to up to 70% of patients. Only 30% to 50% of patients with brain metastases are candidates for resection (Table 40.8).[45,48,52,55,71,74,77 and 79] Reasons for inoperability are: (a) location of metastasis in a surgically inaccessible area, (b) other distant sites of failure detected concurrently, (c) poor general medical condition, and (d) anticipated life expectancy of less than three months.[80]

Author (Year)	Patients Autopsied	Patients with Solitary Metastasis (%)
Flavell (1949)[101]	85	26 (31)
Galuzzi (1955)[55]	741	103 (14)
Richards (1963)[60]	127	24 (19)
Deeley (1968)[64]	63	30 (48)
Total	1,016	183 (18)

TABLE 40.8. PERCENTAGE OF NSCLC PATIENTS WITH SOLITARY BRAIN METASTASIS-AUTOPSY SERIES

One percent of patients diagnosed with lung cancer are found to have a synchronous solitary brain metastasis. A metachronous presentation is more common, and the median interval between resection of the lung primary and the diagnosis of a metachronous brain metastasis is 12 months (Table 40.9).[81]

Author (Year)	Patients	Synchronous Disease (%)	Metachronous Disease (%)
Read (1989)[83]	92	28 (30)	64 (70)
Macchiarini (1991)[87]	37	10 (27)	27 (73)
Burt (1992)[81]	185	65 (35)	120 (65)
Total	314	103 (33)	211 (64)

TABLE 40.9. INCIDENCE OF SYNCHRONOUS AND METACHRONOUS BRAIN METASTASIS

Supratentorial metastases develop in 66% to 84% of patients. The frontal and parietal regions of the brain are affected most often. Cerebellar metastases account for approximately 25% of brain metastases, are solitary about 25% of the time, and may cause symptoms earlier than lesions in other regions.[45,47,73] The distribution of brain metastasis reflects a vascular pattern of dissemination, most commonly via the middle cerebral artery.[71]

Treatment

When deciding upon the most appropriate treatment option for an individual patient, the following need to be taken into consideration: (a) symptoms, (b) general condition of the patient, (c) extent and status of cerebral disease, and (d) extent and status of extracranial disease. Modalities include external beam radiotherapy, brachytherapy, surgical resection, stereotactic radiosurgery, and combinations thereof. Chemotherapy can also be used in an adjuvant setting. Mandell and colleagues have developed a management algorithm for solitary brain metastases (Figure 40.8).[49]

FIGURE 40.8. Algorithm for management of solitary brain metastasis.

Surgery is preferred for (a) solitary lesions associated with significant edema, (b) large lesions, (c) superficial lesions, (d) patients with symptoms requiring immediate relief, and (e) lesions associated with hemorrhage.[69] Radiosurgery is recommended if the lesion is deep but less than 3 cm in diameter, if there are medical contraindications to surgery, or, in some cases, when the tumor is recurrent.

In the metachronous setting, resection of the intracranial metastasis follows the guidelines above. In the synchronous setting, craniotomy is generally completed first, because patients are more often symptomatic from their brain metastasis. If the radiographic appearance of the lung primary suggests it to be unresectable, however, thoracosopy may be used to assess this prior to proceeding with craniotomy, if the lung primary is resectable, or other palliative treatment, if it is not.[82]

Operative mortality following craniotomy is between 0% to 11.1% in recent series.[70,73,76,81,83,84,85 and 86] Complete resection was accomplished in 90% of the 583 patients treated at one major cancer center.[46] Morbidity averages 20% and is primarily neurological in nature. Improvement in neurological status is reported in between 57% and 84% of patients, while 13% to 33% of patients have either stable or worsening neurological status.[47,70,73,77,76,83,86,87] The median duration of neurological improvement is 15 months.[73,86]

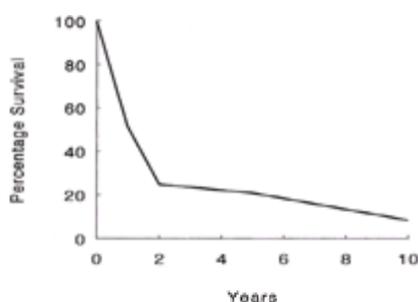
Five-year survival after resection of solitary brain metastasis is approximately 20% (Figure 40.9). Median disease-free survival after resection is between six and 20 months. A randomized trial comparing surgery plus radiation to radiation alone in patients with solitary brain metastases from solid tumors revealed a decreased incidence of local recurrence, increased survival, and prolonged improvement in functional status in the group treated with surgery plus radiation compared to the radiation-alone group (20% versus 52%, 40 weeks versus 15 weeks, and 38 weeks versus 8 weeks, respectively).[70]


FIGURE 40.9. Survival after resection of solitary brain metastasis from non–small cell lung cancer.

Recurrent cranial disease develops in approximately 50% of patients following surgical management of brain metastasis, and in some series as many as half of these recurrences involve the site of original disease.[51,78,81] Craniotomy has been recommended for recurrence only if the disease continues to be limited to the brain. This approach can be expected to result in an improvement in neurological status in two thirds of patients and a two-year survival rate of 25%. Despite these modest results, most reports caution that the uniformly dismal prognosis of recurrent brain metastases should preclude surgery, and that radiosurgery or a boost of external beam radiation therapy is appropriate for most patients. The roles of brachytherapy and chemotherapy have not been assessed. The cause of death in patients with brain metastasis from any cancer is due most commonly to either the brain metastasis (25% to 50%), diffuse systemic disease (20% to 25%), or both (10%).[74,78,83]

Prognosis

Among patients with lung cancer metastatic to the brain, the most favorable prognosis is associated with a completely resected primary lung tumor. [84,85,86 and 88] Control of the primary site of cancer is mandatory for long-term survival. [52,80] Multivariate analysis revealed that wedge resection of the primary lung cancer was the only significant prognostic factor, implying that patients with tumors amenable to wedge resection were more likely to survive. [78] The completeness of resection of the lung primary was found to impact significantly on the survival of a group of 256 patients with brain metastases from NSCLC. [85] Solitary metastases have a better prognosis than multiple metastases, [81,88] and surgical management of multiple metastases is rarely indicated. [88] An improved prognosis is associated with brain metastases less than 3 cm in diameter. [47,80] The prognosis may also be better if the metastasis is either asymptomatic or mildly symptomatic. [74] Whether a brain metastasis is metachronous or synchronous has not generally been found to influence survival. [50,78,81,83,87 and 89] It has been reported that both disease-free survival and actuarial survival were better among the 35 patients with metachronous disease compared to 15 with synchronous disease (actuarial survival 31% versus 6%). [90] In the metachronous setting, however, a prolonged interval between resection of the lung primary and diagnosis of the brain metastasis is associated with improved prognosis, [90,91] but this has not been a universal finding. [81] While age has not been found to affect prognosis in most reports, a univariate analysis by Hankins and associates found that age younger than 55 years was a favorable sign. [47,57,59,61,81,85,90,92] It is unclear whether or not the lymph node status of the primary tumor is of prognostic significance in patients who undergo resection of a solitary brain metastasis. [50,78] Similarly, whether or not a supratentorial metastasis is more favorable than an infratentorial one is uncertain. [45,51,81,85,87] A recent abstract reported that 31 of 256 patients with cerebellar metastasis had a decreased survival when compared to patients with a supratentorial metastasis. [89] Salvati's review of eighteen ten-year survivors, however, revealed that none had had a posterior fossa metastasis. [76]

METASTASIS TO OTHER SITES

Sporadic reports have addressed the role of surgery with curative intent in settings where lung cancer has metastasized to sites other than those discussed in the preceding sections. [1,2,93] Surgical management of lung cancer that has metastasized to bone is palliative and is aimed at restoring functional status. The bone represents an isolated site of first recurrence in approximately 5% of lung cancer patients. The prognosis is similar to that of patients who develop brain metastases and is worse than in patients who recur in either the ipsilateral or contralateral lung. [58] Bone biopsy is indicated when a solitary focus of suspected metastasis is discovered in a patient who is otherwise operable.

Adrenal metastases are found at autopsy in 10% to 59% of NSCLC patients. [94,95,96] Unilateral adrenal masses are discovered in approximately 4% of patients with otherwise operable NSCLC but only 40% represent metastatic disease. [3,97] In one series of 598 patients with operable or operated NSCLC, 39 had adrenal masses (18 benign, 21 malignant) and 11 of the patients had their adrenal metastasis resected. [4] Patient age, lung cancer stage, or mass size did not help to distinguish benign from malignant lesions. [96] Proper treatment planning, therefore, mandates cytologic or histologic confirmation of the true nature of a unilateral adrenal mass in a patient with NSCLC. In one series, the specificity of needle aspiration biopsy in detecting metastatic disease was 100%; however, nondiagnostic results necessitated adrenalectomy in five of ten patients, all of whom had benign glands. [96] The report that 12% of adrenal glands that appeared normal on CT scan harbored metastatic disease in a group of 32 NSCLC patients needs to be confirmed. [98] A series of 14 patients found to have isolated adrenal metastasis associated with NSCLC revealed a median survival of 22 months for the eight patients treated surgically, compared to 8.5 months for the six patients treated with platinum-based chemotherapy. [99]

Pleurectomy for metastatic lung cancer has been attempted in a handful of patients, either alone or with concomitant lung resection, in the hope of improving quality and duration of survival. Disease status was reported in five patients, one of whom had died ten months after lobectomy and pleurectomy. The remaining four patients were alive between 15 and 35 months postoperatively; however, only one patient was free of disease. [93] The presence of pleural metastases precludes surgery with curative intent. [100]

COMPLICATIONS OF SURGERY

L. PENFIELD FABER
WILLIAM PICCIONE

Surgical resection remains a mainstay of therapy for patients with carcinoma of the lung. Unfortunately, any surgical intervention carries with it the potential of morbidity and mortality. Although many advances have occurred in the preoperative, intraoperative, and postoperative care of these patients to minimize the risk of surgery, complications still occur.[1] Complications after surgery can never be totally eliminated, but they can be minimized by careful attention to the many details of prevention. When complications do occur, proper management usually yields a satisfactory result. Prevention includes accurate preoperative assessment, meticulous surgical technique, and a knowledge of surgical maneuvers to minimize potential problems.

PREOPERATIVE ASSESSMENT

Traditional attempts to assess surgical morbidity and mortality after pulmonary resection have primarily focused on clinical assessment and static pulmonary function testing, such as spirometry, radionuclide scans, and temporary unilateral pulmonary artery balloon occlusion. Nagasaki and associates [2] studied 961 patients undergoing surgical treatment for carcinoma of the lung. Variables including age, gender, cell type, extent of resection, cardiopulmonary status, and stage of disease were evaluated. The authors found that certain high-risk groups could be identified:

1. patients older than 70 years of age in whom a major resection is necessary;
2. patients with a positive cardiac history;
3. patients with severely restricted pulmonary reserve, regardless of age.

Gender, stage of disease, and cell type were found to have little influence on the frequency of postoperative complications. Kohman and colleagues [3] studied 476 patients undergoing thoracotomy more thoroughly by analyzing 37 preoperative risk factors, including the forced-expiratory volume at 1 second (FEV1) and arterial blood gases, and their effects on morbidity and mortality. Only three of these factors were found to have a significant association with mortality. These consisted of age 60 years or older, need for pneumonectomy, and premature ventricular contractions on admission electrocardiogram. However, all these preoperative risk factors together were found to account for only 12% of the risk of mortality observed. The authors speculated that most deaths after pulmonary resection might therefore be random, unpredictable events. Clearly then, increased accuracy in preoperative assessment necessitates measure of more physiologic parameters.

Boysen and colleagues[4] studied the predictive value of simple spirometric testing with and without more specific testing, and concluded that additional testing over spirometry did not appear to add any predictive value. In contrast, most investigators believe that static pulmonary function tests lack the specificity and sensitivity to predict postoperative cardiopulmonary complications accurately. [5,6] The dilemmas are to define which additional patient parameters will add to the predictive value and to accomplish this task in a minimally invasive, cost-effective manner. Keagy and associates [7] sought to increase the predictive value of preoperative spirometry in 90 patients undergoing pneumonectomy. All patients had forced vital capacity (FVC), FEV_1, and FEV_1/FVC ratio measured. The results demonstrated no correlation between postoperative morbidity and mortality with FVC, FEV_1, and FEV_1/FVC ratio. A further limitation of standard spirometric measurements is that they do not compensate for variations in body surface area. This reduces the usefulness of such measures when applied to either very large or very small patients.

The diffusing capacity of the lung for carbon monoxide (DLCO) was included in the preoperative assessment of 165 pulmonary resection patients by Ferguson and colleagues.[6] Using logistic regression analysis, the authors found that the most important single predictor of postoperative complications or death was the preoperative DLCO. The DLCO estimates pulmonary capillary surface area and can reveal diffusion defects and emphysematous changes even with acceptable spirometric values. This increase in sensitivity and predictive value appears to justify measurement of diffusion capacity as part of the preoperative assessment. In a retrospective review of 376 patients, Ferguson [8] noted that the most reliable predictor of postoperative complications was the percent predicted postoperative diffusing capacity. Predicted postoperative FEV_1 percent was also analyzed in this review, and statistical analysis determined that there was no correlation between PPO FEV_1 percent and PPO DLCO percent in predicting morbidity or mortality after major lung resection. Each value should be analyzed separately and correlated with the planned amount of lung tissue to be removed. Ferguson[9] concludes that a preoperative diffusing capacity under 60% of predicted indicates an increased risk for complications following pneumonectomy. This increase in sensitivity and predicted value appears to justify measurement of diffusion capacity as part of the preoperative assessment.

Several investigators have sought a more accurate measurement of functional cardiopulmonary reserve. The measurement of maximum oxygen consumption during exercise (VO_{2max}) has been used to predict postoperative complications. A postulate is that oxygen consumption is directly related to cardiac output and that a reduced peak oxygen consumption may correlate with increased postoperative complications. Bechard and Wetstein [10] reported minimal risk of postoperative complications in 50 consecutive patients in whom the VO_{2max} was greater than 20 mL per kg per minute. Patients with a VO_{2max} of less than 50 mL per kg per minute accounted for 75% of all postoperative complications observed. Bolliger [11] concluded that a VO_{2max} under 10 mL per kg per min is predictive of a high risk of complications following any pulmonary resection and could even be considered prohibitive. A value greater than 20 mL per kg per min or greater than 75% of predicted normal is safe for major pulmonary resection, including pneumonectomy.

Recent studies have evaluated exercise oximetry to predict operative risk. Rao [12] carried out a retrospective analysis of 299 patients who underwent both exercise oximetry and spirometry. Sensitivity of oximetry was low, but compared with spirometry it more reliably predicted prolonged hospital stay and respiratory failure. Ninin and colleagues[13] evaluated 46 consecutive patients undergoing pneumonectomy with exercise oximetry and concluded that exercise oximetry was predictive of morbidity and prolonged intensive care stay following pneumonectomy. Prospective randomized trials are needed to confirm the reliability of this test.

Although much effort has been expended to define high-risk patient populations for pulmonary resection, the dilemma of choosing appropriate therapy for such patients remains. Postoperative deaths are dreaded by all involved. However, a more conservative approach might deny a patient a potentially curative resection. Vigorous preoperative respiratory therapy, cessation of smoking, bronchodilator therapy, and even short-term corticose steroid therapy have been shown to improve the operability of lung cancer patients with marginal pulmonary reserve. [14] Finally, tailoring the procedure to the patient, such as a segmentectomy versus a lobectomy or sleeve lobectomy versus a pneumonectomy, might also offer an otherwise marginal patient the chance of a curative procedure. For more discussion of preoperative risks see Chapter 36.

ARRHYTHMIAS

Atrial and ventricular arrhythmias can occur after pulmonary resection. Many factors may contribute to the development of arrhythmias postoperatively (Table 41.1), with potentially serious complications. As early as the 1940s, several investigators noted the increased incidence of arrhythmias after pulmonary resection. [15],[16] The incidence of arrhythmias after pulmonary resection has been cited as 3.4% to 30%. Atrial arrhythmias are far more common, consisting of fibrillation, flutter, and supraventricular tachycardia. [17],[18] and [19] Loss of sinus rhythm adversely affects cardiac output, with resultant decrease in coronary, renal, and cerebral blood flow. When arrhythmias do occur, it is usually during the first few days after surgery and most commonly on the second or third postoperative day. Shields and Ujiki [18] studied 125 consecutive patients and reported a 22% mortality in those patients who developed a postoperative arrhythmia, as compared with a 7% mortality in patients who remained in normal sinus rhythm. These findings are consistent with a series of 236 pneumonectomy patients studied retrospectively by the Mayo Clinic. [15] In this study, the authors observed a 25% 30-day mortality in patients developing tachyarrhythmias after surgery.

Pericardial irritation
Increased sympathetic discharge
Atrial damage
Electrolyte disturbance
Atrial distention
Underlying coronary or valvular heart disease
Postoperative myocardial ischemia
Hypoxia
Preoperative theophylline use

TABLE 41.1. POTENTIAL FACTORS RELATING TO POSTOPERATIVE ARRHYTHMIAS

The relation of age to the development of postoperative arrhythmias is somewhat conflicting in the literature. Although some authors [17] have reported a near linear relationship between the incidence of arrhythmias with increasing age, Krowka and associates [20] studied 236 pneumonectomy patients and failed to demonstrate any significant association between the patient age and development of arrhythmias. It seems intuitive, however, that age should be a strong predictor of postoperative arrhythmias, because the conduction system also ages, as reflected by a decreasing number of functional sinus node pacemaker cells. [21] In addition, patients of advanced age are more likely to also have coexisting predisposing factors. This is consistent with the findings of Wheat and Burford [19] of a 50% incidence of postoperative arrhythmias in patients 70 years and older who underwent pulmonary resection.

Several series have confirmed a direct relationship between the magnitude of resection and the incidence of postoperative arrhythmias. Mowry and Reynolds [17] reported an overall incidence of 19.4% after pneumonectomy as opposed to 3.1% after lobectomy in their series of 301 patients. Other series [18],[19] have observed a less dramatic disparity and have suggested that the relationship between the incidence of arrhythmias and the magnitude of resection is less pronounced in the older population. Krowka and associates[20] studied the relationship between preoperative pulmonary function and the incidence of postoperative arrhythmias. Although they did not demonstrate a firm correlation, they did report an increased incidence in patients with radiographic evidence of fluid overload after a pneumonectomy. This would follow, because right heart distention is felt to be an important factor in the development of postoperative arrhythmias. Wittnich and associates [22] pointed out that Swan-Ganz measurements of pulmonary artery pressures may not be accurate after pneumonectomy. In this situation, the inflation of the balloon tip catheter to measure pulmonary wedge pressure may in fact increase right ventricular afterload, with resultant decreased cardiac output and therefore decreased left atrial pressure. The authors suggest that in this situation, central venous pressure measurements may in fact be a more accurate measure of true cardiac output.

Although many known factors contribute to postoperative arrhythmias, we still cannot accurately identify patients that are of the greatest risk of developing them. In addition, while may studies have used preoperative digoxin or low-dose beta-blockage in the prevention of postoperative arrhythmias, the data are conflicting. Digoxin has long been the drug of choice for the prevention of arrhythmias following thoracic surgery. However, potential side effects and the development of newer pharmacologic agents have diminished its popularity. Digoxin's predominant action is thought to be a slowing of conduction through the AV node, mediated by enhanced vagal tone. This is consistent with the known effect of digoxin in slowing the ventricular response to a rapid supraventricular rate while at the same time being relatively ineffective in converting to a sinus rhythm. This mechanism is also consistent with the observation of a reduced efficacy of digoxin in the immediate postoperative period, when andrologic influences are more pronounced.

There is some evidence that low-dose beta-blockage may have a beneficial prophylactic effect. However, many of the patients presenting for pulmonary resection have underlying pulmonary disease or reduced ventricular function and are therefore not ideal candidates for the administration of beta-blocking agents. [23],[24]

The prophylactic administration of the calcium-channel-blocking agent verapamil has been shown to reduced significantly the occurrence of postoperative arrhythmias following thoracotomy.[25] In addition, verapamil was found to lower right ventricular systolic and diastolic pressures, an important action because elevated right-sided pressures are felt to predispose to atrial arrhythmias. [26] A recent study by Van Mieghem and associates[27] demonstrated that a relatively large dose of intravenous verapamil (10 mg bolus) following pulmonary resection effectively reduced the incidence of atrial arrhythmias by 50%. However, side effects such as bradycardia and hypotension seen with this dosage led to discontinuation of the drug in many patients.

Diltiazem, also a calcium-channel-blocking agent, has been shown to be equally efficacious to verapamil in treating atrial arrhythmias, but with fewer side effects. This has led to the greater acceptance of this agent in the postthoracotomy patient. [28],[29] Amar[30] recently reported on a comparison of diltiazem and digoxin for the prevention of postoperative atrial arrhythmias in pneumonectomy patients. They found that when compared to digoxin, diltiazem was safe and more effective in preventing atrial arrhythmias in these patients. In addition, the observed incidence of postoperative arrhythmias in digoxin treated patients was similar to that observed in the untreated controls. Amiodarone has also been used in the treatment of postoperative atrial arrhythmias; however, its association with the development of pulmonary infiltrates and dysfunction has prevented its widespread acceptance in pulmonary resection patients.

Once postoperative arrhythmias such as atrial fibrillation occur, there are several therapeutic guidelines that should be followed. First, the heart rate should be acutely controlled. Rapid atrial fibrillation results in poor cardiac filling and therefore reduced cardiac output. Digoxin can be administered intravenously over several hours to a total loading dose of 1 mg in the adult patient. However, digoxin does not slow the ventricular rate acutely and often requires several hours to produce an effect. In addition, digoxin does not reliably convert the patient to a sinus rhythm nor maintain the sinus rhythm. Postoperative atrial fibrillation with a rapid ventricular response requires prompt intervention and generally responds to intravenous calcium-channel-blocking agents such as diltiazem, as previously discussed. In addition, underlying predisposing conditions such as metabolic derangements or hypoxia should be accurately sought and corrected. Digoxin may be used as an initial drug in patients with compromised ventricular function and in patients not hemodynamically compromised by the increased ventricular rate, which would require a more rapidly acting agent. Conversion to normal sinus rhythm in patients with refractory atrial fibrillation or flutter generally requires administration of other pharmacologic agents such as quinidine or procainamide. Rarely do patients become so refractory that they require electrocardioversion unless they have a long history of preoperative atrial fibrillation. Patients who require pharmacologic conversion should generally be kept on these medications for at least three months after surgery.

Patients undergoing lobectomy are generally not prophylactically digitalized. If postoperative atrial arrhythmias occur, the patient is treated pharmacologically. In contrast, pneumonectomy patients are generally prophylactically digitalized and maintained on a daily dose postoperatively. As previously mentioned, there are no data indicating that this prevents the patient from experiencing atrial fibrillation, but it should prevent a rapid ventricular response should atrial fibrillation occur. Occasionally a planned lesser resection results in a pneumonectomy secondary to intraoperative findings. In these situations, the patient is loaded with digoxin postoperatively and maintained on a daily dose. All pulmonary resection patients should have cardiac monitoring for at least 24 hours postoperatively. We generally extend the observation period in pneumonectomy patients and in older patients with other comorbid conditions that might predispose them to arrhythmias.

POSTRESECTION PULMONARY EDEMA

Noncardiogenic pulmonary edema following lung resection was first discussed by Gibbon and Gibbon [31,32] in 1942. At that time, they reported on two patients who had undergone bilateral lobectomies and succumbed within 12 hours of surgery. This clinical experience as well as experimental studies conducted in a feline model led the authors to conclude that edema occurs because of increased capillary blood pressure following acute reduction of the pulmonary vascular bed. More recently Zeldin and associates [33] compiled ten cases from several institutions and retrospectively compared them with controls. After comparison, the authors identified three significant risk factors for postresection pulmonary edema (PPE); right pneumonectomy, increased administration of perioperative fluid, and high urine output as a sign of relative overhydration. In conclusion, it was recommended that "the anesthesiologist must not boldly load the patients up with fluids prior to induction." Since then, several more recent studies have confirmed and expanded upon this earlier work. Verheijen-Breemhaar [34] and associates reviewed 243 pneumonectomy patients in the Netherlands and found that postoperative pulmonary edema occurred in 4.5% of patients, with a mortality rate of 27% in affected patients. As in Zeldin's [33] report, the authors found an increased incidence of PPE in right versus left pneumonectomy patients and in those who had a more positive fluid balance as well as in patients who required reoperation for bleeding. Patel and associates [35] retrospectively studied 197 pneumonectomy patients in England and found a 15% incidence of postoperative pulmonary edema and a mortality rate of 43%.

A larger series involving 402 lung resection patients from Leeds, England, was reported by Waller and associates. [36] In this series, PPE occurred in 5.1% of right pneumonectomies, 4.0% of left pneumonectomies, and 1% of all lobectomies. The mortality rate was 55% in patients who developed this complication. Interestingly, these authors did not observe a correlation between perioperative fluid administration and postresection pulmonary edema, which prompted discussion regarding other possible mechanisms. Turnage and Lunn [37] retrospectively reviewed charts on 806 pneumonectomy patients at the Mayo Clinic and found 21 cases (2.6%) who experienced postresection pulmonary edema. Affected patients had a 100% mortality rate and histologic evidence of adult respiratory distress syndrome (ARDS) at autopsy. Patients who had a right-sided resection had a threefold higher incidence of PPE as compared to left pneumonectomy patients. Interestingly, no significant difference was found between the affected patients and age- and sex-matched control groups with regard to administration of perioperative fluids. The authors concluded that while postresection pulmonary edema is more common following right pneumonectomy, the etiology was still uncertain. Shapira and Shahian [38] reviewed the literature in their report and confirmed that pulmonary edema developed in approximately 4% of patients following a major lung resection. They further concluded that several factors were involved in the pathogenesis of interstitial pulmonary edema. Finally, in a recent review by Deslauriers and colleagues, [39] current understanding of factors associated with the development of postresection pulmonary edema was presented and summarized in Table 41.2.

Incidence of 2% to 5% after pneumonectomy
Appears two to three days after otherwise uncomplicated
 postoperative period
Radiologic onset may precede symptoms by 12 to 24 hours
Radiologic image of interstitial pulmonary edema
Unresponsive to conventional therapies
Mortality of 50% to 100%
Histology compatible with ARDS
Occurs despite a normal pulmonary wedge pressure

From Deslauriers J, Aucoin A, Gregoire J. Postpneumonectomy pulmonary edema. Chest Surg Clin N Am 1998;8(3):611, with permission.

TABLE 41.2. POSTPNEUMONECTOMY EDEMA

Pathogenesis

Slinger [40] pointed out in his review that the cause of PPE was probably multifactorial since no single factor could adequately explain the clinical experience. He further characterized the causes of PPE into probable, possible or of questionable influence (Table 41.3).

1. Probable: Fluid overload
               Interrupted lung lymphatics
               Increased pulmonary capillary pressure
               Pulmonary endothelial damage
2. Possible: Hyperinflation
               Right ventricular dysfunction
               Cytokine release
               Oxygen toxicity

From Slinger PD. Perioperative fluid management for thoracic surgery: the puzzle of postpneumonectomy pulmonary edema. J Cardiothorac Vasc Anesth 1995;9:442, with permission.

TABLE 41.3. CAUSES OF THE POSTPNEUMONECTOMY PULMONARY EDEMA

Fluid overload has been implicated in the pathogenesis of PPE since the early work of Gibbon and Gibbon, [31,32] and almost certainly plays a major role. Forty years later, Zeldin and associates [33] confirmed the role of overhydration in the canine model. In their study, dogs were randomized to receive lactated Ringers at 100 mL per kg before or during a right pneumonectomy, and compared to a control group that received lactated Ringers but no resection. Six of the 12 pneumonectomy dogs developed PPE, while none of the controls did [p = less than 0.05]. The authors concluded that following pneumonectomy, the entire cardiac output is directed to the remaining lung with resultant increase in the intracapillary pressure, which predisposes to edema formation. Increased cardiac output from catecholamine release secondary to pain or from excessive fluid administration will exacerbate this situation.

Interruption of mediastinal lymphatics probably also plays a role in the formation of PPE. In normal lungs, it has been estimated that lymph flow can increase seven- to tenfold without leading to pulmonary edema. Following pneumonectomy, a proportional amount of lymphatic channels is removed with the specimen. In addition, mediastinal and subcarinal dissection can effectively compromise the lymphatic drainage from the remaining lung. Little and colleagues [41] studied the effect of pneumonectomy and mediastinal lymphatic interruption in a canine model. Their findings suggested that following pneumonectomy, the contralateral lung was more prone to extravascular fluid development secondary to the loss of parenchymal and hilar lymphatic drainage routes. Nohl-Oser [42] has further described the lymphatic drainage of the lung and mediastinum and reported that the lymphatics from the right and left lungs are notably different. The majority of lymphatic channels from the left lung cross the midline. Therefore a right pneumonectomy is more likely also to disrupt lymphatic drainage from the remaining left lung, possibly contributing to edema formation.

Other possible factors implicated in the formation of PPE include increased capillary pressure and endothelial cell damage producing a "leaky capillary" situation. This is consistent with an ARDS histology previously described in these patients.

Preventative Maneuvers

As previously described, following pneumonectomy the entire cardiac output is directed to the remaining lung, with resultant elevation in pulmonary capillary pressure. Because of this, efforts should be made to restrict fluid administration during the intraoperative and early postoperative periods. Total positive fluid balance in the first 24 hours perioperatively should not exceed 20 mL per kg, typically, less than 2 liters intraoperatively followed by less than 50 mL per hour postoperatively for an average adult. Urine output greater than 0.5 mL per kg is unnecessary in the early postoperative period unless renal insufficiency exists. Placement of a central

venous pressure monitoring line is often useful in assessing intravascular volume and will aid in the decision to administer diuretic or inotropic therapy.

Adequate pain control is essential to minimize catecholamine release with resultant increase in cardiac output. Recently, lumbar or thoracic epidural anesthesia has proved extremely useful in this situation by providing adequate pain control without oversedation of the patient.

Avoidance of mediastinal shift and overdistention of the remaining lung is also essential. Experimental work by Raffensperger and colleagues [43] in dogs confirmed that overdistention of the contralateral lung following pneumonectomy led to deterioration in lung function. These changes were reflected by an increase in the alveolar-arterial gradient. It is now believed that acute hyperinflation of the remaining lung is probably a significant factor in the development of PPE.

Treatment

As previously stated, the development of PPE is associated with a mortality rate in excess of 50%. Current therapy advocated is supportive and essentially the same as for ARDS. This generally consists of fluid restriction, diuretic therapy, and maintenance of adequate oxygenation and nutritional support. Most patients will require intubation and mechanical ventilation. Unfortunately, prolonged ventilation may increase barotrauma and bronchial stump dehiscence. Inspired oxygen concentrations of 80% to 100% may be required to maintain adequate arterial saturation. Peak inspiratory pressures greater than 30 mm of mercury should be avoided if possible. Empiric administration of antibiotics is probably of little benefit because the underlying process is not infectious in nature.

Mathisen and colleagues[44] have recently reported on the use of inhaled nitric oxide in a series of ten PPE patients with reasonable success. In their series affected patients were treated with standard supportive measures plus inhaled nitric oxide at 10 to 20 parts per million. Overall mortality for this limited series was 30%. Finally, in refractory cases, extracorporeal membrane oxygenation (ECMO) may improve survival, but its role is not yet fully defined.

CARDIAC HERNIATION

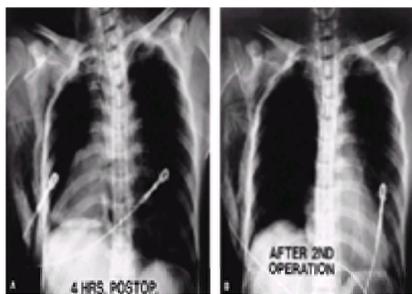
Cardiac herniation is a rare but potentially lethal complication that can occur after pulmonary resection when a pericardial defect is created. The mechanism is simply anatomic displacement of the heart through the pericardial defect, which results in entrapment of the heart, thereby effectively obstructing both venous inflow and arterial outflow. This results in elevation of central venous pressure and resultant diminished cardiac output. [45] This complication was first reported in 1948 after a left intrapericardial pneumonectomy with resultant pericardial defect. [46] Since then, about 30 additional cases of cardiac herniation have been reported after both left and right pneumonectomies. Patients who develop cardiac herniation typically experience cardiovascular collapse, and if not promptly reoperated to reposition the heart within the pericardial space, death ensues. Most series in the literature have reported about a 50% mortality rate with this complication. [47,48] Physical findings include cardiovascular collapse with tachycardia, hypotension, and jugular venous distention. This complication usually occurs either during the procedure or in the immediate postoperative period. Beyond that time, intrapericardial adhesions usually form, thereby preventing gross displacement of the heart. The precipitating event is often a change in the patient's position, coughing, positive pressure ventilation, or excessive negative pressure in a pneumonectomy space. A chest radiograph often diagnoses right-sided herniation (Figure 41.1), but left-sided herniation can be somewhat more difficult to appreciate on a standard posteroanterior film. A lateral chest radiograph may help to demonstrate posterior displacement of the heart. Fluoroscopy has also been suggested as a diagnostic aid in this condition, but this may needlessly postpone timely reexploration to reduce the herniation. Any patient suspected of having cardiac herniation should undergo prompt reexploration and repositioning of the heart into the pericardial space. The pericardial defect should then be closed to prevent reoccurrence.


FIGURE 41.1. A: Cardiac herniation after radical right pneumonectomy. **B:** Chest radiograph after repair with prosthetic patch to close the defect in the pericardium.

To prevent cardiac herniation, some authors have advocated wide excision of the pericardium to prevent entrapment and strangulation of the heart through a small defect. Others have documented the inability of partial pericardiectomy to prevent hemodynamic embarrassment when cardiac displacement does occur. [49] Closure of the pericardial defect after a resection is the more widely held method of prevention. Many authors have advocated closure of pericardial defects with a variety of materials, including pleura, Vicryl mesh, [24] fascia, and even a latticework of catgut. [48] Dippel and Ehrenhaft[50] have advocated a technique of suturing the pericardial defect edge to the adjacent atrial and ventricular myocardium.

We believe that all small pericardial defects should be closed. On the right side, large pericardial defects must be closed, owing to the fact that right-sided displacement of the heart, even without entrapment, causes hemodynamic compromise. In contrast, large left-sided defects do not necessarily have to be patched because the heart normally resides in the left thorax, and further displacement will not result in hemodynamic compromise unless the heart is strangulated through a small defect. We generally do not attempt primary closure of pericardial defects but rather place a material such as Gore-Tex, which is durable and easy to suture. Suturing of the edge of the pericardial defect directly to the myocardium should be discouraged because of unwarranted risk to the coronary vessels. [51]

LOBAR TORSION

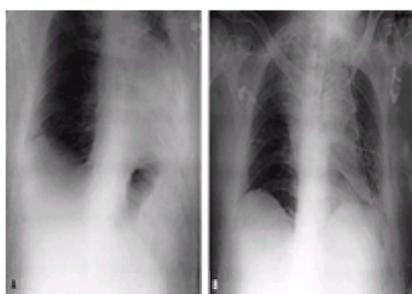
Postresection lobar torsion has been most commonly described involving the right middle lobe after a right upper lobectomy. [52] If the middle lobe is not secured by either an incomplete transverse fissure or by direct suturing to the remaining lower lobe, the middle lobe can rotate on its bronchovascular pedicle, with resultant circulatory embarrassment of the involved lung parenchyma. Schuler[53] reviewed this complication and reported a 16% mortality rate in a series of 31 patients. Less commonly, lobar torsion can occur on the left side, either in the left upper lobe after lower lobectomy (Figure 41.2) or in the lower lobe after upper lobectomy.[54,55,56] Pulmonary lobar torsion involves rotation of the lung parenchyma on its bronchovascular pedicle. This results in occlusion of the pulmonary veins, with resultant infarction and eventual gangrene of the parenchyma involved. Angulation of the bronchus also compromises the bronchial circulation, which further endangers remaining lung parenchyma. Pulmonary infarction can also occur postoperatively in the absence of lobar torsion. Pulmonary vein thrombosis, pulmonary artery occlusion, and intraoperative damage to the bronchial circulation have all been implicated in postoperative pulmonary infarction. [57]


FIGURE 41.2. A: Torsion of the left upper lobe after left lower lobectomy. **B:** Chest radiograph after repositioning of the left upper lobe and fixation with a pleural flap.

Early recognition of this complication is essential to prevent irreversible damage to the involved lobe. A baseline chest radiograph should be obtained shortly after the completion of any pulmonary resection. This is done to ascertain that all remaining lung tissue is fully expanded, with proper positioning of chest tubes. Radiographic findings consistent with torsion include hilar displacement, bronchial cutoff, and lobar consolidation. Nuclear perfusion scans and pulmonary angiography can support the diagnosis by demonstrating lack of arterial blood flow to the affected lobe. However, pulmonary artery blood flow is also decreased in patients with large areas of atelectasis or postoperative parenchymal hematomas. Urgent flexible bronchoscopy should be considered to examine the bronchus and remove any retained secretions, thereby facilitating reexpansion of the pulmonary parenchyma. A bronchus with a "fish-mouth" occlusion generally indicates that torsion has taken place. The bronchoscope can be manipulated through the narrowed area, only to have the bronchus reobstruct after removal of the bronchoscope, which is a diagnostic finding. Clinically, the patient may lack any significant symptoms early in the postoperative period. However, once the parenchyma has infarcted with ensuing gangrene, patients commonly develop foul-smelling or blood-tinged sputum, fever, and malodorous chest drainage. [58,59] If left untreated, these patients can progress to frank sepsis with hemodynamic instability and even death. Treatment consists of early recognition of this condition in the postoperative period and a low threshold for performing flexible bronchoscopy in any patient suspected of having this condition. Reexploration is required with repositioning of the affected lobe, securing it to the adjacent lobe to prevent recurrence. If the affected lobe is clearly infarcted at the time of reexploration, resection is mandatory.

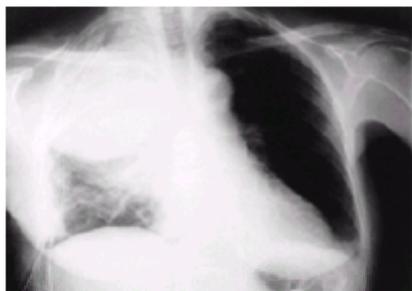
Prevention of lobar torsion is essential and begins in the operating room after pulmonary resection. Careful inspection of the remaining lung tissue should be performed while the lung is carefully reexpanded. Complete interlobar fissures permit rotation of a remaining lobe and should be prevented by placement of sutures to the adjacent lobe. Avoidance of unnecessary dissection of a fissure also minimizes this complication. Finally, any inadvertent compromise of lobar venous drainage results in pulmonary infarction (Figure 41.3). When recognized intraoperatively, the affected lobe should be resected if the venous injury is not easily repaired. Accidental ligation of the middle lobe vein requires middle lobectomy.


FIGURE 41.3. Pulmonary infarction caused by obstructive venous drainage of the right upper lobe.

ATELECTASIS

Atelectasis after thoracotomy is probably the most common postoperative complication. The reported incidence varies widely in the literature as a result of an inability adequately to define significant atelectasis. An incidence as high as 70% has been reported, but other large series of patients generally agree on an overall incidence of 20% to 30% after thoracotomy.[2,60,61]

Atelectasis was previously believed to result from mucus plugging of small airways, with resultant distal gas absorption and alveolar collapse.[62] Although airway occlusion from retained secretions, blood, foreign bodies, or bronchospasm can lead to atelectasis, the etiology is far more complex. Other causes of atelectasis include prolonged shallow breathing or splinting secondary to pain, absorption atelectasis with high inspired oxygen concentration, and parenchymal compression from retraction, hemothorax, pneumothorax, or other space-occupying lesions.

At least two mechanisms normally prevent alveolar collapse. The first is a periodic sigh breath, which is generally twice the usual resting tidal volume and serves to recruit collapsed alveolar. Patients who have shallow breathing secondary to pain and ventilated patients with inadequate tidal volumes may experience progressive alveolar closure with resultant atelectasis. [63,64]

The second preventive physiologic mechanism involves surfactant, a normally occurring wetting agent in the alveoli. LaPlace's theorem states that the surface tension of a distensible sphere increases proportionally as the radius decreases. This relation alone would favor collapse of smaller alveoli into larger units. Surfactant, however, acts to reduce the surface tension within alveoli and thereby prevent preferential collapse of smaller alveoli. Conditions such as malnutrition, sepsis, parenchymal injury, and prolonged collapse can adversely affect production of surfactant and predispose to alveolar collapse.

A condition known as absorption atelectasis merits comment. Normally, the sum of the partial pressures of gases in the alveoli exceeds the partial pressure in mixed venous blood. It follows that, with proximal airway occlusion, distal gases in the alveoli are absorbed, resulting in alveolar collapse. In addition, a higher concentration of oxygen in the trapped or anesthetic gases is more readily absorbed, thereby hastening the process.

Physiologically significant atelectasis results in decreased lung compliance, functional residual capacity, and vital capacity. This results clinically in increased work of breathing and impaired gas exchange.[65,66] Patients typically manifest with varying degrees of fever, tachycardia, tachypnea, and impaired gas exchange. Atelectasis may also render the lung more susceptible to infection. [67] Physical findings usually include crackles over the affected area. More extensive atelectasis results in tubular breath sounds, indicating involvement of entire segments or lobes. Sudden stoppage of an air leak frequently occurs with atelectasis. The radiologic appearance of atelectasis varies depending on the extent of involvement. Linear horizontal densities in the basilar segments are typical of small areas of atelectasis and usually occur near the diaphragm. Larger areas can usually be visualized if entire segments are involved, and this can progress to collapse of an entire lobe.

Several maneuvers can be extremely valuable in the prevention of postoperative atelectasis. Patients must refrain from smoking for as long as possible before thoracotomy. In addition, any bronchospasm detected either clinically or on preoperative pulmonary function testing should be minimized with medical therapy. Patient training and use of incentive spirometry should be initiated in the preoperative period and continued postoperatively. Adequate analgesia is essential to prevent splinting and to allow adequate pulmonary hygiene. We continue to use epidural analgesics routinely for three to five days postoperatively because they provide excellent pain relief with minimal adverse effects. [68]

Treatment of postoperative atelectasis involves many of the principles used in its prevention. Airways must remain free of retained secretions, and collapsed lung tissue must be reexpanded. Adequate postoperative analgesia is essential to allow for deep breathing, effective cough, and therapeutic physiotherapy. Epidural analgesia is an effective means of obtaining adequate analgesia without significant sedation. Local analgesics or opiates are injected into the epidural space continuously to achieve the proper level of analgesia. Contraindications to placement of an epidural catheter include bleeding diathesis, spinal deformity, neurologic deficit, or local infection in the area of catheter placement. Side effects and symptoms of overdosing include respiratory depression, nausea, pruritus, urinary retention, and hypotension secondary to peripheral vasodilatation. We routinely leave epidural catheters in place for 72 hours postoperatively but have maintained selected patients for up to five days.

Patient positioning in the early postoperative period is also important. Functional residual capacity declines by about 40% in the supine position as compared with upright. Routine elevation of the head of the bed to 45 degrees and early ambulation promote effective inspiration. Incentive spirometry is inexpensive and effective in

preventing atelectasis. Patients are best trained in this technique preoperatively.

Intermittent positive-pressure breathing may be of some benefit in selected patients but has generally not been effective in treating postoperative atelectasis. [60,65] These results, along with increased cost, have persuaded many to abandon this technique.

Patients with thick or copious secretions require a more aggressive approach. Nasotracheal aspiration is effective when performed by personnel experienced in passing the catheter into the trachea. Passing a catheter through a nasal trumpet may facilitate the process while decreasing patient discomfort. Caution should be exercised when passing the catheter blindly into a patient's airway after pneumonectomy or a bronchoplastic procedure. Also, prolonged suctioning can precipitate hypoxia and should therefore be performed only intermittently for short periods following administration of supplemental oxygen.

A technique of percutaneous cricothyroidotomy, or "minitracheostomy," has been developed. A 20F tracheostomy tube is inserted into the trachea through the cricothyroid membrane under local anesthesia. Au and colleagues [69] reported using this technique in 144 postthoracotomy patients. The minitracheostomy tract was found to be a relatively safe and effective means to prevent postoperative sputum retention. Others [70,71,72] have confirmed the efficacy of this technique for pulmonary hygiene and treatment of atelectasis secondary to retained secretions. Complications with this technique are uncommon and consist mostly of bleeding at the insertion site. Catheter aspiration, pneumothorax, and vocal cord dysfunction from hematoma have also been reported. [73,74]

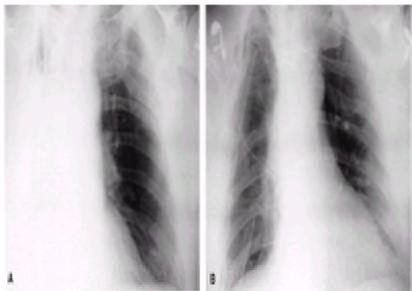
Patients who require more aggressive treatment of secretions should undergo flexible bronchoscopy (Figure 41.4). Routine use of flexible bronchoscopy for the prevention of postoperative atelectasis has been studied prospectively and found to offer no advantage over other less invasive techniques. [63,75] However, in the setting of significant pulmonary collapse or after bronchoplastic procedures, fiber-optic bronchoscopy is a safe and effective method to aspirate secretions under direct vision. Bronchoscopy can be easily performed at the bedside using local analgesia and, if necessary, can be repeated often. [76] Treatment of postoperative atelectasis should be graded according to the patient's clinical status and risk factors as described by Massard. [77]


FIGURE 41.4. A: Atelectasis of the residual right middle and lower lobes after right upper lobectomy and chest wall resection. B: Full expansion after aspiration of retained secretions by flexible fiberoptic bronchoscopy.

BRONCHIAL FISTULA

The incidence of bronchopleural fistula after pulmonary resection is reported to be under 5%. [78,79,80] Both systemic and local factors are associated with the development of a bronchopleural fistula, and a lung cancer patient may be particularly prone to this complication. Systemic factors include the patient's general nutrition status and the presence of sepsis. Lung cancer patients frequently lose weight, and the ability of tissues to heal is decreased. Sepsis can also retard bronchial healing, and many patients with an obstructive endobronchial neoplasm have distal pneumonitis producing chronic low-grade infection. Neoadjuvant protocols for the treatment of clinically advanced lung cancer include chemotherapy and radiation. Effects of chemotherapy can be debilitating to the patient, and depleted nutritional status can be a significant factor in the development of a bronchial fistula. Radiation destroys small blood vessels, creates fibrous tissue, and is associated with an increased incidence of bronchial fistula. [81] Vester and colleagues[78] reported that, of 33 patients who developed a bronchopleural fistula after resection for bronchogenic carcinoma, 20 had received radiation or chemoradiation. It is mandatory that special care be given to the bronchial stump in all patients who have received neoadjuvant therapy.

Numerous studies indicate that the causes of bronchial fistula include devitalization and devascularization by excessive dissection, parabronchial infection related to nonabsorbable suture, residual bronchial disease, poor approximation of the mucosa, the length of the stump, and the surgeon's lack of experience. [82] The avoidance of the complication of a bronchial fistula implies prevention, and several technical factors can minimize this complication.

Preoperative bronchoscopy is an important step in evaluating the status of the bronchial mucosa at the site of the planned resection. If inflammation is present, specific attention is made to the stump closure along with coverage by flaps of tissue for reinforcement and added blood supply. If surgery for the cancer is semielective, then it can be delayed for additional supportive therapy and antibiotics.

In a patient with lung cancer, the bronchial tissues must be cleared with care and precise sharp dissection. It is important for the surgeon to have knowledge of the anatomic location of the bronchial arteries and to preserve as many as possible despite the necessity for a radical procedure. This is particularly true when carrying out mediastinal lymphadenectomy in the lung cancer patient. The subcarinal area is traversed by feeding bronchial arteries, and this dissection must be done as carefully as possible to preserve some of these nutrient vessels. The right mainstem bronchus receives its blood supply from vessels posterior to the trachea and bronchus, and it is appropriate to not dissect this area if at all possible. The lymphadenectomy between the vena cava and trachea is done carefully to minimize damage to the blood supply to the lateral walls of the trachea. On the left side, a large bronchial artery has its origin from the distal transverse aorta and, on occasion, can be preserved despite removal of lymph nodes in the aorticopulmonary window. An excessively long bronchial stump accumulates excessive secretions, and its distal margin has a limited blood supply; both factors predisposing to poor healing. The bronchus should always be divided as proximally as possible, but closure must not compromise the adjacent trachea or bronchial lumen.

The method of bronchial stump closure is generally the surgeon's preference. In 1980, Forrester-Wood [83] reported results of 450 pneumonectomies. Bronchial closure was carried out by using stapling techniques in half of the patients, and the other half had bronchial closure with nonabsorbable suture or stainless steel. The incidence of fistula formation was 11% in the suture group and 2.6% in the staple group. Vester and colleagues [78] reported on 30 bronchial fistulas in 1773 pulmonary resections (1.7%) after staple closure of the bronchus. There were 23 fistulas in 506 pneumonectomy patients (4.5%). Al-Kattan and associates [84] reviewed the incidence of bronchopleural fistula in 530 consecutive pneumonectomies after hand-suture closure of the bronchus. Polypropylene suture was used for the closure, and there were seven fistulas (1.3%). In 1982, Lawrence and colleagues[79] studied 378 patients undergoing pulmonary resection and found no significant difference between the hand-sewn and stapled bronchial closure. The surgeon must be aware of contraindications to close the bronchus by stapling techniques. If the cancer is close to the bronchial orifice, as observed by bronchoscopy or identified during hilar dissection, the stapling techniques should not be used. In this instance, the bronchus is transected by a knife, and both the proximal and distal margins are inspected. Whenever there is a question about the proximal extent of the cancer, the bronchus is transected by knife dissection, and suture closure of the bronchus is carried out. After neoadjuvant therapy, the bronchial tissues can be particularly thick and fibrotic. In this instance, careful judgment is required to determine the appropriate type of bronchial closure. A thickened bronchus does not hold the staples, and excessive tension permits edges of the bronchus to separate. In this instance, it is recommended that the hand-suture technique be carried out with either nonabsorbable or absorbable monofilament suture (see also Chapter 38).

The same principles used in dissecting and closing the bronchus for a pneumonectomy apply to the bronchus after lobectomy. If the tissues are too thick or the cancer is too close to the margin of resection, stapling techniques are not used. We prefer to use a 4.8-leg-length staple for the lobar bronchus because there is less compression of the tissue and distal blood supply is preserved through the B shape of the staple. Special attention must be given to the bronchial stump of a bilobectomy. Vester and colleagues [78] reported ten bronchial fistulas in 965 patients receiving either bilobectomy or lobectomy, and there were nine fistulas after bilobectomy for primary cancer of the lung (right upper lobe and right middle lobe, four; right middle lobe and right lower lobe, five). The increased incidence of fistula after a bilobectomy undoubtedly relates to the extensive dissection of the bronchus, with a probable decrease in blood supply to the surrounding tissues. It is

important to consider tissue coverage of the bronchial stump after bilobectomy to minimize this complication. This is particularly true if the patient has received neoadjuvant therapy.

Tissue coverage of the pneumonectomy stump can minimize the complication of a small bronchial fistula and can also bring additional blood supply to the bronchus to promote healing. All right pneumonectomy stumps should be covered with some form of tissue. The left pneumonectomy stump, if done correctly, retracts deeply into the mediastinum, and the decision for tissue coverage requires careful judgment. All pneumonectomy patients who have received neoadjuvant therapy should have both the right and left pneumonectomy stumps covered with tissue.

Several methods are available for tissue coverage of a pneumonectomy stump. Al-Kattan and colleagues [84] recommend burying the bronchial stump beneath the mediastinal tissues. Azygos vein, adjacent pleura, pericardium, and esophageal wall can all be used for this technique. It was noted that this maneuver is important to decrease the incidence of bronchial fistula in patients older than 60 years and in those who underwent resection for lung cancer. A broad-based pleural flap can also be used to cover the bronchial stump. The pleura is tacked to both sides of the bronchus with a 4–0 absorbable suture. Only the parabronchial tissues are sutured to the pleura, and every attempt is made to avoid placing the needle through the entire thickness of the bronchial wall. This only distorts the bronchus and decreases its blood supply. However, the pleura contains few blood vessels and does not enhance the healing process with additional blood supply. For this reason, other tissue coverage is generally recommended. The intercostal muscle pedicle flap provides good reinforcement of a bronchial closure. It has also been demonstrated to deliver increased blood supply to the bronchial tissue. [85] It is helpful to have made the decision to use the intercostal muscle flap before opening the chest, because the flap can be developed with a portion of parietal pleura, ensuring its viability and blood supply. This flap is best created through a posterolateral thoracotomy. When the flap is used after completion of the resection, it is not as suitable. The rib spreader can traumatize the intercostal muscle, and the vessel can be damaged by retraction or extension of the thoracotomy incision posteriorly. Rendina and associates [85] clearly described the construction of the intercostal pedicle flap. It was used in 59 patients, and postoperative angiographic studies of the intercostal artery in 14 patients demonstrated full patency of this vessel.

The serratus anterior muscle provides excellent coverage to the bronchial stump and is the muscle flap of choice for some thoracic surgeons. [86,87] The serratus anterior muscle is mobilized at the time of the posterolateral thoracotomy, and its insertion is detached from the ribs with a cautery technique. The lateral thoracic artery is preserved, and the muscle is not separated from its scapular attachments until a final decision is made to use it as a tissue flap. Muscle is easily brought through the incised third intercostal space or through a defect made by a subperiosteal excision of a small portion of the third rib. The muscle is then sutured in place with 4–0 absorbable sutures and amply covers the stump and areas of mediastinal dissection. Care must be taken that the muscle flap is not under tension and that its vascularity is not compromised by compression of tissues in the intercostal space. Regnard and colleagues [87] used this technique in seven patients who underwent pneumonectomy after 6,000 to 6,500 cGy of radiation. There were four empyemas in this group of patients, but only one recurrent fistula, which was successfully treated by antibiotics and additional tissue placed into the pneumonectomy space.

The use of this flap for bronchial coverage is reserved for patients who have received an excessive amount of radiation or when there is concern about the viability of the bronchial stump closure. In patients who have received neoadjuvant therapy, the serratus anterior muscle can be preserved during a posterolateral thoracotomy. Added exposure is obtained by detaching it from several ribs. If the surgeon decides to use this muscle flap to cover the bronchus, the construction of the flap can be completed at the end of the procedure. If this muscle flap is not used to cover the bronchus, then it can be resutured to the tissue adjacent to the ribs, with the incision closed in the standard fashion. One problem associated with the serratus flap is that the patient may complain of a winged scapula due to detachment of the fibers from the inferior portion of the scapula. We use a broad-based mediastinal fat pad for coverage of both the right and left pneumonectomy stumps (Figure 41.5). Most patients have an adequate amount of fat that extends down to the cardiophrenic angle, and dissection frequently encompasses the lateral wall of the thymus gland. The fat pad is sharply dissected from the pericardium and freed to the upper mediastinum; it is easily brought over to the bronchial stump. Its blood supply is not as generous as that of a serratus anterior muscle or intercostal muscle flap, but secure tissue coverage is obtained (see Figure 41.5). Again, it is important to place fixation sutures in the peribronchial wall, both anteriorly and posteriorly, to secure the coverage. It is not appropriate just to place the fat pad over the bronchus and suture to the adjacent pleura, because this does not provide an adequate seal.

FIGURE 41.5. Large mediastinal fat pad covers the right pneumonectomy stump. Arrows depict the superior vena cava, and the head of the patient is to the left.

Use of the omentum is not recommended for routine coverage of pneumonectomy stump. It requires the placement of additional incision in the abdomen and a longer operating time than the flaps described earlier. The omentum is reserved for closure of a bronchial fistula if the complication does develop. [88]

Patients who develop a bronchial fistula three to four weeks after pneumonectomy expectorate varying amounts of serosanguineous fluid, may become dyspneic, and frequently develop subcutaneous emphysema. Chest radiograph illustrates a decreasing amount of fluid in the pneumonectomy space and the presence of subcutaneous air. In the hospital, the patient should be positioned with the operated side down to prevent spillage of the pleural fluid into the contralateral lung. Without delay or diagnostic studies, a chest tube is inserted into the pleural space to remove all of the fluid. Balanced pleural drainage is preferable, but a standard underwater-seal drainage system can also be adequate. The drainage system must not be connected to suction, because detrimental physiologic mediastinal shift can occur. Flexible fiber-optic bronchoscopy should be done to evaluate the status of the pneumonectomy stump and clear the airway of any secretions or fluid. With the development of vascular tissue flaps for stump coverage, new antibiotics, and the success of antibiotic irrigation in combating empyema, reoperation and bronchial stump reclosure can be considered up to 14 days after the initial operation.

If the patient undergoes reoperation, a long single-lumen endotracheal tube is placed into the contralateral bronchus with the aid of the flexible fiber-optic bronchoscope under local anesthesia. Precise placement of the endotracheal tube is achieved under direct bronchoscopic visualization and eliminates any possibility of contamination of the dependent lung during positioning of the patient. A double-lumen catheter can be used, but it can be difficult to position in the presence of a mainstem bronchial fistula, and excessive manipulation of the tube may only make the fistula larger. Proper position of the double-lumen tube must be documented with the small-diameter flexible bronchoscope.

The necrotic edges of the bronchial stump are carefully debrided back to viable tissue, and the stump is closed with an interrupted suture technique using nonabsorbable monofilament suture. Omentum provides excellent coverage and blood supply to a dehisced bronchial stump, and the pedicle would have been prepared before opening the chest. [88] If the serratus anterior muscle was preserved at the time of the original thoracotomy, it is also an excellent flap to provide coverage for the bronchial fistula. Intercostal muscle and mediastinal fat can also be used, but their blood supply is not as generous as the previously mentioned flaps.

The pleural space is cultured to determine whether infection is present and also to obtain antibiotic sensitivities for postoperative antibiotic irrigation. Antibiotic irrigations are begun in the first postoperative 48 hours through a previously placed intercostal catheter, and the pleural space is filled twice daily with an appropriate concentration of antibiotics and 1,000 mL of sterile saline. The tube is clamped, and the chest is emptied every ten hours. Serum levels of the antibiotics are obtained to be certain that toxic blood levels are not present. After ten days of antibiotic irrigation, cultures of the draining fluid are obtained to be certain that the effluent fluid is sterile, and the chest tube is then removed. Before removal, the space is filled with the antibiotic solution. If an empyema develops at a later date, it is treated by adequate dependent drainage, and the space eventually closed by thoracoplasty or myoplasty or both. The antibiotic sterilization can again be attempted if a fistula is not present, as described by Claggett and Gerace. [89]

A two-stage procedure is advocated by Deschamps et al.[90] for fistula closure and sterilization of the empyema space. The first stage consists of opening of the thoracotomy incision with debridement and closure of the bronchial fistula and coverage with viable tissue. The empyema cavity is thoroughly debrided and the cavity is packed open with gauze soaked in povidone-iodine solution diluted 20 to 1. The packing is changed daily, and when healthy granulation tissue appears in the pleural space, the cavity is filled with antibiotic solution and a watertight chest wall closure is obtained.

The management of a bronchopleural fistula that occurs several weeks or months after pneumonectomy requires that the space be clean and dependently drained. This is best accomplished with the open-window thoracostomy or Eloesser flap.[91] The presence of a chronic bronchopleural fistula requires direct closure because it will not heal on its own, and the pneumonectomy space cannot be closed or sterilized until the fistula has healed. Puskas and colleagues[91] described successful closure of chronic bronchopleural fistulas in 40 of 47 patients (85%) using direct suture closure of the bronchial stump in 37 patients and suturing of omental or tissue flaps over the fistula in ten patients. All of these closures were buttressed with vascularized pedicle flaps of omentum, muscle, or pleura. At the time of the bronchial fistula closure, the empyema cavity can be obliterated using myoplasty and thoracoplasty techniques. Any residual cavity that remains can be successfully sterilized using the Claggett[85] technique.

Failure of sterilization of the residual space can be successfully managed with packing and daily dressing change, with expected obliteration of the space by granulation tissue over several months. Pairolero and colleagues[86] used muscle grafts of pectoralis, serratus anterior, latissimus dorsi, and rectus abdominis, along with the omentum, and achieved an 88% success rate in closing fistulas and controlling intrathoracic sepsis. Extrathoracic muscle transpositions, along with omentum, are now the accepted standard of therapy for treatment of the chronic bronchopleural fistula and empyema. These techniques have significantly decreased the need for a disfiguring thoracoplasty, which is the alternative method of treating postpneumonectomy empyema and fistula.

If a pneumonectomy fistula occurs in a long bronchial stump, consideration can be given to the transsternal approach for reamputation of the stump. This is a technically demanding procedure, and the surgeon must thoroughly review the literature before embarking on this repair.[93] After successful transsternal closure of the fistula, antibiotic sterilization of the pneumonectomy space is done.

Fibrin glue can successfully close a small fistula up to 4 mm in size, and its use should be considered when a small fistula has been identified. Tissue glue in the United States can be made from cryoprecipitate and thrombin, and the European version with a stronger tensile strength is now available. Closure of small fistulas in both pneumonectomy and lobar stumps has been achieved. The cryoprecipitate and thrombin are instilled through catheters passed through the channel of a fiber-optic bronchoscope. This technique is associated with low morbidity and can be the initial therapeutic maneuver if the fistula is small.[94,95]

Bronchial fistula after lobectomy is a rare occurrence, and it is more common for a lobar bronchial fistula to occur after a bilobectomy than a standard lobectomy. A cancer resection requires an extensive dissection when carrying out a bilobectomy, and bronchial blood supply is jeopardized. The surgeon must pay particular attention to closure and coverage of bilobectomy stumps.

Early dehiscence of a bronchial stump after lobectomy is evidenced by a persistent and moderate air leak, a sudden increase in the size of an air leak, or the development of a space after chest tubes have been removed. Other symptoms include fever and a cough productive of serosanguineous fluid or purulent material from a developing empyema. If a fistula is suspected, bronchoscopy should be carried out. Complete separation of a bronchial closure is obvious, but small defects in a lobar bronchus may be difficult to identify. A to-and-fro motion of secretions at the stump, necrotic tissue, and granulations are all indicators of a fistula. If the chest tubes have been removed, a new chest tube must be inserted into the developing space as soon as the diagnosis of a lobar stump fistula is made. A decision is then made about appropriate therapy.

In general, it is better to treat lobar bronchial fistula in a long-term conservative manner, for several reasons. First, acute debridement of a dehisced lobar stump may result in little remaining bronchus to reapproximate, and closure would compromise a mainstem bronchus. Second, to achieve closure of viable bronchial tissue, a completion pneumonectomy may be required, with increased morbidity and mortality. Third, the probable infected space may predispose the fistula closure to failure, resulting in an increase in morbidity and mortality.

If reoperation for a lobar fistula is decided on, the surgeon has several options. The bronchus can be resected to obtain more healthy tissue, and the stump is reapproximated with a fine, nonabsorbable, monofilament suture. If the bronchial tissues are necrotic, the amputation of the bronchus at a higher level must be considered. This technique is applicable when a right lower lobectomy stump has developed a fistula, and the middle lobe can be resected with bronchial closure at the proximal bronchus intermedius. Sleeve lobectomy can be considered after an upper-lobe bronchial fistula, but the surgeon must be aware of possible anastomotic failure along with probable difficulty in reexpansion of the residual lung tissue. All reoperative bronchial closures must be covered by a viable tissue flap.

Despite the fact that adequate tube drainage after lobar bronchial fistula may result in a more protracted course, a successful long-term result can usually be achieved. Myoplasty or thoracoplasty, or both, may be necessary to close the fistula and obliterate the associated space, but they are accomplished at less risk when the patient's condition is able to withstand a second operation. Tube drainage is maintained until the residual lung tissue is adherent to the parietal pleura, and the fistula is then treated as a chronic problem. A small fistula may eventually close with fibrotic resolution of the space, but most remain open. Basic criteria to be carried out include control of the underlying disease process and a clean, dependently drained space.[96]

SPACES AND AIR LEAKS

A decrease in the incidence of the development of the postoperative space and prolonged air leak directly results in a decreased incidence of postoperative complications. The lung cancer patient is particularly prone to the development of these complications. The normal mechanisms of compensation for the loss of lung tissue are (a) expansion of the residual lung, (b) mediastinal shift, (c) narrowing of the intercostal spaces, and (d) elevation of the diaphragm. Frequently, lung cancer patients have had neoadjuvant irradiation and chemotherapy, and there is fibrosis in the mediastinum that limits its ability to shift its position. The lung tissue, if fibrotic from irradiation, does not fully expand, and parenchymal air leaks fail to heal. The elderly lung cancer patient is prone to prolonged air leaks from emphysematous lung tissue.

Most persistent air leaks originate from small bronchi or disrupted alveoli and can be termed alveolo-pleural fistulas. Most air leaks close within seven days of the operative procedure, but some require special maneuvers in an attempt to stop the leak. Alveolo-pleural fistulas originate from lung tissue that has been denuded of its visceral pleura, incomplete lung fissures, the raw surface of a segmentectomy, and nonanatomic resections for neoplasms. These leaks can be minimized at the time of resection by careful attention to technical detail, and prevention is the best method of treatment.

The use of the stapler can minimize air leaks from a divided minor or major fissure and helps to separate the upper lobe from the middle lobe. The stapling device can also minimize air leaks when carrying out wedge resection or segmental resection, depending on the surgeon's technique. The staple line should be reinforced with a bovine pericardium or Gore-Tex when the lung tissue is emphysematous. At the close of the operation, the anesthetist fully expands the lung to 20 to 25 cm of airway pressure with the lung and bronchus submerged in saline, and the bronchial stump and lung parenchyma are carefully observed. Air leaks from staple lines and disrupted parenchyma are closed with fine, interrupted absorbable sutures. Small air leaks near the hilum can be approximated with carefully placed sutures to avoid damage to major arteries or veins. A defect in the bronchial stump is repaired.

A pedicle flap of pleura can be used to cover air leaks from tissue just as well as it can cover a bronchial stump. Absorbable sutures can be placed through the pleura and then through the lung tissue to anchor the pleura flap securely over the leaking area of lung. On occasion, a free graft of pleura can be used to reinforce sutures. If a segmentectomy has not been done by the stapling technique, the residual segmental lung surface can be approximated to the adjacent lobe. This technique is particularly applicable to posterior, superior, anterior, and medial basal and lingular segmentectomies.

If an air leak persists at seven days, there are several therapeutic maneuvers that can be attempted. Suction can be discontinued, because it is possible that the increased negative intrapleural pressure is maintaining the air leak, and discontinuing the suction will cause the leak to close. A chest radiograph is obtained in 24 hours, and if a space is developing, the suction is restarted. Chest-tube suction is maintained for the initial postoperative seven days because it has been our experience that if the lung collapses in the early postoperative period, reexpansion can be difficult, with a resultant residual space. A second maneuver is to withdraw the anterior chest tube by 1 or 2 inches. A chest-tube hole may be directly adjacent to a small air leak; repositioning the tube allows the lung to expand, and the leaking lung surface adheres to the parietal pleura. Suction is never increased if the residual lung is fully expanded because increased suction may potentiate the air

leak.

If the lung remains expanded after discontinuation of suction, consideration can be given to removing the chest tubes, despite the presence of a small air leak. This technique can be successful, but if a space does develop, a chest tube must be reinserted. Suction is maintained until the air leak stops or the patient is discharged with a Heimlich valve attached to the leaking chest tube. The patient is seen at weekly intervals in the office. The leak usually stops by the time of the first office visit, and the tube is then removed. It may be necessary to leave the tube in place for an additional two to three weeks until the air leak stops. If the air leak persists four weeks after hospital discharge, the patient is considered to have an empyema, and open drainage is instituted. The tube is then shortened by 1 or 2 inches at weekly intervals until it is removed. This method of tube management is predicated on the fact that the patient does not have an infected space and the lung is expanded.

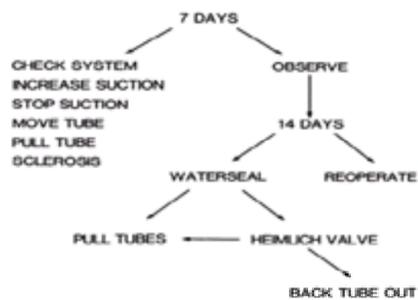
There are no specific guidelines for the indications of reoperation of a patient with a persistent air leak at seven to 14 days. Factors that play a role in this decision include the general condition of the patient, the emphysematous nature of the remaining lung, the speculated cause of the persistent air leak, and the presence and magnitude of an intrapleural space. Reoperation and necessary decortication can create new air leaks, and careful judgment is required to reoperate for a persistent air leak. A large and increasing air leak may make reoperation necessary. The management of a persistent air leak is noted in Figure 41.6.


FIGURE 41.6. Suggested management of prolonged air leak. (From Piccione W Jr, Faber LP. Management of complications related to pulmonary resection. In: Waldhausen JA, Orringer MB, eds. *Complications in cardiothoracic surgery.* St. Louis: Mosby Year Book, 1991:336, with permission.)

The development of a postoperative space is commonly related to a persistent and large air leak, but other causes include resection of two lobes on the right side, only the basal segments of either lobe remaining, fibrosis in the remaining lung that limits expansion, and incomplete decortication from prior pleural effusion or infection. Postoperative atelectasis and a fixed mediastinum due to irradiation or prior inflammation also contribute to the development of a space. All of these factors are seen in patients undergoing resection for lung cancer. Kirsch and colleagues [97] reported on the natural history of the pleural space and noted that 74% undergo spontaneous resolution, 13% require temporary drainage, 7% are persistently sterile, and only 6% become infected. Despite the relatively low incidence of major complications associated with a persistent space, the thoracic surgeon must make every attempt to minimize it because an infected space is a problem for both the patient and the thoracic surgeon.

Practical steps can be carried out in the management of a postoperative space. The first is to be certain that the residual lung tissue is clear of all secretions and that postoperative atelectasis is aggressively treated. Early postoperative consideration must be given to increasing the amount of chest-tube suction. We routinely start with 20 cm of water suction immediately after the operation and recommend increasing suction to 30 or 40 cm of water pressure if there is a space in association with an air leak. Evacuation of the air permits the raw lung surface to reach the parietal pleura, and small air leaks close. The patient can be dyspneic owing to a decrease in tidal volume as inspired air is removed by increasing suction. Significant pleural pain can also be troublesome. Suction should be increased in increments of only 10 cm of water to evaluate the patient's ability to tolerate it. We do not use suction set at more than 40 cm of water pressure because of patient discomfort.

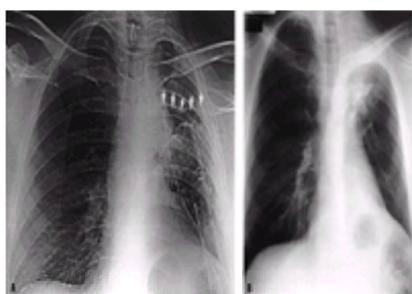
Certain intraoperaive maneuvers can also minimize the possible complications of the postoperative space. One method is to use a pleural tent (Figure 41.7). If an extrapleural dissection was required to resect an upper-lobe lesion, then a pleural tent is obviously not available. Even if a constructed pleural tent is not airtight, the large pleural flap can cover residual lung tissue and expedite the closure of parenchymal air leaks, which effectively eliminates a space problem. Transplantation of the diaphragm and crushing of the phrenic nerve have been advocated to minimize the postoperative space, but have not been used in our experience. Disadvantages include the time involved to transplant the diaphragm and the loss of diaphragmatic motion, which decreases the patient's ability to cough as well as long-term pulmonary function. The most extensive intraoperative procedure is to bring the chest wall to the lung tissue. This is accomplished by either a tailoring or an osteoplastic thoracoplasty. A tailoring thoracoplasty entails subperiosteal resection of the first and second ribs along with a portion of the third rib to decrease the size of the apex. An osteoplastic thoracoplasty is a subperiosteal resection of the posterior portions of ribs 2, 3, 4, and 5, with wire fixation of these ribs to the posterior sixth rib. A standard five- or seven-rib thoracoplasty in association with an extended pulmonary resection is not recommended, because it will result in inadequate postoperative ventilation owing to paradoxical chest wall motion.


FIGURE 41.7. A: Pleural tent constructed to minimize air leak and pleural space after left upper lobectomy and resection of a portion of the superior segment of the left lower lobe. Arrows depict the location of the pleural tent. One chest tube drains the space above the pleural tent, and two chest tubes drain the normal pleural space. B: Chest radiograph six months later in the same patient.

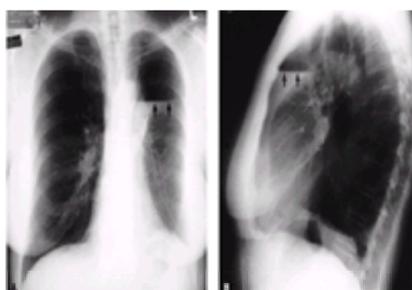
If the air leak stops and there is a persistent space, the chest tube is removed, and the space is treated as if it were sterile. The patient can be safely discharged without antibiotic therapy and is followed with periodic chest radiographs (Figure 41.8). The sterile space obliterates with fibrous tissue over time.


FIGURE 41.8. Frontal **(A)** and lateral **(B)** views of a sterile space after left upper lobectomy. Space will obliterate in several weeks with no postoperative sequela.

If an empyema does develop in a postoperative space, tube drainage is mandatory. If the space is small, it is managed with open-tube drainage, and the tube is slowly backed out as the space obliterates. If closure of an infected space does not occur after several weeks, or if the space is large, there remain two surgical options. The first is thoracoplasty, and the space must be located so that the appropriate type of thoracoplasty obliterates it. A large space necessitates a standard posterior seven-rib thoracoplasty.

The pedicle muscle flap is the most effective method of obliterating almost any infected residual space, and the muscle can be used to close any residual bronchial fistula.[98] The pectoralis major is particularly well suited for placement into the apex of the chest and avoids the deformity of a thoracoplasty. Other tissues that can be used include the omentum, serratus anterior muscle, and latissimus dorsi muscle if it has not been transected by the previous thoracotomy.

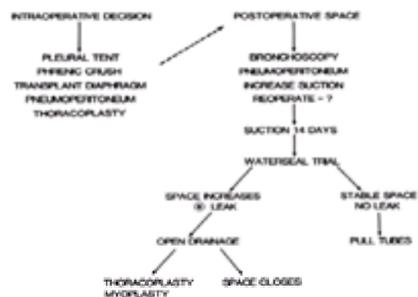
Careful attention to all the preoperative and postoperative details in managing the lung cancer patient minimizes the complications of the postoperative space. Space management is detailed in Figure 41.9.


FIGURE 41.9. Suggested management of the postoperative space. (From Piccione W Jr, Faber LP. Management of complications related to pulmonary resection. In: Waldhausen JA, Orringer MB, eds. *Complications in cardiothoracic surgery.* St. Louis: Mosby Year Book, 1991:336, with permission.)

INTRAOPERATIVE HEMORRHAGE

Hilar dissection can be extremely difficult when central lung cancers are removed, because they often invade major vascular structures, and the avoidance of damage to these vessels is difficult. Neoadjuvant therapy for a clinically advanced lung cancer frequently obliterates tissue planes and makes the hilar dissection extremely difficult. The normal tissue plane of the pulmonary artery and its branches can be totally obliterated, and meticulous sharp dissection is necessary to remove the cancer from these structures. Neoadjuvant therapy, coupled with prior mediastinoscopy, also renders the paratracheal tissues fibrotic and further complicates mediastinal lymphadenectomy. The thoracic surgeon must be prepared to handle intraoperative hemorrhage, and there are various technical maneuvers that can be undertaken to minimize its occurrence.

Right Hilum

The primary cancer or involved regional lymph nodes may render approach to the pulmonary artery or its branches technically difficult. In this instance, it is appropriate to obtain provisional control of the more proximal pulmonary artery. Also, in many instances, the cancer obliterates the standard approach to the main pulmonary artery, and other maneuvers must be undertaken to ligate it more proximally.[99]

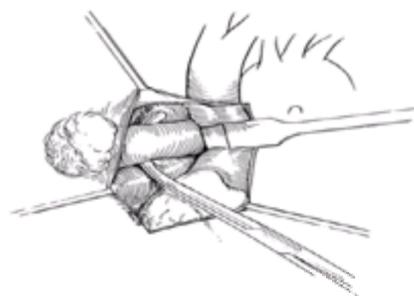
An approach to the right main pulmonary artery is to open the pericardium at the level of the superior pulmonary vein and extend this opening to a level onto the superior vena cava above the azygos vein. If the azygos vein can be encircled, it is ligated proximally and distally and transected to provide added exposure. The right main pulmonary artery can then be isolated medial to the superior vena cava (Figure 41.10). If a difficult lobectomy is to be attempted, a provisional Rumel tourniquet can be applied to control the main pulmonary artery if bleeding does occur during the dissection. This approach can also be used to transect the pulmonary artery either by using the stapling technique with vascular staples or by placing a vascular clamp proximal and then suturing the transected pulmonary artery stump.


FIGURE 41.10. The right main pulmonary artery is isolated medial to the superior vena cava after the pericardium is widely opened.

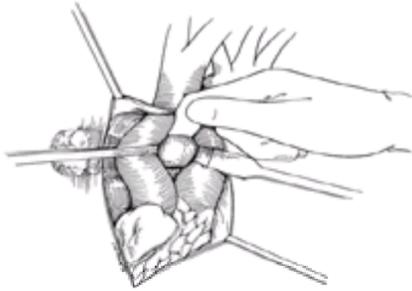
A second approach to the right pulmonary artery is more medial, and it is necessary to open the pericardium widely to provide exposure to the pulmonary artery between the ascending aorta and superior vena cava (Figure 41.11). A significant portion of this dissection must be done by blunt finger dissection, and care must taken not to disrupt the main artery with this maneuver. It is rare that a tumor extends to this level of the main pulmonary artery, and provisional proximal control can usually be obtained by this technique. If a pneumonectomy is being done, the artery is usually ligated at this level with a heavy permanent suture. Transection of the main artery is then done on the other side of the superior vena cava. The vascular stapling technique can also be used to divide the main artery, but the instrument can be difficult to position.


FIGURE 41.11. The proximal right main pulmonary artery is isolated between the aortic arch to the right and the superior vena cava. The pericardium has been widely opened, and the technique of isolation is by both sharp and blunt finger dissection.

An upper-lobe tumor may totally occlude the anterior approach to the pulmonary artery, but the mainstem bronchus remains free of cancer involvement. In this instance, the posterior aspect of the pulmonary artery is readily accessible and it can be isolated by initially dissecting the right mainstem bronchus so that it can be transected. The pneumonectomy stump is closed by the staple technique (Figure 41.12). To avoid contamination of the space during continued aspects of the dissection, the stapler can also be used to close the distal bronchus. After transection of the bronchus, the posterior aspect of the pulmonary artery becomes readily available, and a more proximal dissection with ligation and transection of the right main pulmonary artery can be carried out. This approach is predicated on the finding that the proximal right mainstem bronchus can be freed for transection and closure. Despite proximal control of the main pulmonary artery, a defect in a large lobar branch can bleed profusely from atrial back bleeding and large bronchial arteries supplying the tumor. In this instance, distal control of the pulmonary artery must be obtained, or vascular clamps can be placed on both the superior and inferior pulmonary veins to minimize blood loss while the arterial defect is closed.

FIGURE 41.12. The right main pulmonary artery is approached posteriorly after transection and closure of the right mainstem bronchus. Tumor obliterates the customary anterior approach to the right main pulmonary artery.

Involvement of either the superior or inferior pulmonary vein by the cancer necessitates opening of the pericardium to obtain more proximal control. The vascular stapling device can be placed on the atrium to obtain an adequate margin of resection beyond the tumor, and proximal control is achieved. On occasion, both the superior and inferior pulmonary veins are involved by the tumor, and the stapling instrument is not long enough to close a single atrial cuff. In this situation, a large vascular clamp is placed to occlude the atrium, and it is transected. The atrial tissues are then reapproximated by a running monofilament suture.

The primary tumor or involved lymph nodes may invade the superior vena cava. If the invasion is minimal, a partially occluding vascular clamp can be placed, and a portion of the vena cava wall is transected. The defect is closed with a running monofilament suture. In other instances, a portion of the wall of the vena cava may require resection to remove all of the tumor. The right and left innominate veins must be isolated, and provisional ligatures are placed. The pericardium is opened, and a provisional tourniquet is placed at the level of the caval-atrial junction. The vena cava can be bypassed by a catheter technique, as described by Piccione and colleagues,[100] and the defect in the vena cava is repaired by a patch graft of pericardium. The vena cava can also be replaced or bypassed by Gore-Tex grafts, as described by Dartevelle and associates.[101] For more on these techniques, see Chapter 62.

Left Hilum

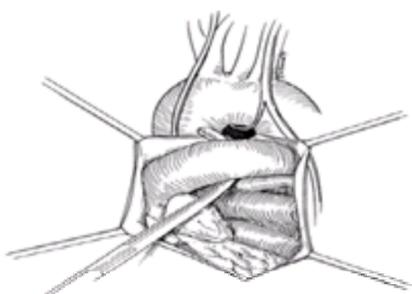
Left-sided lung cancer frequently invades the aorticopulmonary window, and the pulmonary artery cannot be dissected safely outside the pericardium. The pericardium is then opened medial or lateral to the phrenic nerve, and this opening is extended up above the aortic arch. The main pulmonary artery is identified, and the proximal left main pulmonary artery is dissected free (Figure 41.13). It is usually necessary to isolate and transect the ligamentum arteriosum to provide exposure for proximal transection and closure. It is also necessary to identify the proximal portion of the right pulmonary artery to ensure that the main pulmonary artery is not ligated or compromised. Staple closure of the artery with the vascular stapling technique is effective in this instance. Provisional proximal left pulmonary artery control can also be obtained with a Rumel tourniquet after the pericardium is opened during a difficult lobar dissection.


FIGURE 41.13. The left main pulmonary artery is isolated after the pericardium is opened. The right main pulmonary artery must be clearly identified before transection.

The left main pulmonary artery can also be approached posteriorly after dissection and transection of the left mainstem bronchus. This approach provides additional exposure if the anterior, intrapericardial approach is particularly difficult. The atrium is handled in similar fashion as described for the right side.

The primary tumor or involved lymph nodes frequently are densely adherent to the transverse aortic arch. This is particularly true when a large hilar tumor has been treated with neoadjuvant therapy and the fibrotic tissues are difficult to dissect. In this instance, careful sharp dissection is necessary to free the tumor from the aorta. It is important to avoid development of a plane of dissection between the adventitia of the aorta, because this defect can rupture during the dissection or in the postoperative course. It is rarely indicated to resect a portion of the transverse or descending thoracic aorta *en bloc* with a primary lung cancer. This type of invasion

usually precludes long-term survival of the patient, and aortic graft replacement with its attendant morbidity is not indicated.

POSTOPERATIVE HEMORRHAGE

Postoperative bleeding usually occurs from the site of the pulmonary resection or from an intercostal vessel in the thoracic incision. Lung cancers invade the mediastinum, chest wall, and diaphragm, and blood vessels, both large and small, are transected during the resection. Frequently, it is necessary to carry out an extrapleural dissection, and the persistent oozing of blood from the chest wall can be difficult to control. A ligature can roll off a previously tied branch of the pulmonary artery or pulmonary vein, and blood loss in the recovery unit can be sudden and precipitous. The second major cause of postoperative bleeding is a coagulation defect related to transfusion of several units of stored bank blood during the operative procedure.

Many elderly patients who undergo resection for lung cancer take aspirin as a prophylactic measure to avoid vascular problems. This is particularly true in patients who have had either transient ischemic attacks or coronary bypass surgery for atherosclerotic heart disease. Others may take aspirin for chest pain, arthritis, or prophylaxis to avoid a stroke because of a prior family history. This information should be obtained in the patient's history, and all aspirin-related products must be stopped before the surgical procedure. It is appropriate to stop aspirin two weeks before the operation. Aspirin affects platelet function, and if generalized oozing persists during an extended difficult dissection for lung cancer, then platelets can be administered to the patient who did not stop aspirin before the thoracotomy.

Symptoms of postoperative hemorrhage include tachycardia and hypotension. The usual evidence of significant postoperative bleeding is the drainage of about 200 mL or more of blood per hour through the chest tubes into the drainage system. A portable chest radiograph should be obtained to ensure that blood is not accumulating in the thorax, because the quantity of chest-tube drainage is not a reliable indicator. It is important to obtain the chest radiograph in the upright position to quantitate better the amount of retained blood in the chest cavity.

Blood replacement is carried out dependent on measured blood loss during the operative procedure, the patient's physiologic status, and the measured blood loss through the chest tubes. Continued blood loss at a rate of 200 mL per hour for four hours is generally an indication for reoperation to identify and control the source of bleeding. In this situation, continued observation can be carried out if the surgeon thinks that the trend of blood loss is slowing and the patient's condition is stable. This decision must be carefully correlated with the operative findings and the speculative cause for the postoperative bleeding. Coagulation studies are obtained, and when defects are identified, they are corrected. Agents used include fresh frozen plasma, cryoprecipitate, or platelets as indicated.

A sudden rush of blood into the chest drainage system approximating several hundred milliliters mandates immediate reexploration. A ligature may have slipped from a large vessel, or a vascular repair may have partially separated.

Prevention is the key to the avoidance of the postoperative complication of bleeding. Meticulous hemostasis is carried out during and after the resection. Cautery is used generously on the chest wall or pleural surface to stop the ooze from the many disrupted small vessels after pleurectomy. The mediastinum is carefully explored for a large bronchial artery that may have clotted off but that will start bleeding after the clot moves or the patient has an episode of postoperative hypertension. The main pulmonary artery and veins are carefully inspected for any defects in the closure, and persistent bleeding is controlled with fine interrupted sutures. Lobar branches from the pulmonary artery must be securely tied, and the operator can feel a break in the intima as the initial knot is placed. Large vessels require suture ligation, including the more proximal ligature, to prevent slippage. The anterior and posterior portions of a thoracotomy are always carefully inspected to ensure that there is no bleeding from a traumatized intercostal artery.

POSTOPERATIVE CHYLOTHORAX

Chylothorax after pulmonary resection is a rare complication and occurs more frequently after pneumonectomy than after lobectomy or segmentectomy. The thoracic duct enters the chest through the aortic hiatus at the level of T-12 and is adjacent to the aorta. It remains on the right side of the vertebral bodies until it crosses to the left at the level of the fifth or sixth thoracic vertebra. It then passes behind the aortic arch to an area adjacent to the esophagus and exits the mediastinum to drain into the left subclavian vein. The duct can be multichanneled and have many tributaries in the area of the subcarinal space. Damage to the main duct or tributaries can occur anywhere along the mediastinum. Subcarinal lymphadenectomy requires exposure of the esophagus, and the removal of these lymph nodes may result in unrecognized thoracic duct injury. Damage can also occur on the left side when the proximal left mainstem bronchus is freed for transection, and lymph nodes involved by a tumor are removed along the descending thoracic esophagus.

Frequently, damage to the duct or its tributaries is clearly identified during the dissection. Whenever a small flow of milky fluid is identified, it is mandatory that the defect in the main duct or one of its branches be closed with interrupted permanent sutures. If the patient has not eaten for several hours before the surgical procedure, the chyle can appear more golden-yellow than milky, and this is a clue to the fact that a defect has been created.

Often, patients do not eat solid food after a major pulmonary resection, and the chest-tube drainage is not the characteristic milky color. However, the continued drainage of serous fluid measuring more than 1,000 mL in 24 hours alerts the surgeon to the possibility of a thoracic duct fistula. As soon as the patient begins to eat solid food, the classic milky appearance of the fluid appears. Analysis of the pleural fluid shows chylomicrons with lipoprotein electrophoresis, and the triglyceride level is more than 100 mg per dL if the fluid is chyle.

After pneumonectomy, the development of a chylothorax is indicated by rapid filling of the pneumonectomy space with deviation of the mediastinum away from the operated side.[102] The initial treatment of a postresection chylothorax is conservative. Chest-tube drainage is maintained to provide expansion of the remaining lung or mediastinum stabilization, and total parental nutrition is carried out. All oral feedings are discontinued, and meticulous observation of the amount of daily drainage is recorded. Miller[103] reported that spontaneous closure after an operative injury may be expected in only about half of patients. The maximal amount of time for observation is two weeks, but if fluid loss is persistent at seven days, operation for closure of the fistula is undertaken. Sarsam and colleagues [102] reported postpneumonectomy chylothorax in nine patients; in five patients, conservative therapy managed the problem, and in four, reoperation was required. The pneumonectomy space must be drained by tube thoracostomy, and central hyperalimentation is carried out. Although two weeks can again be used as a time limit for conservative management, a persistent loss of fluid at seven days indicates the need for reoperation in our experience.

At reoperation, the chest should be opened on the side of the fistula. The patient can be given cream or olive oil two to three hours before the thoracotomy, and this will enhance recognition of the site of the fistula. Frequently, the area of the fistula is edematous, and tissues do not hold sutures well. Further dissection to visualize the fistula better can result in bleeding, and secure closure of the boggy tissues is not obtained. We recommend that in reoperation for a thoracic duct fistula after pulmonary resection, supradiaphragmatic ligation of the main duct should be carried out, as reported by Lampson. [104] Just above the diaphragm, the tissue between the aorta and the azygos vein is bluntly freed with an angled clamp, and mass ligation of this tissue is carried out with a heavy silk suture. Clips should be avoided because they damage the duct and a new fistula will occur where the duct is clipped. This ligation can be accomplished through either a right or left thoracotomy. However, it is more easily accomplished through a limited lower right thoracotomy, and on occasion, this approach has been used despite a left-sided chylous fistula.

Other surgical options include pleurectomy, placement of a pleural peritoneal shunt, application of fibrin glue, and thorascopic ligation of the thoracic duct. However, the gold standard to which all other techniques must be compared is direct ligation of the duct.

Long-term conservative management of the postoperative chylous fistula is to be avoided, because the patient's condition will only deteriorate and nutritional depletion will cause further complications and possible mortality.

ESOPHAGOPLEURAL FISTULA

The anatomic pathway of the esophagus is in close proximity to the lower trachea and right mainstem bronchus, and its muscular wall can be directly invaded by a large hilar cancer. Pneumonectomy and resection of the neoplasm may result in an unrecognized defect in the wall of the esophagus, with resultant esophagopleural fistula. The esophagus is also directly posterior to the subcarinal space, and it can be damaged during subcarinal lymphadenectomy from either the right or left side. The performance of a left pneumonectomy requires exposure of the carina and the medial aspect of the proximal right mainstem bronchus, and during this aspect of the dissection, the esophagus must be freed from the adjacent tissues to permit a high amputation of the left mainstem bronchus. Damage to the esophagus can also occur during this phase of the dissection.

A careful review of the preoperative computed tomographic scan usually reveals the presence of the tumor in close proximity to the esophageal wall. This finding

alerts the surgeon to the need for clear anatomic definition of the esophageal wall during the dissection, and the placement of a nasogastric tube before the procedure assists in early definition of the entire thoracic esophagus. If a defect is made in both the muscular and mucosal layers of the esophagus, a two-layer repair is accomplished with a fine absorbable monofilament suture. Interrupted sutures are evenly placed to achieve a watertight seal. An adjacent pleural flap is easily constructed to buttress the repair. If it is determined during the resection that only the muscularis of the esophagus has been removed and that the mucosa is intact, the muscularis is reapproximated with similar suture material.

Several bronchial arteries traverse the subcarinal space and are in close proximity to the esophageal wall because they originate from the aorta. These arteries can be large because they have nourished the cancer or involved subcarinal lymph nodes. These vessels should be individually ligated as they are encountered; on occasion, bleeding can be significant if the vessels are not seen and cut. In this instance, vigorous cautery should be avoided because unrecognized damage and subsequent necrosis of the esophageal wall can occur. Cautious use of cautery in the subcarinal space is directly applicable to subcarinal lymphadenectomy from both the right and left sides.

An esophagopleural fistula after a pulmonary resection can occur either in the early or late postoperative period. The signs and symptoms are those of an empyema, with fever, chest discomfort, loss of appetite, a falling air fluid level in the pneumonectomy space, and the appearance of an air fluid level in a previously opacified hemithorax. The placement of a chest tube may reveal food particles, but a diagnosis of empyema is obvious. Bronchoscopy is usually carried out to detect the presence of a bronchial fistula, and an immediate esophagogram confirms the presence of the clinically suspected esophageal fistula (Figure 41.14). Massard and associates[105] recommend the routine use of a barium swallow whenever a postpneumonectomy empyema develops. This diagnostic study is particularly important after the development of a late empyema.

FIGURE 41.14. Bronchoscopy is usually carried out to detect the presence of a bronchial fistula, and an immediate esophagogram confirms the presence of the clinically suspected esophageal fistula.

In the early postoperative period, therapy is directed toward direct repair of the fistula. The previous thoracotomy space is opened, and careful debridement of the pneumonectomy space is carried out. The esophageal fistula is identified and repaired in two layers. It must be buttressed with a vascularized tissue flap that includes intercostal muscle, serratus anterior muscle, and omentum. A gastrostomy for drainage and jejunostomy for feeding and postoperative alimentation are also recommended. The pneumonectomy space is lavaged with antibiotic solution, and if sterilized, the chest tube can be removed. However, this is a difficult empyema to sterilize, and it may be necessary to provide long-term open drainage with attempted later sterilization by the Claggett technique. An alternative approach is to exclude the esophagus by a proximal cutaneous fistula and perform a distal ligation with a second-stage reconstruction. However, the one-stage repair is generally recommended.[106] The development of an esophagopleural fistula in the late postoperative period requires rib resection and adequate drainage of the pleural space. Gastrostomy and jejunostomy are required for alimentation and drainage of gastric con- tents. When the patient's condition is stabilized and the pleural space is clean, thoracotomy and direct repair of the esophageal defect are carried out. The fistula must be buttressed with tissue, and in this instance, omentum is an excellent choice because of its vascularity and adhesive qualities. The pneumonectomy space must be obliterated; this is accomplished by thoracoplasty in association with thoracoplasty and myoplasty. A small pneumonectomy space can be obliterated by myoplasty alone. The development of an esophageal pleural fistula after pulmonary resection is associated with high mortality and morbidity. The fistula must be treated aggressively because it will not close spontaneously.

SURGERY AND CHEMOTHERAPY

KATHERINE M.W. PISTERS

Surgery remains the best treatment modality for potential cure for patients with non–small cell lung cancer (NSCLC). However, at the time of initial presentation, only about half of all patients will have localized disease and less than a third are actually candidates for surgical exploration. [1] Survival following surgical resection is best predicted by pathologic stage at surgery [2] (see also Chapter 32).

The major prognostic determinants for patients with early stage disease are the size of the primary tumor and the presence or absence of lymph node metastases. [2] Therefore, precise information concerning staging, both with respect to the primary tumor and lymph node involvement is critical to ensure proper balance in randomized clinical trials. This requires thorough intraoperative staging with at least lymph node sampling if not dissection. The staging system gives general guidelines for expected survival within each T and N classification. Survival also varies by the number and extent of nodal involvement. Although potentially resectable, once ipsilateral mediastinal and subcarinal lymph nodes are involved, the prognosis is much worse. When diagnosed preoperatively by imaging or invasive techniques, less than 10% of all patients treated with surgery survive five years. Adverse prognostic factors include multiple levels of N2 disease, multiple lymph nodes at one level involved with tumor, adenocarcinoma, and extranodal extension of disease. More than 75% of patients with N2 disease present with involvement extending beyond one lymph node station. [3] The presence of N2 disease is not a contraindication to surgery as a single modality therapy, because it may be curative in very select patients. However, the survival of the N2 patients as a whole is poor, and effective combined modality treatment strategies need to be identified.

Histology has also been found to impact on survival in surgically resected patients. The former North American Lung Cancer Study Group (LCSG) has carefully analyzed approximately 1,000 resected patients and found a survival of 83% for T1N0 squamous cell carcinoma patients, compared to 69% for T1N0 adenocarcinomas. [4] Similarly, the survival of resected stage IB or II adenocarcinoma patients was significantly worse than those of identical stage with squamous cell carcinomas. Others have reported that the outcomes for large cell carcinoma are possibly different from those for resected squamous or adenocarcinomas. [5]

The identification of biologic markers, which may influence prognosis, is an active area of research. Growth factor production (epidermal growth factor or transforming growth factor alpha), surface epitopes (blood group antigen expression), oncogenes (*RAS* mutations) and tumor-suppressor genes (*p53* or *RE*) have been reported to influence prognosis. [6] Further research is necessary to validate the prognostic importance of these markers and identify other markers of importance (see also Chapter 33).

Recognition of prognostic and surgical factors that predict for specific anatomic failure patterns can allow selection of patients for local, systemic, or combined therapy. [3] After surgical resection, patients with pathologic stage I disease have survival rates in excess of 50%. Isolated mediastinal or local recurrence is unusual, and postoperative radiotherapy should not be employed. For patients with T1N1 or T2N1 disease, local recurrence is uncommon (12% to 14%), while distant failures occur in roughly one third of patients. [3] Survival decreases for patients with N2 disease discovered intraoperatively. When no adjuvant therapy is used, thoracic recurrence rates approach 20% and distant metastases become even more common. [7] Further evidence of occult metastatic disease comes from an autopsy series of patients who died within 30 days of "curative" surgical resection. In that series, one third of squamous carcinomas had locally persistent disease, and 17% had distant metastases. Adenocarcinoma patients had a 40% incidence of persistent local disease, and a similar percentage had metastatic disease. [8] Given that death in the majority of resected patients is cancer-related and follows systemic recurrence, efforts at improving survival following surgical resection have focused on the use of postoperative chemotherapy and irradiation.

EARLY TRIALS

Randomized, prospective studies examining postoperative adjuvant chemotherapy in bronchogenic carcinoma were initiated in the 1960s and 1970s. The University Surgical Adjuvant Lung Project Cooperative Group reported its experience with over 1,100 patients randomized to receive nitrogen mustard intrapleurally and intravenously in the perioperative period, or placebo. [9] No difference in disease-free survival or overall survival was seen. Moreover, a significantly higher postoperative complication rate was found in those patients treated with chemotherapy. The investigators concluded that nitrogen mustard, as administered in this study, was not beneficial.

The Veterans Administration Surgical Adjuvant Group conducted a series of adjuvant chemotherapy studies in resected lung cancer patients. [10] Its first trial examined the effect of intrapleural and intravenous nitrogen mustard administered in the perioperative period. Similar to the University Surgical Adjuvant Lung Project, no difference in disease-free survival or overall survival was found. The next adjuvant trial examined cyclophosphamide. Well over 800 patients were randomly assigned to receive cyclophosphamide (6 mg per kg), daily for five days following surgery. A second course, administered in the fifth postoperative week, consisted of cyclophosphamide (8 mg per kg) for five days. Only 65% of the patients assigned to receive adjuvant chemotherapy were able to begin the second cyclophosphamide course, and an increased complication rate in the chemotherapy-treated patients was seen. Again, long-term follow-up revealed no benefit in overall survival for those patients treated with adjuvant chemotherapy versus surgery alone. The third Veterans Administration Surgical Adjuvant Group trial was a three-arm randomized study comparing no adjuvant therapy versus adjuvant cyclophosphamide versus adjuvant cyclophosphamide alternating with methotrexate. Chemotherapy was administered daily for five days every five weeks for a total of eighteen months, beginning two to four weeks postoperatively. Over 130 patients were enrolled into each arm of the study, and again the results were disappointing, with no significant difference in overall survival detected at five years. The fourth trial examined the combination of lomustine (CCNU) and hydroxyurea given orally for one year following surgery, versus no further treatment. [11] Again, no significant difference in disease-free or overall survival was found.

Data from the Swiss Group for Clinical Cancer Research was reported by Brunner and colleagues. [12] The group conducted a randomized, long-term adjuvant chemotherapy trial of cyclophosphamide versus placebo following radical resection of bronchogenic carcinoma. The study assigned 172 patients to receive no further treatment or intravenous cyclophosphamide administered as eight to nine weekly injections every four months for two years. At follow-up ranging between 3.5 to 5.5 years, 68% of the patients treated with adjuvant cyclophosphamide had experienced recurrences and 63% had died. In contrast, of the untreated control group, only 49% had recurred and 39% had died. Moreover, the median times to recurrence and death were eight months earlier in the cyclophosphamide arm. The authors concluded that treatment with intermittent courses of cyclophosphamide over a two-year period seemed to increase the recurrence and death rates significantly over that observed in the untreated control group. Despite a careful analysis, no factor other than the cyclophosphamide itself was found to explain these observations.

In 1985, Girling reported the 15-year follow-up of 726 bronchogenic carcinoma patients entered into a double-blind, randomized trial. [13] Patients received oral adjuvant cytotoxic chemotherapy with either busulfan or cyclophosphamide for two years, or placebo. At 15 years, 8% of the busulfan-treated patients, 9% of the cyclophosphamide-treated patients, and 10% of the placebo-treated patients were alive. The authors concluded that prolonged oral cytotoxic chemotherapy with cyclophosphamide or busulfan did not improve survival over surgery alone.

None of the prospective trials reviewed above demonstrated improvement in disease-free or overall survival for adjuvant chemotherapy in bronchogenic carcinoma. However, these trials have been criticized, as factors such as histology, nodal involvement, performance status, age, or intraoperative staging were not considered in the design of these trials. In addition, the chemotherapeutic agents studied have minimal activity in NSCLC. Other trials have examined the potential benefit of

adjuvant immunotherapy in resected bronchogenic carcinoma. BCG (bacillus Callmette-Guerin) has been studied extensively. It has been given intrapleurally [14] or subcutaneously.[15] Intrapleural BCG has been associated with increased postoperative complications, and neither route of administration has yielded improved survival.

In the late 1970s cisplatin-based combination chemotherapy regimens were developed and found to have activity in NSCLC patients with metastatic disease. This led to renewed interest in adjuvant chemotherapy in the mid 1980s. In addition, improved pre- and intraoperative staging of patients with NSCLC and the identification of important prognostic factors allowed better selection of those patients who could potentially benefit from this approach, and allowed for proper stratification of patients on study.

CISPLATIN-BASED REGIMENS

The Lung Cancer Study Group (LCSG) has conducted a series of prospective, randomized trials evaluating combination chemotherapy in the surgical adjuvant setting.[16] In LCSG trial 772, completely resected stage II and stage III (AJCC criteria) adenocarcinoma and large cell undifferentiated carcinoma patients were randomized to receive postoperative chemotherapy or immunotherapy (see Table 42.1). Chemotherapy consisted of cyclophosphamide 400 mg per m^2, doxorubicin 40 mg per m^2, and cisplatin 40 mg per m^2 (CAP) monthly for six months. Immunotherapy was comprised of intrapleural BCG and 18 months of oral levamisole. Careful intraoperative nodal sampling of all patients was performed to insure adequate staging. Before randomization, patients were stratified by stage, weight loss, history of cardiac arrhythmia and institution. Of the 130 eligible patients, 23 did not receive the assigned treatment but were included in the final analysis. Disease-free survival was significantly prolonged in the treatment arm receiving adjuvant CAP chemotherapy (p = 0.018). Median survival was also increased by seven to eight months on the CAP arm, but this difference was not statistically significant. Follow-up of both treatment groups revealed systemic recurrence to be the most frequent type of relapse.

TABLE 42.1. SELECTED ADJUVANT CHEMOTHERAPY TRIALS

The next LCSG trial examined the use of postoperative CAP chemotherapy plus thoracic irradiation versus adjuvant radiation therapy alone. [17] Eligible patients had incomplete resection, defined as the presence of residual tumor in the resection margin or tumor in the highest lymph node sampled. Radiation therapy was administered on a split-course schedule with 20 Gy delivered in five fractions over five days as two courses separated by three weeks. In the group randomized to receive chemotherapy, cyclophosphamide, doxorubicin, and cisplatin were administered every four weeks for six cycles, with the first two cycles administered on the first day of each radiation course. Patients were stratified according to histology, extent of residual disease and performance status. The study accrued 172 patients of whom 164 were eligible. The distribution of nodal disease was significantly imbalanced in favor of the CAP-treated patients. A significant difference in disease-free survival was found in favor of combined postoperative therapy (14 versus eight months), and a nonsignificant improvement in median survival was noted (20 versus 13 months). Analyses adjusted for nodal status yielded similar results. With further follow-up, the survival curves converged at about 2.5 years.

The final adjuvant trial from the LCSG enrolled patients with completely resected T2N1 and T2N0 NSCLC. [18] This trial randomized eligible patients to receive or not to receive four courses of postoperative CAP (same doses as above except for cisplatin 60 mg per m^2) chemotherapy beginning 30 days after surgery. Stratification by prognostic factors included histology (squamous versus nonsquamous), white blood cell count before surgery (more than or equal to 9,100 per mm^3 versus less than 9,100 per mm^3), and Karnofsky performance status before surgery (100% versus less than 100%). A total of 269 eligible patients were entered into the study. Only 53% of the eligible patients received all four courses of CAP, and only 57% of such patients received all four cycles on time. In 74% of the patients, the site of recurrence was distant. No difference in time to recurrence or overall survival was found.

A study from Finland reported in 1992 randomized 110 completely resected T1-3N0 NSCLC patients to postoperative CAP chemotherapy for six cycles or no further treatment.[19] The doses of chemotherapy employed were cyclophosphamide 400 mg per m^2, doxorubicin 40 mg per m^2, and cisplatin 40 mg per m^2. Eligible patients had a good performance status (over 60%) and were less than 70 years of age. After ten years of follow-up, survival in the chemotherapy arm was significantly better than control (61% versus 48%, p = 0.050). Disease free survival also favored the use of chemotherapy (69% versus 52%, p = 0.01). Although time to recurrence and death was significantly delayed, a major imbalance in randomization resulted in the assignment of twice as many patients who underwent pneumonectomy (and therefore likely to have more advanced disease) to the control arm. After adjustment for this imbalance, results were no longer significant. In addition, only 57% of patients received all their cycles of chemotherapy.

Two published trials have examined the use of postoperative vindesine and cisplatin. [20,21] A trial conducted in Japan[20] randomized 181 eligible patients with completely resected stage III NSCLC to receive postoperative cisplatin 80 mg per m^2 and vindesine 3 mg per m^2 on day 1 and 8 for three months or no further treatment. Patients were stratified by histology (squamous versus nonsquamous), and prognostic variables such as histology, performance status, extent of operation, tumor and nodal status were equally distributed among the two study arms. There was no difference in disease-free survival (18 versus 23 months, p = 0.5954), with the majority of recurrences being distant in both groups. Moreover, there was no difference in survival between the two groups, with a median survival time and five-year survival of 31 months and 35% in the chemotherapy arm versus 37 months and 41% in the control arm (p = 0.8606). The average cumulative dose of chemotherapy received was only 68% of the full protocol dosage.

The second study using adjuvant vindesine-cisplatin was conducted at Memorial Sloan-Kettering Cancer Center. [21] This study entered 72 patients with histologically confirmed T1-3N2 NSCLC. Patients were stratified by extent of resection (complete versus incomplete) and histology (squamous versus nonsquamous). Thirty-six were randomized to receive postoperative vindesine 3 mg per m^2 weekly for five weeks, then every two weeks eight times and cisplatin 120 mg per m^2 every four weeks four times plus thoracic irradiation (40 Gy beginning six to seven weeks postthoracotomy). Incompletely resected patients had intraoperative I ^{125} and/or Ir^{192} implantation. There was no difference in time to progression (9.2 months for radiation and chemotherapy versus nine months for radiation alone, p = 0.35), with the majority of recurrences being distant in both groups. Overall survival was slightly better for the patients treated with postoperative radiotherapy alone (16.3 months for radiation and chemotherapy versus 19.1 months for radiation, p = 0.42). Similar to the findings in the Japanese trial above, only two-thirds of patients received the fully planned dosages of chemotherapy.

The results of Intergroup trial E3590 were recently presented. [22] This study was designed to determine if concomitant chemoradiotherapy was superior to radiotherapy alone in prolonging survival and preventing local tumor recurrence in completely resected stage II and IIIA NSCLC patients. The study randomized 488 patients between April 1991 and February 1997 to receive either four cycles of cisplatin (60 mg per m^2, day 1) and VP-16 (120 mg per m^2, days 1 to 3) administered concurrently with thoracic radiotherapy (5,040 cGy) or radiotherapy alone. Patients were stratified by weight loss (less than 5% versus more than 5%), histology (squamous versus other), nodal biopsy technique (sampling versus complete lymph node dissection), and stage (II versus IIIA), and 351 patients were eligible for analysis with a median follow-up of 37 months. Similar to the two vindesine-cisplatin adjuvant studies presented above, [20,21] only two-thirds of the chemoradiotherapy patients received all four planned cycles of chemotherapy, while 76% of these patients received the entire planned course of radiation. Slightly more (83%) patients in the radiation-alone arm completed the radiation as prescribed. Grades 3 and 4 toxicity, consisting largely of leukopenia and esophagitis, occurred in 8.8% and 1.3% of patients who received radiotherapy only, and 25% and 65% of patients who received the combined treatment. Treatment-associated mortality was roughly 2% in both arms of the study. Median survival overall was 38.6 months for the combined postoperative treatment and 41.1 months for patients treated with adjuvant radiation (p = 0.99). Three- and five-year survival rates were approximately 50% and 35%, and did not differ between the two arms. No difference was detected in disease-free

survival or local recurrence rates. The authors concluded that postoperative chemoradiotherapy with etoposide and cisplatin does not prolong survival or alter local recurrence rates in patients with completely resected stages II and IIIa NSCLC when compared to postoperative radiation alone.

NON-CISPLATIN-BASED REGIMENS

Several interesting studies have been conducted in Japan. These trials have examined the use of tegafur (FT), a fluorouracil (5-FU) derivative, or UFT (a combination of tegafur and uracil at a molar ratio of 1 to 4). These agents can be administered orally. [23] FT has good absorption following oral administration and is gradually converted to 5-FU *in vivo*.[24] Degradation of 5-FU is inhibited by uracil; therefore the oral combination of UFT results in sustained levels of 5FU in tumor tissue. [25] The first two studies reported were conducted by the Chuba Branch of the Japan Society of Lung Cancer. In the first study, postoperative mitomycin, cyclophosphamide, and tegafur were compared to surgery alone.[26] After 2.5 years of follow-up, no significant difference in survival was seen between the two arms. The second Chuba study examined the effect of postoperative cisplatin, doxorubicin, and tegafur plus uracil (UFT) on completely resected stage I to III NSCLC. [27] The study randomized 309 eligible cases: 155 to surgery and chemotherapy, and 154 to surgery alone. The majority of patients entered had stage I disease (n = 118), while a few patients had stage II (n = 13), and the remainder, stage III (n = 78). In the combined modality arm, chemotherapy consisted of cisplatin 66 mg per m2 and doxorubicin 26 mg per m^2 within two weeks of surgery, followed by UFT orally at a dose of 8 mg per day for six months or more. Chemotherapy was interrupted because of side effects of postoperative complications in only 14.9% of cases (in contrast to the cisplatin-based adjuvant studies discussed above, where usually only two-thirds of the planned chemotherapy is actually administered). Despite no planned stratification for known prognostic factors, gender, age, pathologic T-stage, histology, surgical procedure, and performance status were equally distributed between the two groups. There was an imbalance with respect to pathologic N stage, with more advanced cases assigned to the combined modality arm (p = 0.018). The overall five-year survival rate was 62% for surgery and chemotherapy versus 58% for surgery alone (not significant). Because a significant difference was observed between the two groups regarding pathological lymph node metastasis, a reanalysis incorporating prognostic factors using the Cox proportional hazard model was performed. With this prognostic-factor-adjusted analysis, a significant difference in overall and disease-free survival rates favoring the use of adjuvant chemotherapy was found (p = 0.044 and p = 0.036, respectively).

A third trial from Japan also evaluated the use of UFT in the postoperative setting. [28] In this trial, 310 eligible completely resected NSCLC (stages I to III) patients were enrolled. After surgery, patients were randomly assigned using the envelope method to one of three treatment groups. The first group (CVUFT) received cisplatin 50 mg per m^2 and vindesine 2 to 3 mg per kg, one to three weeks after surgery. In addition, vindesine 2 to 3 mg per kg was administered twice at intervals of one to two weeks. Two weeks later, a one-year period of oral administration of UFT 400 mg per day was started. The second group received one year of oral UFT 400 mg per day beginning one to three weeks after surgery. The control group received no postoperative adjuvant chemotherapy. Of the eligible patients, 109 received CVUFT, 103 got UFT, and 98 received no further therapy; 210 patients had stage I disease, 36 had stage II and 62 had stage III (including seven patients with stage IIIB disease). Although there was no planned stratification, no significant differences between the three groups with respect to gender, age, histology, pathologic T, N, or stage were observed. Compliance with the UFT was better than seen in other adjuvant trials, with the mean total dose being approximately 70% and 80% on the CVUFT and UFT arms, respectively. The five-year survival rates were 61% for CVUFT, 64% for UFT and 49% for the control group (differences among the three groups: p = 0.053 by log-rank and p = 0.044 by Wilcoxon). In addition, a significant difference was observed between the UFT group and the control group (p = 0.022 by log-rank and p = 0.019 by Wilcoxon). Postoperative adjuvant chemotherapy was also found to be a significant prognostic factor for survival, with hazards ratios (against control) of 0.64 (95% confidence intervals (CI): 0.42 to 0.97) in the CVUFT group and 0.55 (95% CI: 0.36 to 0.86) in the UFT group. Adverse effects were generally mild. Hematologic toxicity above or at grade 1 occurred in 29% of the CVUFT group versus 12% of the UFT group. A lower incidence of fatigue, anorexia, and nausea/vomiting were seen in the UFT group. Hepatic dysfunction was more common in the UFT group (13% versus 9% in the CVUFT). However, adverse reactions were tolerable and generally did not require interruption of UFT administration. Overall recurrence rates were 39% (29% distant) for the CVUFT group, 40% (28% distant) for the UFT-alone group, and 43% (33% distant) for the control group. Death from primary lung cancer occurred in 31%, 28%, and 39% of CVUFT, UFT, and control patients respectively. Deaths attributable to nonrecurrent second primary lung cancers occurred in 2.8%, 1.9% and 5.1% of CVUFT, UFT, and control patients respectively.

UFT administered in these studies was well tolerated and appeared to inhibit recurrences and prolong survival when administered over a long time period after complete resection. There is little data about the use of UFT in metastatic NSCLC. However, the results of these trials are compelling. Further study of this agent in randomized trials entering a more homogeneous patient population is warranted to confirm the effects of UFT therapy on survival following complete resection of NSCLC.

THE METAANALYSIS

The role of chemotherapy in NSCLC was extensively examined in a metaanalysis published in 1995. [29] This analysis was undertaken to determine the effect of cytotoxic chemotherapy on survival in patients with NSCLC. The vast majority of randomized trials conducted in NSCLC have been too small to detect a moderate treatment effect. Consequently, although a few trials have reported significant results, most have been inconclusive. In order to assess the evidence and establish the size of any possible treatment effect, a metaanalysis was conducted. Updated data on individual patients from all available randomized trials, both published and unpublished, were gathered, and 9,387 patients (7,151 deaths) from 52 randomized trials were analyzed. Patients with NSCLC were classified into three broad categories according to the primary treatment they received: surgery, radical or potentially curative radiotherapy, and supportive care. The main objective was to investigate the effect of chemotherapy on survival in these treatment settings. Trials were eligible if recruitment started after January 1, 1965 and was completed by December 31, 1991. For the purposes of this chapter, only the data regarding the use of postoperative chemotherapy will be presented here. Only adjuvant trials where patients had undergone a potentially curative resection and had no prior history of treatment for other malignancy were analyzed.

Surgery versus Surgery plus Chemotherapy

Data were available from 14 trials (4,357 patients and 2,574 deaths). Five trials used long-term alkylating agents (mainly cyclophosphamide and nitrosourea); eight employed cisplatin-based regimens, three trials had CAP chemotherapy (cyclophosphamide, doxorubicin, and cisplatin), and the remaining three employed cisplatin/vindesine. The intended dose of cisplatin ranged from 40 mg per m ^{2} to 80 mg per m2 per cycle and total dose from 50 mg per m2 to 240 mg per m2. A further three trials used other drug regimens, all of which included tegafur or UFT (tegafur plus uracil). In all the trials, chemotherapy was scheduled to start no later than six weeks after surgery.[29]

The results showed considerable diversity and evidence of a difference in direction of effect between the predefined categories of chemotherapy (see Table 42.2). The results for long-term alkylating agents were consistent. The hazard ratio estimates all favored surgery alone with a combined hazard ratio of 1.15 (p = 0.005). This 15% increase in the risk of death translated to an absolute detriment of chemotherapy of 4% at two years and 5% at five years. [29] For regimens containing cisplatin, the pattern of results was consistent with most trials favoring chemotherapy. An overall hazard ratio of 0.87 (p = 0.08) or a 13% reduction in the risk of death was found. The absolute benefit from cisplatin-based chemotherapy was 3% at two years and 5% at five years (95% CI: -1% to 10%). The trials that were classified as using "other" regimens were found to have an estimated hazard ratio of 0.89 in favor of chemotherapy (p = 0.30), but there was insufficient information to draw reliable conclusions (see Table 42.2).

| Chemotherapy | Surgery | | | | Surgery and Radiotherapy | | | |
| | Hazard Ratio (95% CI) | p Value | % Absolute Benefit | | Hazard Ratio (95% CI) | p Value | % Absolute Benefit | |
			2 y	5 y			2 y	5 y

TABLE 42.2. RESULTS OF METAANALYSIS FOR ADJUVANT CHEMOTHERAPY IN NSCLC

Surgery plus Radiotherapy versus Surgery plus Radiotherapy plus Chemotherapy

Data were available from seven trials (807 patients, 619 deaths). Six trials used a cisplatin-based regimen, with intended doses of cisplatin ranging from 40 mg per m2 to 100 mg per m2 per cycle and total dose from 80 mg per m2 to 400 mg per m2. Total planned doses of radiotherapy ranged from 40 Gy in ten fractions to 65 Gy in 33 fractions, and the delay between surgery and the first adjuvant treatment was scheduled to be no longer than seven weeks. [29]

The overall hazard ratio of 0.98 (p = 0.76) was marginally in favor of chemotherapy (see Table 42.2). For the cisplatin-based trials, a hazard ratio of 0.94 (p = 0.46) or a 6% reduction in the risk of death favored chemotherapy, suggesting a 2% absolute benefit at both two and five years.

This metaanalysis suggests that cisplatin-based chemotherapy regimens may provide an absolute benefit of about 5% in the surgical adjuvant setting. The confidence intervals are such, however, that the results are consistent with benefits of as much as 10%, or as little as a 1% detriment. The authors concluded that although the effects of postoperative cisplatin-based chemotherapy were modest, these improvements, given the high incidence of lung cancer, could be important in public health terms. In addition, studies of patients' opinions of treatments for cancer have shown that many patients accept considerable toxicity in return for small improvements in survival. [30]

ONGOING TRIALS

Currently, there are several ongoing international trials evaluating the use of postoperative chemotherapy. The International Adjuvant Lung Cancer Trial (IALT) should determine the impact on survival of three to four cycles of cisplatin-based chemotherapy in completely resected stage I, II, or III NSCLC. Eligible patients receive cisplatin (80 to 120 mg per m^2 per cycle) and either a vinca alkaloid (vinblastine, vindesine, or vinorelbine) or etoposide, or no further therapy. [31] Chemotherapy must begin within 30 to 60 days of surgery. In the first 3.5 years since the study was opened, approximately 1,300 patients have accrued. The trial was designed to show a reduction in mortality of 5% to 10% with the use of adjuvant cisplatin-based chemotherapy. No results are available to date.

The ALPI trial (Adjuvant Lung Project Italy) is another large study evaluating the role of postoperative cisplatin chemotherapy. This trial, being conducted in Italy with participation from the EORTC, randomizes completely resected stage I, II, and IIIA NSCLC patients to receive either MVP (mitomycin 8 mg per m^2 on day 1, vindesine 3 mg per m2 on day 1 and 8, cisplatin 100 mg per m2 on day 1) every three weeks for three cycles, or control. [32] Chemotherapy must begin within 14 to 42 days after surgery. Radiotherapy can be given at the discretion of the participating center, beginning three to five weeks after completion of chemotherapy or four to six weeks following surgery (control group). Patients are stratified by center, T- and N-stage, and use of radiotherapy. The study was designed to detect a 20% relative reduction in five-year mortality rate, with 80% power at the 5% level of statistical significance. Since the trial opened in 1994, accrual has been relatively constant at about 250 patients per year. Approximately 1,200 patients have been enrolled as of October 1998. Analysis of survival and recurrence will occur when a predefined number of events (635) have occurred.

The results of these two large, randomized, prospective adjuvant trials will likely shed light on the controversial issue of the efficacy of cisplatin-based adjuvant chemotherapy in the treatment of stage I, II, and IIIA NSCLC. These results are anxiously awaited.

Cisplatin plus vinorelbine as a surgical adjuvant is currently undergoing evaluation in North America in the NCIC BR10 trial. This trial, chaired by the National Cancer Institute of Canada with participation by several cooperative groups in the United States, randomizes completely resected stage IB and II NSCLC to observation or cisplatin plus vinorelbine. Patients are stratified based on the presence or absence of *RAS* mutations. Another North American cooperative group (Cancer and Leukemia Group B) is using carboplatin plus paclitaxel postoperatively in patients with resected stage IB NSCLC. This regimen is being compared to observation. These two studies will help define the role of "newer" drug combinations in the adjuvant setting.

FUTURE STRATEGIES

When designing future trials of adjuvant therapy in NSCLC, it is important to keep in mind a number of guiding principles. [1,33] Table 42.3 outlines various issues relevant in the design and reporting of adjuvant chemotherapy trials. Appropriate preoperative evaluation to exclude metastatic disease should be performed in all patients. An exciting new modality, whole-body positron emission tomographic (PET) scanning, appears to add to the precision of preoperative staging accomplished by CT and mediastinoscopy.[3] More experience with this technique is required fully to define its role in the staging of NSCLC, but it may play a central role in identifying resectable patients in the near future. Trials should enter patients of similar prognosis who have undergone a complete surgical resection with negative pathologic margins. In order to insure accurate staging, all patients should have extensive nodal sampling or dissection performed intraoperatively. At present, an untreated control arm is best to most accurately assess the impact of the experimental adjuvant therapy. Patients should be stratified for known major prognostic factors. Randomization should occur after pathologic staging is known and following clinical recovery from surgery. Efforts should be made to collect tumor specimens prospectively to facilitate biologic studies that might lead to the identification of new biologic prognostic factors. The adjuvant chemotherapy regimen chosen for study should be the most active one known for metastatic disease at the time of the trial design. Analysis of adjuvant trials should be done on an intent-to-treat basis. Compliance with adjuvant therapy should be noted, because trials to date have often found a significant number of patients not completing the adjuvant therapy as planned. Disease-free and overall survival rates as well as site of initial recurrence—local, distant, or both—should be reported. The occurrence of second primary tumors should also be noted.

Trial Design:
- Appropriate preoperative evaluation to exclude metastases
- Complete surgical resection, negative pathologic margins
- Careful intraoperative staging, extensive nodal sampling or dissection
- Tissue banking for analysis of biologic markers
- Untreated control arm
- Stratification for known major prognostic factors
- Randomization after pathologic staging and clinical recovery from surgery
- Optimal chemotherapy regimen

Trial Reporting
- Intention to treat analysis
- Compliance and toxicity of adjuvant therapy
- Disease-free and overall survival rates
- Recurrence patterns—local, distant, or both
- Second primary tumor rates

TABLE 42.3. ISSUES IN ADJUVANT CHEMOTHERAPY TRIAL DESIGN AND REPORTING

Despite what appears to be a complete resection of NSCLC, death follows in the majority of patients after developing recurrent disease. Therapy aimed at eradicating micrometastatic disease has been the primary goal of adjuvant chemotherapy. The majority of clinical trials performed have not found unequivocal, reproducible evidence of efficacy for adjuvant therapy. The chemotherapy regimens tested to date have been marginally effective, if at all. This may in part be due to the frequent discontinuation of chemotherapy in most of the adjuvant studies preventing demonstration of a benefit that might otherwise have been proven. [34]

The past few years have witnessed the identification of new chemotherapeutic agents with improved activity against metastatic NSCLC (taxanes, camptothecins, vinorelbine, and gemcitabine). Incorporation of these new agents into the adjuvant setting may improve survival for resected patients. Trials confirming the efficacy of postoperative UFT are clearly warranted. In addition, the role of even newer classes of antineoplastic therapies, such as the antiangiogenesis inhibitors, matrix metalloproteinase inhibitors, farnesyl transferase inhibitors, tyrosine kinase inhibitors or other biologic therapies, should be defined in the upcoming years.

POSTOPERATIVE IRRADIATION IN NON–SMALL CELL LUNG CANCER

TIMOTHY E. SAWYER
JAMES A. BONNER

Surgical resection is the cornerstone of management for non-small cell lung cancer (NSCLC). Postoperative irradiation likely has no benefit for patients with pathologic T1N0 or T2N0 lesions, which have low rates of local failure. Moreover, the role of adjuvant therapy after complete resection and modal dissections of tumors that are found to involve hilar (N1) or mediastinal (N2 or N3) lymph nodes, as defined by the American Joint Committee on Cancer (AJCC), is controversial. [1]

Attempts to define the potential benefits of postoperative therapy have been reported from a large number of retrospective and prospective studies (see Table 43.1). Several retrospective studies suggest benefit from mediastinal postoperative irradiation for various groups of patients; however, survival benefit has not been corroborated by any randomized study. Each retrospective study is limited by selection bias inherent in all retrospective analyses. However, the randomized studies that have considered this question have also been limited, to various extents, by substantial design flaws. The majority of them have more than one limitation.

TABLE 43.1. TRIALS EVALUATING THE EFFICACY OF POSTOPERATIVE RADIATION THERAPY FOR NON–SMALL CELL LUNG CANCER

First, several published randomized trials include some patients who have low risk for local-regional recurrence. So any potential benefit of postoperative radiation therapy, in terms of survival, may be diluted by the low-risk patients in these local trials, which did not stratify or analyze patients according to level of risk. Emerging information about prognostic factors has recently become available, and imbalances of these factors in the randomized studies may influence the results of randomized studies. Some trials have analyzed patients of varying risk groups independently. However, these subgroup analyses are essentially retrospective reanalyses that were not initially planned and do not possess statistical validity that is significantly superior to that of retrospective studies.

Second, many of the randomized trials took place in the 1960s and 1970s, a period during which the technical quality of radiation therapy was significantly inferior to current techniques. Many of these trials occurred before the regular use of linear accelerators. Linear accelerators have significantly enhanced the ability to deliver high doses to target tissues while reducing the dose to superficial tissues and structures. Most of these trials occurred before the availability of computed tomography, which allows better staging radiographically and definition of the target volume, and also facilitates more sophisticated radiation treatment planning and beam directing. All the trials were limited to varying extents by other limitations, including the use of spinal cord blocks (which potentially block mediastinal disease), poor quality control relating to both irradiated volume and target volume dose, and split-course and hypofractionation regimens.

Third, the majority of randomized trials included a very small number of patients, with little or no statistical hope of demonstrating even a moderate-sized difference in outcome. Had these trials demonstrated a radiation-related improvement in outcome (assuming a difference actually exists), it would have to have been due to a statistical fluke. The absence of a statistically significant difference in outcome in these trials should be considered as nothing more than a self-fulfilling prophecy. Possibly, trials that are extremely limited in power do more harm than good in improving our therapeutic knowledge.

There are nine published randomized trials considering postoperative irradiation. [2,3,4,5,6,7,8,9 and 10] Some of the technical and methodologic limitations of these trials are given in Table 43.1. (Two other trials are not listed in Table 43.1 because the results have not been published except in abstract form. [11,12])

The Ideal Patient

Despite the popularity of neoadjuvant (preoperative) chemotherapy and radiation therapy in lung cancer, surgery has a significant advantage as the initial therapeutic modality: the undisturbed pathologic features. The findings can be used to categorize patients as to ultimate risk for death, systemic failure, and local failure. The best patient category to investigate benefit of postoperative radiotherapy probably has a higher frequency of local failure, but the precise factors need clearer definition. Multiple series do suggest which patients are at highest risk. Matthews and colleagues' [13] autopsy study assessed 202 patients who died within 30 days after purportedly curative resection for NSCLC. The pattern of documented residual disease was telling. Cancer recurrence was found within the chest of 24 of these patients. Subsequent data have suggested that conventional histologic techniques underestimate the true incidence of subclinical disease. [14,15]

If adjuvant irradiation confers a survival advantage, it most likely would rise in conjunction with the risk for local-regional recurrence. However, there may be a "leveling off" effect. This "leveling off" hypothesis suggests that the risk for distant metastasis increases in conjunction with the risk for local-regional recurrence. Thus, patients with an extremely high risk for local-regional recurrence may possibly be less likely to benefit from local therapy than patients with a lower risk, because their

distant metastasis risk would diminish the chance of cure.

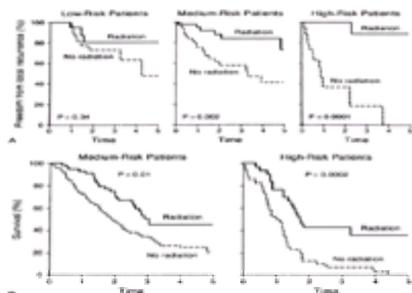
Many studies have attempted to define outcome-related prognostic factors in cases of completely resected NSCLC. The majority have focused on survival as the only end point. The data evaluating prognostic factors with respect to local-regional recurrence have allowed one to assess the efficacy of radiation therapy within risk-related subgroups, with possibly one exception. A Mayo Clinic study of patients with completely resected N2 disease attempted to evaluate the role of postoperative irradiation in relation to local-regional recurrence risk. The analysis suggested that as local-regional recurrence and mortality risks increase, the benefit from postoperative irradiation also appears to increase [16] (Figure 43.1). The "leveling off" effect was not seen, but it may be that the patients with a very high risk of developing distant metastases were not included in the population of patients who were able to undergo complete resection or who were selected for postoperative therapy.


FIGURE 43.1. In a cohort of 224 consecutive patients undergoing complete resection for pathologic N2 non–small cell lung cancer, the radiation-related improvement in outcome appeared to increase with increasing risk for local recurrence **(A)**, and death **(B)**. (From Sawyer TE, Bonner JA, Gould PM, et al. Effectiveness of postoperative irradiation in stage IIIA non-small cell lung cancer according to regression tree analyses of recurrence risks. *Ann Thorac Surg* 1997;64:1402. By permission of the Society of Thoracic Surgeons.)

The Ideal End Point

The theoretic "leveling off" effect (the disappearance of a survival benefit with increasing local-regional recurrence risk) mentioned above may become irrelevant depending on the end point used as justification for the use of adjuvant therapy. This effect would apply primarily to the use of survival as an end point. Many have cited a decreased rate of local-regional recurrence as sufficient justification for recommending adjuvant radiotherapy. In this case, the absence of a survival benefit would not, in itself, be enough to dissuade one from recommending irradiation. However, if the justification for a potentially toxic therapy is improvement in local control with or without an associated survival advantage, it becomes particularly important to ensure that the benefits of postoperative therapy are not outweighed by the toxicity.)

Radiation therapy to the mediastinum is associated with numerous potential side effects, and at least three randomized studies and one metaanalysis showed a *decreased* survival rate with the use of adjuvant irradiation for patients at relatively low risk for local-regional recurrence. [2,3 and 4,17] Two of these trials used 60 Gy as a standard postoperative dose[2,4] and one trial allowed doses of up to 60 Gy.[3] Treatment-related mortality was not reported from the Mayo Clinic series, which used 50 Gy.[16] However, because of the potential for irradiation-associated mortality, postoperative irradiation should be considered only in patients for whom a reasonable improvement in the chance of survival is expected (that is, patients for whom the absolute magnitude of an improved survival rate is likely to outweigh a small potential incidence of radiation-induced fatality). Another argument against the administration of postoperative irradiation only for local control after complete resection is that 50 Gy to the mediastinum is associated with several acute side effects, including fatigue, malaise, odynophagia, dysphagia, anorexia, and others. It is unclear whether the prevention of a symptomatic local progression (which can often be palliated effectively) justifies the delivery of therapy that has these associated side effects.

Still unanswered is the question: For whom should adjuvant irradiation be recommended? Despite much evidence, no survival benefit has been proved for any subgroup of patients. Despite this absence of proof, there are patients for whom radiation therapy may be justified on the basis of a large body of evidence that is not conclusive. Specific recommendations are given and supported in the following sections.

AJCC STAGE I (T1N0, T2N0)

Efficacy Data Multiple randomized trials of postoperative irradiation have included patients with AJCC stage I (T1N0, T2N0) disease. Two trials included only patients with node-negative disease.[2,3] The findings from these trials, as well as a randomized trial[4] that analyzed but did not stratify according to nodal status, and a recent metaanalysis[17] are the basis for current treatment recommendations for node-negative disease.

The first trial, published in 1980 by Van Houtte and colleagues,[2] included 224 patients with node-negative disease (175 evaluable). Three patients in each arm had T3 disease; all other patients were found at surgery to have either T1 or T2 tumors. After complete resection, patients were randomly assigned to either 60 Gy delivered in 2 Gy fractions via a three-field technique using ^{60}Co or to no adjuvant treatment. Local-regional recurrences, defined as recurrences within the treatment field, were slightly less common in irradiated patients. The incidence of local recurrence was 8% for the irradiated group compared with 13% for the control group (this difference did not reach statistical significance). However, there was a high frequency of radiation-associated late tissue effects in the study arm, and patients in the irradiated group had an inferior rate of survival (but this difference did not reach statistical significance).[2]

In 1996, Lafitte and colleagues[3] reported the results of a study that used megavoltage radiation therapy. Only patients with T2 tumors were included. In this study, 132 evaluable patients were randomly assigned either to postoperative irradiation or to no further treatment. The five-year survival rate for all patients in the study was 44.2%. There was no difference between the two groups in the pattern of recurrence. The difference in survival between the two groups was of borderline significance in favor of the nonirradiated group (p = 0.049). However, the report contained few technical details about the radiation therapy, other than that the total radiation doses were between 45 and 60 Gy and that treatment was centered on the hilum and upper mediastinum. The inferior mediastinum was not routinely treated.

In a recently reported trial by Dautzenberg and colleagues,[4] 728 patients with stage I, II, or III NSCLC were randomly assigned, after complete resection, either to postoperative radiation therapy (60 Gy at 2 to 2.5 Gy per fraction) or to no further therapy. The trial included 221 patients with stage I disease. Although the first 189 patients in the trial were stratified by stage, the next 539 were not. For all patients, the five-year overall survival rate was 43% for the control group, and 30% for the irradiated group (log-rank p = 0.002). The excess mortality rate in the irradiated group was due to an excess of intercurrent deaths, the rate of which increased with increasing dose per fraction. The excess overall (log-rank p = 0.07) and radiation therapy-related (p value not available) death rates were also present for stage I patients. As discussed below in AJCC Stage III—Perspectives, this trial had several methodologic flaws.

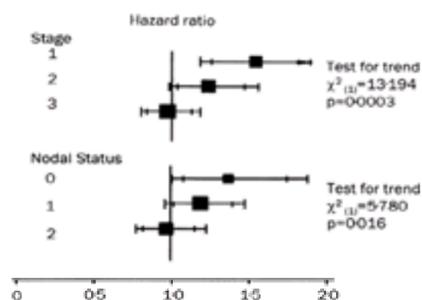
A recently reported metaanalysis from the Medical Research Council Lung Cancer Working Party (MRC) organized and updated the results from these and other trials. This analysis included nine randomized trials (2,128 patients) comparing surgery alone versus surgery plus postoperative radiation therapy. For patients with all stages of disease, postoperative irradiation was associated with an absolute survival rate decrement of 7% at two years. This hazard was most pronounced for patients with early-stage disease (N0, N1)[17] (Figure 43.2).


FIGURE 43.2. Stage- and lymph node status-based hazard ratios for PORT (postoperative radiation therapy) versus no PORT. (From PORT Meta-analysis Trialists Group. Postoperative radiotherapy in non-small-cell lung cancer: systemic review and metaanalysis of individual patient data from nine randomised controlled trials. *Lancet* 1998;352:257. By permission of the Lancet Ltd.)

Patterns of Recurrence

Although randomized studies have not demonstrated a benefit for the addition of postoperative irradiation for stage I disease, the concept of adjuvant local treatment may still be worth exploring if subgroups of patients with stage I disease with particularly high risks of local failure were identified. It would be reasonable to continue to study the efficacy of postoperative irradiation in patients at high risk for local-regional recurrence, especially if ongoing trials reveal that adjuvant chemotherapy is helpful in reducing systemic failure (which would then bring local control more relevance and prominence).

Several recently published studies have used multivariate analyses to determine which patients with stage I disease are at highest risk for local recurrence after complete resection.[18,19,20,21 and 22] Factors influencing prognosis in this setting had included the preoperative presence of cancer-related symptoms,[22] tumor size,[21,22] T stage,[18] tumor grade,[19] tumor histology,[21] presence of satellite nodules,[21] blood vessel invasion,[20,22] pleural invasion,[22] high mitotic index,[20,22] DNA ploidy pattern,[23] and extent of surgery (wedge resection versus lobectomy).[22] However, all of these studies used overall survival or disease-free survival as the end points for their multivariate analyses. None considered local-regional recurrence; thus these studies are silent on issues pertaining to local recuirrence and control.

Two recent studies have identified factors that appear to independently predict the rate of local-regional recurrence. A randomized trial from the Lung Cancer Study Group (LCSG) indicated that a lobectomy, instead of a wedge or segment resection, leads to a lower local-regional recurrence rate (local-regional recurrence, two-sided p = 0.008; survival, one-sided p = 0.08).[24] In addition, a recent study considered 13 potential prognostic factors for independent prognostic significance and, with the use of multivariate analyses, evaluated freedom from local recurrence, freedom from distant metastasis, and survival. The study included 370 consecutive patients with stage I disease who, over a four-year period, had complete resection at the Mayo Clinic. The five-year actuarial local recurrence risk for all 370 patients (defined as a recurrence in N1, N2, or N3 lymph nodes or at the bronchial stump) was 15%. Factors that independently predicted a lower rate of local recurrence included the presence of a T2 lesion (as opposed to T1, p = 0.04) and less than 15 lymph nodes resected (p = 0.001). The adverse outcome associated with fewer removed lymph nodes was possibly simply a function of staging (the fewer the number of nodes removed, the greater the likelihood of not accurately detecting stage II or III disease). Alternatively, a full lymph node dissection may be therapeutic. The analysis of survival revealed that greater tumor size and the removal and/or pathologic evaluation of fewer lymph nodes were independent predictors for an inferior survival rate (p = 0.001).[25]

Perspectives

Presently, in the setting of completely resected stage I NSCLC for which mediastinal lymph nodes have been dissected or at least sampled, there appears to be no established role for postoperative irradiation. Postoperative radiation therapy does not improve the rates of local control or survival, and may increase noncancer deaths in patients with stage 1 disease.

Efforts continue to identify patients at particularly high risk for local-regional recurrence. Recent data from the Mayo Clinic, outlined above, represent an attempt to identify such prognostic factors and to use a regression tree analysis to assign patients to risk groups[26] (Figure 43.3). These results, from a retrospective review from a single referral institution,[25] cannot be considered definitive, and corroboration from other institutions or within cooperative groups is needed. If these results are confirmed, they may establish the ideal patient group for future study in a large randomized trial.

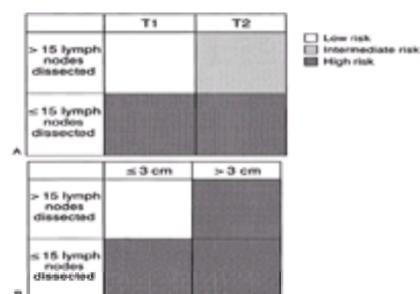

FIGURE 43.3. Risk groups for freedom from local recurrence **(A)**, and survival **(B)**, based on a regression tree analysis[26] in a cohort of 370 consecutive patients undergoing complete resection for pathologic stage I non–small cell lung cancer. (From Sawyer TE, Bonner JA, Gould PM, et al. Patients with stage I non-small cell lung carcinoma at postoperative risk for local recurrence, distant metastasis, and death: implications related to the design of clinical trials. *Int J Radiat Oncol Biol Phys.* By permission of Elsevier Science LTD.)

Another clinical situation deserves discussion. Although it is believed that mediastinal nodes should be dissected or at least sampled whenever possible, the radiation oncologist may occasionally be asked to consult postoperatively on a patient with stage I disease from whom no mediastinal lymph nodes were removed or evaluated. No definitive recommendations can be made about the role of postoperative mediastinal irradiation in this setting.

The most relevant data that can be used to address this question are related to the early-stage (radiographically uninvolved mediastinum) medically inoperable setting when the primary tumor is irradiated to definitive doses. Although several retrospective series imply no adverse outcome associated with omission of irradiation to clinically uninvolved nodes,[27,28,29 and 30] other series suggest that both local control and survival rates decrease when the mediastinum is not treated.[31,32] Factors associated with subclinical nodal involvement have been assessed.[33,34,35,36 and 37] Recently, Sawyer and colleagues[33] employed regression tree analysis in an attempt to use clinical (preoperative) factors to predict the incidence of subclinical N1 or N2 involvement in the clinical N0 setting. In relatively rare patients with low-grade (grade 1 or 2) and peripheral tumors, the incidence of subclinical involvement was approximately 15%. In all other patients, the incidence of subclinical involvement depended on the status of the preoperative bronchoscopy and maximal tumor diameter, but it was at least 35% (Table 43.2). It was also found that the risk of skip metastases (positive mediastinal nodes with negative N1 nodes) was 15% when a group of more than 300 consecutive patients who had thoracotomy for any stage NSCLC was considered.[36] The incidence of skip metastasis was higher when patients without nodal involvement were excluded. In summary, whereas irradiation to the mediastinum cannot be definitively recommended in the clinical N0 setting when no mediastinal lymph nodes have been removed, it may be of some benefit, and it cannot be considered inappropriate when the risk of subclinical involvement is considered. Postoperative pulmonary function and the volume of lung irridated to high dose should be considered in attempting to determine the therapeutic ratio associated with mediastinal treatment.

Risk for Subclinical Nodal Involvement		Incidence (%)
Low (n = 32)	Negative bronchoscopy* Tumor grade 1/2	15.6
Low-intermediate (n = 227)	Negative bronchoscopy* Tumor grade 3/4	35.2
High-intermediate (n = 24)	Positive bronchoscopy CT tumor size 3 cm or less	41.7
High (n = 44)	Positive bronchoscopy CT tumor size over 3 cm	68.2

* Includes patients with no preoperative bronchoscopy performed.
CT, computed tomography.

AJCC STAGE II (T1N1, T2N1, EXCLUDING T3N0)

Efficacy Data

Several retrospective studies have examined the efficacy of postoperative irradiation after complete resection of NSCLC. [39,40,41 and 42] However, most studies contain few patients with N1 disease[39,40,42] and consider patients with N1 and N2 tumors together as a group without providing statistical comparisons for the N1 group separately.[39,40] These studies demonstrate radiation-associated benefits only within narrow subgroups[40] or no benefit at all.[41,42] The retrospective study with the greatest number of patients, by Martini and colleagues,[41] suggests an independent radiation-associated survival decrement. However, these studies do not provide definitive, or even strong, evidence that adjuvant irradiation leads to an improved outcome in patients with N1 tumors, with respect to either local-regional recurrence or survival.

Several published randomized trials have studied the issue of postoperative irradiation and have included patients with N1 tumors. [4,5,6,7,8 and 9] However, the majority of studies grouped patients with N1 tumors together with other patients and thus provided few meaningful conclusions related exclusively to N1 disease. Two studies used stratification techniques and provided important information for patients with stage II disease or N1 tumors. [8,9]

In the Lung Cancer Study Group (LCSG 773), 230 patients with stage II or III squamous cell carcinoma were randomly assigned, after complete resection, to either 50 Gy or no further treatment.[8] Patients were stratified by stage, and approximately two thirds of them had stage II disease. Approximately 75% of the patients had N1 tumors. For the entire group of 230 patients, adjuvant irradiation produced a significant reduction in local recurrence (defined as a first recurrence in the ipsilateral lung or mediastinum) (p less than 0.001), with only one documented local recurrence in the irradiated group. However, a local recurrence analysis was not performed in the separately stratified group of patients with stage II disease. Although patients were stratified by overall stage, separate overall recurrence or survival analyses were performed according to nodal status; therefore the results for patients with N1 tumors represent a retrospective subgroup analysis. Patients with N1 disease did not experience even a trend toward improvement in outcome due to radiation therapy, either for overall recurrence (p = 0.92) or for survival (p = 0.95).

In a more recent effort from the MRC, 308 patients with T1 or T2, N1 or N2 lesions were randomly assigned postoperatively to 40 Gy in three weeks or to no further therapy.[9] Patients were stratified by the TNM classification, and 183 patients had N1 disease. Postoperative radiation therapy did not improve survival (p = 0.99) or local control (p = 0.24) when the entire population was analyzed. However, the rate of definite local recurrence was lower in the irradiated group (p = 0.04). (Whether a recurrence was considered definite or suspected was at the discretion of the individual clinician.) Specifically for patients with N1 tumors, radiation therapy was not associated with improved rates of survival (p = 0.26), local recurrence (p = 0.96), or distant metastasis.

Although the majority of patients were not stratified with respect to nodal status, one other trial deserves special mention. In the trial of Dautzenberg and colleagues,[4] subgroup analysis suggests that the patients with stage II disease receiving adjuvant irradiation had an inferior survival rate compared with patients observed without treatment (log-rank p = 0.003). This difference in patients with stage II disease appeared to be related to radiation-induced toxicity.[4]

The postoperative radiotherapy (PORT) metaanalysis suggests a radiation-related hazard for patients with N1 disease, although the risk was less than for patients with N0 disease[17] (Figure 43.2).

Patterns of Recurrence

Several prognostic factors have been identified in completely resected N1 NSCLC, including T stage,[43,44,45 and 46] size,[41,42,43,44,45 and 46] extent of N1 nodal dissection,[25] findings on the preoperative bronchoscopy,[46] specific site of N1 node involvement,[42,44] and histologic features.[21,41,42] However, the majority of studies have not focused on local-regional recurrence as an important end point and/or have not used multivariate analyses to assess for independent local-regional recurrence-prognostic factor relationships. Thus they provide limited information about predicting which patients might most likely benefit from adjuvant irradiation and thus which patients might be most appropriate for inclusion in future studies.

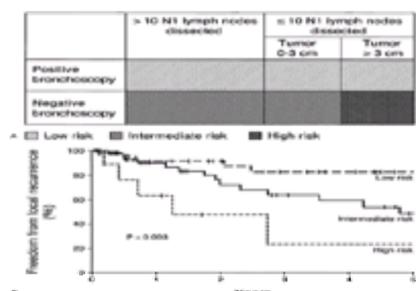
Recently, the Mayo Clinic group[46] examined retrospectively the potential prognostic significance of multiple patient-, treatment-, and tumor-related factors in a series of 107 patients with completely resected N1 tumors who did not receive therapy other than surgery. Separate multivariate analyses were performed with respect to freedom from local recurrence (defined as a recurrence in N1, N2, or N3 nodes or at the bronchial stump), freedom from distant metastasis, and survival. The main factor that independently predicted a higher freedom from local recurrence rate was the presence of a central tumor (positive preoperative bronchoscopic findings, p = 0.005). The main factors that independently predicted higher freedom from distant metastases and improved survival rates were removal of more than ten N1 nodes (p = 0.02) and the presence of a T1 tumor (p = 0.01), respectively. Regression tree analyses were performed for each end point (by the method of Breiman and associates[26]). The results for the local recurrence regression tree are shown in Figure 43.4.[46] The results of this study await corroboration by others and should be considered preliminary.


FIGURE 43.4. Risk groups for freedom from local recurrence based on a regression tree analysis [26] in a cohort of 107 patients undergoing complete resection and receiving no adjuvant therapy for pathologic N1 non–small cell lung cancer **(A)**. Patients in each risk group were well separated for outcome (log-rank p = 0.003) **(B)**. (From Sawyer TE, Bonner JA, Gould PJ, et al. Identification of risk groups in patients with completely resected N1 non–small cell lung carcinoma (*abstr*). *Int J Radiat Oncol Biol Phys* 1997;39:317, with permission.)

Perspectives

At many institutions, the administration of adjuvant thoracic irradiation after complete resection of pathologic N1 NSCLC has long been the standard of care. A local-regional recurrence benefit is frequently cited as justification for this, along with a possible, yet unproven, survival benefit. Currently, however, the data do not support any survival benefit in this setting, nor has a local-regional recurrence benefit been proven definitively or even strongly suggested. Although improvements in local-regional recurrence rate have been reported in some of the retrospective studies, these studies generally considered patients with N1 or N2 tumors as a single group. Few if any retrospective data have demonstrated a statistically significant benefit in the local-regional recurrence rate for a cohort consisting entirely of patients with N1 tumors. In addition, in the randomized studies in which patients were stratified so that those with N1 tumors or stage II disease could be considered independently, neither local-regional recurrence nor survival benefits were demonstrated. [8,9] Moreover, the randomized trial of Dautzenberg and colleagues [4] and the MRC metaanalysis[17] have suggested a radiation-related survival decrement for patients with N1 tumors.

The potential shortcomings of the LCSG study, which are related to both study design and radiation technique, have been cited frequently. [47] Analysis of the MRC study also reveals certain issues that may call into question the validity of using the results of the study to determine treatment. The MRC study design recommended use of a posterior spinal cord block at 35 Gy, which could potentially block mediastinal disease. Also, the MRC study used doses of radiation that may be suboptimal: 40 Gy in 2.67 Gy fractions, which is equivalent to a dose of 42 Gy in 2 Gy fractions, for an alpha to beta ratio of 10. This dose is well below the currently accepted "adjuvant dose" of 50 Gy. Furthermore, both the LCSG and MRC studies lacked the statistical power needed to detect small differences in outcome.

Currently, in the setting of completely resected (negative pathologic margins) AJCC stage II NSCLC for which mediastinal lymph nodes are dissected or at least sampled, there is not a definite role for postoperative irradiation. As for stage I NSCLC, the ideal study should evaluate this topic with appropriate stratification, state-of-the-art radiation therapy techniques, and the statistical power to identify small improvements in survival.

The local-regional recurrence risk for patients with N1 tumors who have had a complete resection is in the range of 21% to 44%. [9,41,45,46] With the potential for distant metastasis, it is unknown whether a treatment that effectively and considerably reduces this risk will lead to an improvement in survival. More work is needed to define the factors that place a patient at high risk for local-regional recurrence; these factors should aid in decisions related to the selection of patients for inclusion in future randomized trials and to the selection of stratification factors within the N1 patient population.

One clinical scenario is occasionally encountered and deserves special mention: the patient with N1 disease who has undergone complete resection but has not had surgical-pathologic staging of the mediastinum. In this setting, there are no data. Today, some institutions will have PET scans available to aid in decision making. Some prefer to irradiate the mediastinum postoperatively when lung function is not prohibitive.

AJCC N2, N3

Efficacy Data Several randomized trials have investigated patients with completely resected N2 NSCLC, but have considered these patients together with patients having N1 and even N0 tumors.[5,6 and 7] These are all negative trials and little can be concluded about the role of adjuvant radiation therapy specifically for patients with N2 tumors. Several trials, however, have considered patients with N2 tumors by themselves, either by limiting the trial to such patients [10] or by considering stage or nodal status as a stratification factor during the randomization process. [8,9]

In the LCSG 773 study mentioned above, 230 patients with stage II or III squamous cell carcinoma were randomly assigned, after complete resection of disease, to either 50 Gy or no further treatment. Although patients were stratified by stage, only 74 of the 210 eligible patients had stage III disease. The results for the entire group of patients have been discussed above (see Stage II— Efficacy Data). Of the 74 patients with stage III disease, only 43 had N2 tumors; thus the results for patients with N2 tumors represent a subgroup analysis rather than an analysis of patients as randomized. Local recurrence rates were given only for the entire group of patients with stage II or stage III disease; however, the overall recurrence rate was reduced for those with N2 tumors (p = 0.03). However, this did not translate to improved survival (p = 0.81).[8]

A recently published randomized study by Debevec and colleagues [10] had only slightly more statistical power for patients with N2 disease than did the LCSG study. Over a five-year period, 74 patients who had complete resection for N2 NSCLC were randomly assigned to 3,000 cGy in ten fractions or no further therapy. Although postoperative therapy was associated with a trend toward improved survival, the difference was not statistically significant.

The randomized study with the most statistical power for evaluating the efficacy of radiation therapy after complete resection of N2 NSCLC was performed by the MRC and published in 1996.[9] This trial stratified 106 patients with N2 tumors and randomly assigned them to 40 Gy in 15 fractions or no postoperative treatment. The results for the entire group have been presented above (see Stage II— Efficacy Data). For patients with N2 tumors, there was a trend toward a lower local recurrence rate with the addition of irradiation (p = 0.07). The three-year survival rates for irradiated and nonirradiated patients were 36% and 21%, respectively. A slight trend toward statistical significance was noted, but the log-rank p-value was only 0.18 (Figure 43.5). The patients in the irradiated group also experienced a superior rate of freedom from distant metastasis (p = 0.03).[9]

Patients at risk

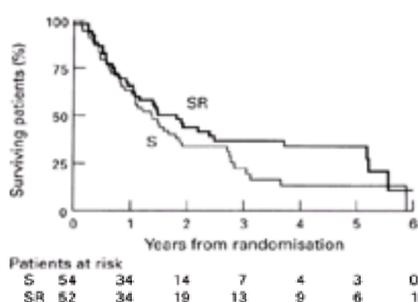
S	54	34	14	7	4	0
SR	52	34	19	13	9	1


FIGURE 43.5. Results of the Medical Research Clinical Lung Cancer Working Party randomized study for patients with completely resected N2 disease. Patients receiving postoperative radiation therapy (SR) had survival rates superior to those of patients receiving surgery alone (S), but the difference was not statistically significant (log-rank p = 0.18). (From Stephens RJ, Girling DJ, Bleehen NM, et al. The role of post-operative radiotherapy in non-small-cell lung cancer: a multicentre randomised trial in patients with pathologically staged T1–2, N1–2, M0 disease. *Br J Cancer* 1996;74:632. By permission of Cancer Research Campaign.)

Although the majority of patients were not stratified according to stage or nodal status before randomization, the trial conducted by Dautzenberg and colleagues [4] warrants specific mention. Details of the trial and the results for all patients as randomized (including those with stage I, stage II, or stage III disease) have been presented above (see Stage I—Efficacy Data). Of the 728 patients in this analysis, 327 had stage III disease and 190 were classified as N2. The subgroup analysis of patients with stage III disease revealed that postoperative radiation therapy was associated with a statistically significant increase in the rate of non-cancer-related deaths (specific log-rank P values, relative risks, and confidence intervals not given, except as shown), a nonstatistically significant trend toward an increased rate of death from any cause (log-rank p = 0.30; relative risk, 1.14; 95% confidence interval, 0.97 to 2.03), and essentially no difference in the cancer-related survival rates. Similar results were seen for patients with N2 tumors. The radiation-related survival decrement was more pronounced for patients who received higher doses per fraction. In the overall study, 22% of all irradiated patients received more than 2 Gy per fraction; however, it was unclear what the corresponding percentage rates were specifically for patients with stage III disease or N2 tumors.

In the N2 setting, perhaps the strongest evidence for the efficacy of postoperative irradiation in patients who have had complete resection is found in the retrospective studies. Several early studies suggested a radiation-associated benefit but provided statistical comparisons only for larger groups of patients, including patients with N2 tumors together with those with other nodal stages.[35,40] These studies often did not use statistical comparison methods at all [46] and showed benefits only in specific N2 subgroups.[40] Most importantly, they did not use regression analyses to attempt to determine whether the administration of radiation therapy was actually an

independent prognostic factor.[39,40,48]

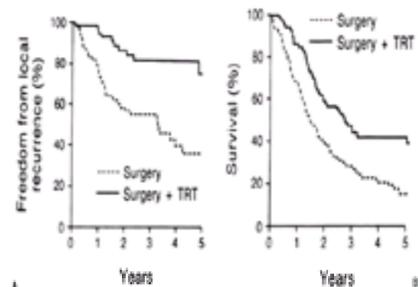
In a retrospective series by Miller and colleagues [49] from the Mayo Clinic, postoperative radiation therapy was found on multivariate analysis to be one of several factors independently associated with an improved survival rate. A later study from the same institution included a more contemporary group of 224 consecutive patients with N2 tumors who had surgical resection from 1987 to 1993, and regression analysis revealed that postoperative irradiation was the dominant independent prognostic factor in predicting both a lower rate of local-regional recurrence (p = 0.0001) (Figure 43.6A) and a higher rate of survival (p = 0.0001) (Figure 43.6B). The actuarial four-year freedom from local-regional recurrence and survival rates with the administration of postoperative radiation therapy were 83% and 43%, respectively, compared with 40% and 22% with surgery alone. During the period of this study, there was controversy among Mayo Clinic radiation oncologists about the benefits of adjuvant radiation therapy, and the views of the particular consulting radiation oncologist were thought to be one of the most important determinants of whether adjuvant therapy was recommended. A X^2 analysis revealed that the 88 patients who had irradiation and the 136 who did not were well balanced with respect to multiple potential prognostic factors, including gender, age, histology, tumor grade, T stage, number of dissected N2 lymph node stations, number of involved N2 lymph node stations, number of involved N1 lymph nodes, level of mediastinal involvement (superior versus inferior versus both), and margin status. Imbalances included the tendency for patients with right lower lobe tumors to receive surgery alone, the tendency for those with multiple (versus solitary) involved N2 lymph nodes to receive postoperative irradiation (suggesting that the patients receiving irradiation were actually a higher-risk group), and the use of adjuvant chemotherapy in 24 of the 88 patients who received radiation therapy (compared with two of the 136 in the nonirradiated group). [50]


FIGURE 43.6. Freedom from local recurrence (log-rank P = 0.0001) **(A)** and survival (log-rank p = 0.0001), **(B)** outcomes for 136 patients with completely resected N2 disease receiving no postoperative thoracic radiation therapy (TRT), compared with 88 patients receiving adjuvant TRT. On multivariate analysis, TRT was the dominant factor in predicting superior local recurrence and survival outcomes. (From Sawyer TE, Bonner JA, Gould PM, et al. The impact of surgical adjuvant thoracic radiation therapy for patients with nonsmall cell lung carcinoma with ipsilateral mediastinal lymph node involvement. *Cancer* 1997;80:1399. By permission of the American Cancer Society.)

The MRC metaanalysis, described above, suggested neither survival decrement nor survival improvement with the administration of postoperative radiation therapy in the N2 setting[17] (Figure 43.2).

Patterns of Recurrence

For patients with completely resected N2 disease, multiple tumor-related prognostic factors have been identified. A lengthy list includes the number of involved N1 nodes,[25] the number of involved N2 nodes,[10,51] the number of involved mediastinal stations,[49,52,53] the location of nodal involvement within the mediastinum,[48,49,51,52,53,54 and 55] the presence versus absence of extracapsular extension,[56] the pathologic margin status,[50] the AJCC T stage,[51,54] the status of the mediastinum on preoperative chest computed tomography,[54,57] and the status of the mediastinum on preoperative mediastinoscopy.[58]

These studies focused largely on survival and either did not attempt to identify prognostic factors related to local-regional recurrence or did not use regression analyses to evaluate for potential independent prognostic significance. Therefore, none of these studies was specifically designed to assess the role of a local modality such as postoperative irradiation in the context of multiple potential confounding prognostic factors.

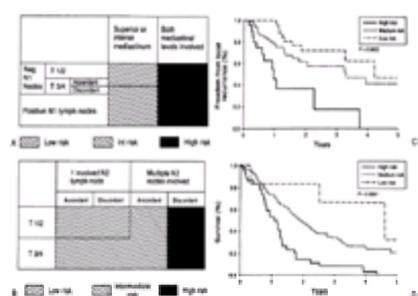
A 1997 study by Sawyer and colleagues[16] evaluated multiple potential prognostic factors and their ability to independently predict local-regional recurrence in 136 consecutive patients with N2 disease who, over a seven-year period at the Mayo Clinic, had complete resection and no adjuvant radiation therapy. This study used regression analyses with respect to both freedom from local recurrence and survival in an attempt to determine independent prognostic factors. Subsequently, regression tree analyses were used to categorize these prognostic factors further and to divide patients into groups according to risk. The actuarial four-year local-regional recurrence risk for the entire group of patients who received no adjuvant therapy was 60%. The results of the regression tree analyses are shown in Figure 43.7. It remains to be seen whether future studies will corroborate these regression tree findings. In particular, other studies have suggested that lower mediastinal involvement (as opposed to superior involvement) is associated with decreased survival. [48,49,53,54] Still other studies have supported the findings of Sawyer and colleagues that superior mediastinal lymph node involvement is a more ominous finding. [51,58]


FIGURE 43.7. Risk groups for freedom from local recurrence **(A)** and survival **(B)** based on regression tree analyses[26] in a cohort of 136 patients undergoing complete resection and receiving no adjuvant therapy for pathologic N2 non–small cell lung cancer. Patients in each risk group were well separated for freedom from local recurrence (**C**, log-rank p = 0.0002) and survival (**D**, log-rank p = 0.0001). ("Accordant" tumors included upper lobe tumors with superior-only mediastinal nodal involvement or lower lobe tumors with inferior-only mediastinal nodal involvement; "discordant" tumors were those that did not fit "accordant" criteria.) (From Sawyer TE, Bonner JA, Gould PM, et al. Effectiveness of postoperative irradiation in stage IIIA non-small cell lung cancer according to regression tree analyses of recurrence risks. *Ann Thorac Surg* 1997;64:1402. By permission of the Society of Thoracic Surgeons.)

Perspectives

In contrast to the N1 and node-negative scenarios, for which neither prospective nor retrospective data support the use of postoperative irradiation, the data as a whole suggest that postoperative thoracic irradiation may lead to both local control and survival benefit after complete resection of N2 NSCLC. However, these data are not conclusive, and further study with adequately powered investigations is warranted in this patient population.

In the Mayo Clinic analysis, patients were selected for radiotherapy or observation predominantly based on the bias of the radiation oncologist. There appeared to be little "referral" bias in terms of directing patients at particularly high risk or low risk toward or away from radiation therapy. [50] However, this study is retrospective;

hence, the potential for undetected selection bias is possible. Although these data can be considered strong evidence, they cannot be considered conclusive.

The strongest support in the randomized literature is found in the MRC study. The p-value associated with the absolute 16% survival rate difference at three years favoring patients who had irradiation was only 0.18, and because of this, the study is termed "negative." However, a p-value of 0.18 means that if the null hypothesis (namely that there is no outcome difference between the two groups) is true, there would be only an 18% chance of finding a difference of the magnitude seen in this study (or of a greater magnitude). An 18% chance is relatively small—were it less than 5%, the majority of the medical community would probably be willing to accept postoperative irradiation as a contributor to improved survival for patients with completely resected N2 disease. Although these results should be considered suggestive evidence that postoperative irradiation leads to survival benefit after complete resection of N2 NSCLC, they cannot be considered conclusive. However, it is possible that the lack of statistical power in this study is related to the negative results.

The trial of Dautzenberg and colleagues,[4] which suggested a radiation therapy–associated survival decrement that appeared in patients with stage III disease to be solely related to radiation-induced toxicity, possesses considerably more power than the MRC trial, with 327 patients with stage III and 190 with N2 tumors. No stratification was performed (with respect to either stage or nodal status) for the majority of patients during the randomization process. The results for stage III disease and/or N2 tumors specifically are thus essentially a retrospective reanalysis of a stage-specific patient subgroup within a large randomized trial. The absence of stratification, the lack of central randomization (patients were randomly assigned separately within each of the 31 treating institutions), the lack of stated quality assurance with respect to either field design or total dose, and the presence of a radiation-associated survival decrement in the setting of total doses (60 Gy) and doses per fraction (up to 2.5 Gy) (which are higher than conventional doses delivered in the United States) make the results of this trial difficult to interpret.

The results of the retrospective studies that examined the issue of postoperative irradiation after complete resection of stage III or N2 NSCLC are frequently discounted, and significantly more weight is placed on randomized trials. In general, this policy is appropriate if the randomized trials are well designed, well conducted, and statistically powerful. In general, retrospective results are limited by the potential for undetected selection bias. It is often forgotten that a reference standard randomized trial has not been performed in this setting. Thus each randomized and retrospective study must be interpreted in the context of its quality. Quality should be assessed by the study's statistical power, appropriateness and uniformity of both surgical and radiation treatment, and the potential for selection or design-related bias. Randomized or retrospective studies that are limited by quality—so that the lack of a radiation-related improvement in outcome is essentially a self-fulfilling prophecy—cannot be considered strong evidence of the lack of a radiation-related benefit.

The discussion above suggests that the potential for a radiation-related benefit exists in patients with completely resected N2 NSCLC. However, it is important to elaborate upon the results of the recently completed MRC metaanalysis, which demonstrated neither survival decrement nor survival benefit associated with the use of postoperative irradiation for patients with N2 tumors.[17] All the trials included in this metaanalysis had one or more flaws (see above and Table 43.1), ranging from the use of sub-megavoltage energies to inadequate treatment volumes, inadequate doses, complete lack of quality assurance, and use of posterior spinal cord blocks that may block tumor. A metaanalysis made up almost entirely of flawed studies must itself be considered flawed. Therefore, it is not unexpected that the metaanalysis did not demonstrate survival benefit. Although proper consideration should be given to these metaanalysis results, they cannot be considered the final word.

On the basis of the above discussion, the recommendation for postoperative irradiation in the setting of completely resected N2 disease must balance the risks of treatment versus the potential of benefit. The benefit has not been glaringly obvious in any trial. This treatment remains controversial.

Currently, a randomized study that considers the issue of adjuvant irradiation for patients with N2 disease is being performed by the Cancer and Leukemia Group B (CALGB).

SPECIAL SITUATIONS

Completely Resected T3 Tumors with Chest Wall Involvement

The relatively favorable prognosis of T3N0 NSCLC, compared with T3 lesions with nodal involvement, is well established. This prognostic finding is reflected in the recent decision by the AJCC to reclassify T3N0 tumors to stage IIB from their previous stage IIIA designation.[1] After either extrapleural dissection or *en bloc* resection (the controversy about which one is the procedure of choice is discussed elsewhere in this textbook) for either node-negative or node-positive T3 lesions, the role of radiation therapy is less clear. This is especially true when the surgical margins are uninvolved. Margin-negative peripheral T3 tumors have the potential to recur either locally (at the chest wall) or regionally (within N1, N2, or N3 lymph nodes), and it is useful to consider these sites separately.

Local (Chest Wall) Issues

Several series have suggested that after either a margin-negative *en bloc* chest wall resection or an extrapleural dissection, the chance of recurrence in the primary tumor bed is low.[55,60] Postoperative irradiation to the chest wall is not recommended in this setting. Although few data exist to suggest that postoperative irradiation is effective when margins are microscopically positive, our recommendation is to consider postoperative radiation therapy to the tumor bed in this setting. Situations such as diffuse chest wall involvement and very close but negative margins are considered on a case-by-case basis.

Ipsilateral Hilum and Mediastinum

Several series, all retrospective and most with very limited power, have attempted to evaluate the efficacy of postoperative irradiation to regional (hilar and mediastinal) lymph nodes after resection of lesions that are T3 because of chest wall/parietal pleural involvement.

When the status of the hilar and mediastinal lymph nodes has been determined pathologically and these nodes are uninvolved, the majority of series have suggested that radiation therapy to the mediastinum (with or without hilar irradiation) is of no benefit.[61,62 and 63] However, an often quoted series by Patterson and colleagues,[55] in which eight of 35 patients received preoperative irradiation and nine of 35 received postoperative irradiation, demonstrated a 56% five-year survival rate for the irradiated group, compared with 30% for the group receiving no neoadjuvant or adjuvant therapy. This difference in survival was not statistically significant, possibly because of the small number of patients in the series. It is of interest that nine of the patients who received irradiation had curative resections for T3N0 lesions. Of these patients, seven (78%) were alive and disease-free at the time of publication, compared with three of the 14 (21%) patients with curatively resected T3N0 disease who did not receive postoperative irradiation. In a larger series by Gould and colleagues,[60] which compared 74 patients with completely resected T3N0 disease and no irradiation with 18 patients who received adjuvant (postoperative) irradiation, special attention was given to the patterns of postoperative recurrence. The actuarial four-year regional recurrence rate (defined as recurrence in N1, N2, or N3 lymph nodes) was 0% with radiation therapy, compared with 32% without radiation therapy (p = 0.05). There was only a slight suggestion of improved survival in favor of the irradiated group (p = 0.10). Of note was that patients with medial tumors (mediastinal pleural involvement) had a four-year nodal recurrence risk of 50% without postoperative irradiation.

No definitive conclusions can be drawn about the role of radiation therapy after complete resection of T3N0 NSCLC. The majority of the studies contained very few patients and often examined the role of radiation therapy as a minor topic. Two of the studies specifically oriented toward examining the efficacy of radiation therapy were inconclusive. The series of Patterson and associates[55] suggested a radiation-related survival benefit; however, the more modern series of Gould and colleagues,[60] with a greater number of patients than the series of Patterson and associates, showed only a statistically insignificant trend. Currently, in the setting of a T3N0 lesion that has been resected with wide negative margins and for which an extensive hilar and mediastinal lymph node dissection or sampling has been performed, postoperative irradiation is not recommended.

The majority of studies that have explored the issue of adjuvant irradiation after complete resection of NSCLC that is designated T3 because of parietal pleural involvement or chest wall invasion contained very few patients with pathologic N1 and N2 tumors. Therefore, little insight can be gained into the efficacy of radiation therapy in the node-positive setting. For T3 node-positive disease, it is reasonable to consider the same data and the same rationale regarding nodal irradiation after complete resection of T1 and T2 and N1 and N2 tumors (explained in preceding sections).

Incomplete Resection

Although the setting of postthoracotomy residual disease is ominous, studies have suggested that the presence of a microscopically positive margin is associated with a better prognosis than the presence of gross residual disease.[64,65 and 66] Therefore, these scenarios should be considered separately.

Incomplete Resection, Microscopic Residual Disease

In the presence of microscopic residual disease, some authors have reported long-term survivors after surgical resection alone. [64,67] It is assumed that when long-term survival occurs any tumor cells that were left behind must not have been viable. However, the potential exists for viable tumor regrowth in this situation, and the recommendation herein is to consider postoperative irradiation for microscopic residual disease.

Reinfuss and colleagues[66] reported on 22 patients with NSCLC who had microscopic residual disease after thoracotomy, all of whom received postoperative radiation therapy. Seven of these patients (five without nodal disease) were alive five years after treatment. In a series of 124 patients with stage III disease, Minet and colleagues[68] reported that the median and five-year survival rates with no postoperative irradiation were 163 days and 3%, respectively, compared with 304 days and 7% for patients who received postoperative radiation therapy. Machtay and colleagues at the University of Pennsylvania have found that the prognosis for patients with microscopically positive margins who received postoperative irradiation is not different from that for patients with margin-negative resections who did not receive irradiation. However, both groups of patients were at high risk for distant metastasis (64% at three years). On the basis of studies such as these, the recommendation herein is to offer postoperative irradiation in the setting of microscopic residual disease.

Few data are available with which to make firm recommendations about the appropriate dose and/or treatment volume in this setting; however, the recent data of Emami and colleagues[69] are useful. In their series of 173 patients who received postoperative irradiation, 32 were treated because of the presence of positive margins. For these 32 patients, local control was greatest if at least 50 Gy was administered and survival was best if at least 60 Gy was given. These and dose response studies for related malignancies of the head and neck[70] suggest that a dose of 50 Gy at 2 Gy per fraction should be delivered to the tumor bed, with a dose of at least 60 Gy delivered to an area encompassing the site of microscopic residual disease. It is recommended that treatment include the tumor bed plus appropriate margin, without an attempt to treat electively regional nodal sites, when the following conditions are met: (a) the involved margin is located within the far lateral parietal pleura or chest wall; (b) in the opinion of the radiation oncologist, the field needed to encompass the tumor bed with margin would not compromise the ability to treat hilar and mediastinal nodes if necessary at a later date; and (c) the patient has had a complete mediastinal and hilar lymph node dissection (or extensive sampling) that revealed no evidence of N1, N2, or N3 disease. In all other patients, provided there is no medical contraindication, we prefer to include regional nodes in the treatment field.

Incomplete Resection, Gross Residual Disease

As mentioned above, several series have suggested that the presence of gross residual disease after thoracotomy is a more ominous finding than the presence of microscopically positive margins,[64,65 and 66] and local control and survival rates are poor regardless of further postoperative therapy. [23,58,64,66,71]

In 1988, the LCSG reported the results of a phase III trial that randomly assigned patients with incompletely resected disease to either radiation therapy alone or radiation therapy with six cycles of cyclophosphamide, doxorubicin (Adriamycin), and cisplatin (CAP) chemotherapy. [71] Incomplete resection was defined as the presence of microscopic residual disease, macroscopic residual disease, or disease in the highest resected paratracheal lymph node. Because patients in both arms of the study were treated with adjuvant irradiation, the magnitude of the radiation therapy–associated benefit could not be ascertained. However, the addition of chemotherapy led to a significantly longer progression-free survival (p = 0.004), with only a marginally improved median survival (p = 0.13). In the setting of macroscopic residual cancer, it is reasonable to institute therapy that would be considered for unresectable disease; combined chemotherapy and radiation therapy are discussed elsewhere in this volume.

TECHNIQUES

In the process of administering radiation therapy after complete resection of NSCLC, the importance of proper technique cannot be overstated. The majority of randomized trials that have been performed are routinely criticized for the use of inadequate techniques or for failing to pay close enough attention to the degree to which proper doses were administered to proper volumes (see Table 43.1). At least one series specifically demonstrated a statistically significantly decreased rate of local-regional control when inferior techniques were used (inferior techniques were defined as the failure to cover at least 90% of the target volume with at least 90% of the prescribed radiation dose). [72] In this series, technical inadequacies were thought to be the reason a majority of patients had local-regional recurrence.

Target Volume

Few data demonstrate the specific pattern of local-regional recurrence after complete resection of NSCLC. Therefore, recommendations for target volume are based largely on what is known about the pattern of nodal involvement at the time of surgery, the risk factors for and patterns of recurrence, and pulmonary tolerance issues.

Many patients with lung cancer have reduced lung function. Furthermore, lung capacity may be compromised after a surgical procedure. Therefore, every attempt should be made to limit the fields to areas at greatest risk for harboring residual subclinical disease.

In the setting of a T1 or T2 tumor or a tumor that is T3 based on other than chest wall or parietal pleural involvement, the following areas are included in the target volume: bronchial resection line, ipsilateral hilum, paratracheal and tracheobronchial angle lymph nodes (stations 1, 2, 3, and 4, as defined by Naruke and associates[44]), and subcarinal lymph nodes (station 7). In the setting of either subaortic or ascending aorta involvement (stations 5 and 6, respectively) or in the setting of left upper lobe tumors, stations 5 and 6 are also included in the field. Stations 8 and 9 (paraesophageal and inferior pulmonary ligament nodes, respectively) are treated only when nodes in these sites are specifically found to be involved, because elective treatment of these regions significantly increases the size of the irradiated field and any benefits of elective treatment are unproved. Supraclavicular regions are included in the setting of upper lobe tumors or when upper paratracheal nodes are found to be involved pathologically, although the need to treat supraclavicular regions in these settings has not been proved.

Additional details about target volume in the setting of chest wall involvement or microscopically positive margins are presented above (see Special Situations—Completely Resected T3 Tumors with Chest Wall Involvement, and Special Situations—Incomplete Resection).

Fields and Energy

To find the appropriate balance between maximizing postoperative healing and minimizing the ability for residual tumor cells to repopulate, postoperative irradiation is generally begun three or four weeks after the thoracotomy. Patients are treated in the supine position, with strict immobilization techniques. We prefer to use a two-field (AP:PA) approach, followed by opposed off-cord oblique fields (right-anterior and left-posterior obliques for left-sided tumors, and left-anterior and right-posterior obliques for right-sided tumors). The oblique fields are begun when the area of the spinal cord that is receiving the greatest dose (generally near the superior aspect of the field) reaches a dose of 43 to 45 Gy, provided that the isocenter is being treated at 2 Gy per day. Therefore, because of the oblique-field scatter dose to the spinal cord, portions of the spinal cord may receive total doses slightly greater than 45 Gy, although this additional dose is delivered at only a few cGy per day. The oblique fields are generally 30 to 45 degrees off vertical. Miller and associates[73] have demonstrated that when the posterior border of the oblique field is placed at the anterior border of the vertebral pedicles, 30-degree fields place slightly more margin on the spinal cord (mean field edge to spinal cord distance, 8.7 mm) than do 45-degree fields (mean field edge to spinal cord distance, 8.0 mm). However, CT planning is routinely used, and oblique angles are adjusted on a patient-by-patient basis to maximize coverage of the above target areas while minimizing the dose to the heart, lung tissue, and spinal cord.

CT-based treatment planning also facilitates the ability to correct for lung inhomogeneities with appropriate software. A case can be made against the use of lung correction in the "gross disease setting," because treatment is based on dose-response studies that did not use lung correction calculations; however, similar dose-response data are much more sparse in the postoperative setting. Therefore, lung correction calculations are routinely used in the postoperative setting to ensure that all at-risk areas are brought to the desired dose. Generally, lower megavoltage energies (6 or 10 MV) are recommended over higher energies such as 18 MV. The data from Miller and associates[74] have demonstrated that 18 MV beams have a wider penumbra in lung tissue than do 10 or 15 MV beams, requiring the use of a greater margin of normal lung tissue.

Field Borders

Because of the above recommendation to include the ipsilateral hilum and bronchial resection line in the field, the fields are almost never perfectly rectangular; shaped fields with custom blocks are used. The following dimensions can be used as general guidelines because these dimensions are similar to those used in recent

trials in the United States (it should be noted that these dimensions will vary on a case-by-case basis with CT planning): for the anterior:posterior fields, the superior border is generally placed 2 cm superior to the suprasternal notch (this border is adjusted further superiorly when the supraclavicular fossae are treated). The inferior border is placed 5 cm below the level of the carina but may extend as inferiorly as the diaphragm when, at the time of surgery, station 8 and/or 9 lymph nodes are found to be involved. The lateral borders are placed either 2 cm lateral to the vertebral bodies or 2 cm lateral to the tracheal edge, whichever is more lateral. For subaortic or aortopulmonary window involvement (stations 5 or 6) or for left upper lobe tumors, a 1 cm margin is placed on the most lateral portion of the shadow of the aortic arch. A 2 cm margin is placed on the ipsilateral hilum and on the bronchial resection line. If CT performed preoperatively showed gross hilar or mediastinal adenopathy, these nodes are transposed to the simulation film and the borders are widened or lengthened as necessary to ensure a 2 cm margin on these preoperative volumes.

The goal of the oblique fields is to include the entire volume at risk to full microscopic tumoricidal doses (see below). The oblique field is not a reduced boost field. Therefore, the superior and inferior borders remain the same in the oblique treatment as in the anterior/posterior treatment. The posterolateral border is placed at the anterior borders of the vertebral pedicles. The anterolateral border is placed so that all the hilar and mediastinal nodes along with the bronchial resection line are treated. Generally, this border is placed at least 3 cm anterolateral to the anterior-most portion of the trachea, although these borders are adjusted in accordance with the preoperative CT hilar and mediastinal nodal volumes.

Additional details about field borders in the setting of chest wall involvement are mentioned above (see Special Situations—Completely Resected T3 Tumors with Chest Wall Involvement).

Dose

Few data are available about the optimal radiation therapy dose in the postoperative NSCLC setting. Therefore, recommendations are based on small retrospective series, on the potential for radiation-induced toxicity with higher doses, and on data from other tumor sites.

In the series of Choi and colleagues,[40] no patient who received at least 50 Gy after complete resection of NSCLC had local recurrence. Similarly, although data from Emami and colleagues[69] demonstrated no statistically significant difference in local-regional control with increasing dose, they did show a trend toward inferior control with mediastinal doses of less than 50 Gy. In an earlier series by Emami and colleagues,[72] none of the patients who received a dose of at least 60 Gy had local-regional recurrence. These data must be considered in the context of the several randomized trials outlined above in this chapter that suggested a decrease in survival rate in patients with early-stage disease treated with doses of 60 Gy [2,3 and 4] (this suggests that radiation therapy doses in the 60 Gy range may be associated with life-threatening toxicity in a percentage of patients) and in the context of the recently reported metaanalysis that demonstrated a radiation therapy–associated inferior outcome in early-stage (N0 and N1) disease [17] (Figure 43.2).

In considering all these data and the subclinical dose-response data from tumors at other sites,[70,75,76] we recommend a postoperative irradiation dose of 50 Gy using 2 Gy fractions. When margins are microscopically positive, similar doses are used, with a boost to bring the site of residual disease to at least 60 Gy (see Special Situations—Incomplete Resection).

CONCLUSIONS

Although the effectiveness of postoperative irradiation for a patient with NSCLC who is found to have positive marins is not of proven benefit, most experts continue to recommend its use, despite a lack of data. Considerably more controversy exists regarding NSCLC that has been resected and has negative margins. Currently, the data do not support the use of adjuvant irradiation for pathologic N0 and N1 disease for the improvement of either local-regional control or survival rates. Although certain data sets suggest that local control and even survival rates improve with the addition of postoperative radiation therapy for patients with completely resected N2 disease, conclusive information is lacking. Therefore, the use of postoperative irradiation is a reasonable treatment option in the N2 setting; however, the importance of informed consent cannot be overstated, considering the suggestion in at least three randomized studies, [2,3 and 4] one metaanalysis,[17] and one retrospective study[41] that this treatment may be associated with a decreased survival rate for low-risk (N0, N1) patients.

The majority of both retrospective and randomized trials have not adequately considered which patients are truly at high risk for either local-regional recurrence or death and instead have examined the efficacy of postoperative irradiation in mixed groups consisting of both low- and high-risk patients. Further research should focus strongly on the development of more effective adjuvant therapies, but it will also be important to identify factors that place patients at high risk for postoperative cancer-related events.

Previously, the majority of retrospective studies attempted to identify prognostic factors in resected NSCLC based on conventional pathologic and histologic techniques. Recently, a growing body of literature has focused on the use of chromosomal, genetic, and nongenetic molecular markers[77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92 and 93] (see also Chapter 33). Some of the genetic markers currently demonstrating the most promising prognostic significance in the postoperative setting include K-*ras* (point mutations of the K-*ras* oncogene[88] or overexpression of the protein product of the K-*ras* oncogene, p21),[79,89,91] particularly in adenocarcinomas; *p53* (gene mutations, or p53 protein overexpression as determined by immunostaining [77,81,83]); C-*erbB-2* (overexpression of the C-ErbB-2 protein product, p185[86]), again mainly in adenocarcinoma; bcl-2 protein;[78,87] and retinoblastoma (RB protein expression.[92]

In addition to these genetic markers, nongenetic molecular markers are being investigated for correlation with the propensity for local recurrence or metastasis. The studies of Chen and colleagues[14] and Passlick and colleagues[15] both demonstrated that immunochemical techniques can frequently detect the presence of cancer in lymph nodes that is not detectable by conventional histologic techniques, and also suggested an adverse outcome for patients with immunohistochemically detected nodal disease, as compared with patients with truly lymph node–negative tumors.[14,15] Another recent study used similar techniques to detect the presence of tumor cells in the bone marrow of patients with completely resected NSCLC,[94] and work of this nature may allow physicians to stage disease in patients more accurately before instituting therapy.

The presence or absence of other tumor-related markers may also be associated with increased risk of recurrence after complete resection. A representative sample includes the expression of cathepsin B (a proteinase that may facilitate invasion and/or metastasis [90]) and the presence of cell membrane proteins such as ABH blood group[82] and Lewis-related antigens. [85] Techniques used to assess the potential for proliferation have been shown to be of prognostic significance and include immunohistochemical analysis for KI-67 antigen[86] and flow cytometry[91,93] (although it is not clear that assessments of either DNA content or the percentage of cells in the synthetic phase of the cell cycle are any more useful than routine histopathologic assessment of mitotic index).

It is hoped that one or more of these markers may be found to predict reliably and consistently the chance of cancer recurrence after surgical resection; such factors will prove to be instrumental in deciding which patients are most appropriate for inclusion in studies examining the efficacy of both adjuvant radiation therapy and adjuvant chemotherapy.

Studies examining the usefulness of these potential prognostic markers frequently have conflicting results. Although some studies may demonstrate the prognostic significance of a particular factor, other studies frequently fail to support this significance or even suggest that the marker is associated with the opposite prognosis. Currently, none of these markers can be considered to be of definitive prognostic significance. Furthermore, many studies have assessed the relationship of various factors with end points such as overall recurrence and survival, but few have specifically evaluated the ability of these factors to predict the risk of local-regional recurrence (an end point that is most likely of great importance in determining which patients are likely to have survival benefit with the addition of postoperative radiation therapy).

Considerable work in the identification of patients at high postoperative risk is ongoing. Recently, an Intergroup study has been initiated to evaluate multiple genetic and nongenetic molecular factors in resected NSCLC. It remains to be seen whether any of these new markers are truly more efficacious than such factors as the size of the primary tumor and the status of the N1 and N2 lymph nodes in predicting the risk of recurrence. Also, it is possible that genetic and nongenetic molecular factors may be found to be independent predictors of outcome in the nonoperative or preoperative setting, while their independent prognostic significance may be lost postoperatively, when the precise status of the primary tumor and regional lymph nodes has been defined. At least two studies, with multivariate analysis, have suggested that factors such as DNA ploidy pattern[25] and mitotic count[20] are better predictors of outcome than T stage in completely resected stage I disease. However, other investigators have suggested that T stage is extremely important. For example, a study by Giatromanolaki and colleagues [95] suggested that C-ErbB-2 protein expression was not as useful as T and N stage in predicting postoperative prognosis. In addition, a recent analysis of 20 potential prognostic factors in 250

consecutive patients with completely resected NSCLC with stage I disease suggested that traditional pathologic features such as lymphatic invasion and adenocarcinoma subtype were more useful in predicting prognosis than contemporary molecular studies such as p185neu immunostaining, K- *ras* oncogene mutations, RB immunostaining, and bcl-2 immunostaining.[96] It is hoped that the Intergroup study, which is seeking correlations between six separate molecular factors and histology, TNM stage, and clinical outcome, will begin to help bridge the relationship between conventional prognostic factors and molecular factors.

INDUCTION THERAPY FOR LOCALLY ADVANCED NON-SMALL CELL LUNG CANCER

KATHY S. ALBAIN
HARVEY I. PASS

A MAJOR CONTROVERSY IN LUNG CANCER THERAPY

Changing Rationale for Induction Therapy over Time

The proper role for chemotherapy with or without radiotherapy (RT) applied as induction therapy before surgical resection in non–small cell lung cancer (NSCLC) is greatly debated.[1,2,3,4,5,6 and 7] The paradigm has changed over time. Initially, the rationale for "neoadjuvant" or induction treatment was to render unresectable disease resectable. However, more recently it was recognized that early eradication of systemic micrometastases was critical to the success of any local approach. The goal in current studies is to optimize control of local bulk disease and distant micrometastases simultaneously through use of systemic chemotherapy, with or without RT. Surgical resection is then utilized for definitive local control, followed by variable postoperative therapy directed at residual local and/or distant disease.

Therefore, the theoretical advantages of a successful presurgery induction program include concurrent cytoreduction of distant and local disease, improvement in resection rates for technically difficult cases, potential sparing of normal lung tissue, an *in vivo* test of chemosensitivity, and, ultimately, improved survival. These benefits must be weighed against the potential risks of increased morbidity and mortality from combined modality induction regimens. Induction programs may result in postoperative pulmonary complications and treatment-related deaths, technical challenges during thoracotomy due to radiation fibrosis, prolonged recovery from surgery, and an altered immune system from the induction treatment.

Two Current Debates

Numerous small trials and, more recently, larger phase II and phase III studies were conducted over the course of the changing paradigm. These trials yielded a broad spectrum of outcomes that set the stage for two ongoing debates. The controversy is defined by two major questions based upon the disease burden and substage (see Table 44.1).

TABLE 44.1. INDUCTION THERAPY BEFORE SURGERY IN NSCLC: TWO CURRENT DEBATES

The first group for which there is controversy regarding induction therapy and surgery are patients with advanced stage subsets who present with bulky disease. These scenarios include bulky N2 disease on CT scan or chest radiograph, T4 (no effusion) primaries, or N3 disease. The standard of care is one of several published programs of chemotherapy plus RT (chemoRT), given either concurrently or sequentially, that have demonstrated significant benefit over RT alone [1,5,8] (see also Chapter 52). The debate in this group is whether surgical resection after induction chemoRT improves outcome over chemoRT alone.

The second controversy involves the group of patients with either early-stage or nonbulky N2 disease (Table 44.1). These stage subsets include T2 or T3N0; T1, T2, or T3N1; and T1, T2, or T3N2 ("minimal"), defined as either nonenlarged N2 nodes on computerized tomography (CT) scan or unexpected microscopic N2 nodal involvement after a normal preoperative CT scan of the mediastinum. Initial surgical resection has been the standard of care for this group, and the amount of mediastinal disease is critical in determining potential for cure after the surgical resection. [9,10 and 11] However, the majority of these patients die of metastatic disease despite a successful complete surgical resection of known disease. Thus the debate on this group is whether induction chemotherapy with or without RT improves survival over the standard approach of surgery alone.

Caveats

Several caveats merit emphasis when considering this debate. The controversy regarding optimal management within both categories of disease burden exists in part because the published pilot studies, and now several small randomized trials, addressed a wide range of stage III and stage IIB(T3N0) subsets. Recent trials included even earlier-stage subsets (IB, IIA). Collectively, only a few studies have attempted to answer one of the questions posed in Table 44.1 within the context of strictly defined and narrow substage categories. In many of the trials there was inconsistent pathologic documentation of nodal status, and variable staging criteria were utilized. Interpretation of bi- and trimodality trials that include surgery requires close attention to the definition of eligible stage subsets and the required method for documentation (radiographic versus biopsy proof of N2, N3, or T4 status).

Furthermore, these trials varied in the definition of "bulky" disease, such as different size criteria for clinically involved nodes on CT scan, the number of positive nodes, the presence of extranodal extension of tumors, and various combinations of these criteria. The published studies utilized different protocol mandates for resection after induction therapy (resection of stable disease also or only resection of the responding tumors). The definition of a complete resection was also variable in that most studies required resection of gross disease, whereas a few mandated negative margins and/or a negative "highest" node. Other factors that may influence survival were variably available in these reports, such as single intranodal N2 disease, involvement of nodal stations N5 or N6 only, or positive N7 nodes. [11] Not all trials properly provided resection rates and overall survival rates for the entire denominator of patients accrued, in addition to those same outcomes for patients eventually eligible for thoracotomy. Other important data only sporadically available in published trials are local and distant relapse rates, postoperative morbidity and mortality, late causes of death, and predictors of long-term survival (optimally addressed in multivariate models).

Chapter Objectives

The objectives of this overview are to provide a perspective on these two critical questions (Table 44.1) via a review of early studies, second- and third-generation trials, and ongoing approaches. Wherever possible, the disease bulk and stage subsets contained within a given study, along with the other caveats emphasized above, will be stated. Throughout, stage classifications will be those in use at the time of the particular study, but with the current modifications of the International Staging System mentioned where appropriate (usually a change in classification of the T3N0 subset from stage IIIA to IIB). [12,13] Other important aspects of the induction controversy will be surveyed, including whether RT is a necessary component of programs that give induction chemotherapy before surgery; if so, should RT be sequenced or given concurrently with chemotherapy; whether surgery is needed after induction therapy; and if there is a defined role for the newer chemotherapeutic agents with or without RT prior to surgery.

Morbidity and mortality considerations unique to multimodality therapy that includes surgery, the importance of multidisciplinary collaboration and comprehensive patient evaluation, and special surgical and radiotherapeutic issues will be outlined. The chapter concludes by addressing whether safety and outcome data are sufficiently mature to recommend new standards of care for the two groups of patients defined by disease burden and if so, are the answers to the questions posed in Table 44.1 "yes"?

FIRST-GENERATION INDUCTION TRIALS

Radiation Therapy as the Sole Induction Modality

The earliest induction therapy studies used preoperative RT alone in an attempt to convert unresectable disease to resectable. [14,15,16 and 17] These initial trials were conducted from the 1950s to the early 1970s without the benefit of modern staging technologies. Nevertheless, initial results were provocative. Pathologic complete responses were reported in up to 15% of patients, but operative morbidity rates rose with RT doses greater than 40 Gy. The consensus was that the resections were technically easier, although in retrospect most cases were probably initially resectable in terms of bulk and extent of disease by modern standards.

This early enthusiasm for preoperative RT alone diminished when subsequent randomized trials demonstrated no survival benefit. [18] The most recent cooperative group study was one arm of a randomized phase II trial of the Lung Cancer Study Group, LCSG 881. [19] Patients who had pathologic stage IIIA(N2) disease were given 44 Gy before surgery. The results were disappointing, with only one pathologic complete response and a median survival of 12 months. Thus, based on more recent studies, RT is no longer recommended as the sole induction modality prior to surgery.

Early Phase II Studies of Induction Chemotherapy with or without RT

The next series of trials, conducted mostly in the 1980s, was of phase II tests of first-generation cisplatin-based chemotherapy with or without sequential RT prior to surgery. [20,21,22,23 and 24] The study designs are described in Table 44.2. These were small trials that accrued a wide mix of stage subsets with broad variability in both the amount of minimal versus bulky disease and in the percentage of biopsy-proven N2 disease. Three trials employed the CAP regimen (cyclophosphamide, doxorubicin, and low-dose cisplatin), whereas two studies used cisplatin plus etoposide-based preoperative chemotherapy.

Investigators	Stage Subsets	Treatment Program	Number of Patients	Biopsy-Proven N2/N3 Disease (%)
Dowlatshahi[20]	T3 or low-bulk stage IIIA(N2)	CAP × 2 → RT → surgery→RT→CAP × 3	41	68
LCSG 851[21]	T3 or low-bulk stage IIIA(N2)	CAP × 2 with split RT → surgery	39	51
U. of Chicago[22]	bulky T3 or T4N2 or N3	VEP × 2 → surgery → RT	21	100
Dowlatshahi II[23]	T1–3N2 (mixed bulk)	CAP × 4 ± RT → surgery → RT	54	94
Pisupati[24]	T1–3N2 (clinically bulky)	EP × 2-3 → surgery → variable RT	42	0

TABLE 44.2. DESIGNS OF FIRST-GENERATION PHASE II INDUCTION TRIALS FOR NSCLC

The outcomes of these trials are outlined in Table 44.3. Response rates from the induction therapy were 39% to 82%, resection rates (percent of original number accrued) were 14% to 88%, and the survivals were highly variable. The stage and bulk mix within these trials precludes conclusions about efficacy or comparisons across trials. However, these were pivotal studies that demonstrated the general safety of surgery after induction therapy and, in some instances, provided intriguing

Investigators	Response Rate (%)	Resection Rate (% original d)	Median Survival (months)	Long-Term Survival
Dana Farber I[20]	43	88	32	31%, 3-year
LCSG 881[21]	51	33	11	8%, 2-year
U. of Chicago[22]	78	14	8	54%, 1-year
Dana Farber II[23]	39	56	18	22%, 5-year
Perugia[24]	82	72	24	24%, 3-year

LCSG, Lung Cancer Study Group.

TABLE 44.3. RESULTS FROM FIRST-GENERATION PHASE II INDUCTION TRIALS FOR NSCLC

Therefore, second-generation trials were designed. These studies were larger, in general enrolled more restricted stage subsets, and required in most instances pathologic documentation of nodal disease. The following three sections review the major categories of second-generation studies and long-term survival from selected trials.

SECOND-GENERATION PHASE II STUDIES OF INDUCTION CHEMOTHERAPY AS THE SOLE INDUCTION MODALITY

Trial Designs

Five phase II second-generation studies of induction therapy tested preoperative chemotherapy. These trials are described in Table 44.4.[19,25,26,27,28 and 29] Although all studies required pathologic documentation of N2 disease, tumors with a wide range of disease bulk were accrued. Four of the studies utilized preoperative vinblastine and cisplatin with or without mitomycin C (MVP, VP) and the fifth trial tested continuous infusion cisplatin and 5-fluorouracil with leucovorin rescue. The RT was variably given (intraoperative, postoperative, or not at all), and information on why RT was either given or withheld was not provided in detail for some of the studies. Thus lack of concordance on the disease bulk and RT utilization variables makes comparison of results among the studies difficult.

Investigators	Disease Burden	Chemotherapy	Radiotherapy
LCSG 881[19]	Most bulky	MVP	None
Memorial[25,26]	Majority 1 nodal station positive; mixed bulk	MVP	Variable, either intra- or postoperative
Toronto[27]	Mixed bulk	MVP	Postoperative
Dana Farber III[28]	Mixed bulk	PFL (continuous infusion)	Postoperative
CALGB I[29]	Most bulky	VP	Postoperative

LCSG, Lung Cancer Study Group; CALGB, Cancer and Leukemia Group B; M, mitomycin C; V, vinblastine; P, cisplatin; F, 5-fluorouracil; L, leucovorin.

TABLE 44.4. DESIGN OF SECOND-GENERATION TRIALS OF INDUCTION CHEMOTHERAPY FOR PATHOLOGIC STAGE IIIA (N2) NSCLC

Results

The outcomes reported in these five trials of preoperative chemotherapy in N2 disease are shown in Table 44.5. Response rates were 46% to 78% and resection rates (of the entire denominator) were 51% to 68%. Pathologic complete response rates (pCR) of 0%, 5%, and 11% were observed in the CALGB, Toronto, and Memorial Sloan-Kettering Cancer Center studies, respectively.[25,26,27,29]

Investigators	No. of Patients (n)	Response Rates (%)	Complete Resection Rates (% initial n)	Operative Mortality (%)	Median Survival (months)
LCSG 881[19]	33	46	68	17.0	12
Memorial[25,26]	136	78	65	4.4	19
Toronto[27]	55	71	51	8.0	21
Dana Farber III[28]	34	65	62	3	18
CALGB I[29]	74	64*	62	3.1	15

LCSG, Lung Cancer Study Group; CALGB, Cancer and Leukemia Group B.
*Includes stable disease.

TABLE 44.5. RESULTS OF SECOND-GENERATION TRIALS OF INDUCTION CHEMOTHERAPY FOR PATHOLOGIC STAGE IIIA(N2) NSCLC

Postoperative mortality rates were 0% to 17% and were predominantly pulmonary or cardiopulmonary events. Significant pulmonary morbidity was also observed in some of these studies, usually in the postoperative time period. Thirteen percent of patients treated with MVP in the Memorial Sloan-Kettering Cancer Center study and 12% of those who received VP on the Cancer and Leukemia Group B (CALGB) trial experienced major pulmonary events.[25,29] It was difficult to complete the planned RT in the "posterior" or postoperative time period, especially when all RT was to be given postoperatively. For instance, only 42% of patients received the prescribed dose in the CALGB study.[29]

Survival outcomes were also variable, with median survivals reported from 12 to 21 months (Table 44.5). Sites of first failure were included in three of the reports: local-regional disease as the only site of first relapse occurred in 26%, 24%, and 25% of patients.[25,28,29] These "local-only" recurrences occurred in the subgroup with residual disease at surgery in the Memorial Sloan-Kettering Cancer Center trial.[25] The Dana Farber investigators noted that 15% of first relapses were solely in the brain.[28]

SECOND-GENERATION PHASE II STUDIES OF INDUCTION CHEMORADIOTHERAPY BEFORE SURGERY

Trial Designs

The other major category within the second-generation studies utilized concurrent chemoRT induction therapy in which the RT began on day 1 of the chemotherapy.

These phase II trials are described in Table 44.6.[30,31,32,33 and 34] The RT varied in schedule across trials from continuous to split-course and in total dose (single fractionation) from 30 Gy to 59 Gy. All induction chemotherapy was cisplatin-based, with the addition of either etoposide, 5-fluorouracil, vinblastine, or some combination of these drugs. The treatment prescribed after surgical resection was highly variable among these five studies. There was no therapy after surgery in the Rush Presbyterian and LCSG 852 trials; two cycles of additional chemotherapy plus 14 Gy of RT were given in the Southwest Oncology Group (SWOG) 8805 study (if residual disease in chest or mediastinum); and one cycle of chemotherapy plus 30 Gy of RT was used in the CALGB trial (all patients). The Tufts investigators initially gave etoposide plus cisplatin postoperatively, but later in the trial allowed use of the carboplatin-plus-paclitaxel regimen.

Investigators	Disease Burden	IIIA(N2) (%)	T3N0–1/T4 or N3 (%)	Biopsy of Mediastinal Nodes or N Required?	Induction Chemotherapy	Induction RT	Postoperative Treatment
SWOG 8805[30]	Bulky	82	0/40	Yes	EP	Continuous, 45 Gy	Chemo × 2 + RT 14 Gy if positive nodes or margins or if unresectable
LCSG 852[31]	Mixed bulk	87	0/13	Yes	PF	Continuous, 30 Gy	None
Rush Presbyterian[32]	Mixed bulk	73	21/6	Yes	PFVP	Split, 40 Gy	None
CALGB[33]	Mixed bulk	80	20/0	Yes	PvF	Continuous, 30 Gy	Chemo × 1 + RT 30 Gy
Tufts[34]	Bulky	47	0/53	No	EP	Continuous, 59 Gy	PE or Carbo T

SWOG, Southwest Oncology Group; LCSG, Lung Cancer Study Group; CALGB, Cancer and Leukemia Group B; E, etoposide; P, cisplatin; F, 5-fluorouracil; V, vinblastine; Carbo, carboplatin; T, paclitaxel; Gy, gray.

TABLE 44.6. DESIGN OF SECOND-GENERATION TRIALS OF CONCURRENT INDUCTION CHEMORADIOTHERAPY

Eligibility criteria for the five second-generation chemochRT induction trials (Table 44.6) were more varied than for the studies of induction chemotherapy alone (Table 44.4). Biopsy documentation of N2 disease or T4 status was not always required. The SWOG trial was unique in this regard, because pathologic proof of N2, T3, or N3 disease was mandated. A broad range of stage subsets was included across trials, so that stage IIIA(N2) accounted for 47% to 87% of patients per trial. Two studies included T3N0 or T3N1 (21% and 20% in the Rush Presbyterian and CALGB studies, respectively), whereas all patients with stage IIIA disease in the SWOG 8805, LCSG 852, and Tufts trials had N2 nodal involvement (Table 44.6). The stage IIIB subsets of T4 and/or N3 were allowed in all trials except the CALGB study and accounted for 6% to 53% of patients per trial. The SWOG 8805 and Tufts trials were designed for bulky disease, whereas the others allowed a mix of minimal and bulky presentations.

Results

The outcomes of the second-generation concurrent chemoRT induction trials are summarized in Table 44.7. Response or "response plus stable " (one study) rates were 56% to 92%, and 52% to 76% of the total number of patients accrued to each study had a complete resection at thoracotomy. Of the 30 patients with stable disease as the "best" response to induction chemoRT, 26 underwent a complete resection of tumor in the SWOG 8805 trial. [30] The pCR rates were 16%, 21%, and 27% in the LCSG, SWOG, and Rush Presbyterian trials, respectively. [30,31 and 32] An additional 37% had rare microscopic foci of tumor cells as the sole residual disease in the SWOG trial. Of the 26 patients with resectable stable disease in the SWOG study, 46% had pCR or only rare microscopic foci. [30] Thus postinduction assessment of nonresponse by CT scan is often misleading.

Investigators	No. of Patients	Response Rate (%)	Complete Resection Rate (% initial)	Operative Mortality (%)	Median Survival (months)
SWOG 8805[30]	126	59	71	8	15
LCSG 852[31]	85	56	52	7	13
Rush Presbyterian[32]	85	92*	71	4	22
CALGB[33]	41	64*	83	15	16
Tufts[34]	55	89*	76	5	20

SWOG, Southwest Oncology Group; LCSG, Lung Cancer Study Group; CALGB, Cancer and Leukemia Group B.
* Includes stable disease.

TABLE 44.7. RESULTS OF SECOND-GENERATION TRIALS OF INDUCTION CHEMORADIOTHERAPY IN NSCLC

The operative mortality rates were 4% to 15% in these trials (Table 44.7). These events were predominantly pulmonary-related, as observed in the induction chemotherapy trials. The cause of death often resembled the adult respiratory distress syndrome (ARDS), to be considered in more detail in the morbidity and mortality section of this chapter. The Tufts trial was unique in that postoperative ARDS was not observed, despite the high total dose of induction RT. [34] A rigid protocol to minimize fluids, transfusions, and the FiO2 was employed in this study. Finally, it is uncertain whether "posterior" treatment, in particular the additional relatively small doses of "boost" RT given after surgery, added anything to the efficacy of the program or only contributed to late morbidity.

Overall survival results for the second-generation studies of concurrent chemoRT are shown in Table 44.7. The median survival for the two studies that excluded T3N0–1 tumors and required pathologic staging were 15 and 13 months. [30,31] In contrast, the other three trials included this better prognostic subset and did not require biopsy proof of the T and N substages. For these studies, the median survivals were 22, 16, and 20 months. [32,33 and 34] Patterns of first recurrence in the SWOG 8805 trial were 11%, locoregional only and 61% distant alone. [30] There was no difference in the sites of relapse between those patients with negative mediastinal nodes at the time of operation (but originally positive) versus those who had persistent involvement of the mediastinal nodes. A significant number of the distant first relapses (and in many cases, the only relapse or the sole cause of mortality) occurred in the brain. [30] The Tufts investigators also reported a very high rate of isolated brain metastases, all of which occurred within the first 32 months of follow-up. [34]

The Stage IIIB Subgroup in Second-Generation ChemoRT Induction Trials

Some data are available regarding the role of induction therapy followed by surgery in selected stage IIIB subsets. Patients enrolled in the second-generation trials of induction chemotherapy alone all had stage IIIA(N2) disease. However, all but one of the chemoRT induction trials allowed inclusion of patients with stage IIIB tumors. The LCSG 852 trial and the Rush Presbyterian study (Table 44.6) included 13% "minimal T4" and 6% "selected T4" lesions (clinically staged), respectively. [31,32] Separate survival data for this subset were not provided. Of note was that two groups of investigators had reported equivalence in outcome of clinical stage IIIA and IIIB disease in combined modality trials *with no surgery*. [35,36] However, these authors suggested that the clinical T4N0 subset may have a better outcome than the other subsets and perhaps should be removed from the IIIB category, just as the T3N0 subset was recently reassigned to stage IIB instead of its former designation of IIIA. [13] Based on this observation in chemoRT-alone trials, the SWOG 8805 study was designed prospectively to include a sufficient sample of the stage IIIB subgroup to allow independent assessment of outcome.

The SWOG 8805 trial stands alone among the other chemoRT trials that included stage IIIB disease. Pathologic documentation of T4 or N3 disease was required and outcome was analyzed separately for this subset. [30,37] The Tufts investigators also reported outcome separately for the IIIB group, but the staging requirements were radiographic rather than pathologic. [34] The resection rates in these two studies for stage IIIA(N2) were 76% and 76%, and for stage IIIB, 63% and 50%, respectively.

The median two-year and three-year survivals were identical for the IIIA(N2) versus the IIIB group in the SWOG 8805 study (27%, 24%). [30] The three-year survivals were 73% and 32% for the clinical IIIA(N2) and IIIB subsets, respectively, in the Tufts trial. Of note was that in the SWOG 8805 study, the T4N0-1 subset had an outcome identical to the T1N2 substage and achieved a two-year survival of 64%. This substage variable was the only independent predictor of favorable outcome

from the time of registration to the study in a multivariate analysis.[30] Exploratory survival analyses were conducted within the N3 subset of the SWOG trial, in which 27 patients were accrued. The two-year survival for the contralateral nodal N3 subgroup was zero, whereas it was 35% for the supraclavicular N3 subset. However, the resection rate in this latter group was only 39%. An update of SWOG 8805 provided six-year survival statistics: IIIA(N2), 20%; T4N0–1, 49%; and N2 or N3, 18%.[38]

A follow-up trial to SWOG 8805 for pathologic stage IIIB disease was conducted by the SWOG (SWOG 9019). Identical induction chemoRT was utilized as in SWOG 8805, but no surgery was given; instead, the RT was continued without a break to 61 Gy, and two additional cycles of EP were given.[35] The overall survival rate in this study was identical to that observed for the stage IIIB group in SWOG 8805. This suggested that in an identically staged patient population, chemoRT with definitive-dose RT may achieve the same benefit as surgical resection after induction chemoRT (and lower RT total dose). However, in the SWOG 9019 trial (chemoRT alone), the two-year survival rate was only 33% for the T4N0–1 subset, compared to 64% for two years and 49% for six years in the surgical study, SWOG 8805.[38,39] This historical comparison of these two consecutive trials in pathologically staged IIIB disease provides a hint that surgery for stage IIIB tumors might be beneficial only in the select substage of T4N0–1. However, a prospective randomized study is needed to validate this observation.

SECOND-GENERATION INDUCTION TRIALS: LONG-TERM SURVIVAL AND PREDICTORS OF OUTCOME

Mature Survival Data

Long-term survival data were reported in several of the trials of induction chemotherapy and induction chemoRT that were reviewed in the preceding two sections (Table 44.4, Table 44.6). Selected studies with a minimum of three years of long-term survival data are summarized in Table 44.8.[25,26,27,29,30,32,33,34,38,40] These studies differed in several critical aspects, including disease bulk, the inclusion of T3N0 or N1 subsets, whether or not pathologic documentation of N2 disease was required, and the inclusion of stage IIIB subsets. The variation in disease bulk and stage subsets as well as potential inaccuracies from staging solely on clinical grounds may to a major degree explain the wide range of three-to-seven-year survivals shown in Table 44.8.

Investigators	Bulky Disease Only?	T3N0 or N1 Included?	Biopsy Proof of N2 Status Required?	Selected Stage IIIB Included?	Long-Term Survival	Predictors of Favorable Outcome
Memorial[25,26]	No	No	Yes	No	17%, 5-year	Pathologic CR
Toronto[27]	No	No	Yes	No	34%, 5-year	Complete resection
SWOG 8805[30,38]	Yes	No	Yes	Yes	IIIA: 20%, 6-year; IIIB: 22%, 6-year	N2 → N0 at resection; T4N0 or 1; Complete resection
CALGB I[40]	No	Yes	No	No	22%, 7(+)-year	No survival advantage for complete resection or pathologic CR
CALGB II[29]	Yes	No	Yes	No	23%, 3-year	Complete resection
Rush-Presbyterian[32]	No	Yes	No	No	31%, 3-year	T3N0 or T3N1
Tufts[34]	Yes	No	No	No	IIIA: 13%, 3-year; IIIB: 22%, 3-year	CR to induction

CR, complete response; SWOG, Southwest Oncology Group; CALGB, Cancer and Leukemia Group B.

TABLE 44.8. SECOND-GENERATION PHASE II INDUCTION TRIALS IN NSCLC:

Long-term follow-up of several of the trials suggested that a plateau emerged on the tails of the survival curves. As shown in Table 44.8, five-to-seven-year survivals of 17% to 34% were recently reported. The SWOG 8805 study suggested a plateau between years 4 and 6,[38] the Toronto study between years 3 and 5,[27] and the CALGB I study from years 5 to 7 and over.[40] However, indefinite plateaus are not expected, because of competing causes of death in a patient population with a high incidence of comorbid diseases.

Factors that Predict Favorable Outcome

The seven phase II trials of induction chemotherapy or chemoRT depicted in Table 44.8 analyzed predictors of long-term survival. Methods of analysis varied: univariate versus multivariate and predictors of overall survival either from registration or from time of thoracotomy. Favorable outcome predictors included postinduction pCR, complete resection, T3N0 or T3N1 disease, T4N0 or N1 disease, and pathologic clearance of initial N2 or N3 involvement (nodal downstaging). The significance of these predictive factors varied across trials, but all factors were not uniformly assessed in each study. Nevertheless, a factor related to the efficacy of the induction therapy was important in most trials. It was suggested that the inclusion of RT in the induction removes the possible importance of pCR as a predictor observed in chemotherapy-only induction programs. However, the Memorial Sloan-Kettering Cancer Center trial of MVP alone did not report statistical significance to pCR.[25,26] Response to induction therapy was not an important predictive factor in some trials, most likely because of the mandate in those studies to resect disease even if "stable" was the best response.[30] This observation underscores the inability of standard CT scanning to detect those patients with major postinduction responses.

The SWOG 8805 trial analysis that described an independent favorable prognostic impact of nodal downstaging on intermediate (two-to-three-year) survival is of interest, given that it was the only significant factor in a multivariate model that included complete resection rate, pCR, and multiple other factors.[30] This variable was also the most important univariate discriminant of six-year survival, although complete resection emerged as a long-term survival predictor as well.[38] The survivals three and six years after thoracotomy for patients with uninvolved nodes at surgery were 41% and 33%, respectively, versus only 11% and 11% if there was persistent mediastinal disease. The prognostic variable of nodal downstaging was not assessed in multivariate models for any other study with second-generation therapy.

Implications of the nodal downstaging observation are that lack of residual disease in the mediastinum may be a surrogate marker for eradication of distant chemotherapy-sensitive micrometastases. These patients may be the optimal candidates for additional postoperative chemotherapy. Conversely, persistent N2 or N3 disease may predict the presence of distant resistant disease. Thus the question must be asked whether surgery was necessary for those cases with nodal downstaging, or were these patients the best candidates for maximal local control with surgery? If postinduction mediastinal status is clearly of prognostic value, then there would be a critical role for a second mediastinal assessment after induction, even though in some cases this would be technically difficult. The question of whether molecular correlates such as proliferative rate, *p53* or K-*ras* status obtained on biopsy material pre- and/or postinduction might improve identification of the optimal patients for surgical resection awaits the results of ongoing ancillary projects within several of these trials and current phase III studies outlined later in this chapter.

THIRD-GENERATION PHASE II STUDIES OF INDUCTION CHEMOTHERAPY PLUS CONCURRENT HYPERFRACTIONATED RADIOTHERAPY

The outcomes of two important phase II pilot studies of concurrent induction chemoRT, in which the RT was given as twice-daily fractions, were recently reported.[41,42]

Trial Designs

The eligibility criteria and treatment programs are described in Table 44.9. Forty-two patients with mixed-bulk, biopsy-proven stage III(N2) disease were treated in the Massachusetts General Hospital (MGH) trial. The West German Cancer Center (WGCC) study required mediastinoscopy, and all 94 patients had advanced disease: either bulky, central T3 (six patients), two or more positive N2 nodes (n = 46), or stage IIIB (n = 42, either T4 or contralateral N3 nodes).

Investigators	Stage Subset(s) No. Patients	Disease Burden	Chemotherapy	Radiotherapy
MGH[a]	Biopsy-proven stage IIIA(N2), n = 42	Mixed bulk	PVF × 2 concurrent with RT → surgery → PVF × 1 concurrent with RT	42 Gy split (1.5 bid × 1 → 10 days rest → 1.5 bid × 1); postoperative 12–18 Gy (1.5 bid)
West German Cancer Center[b]	Mediastinoscopy required: 6, advanced T3; 46, 2 or more N2 nodes; 42, IIIB (T4 or contralateral N3)	Bulky	EP × 3 → reduced dose EP × 1 with RT → surgery	45 Gy (1.5 Gy bid over 3 weeks); PCI later in trial

MGH, Massachusetts General Hospital; P, cisplatin; V, vinblastine; F, 5-fluorouracil; E, etoposide; Gy, gray; PCI, prophylactic cranial irradiation.

TABLE 44.9. THIRD-GENERATION PHASE II TRIALS OF CONCURRENT INDUCTION CHEMORADIOTHERAPY

The MGH group used split-course twice-daily RT, split before the surgery as well as after, when it was given with one additional cycle of chemotherapy. In contrast, the WGCC investigators employed continuous hyperfractionated RT concurrent with the third cycle of induction chemotherapy, and all treatment was completed before the surgery. This trial was amended midway to require prophylactic cranial irradiation (PCI). Surgical resections were not performed in the WGCC study if there was evidence on postinduction radiographs or biopsy of T4, N2, or N3 disease, whereas the MGH trial required resection of stable disease.

Response, Survival, and Predictors of Favorable Outcome

The results of the two studies of induction therapy with concurrent chemoRT (twice daily) are summarized in Table 44.10. Complete resections were accomplished in 93% of 42 patients in the MGH study.[41] Significant nodal downstaging was noted: 10%, T0N0 (pCR); 24%, N0; 33%, N1. The WGCC investigators reported that 60% of 52 patients with stage IIIA disease and 45% of 42 patients with stage IIIB had complete resections.[42] The pCR rate was 26%. The difference in resection rates between the two studies is due in part to a large percentage of cases with nonbulky disease in the MGH study, as well as the mandate to withhold surgery in the WGCC trial if there was residual T4, N2, or N3 disease. Postoperative death rates in both studies (5%, 7%) were no greater than reported in trials that tested either induction chemotherapy alone or induction chemoRT with standard single daily fractionation of RT. No cases of postoperative ARDS were observed in either study, but complex stump insufficiency was a problem in the WGCC trial. Completion of the planned "posterior" chemoRT in the MGH trial was feasible in 60% of patients.

Investigators	No. of Patients	Resection Rate (of initial n)	Postoperative Deaths	Survival	Predictors of Favorable Outcome
MGH[a]	42	93%	5%	37%, 5 year	5-year survival from downstaging at thoracotomy: pStage 0 or I 79%; pStage II 42%; pStage III 18%
West German Cancer Center[b]	94	52%[*] (60% IIIA, 45% IIIB)	7%	28%, 4 year (32% IIIA 26% IIIB)	4-year survival from registration: complete resection* 46% vs 11%, p = 0.007; N2-3 → N0 38% vs 19%, p = 0.11; LDH ≤ 240 or not 37% vs 0%, p = 0.003; PCI Decrease in first brain metastases, p = 0.065

MGH, Massachusetts General Hospital; CR, complete response; p, pathologic; PCI, prophylactic cranial irradiation.
*Resection not mandated if persistent T4 or N2/N3 disease.

TABLE 44.10. RESULTS FROM THIRD-GENERATION TRIALS OF INDUCTION CHEMORADIOTHERAPY WITH HYPERFRACTIONATION IN NSCLC

Sites of initial failure in the MGH study were analyzed in detail. Only locoregional relapse occurred in 15% of those with a recurrence, only brain in 30%, other distant site in 45%, and both local and systemic in 10%. The WGCC investigators also reported a high rate of initial brain relapses that occurred relatively early in the follow-up period. This is a recurring theme of all induction trials for NSCLC. The PCI that was mandated in the latter half of the WGCC trial significantly reduced first and overall brain relapses and prolonged survival for those patients who had a complete or partial response.[43]

Long-term survivals were reported for both pilot studies (Table 44.10). The five-year survival of 37% in the MGH trial was identical to that reported by the Toronto group for their study of induction chemotherapy alone in pN2 disease (Table 44.8). However, it is not possible to determine if the hyperfractionated RT, as given in the third-generation induction trials, might result in a greater benefit than induction chemoRT with a single daily fraction or chemotherapy alone. For example, it is not clear if the percentage of patients with high disease bulk was the same in the MGH and Toronto studies. The WGCC trial clearly accrued more patients with bulky disease, which may in part explain the slightly lower survival (28% overall at four years, with 32% of IIIA and 26% of IIIB alive at four years). Therefore the intriguing results of the MGH and WGCC trials support the conduct of a randomized study of single versus twice-daily fractionation within the context of identical concurrent chemotherapy in patients with pathologically staged tumors with uniform disease bulk.

The analysis of predictors of survival from the MGH investigators (Table 44.10) provides independent validation of the SWOG observation that mediastinal nodal downstaging at time of surgery is a critical favorable determinant for long-term survival.[30,38,41] Patients with stage 0 or I tumors at surgery had a 79% five-year survival after thoracotomy in the MGH trial, and those with N0 or N1 downstaging had a 33% six-year survival in SWOG 8805. These two trials cannot be directly compared due to major differences in disease bulk (higher in SWOG 8805).

Nodal downstaging was also noted in the WGCS study—80% for the subset with N2 or N3 disease.[42] A complete resection predicted statistically favorable four-year survival from time of registration (46% versus 11% if resection or not; Table 44.10). However, survival by this variable should have been reported from time of surgery for those eligible for thoracotomy. Also, a resection was not performed for all patients with nonprogression. Thus it is not surprising that there was no difference in survival by the variable of pCR. The critical group with radiographically stable disease postinduction, some of whom might have had pCRs, were perhaps erroneously included in the group "no pathologic CR." An important observation was that the lactic dehydrogenase (LDH) cutpoint of less than 240 was a strong univariate discriminant of favorable survival at four years (37% versus 0%). A multivariate analysis was not conducted.

COMPLETED RANDOMIZED TRIALS OF SURGERY ALONE VERSUS INDUCTION THERAPY FOLLOWED BY SURGERY IN RESECTABLE DISEASE

This section addresses the second debate outlined on Table 44.1 regarding the role of induction therapy for patients with either early-stage or minimal N2 disease (negative CT scans of mediastinum with either no or microscopic N2 involvement on mediastinoscopy). Up-front surgical resection is the standard treatment for this group of patients. The disease burden in patients enrolled in these trials was generally smaller than trials described in Table 44.4, Table 44.6, and 44.9.

Eligibility Criteria and Trial Design

Four small randomized studies and one large phase III trial were conducted for NSCLC in which the control arms were surgery alone, as described in Table 44.11.[44,45,46,47] and [48] The comparator arms were induction chemotherapy with or without variably timed RT. The first two studies are rarely discussed, the second two are debated frequently, and the last was presented at the 1999 meeting of the American Society of Clinical Oncology.

E, etoposide; P, cisplatin; V, vinblastine; I, ifosfamide; Vd, vindesine; M, mitomycin C; C, cyclophosphamide; NS, not significant; NCI, National Cancer Institute; CH, chemotherapy.
[a] The "mixed" adjusted for stage and N status; p = 0.053 for preoperative chemotherapy.

TABLE 44.11. REPORTED PHASE III TRIALS OF SURGERY WITH OR WITHOUT INDUCTION THERAPY IN RESECTABLE NSCLC

Although surgery alone (with or without some RT) was deemed acceptable for the control arms of these trials, the eligibility criteria for bulk of disease varied among the five studies. Patients with more advanced disease were enrolled in the NCI (multiple N2 nodes on mediastinoscopy) and Japanese (clinically bulky) trials. [44,45] The NCI trial was the most homogeneous in the stage subsets accrued. However, neither the M.D. Anderson nor the Spanish studies required microscopic N2 disease, and mediastinal node biopsy was not mandated if the CT scan was negative. [46,47] In fact, in the surgical control arm of the M.D. Anderson trial, 40% of cases were actually stage IIIB or IV at time of operation. Thus the treatment groups of the small M.D. Anderson and Spanish studies had heterogeneous stage subset distributions. The same stage-mix issues exist in the large French Thoracic Cooperative Group (FTCG) trial, with some imbalance of stage subsets between the two arms (p = 0.07). [48] Furthermore, clinical staging alone was accepted and documentation of N2 status was not required in the FTCG study.

The induction chemotherapy regimens for the five trials were cisplatin-based and were also variably given after surgery depending on the study design (Table 44.11). The use of RT was also different in each trial, so these were not "pure" trials of induction chemotherapy followed by surgery versus surgery alone. For example, RT was employed either postoperatively only in the nonchemotherapy arm, concurrent with the induction chemotherapy, postoperatively only if residual disease in both arms, or postoperatively for all patients.

Outcome of the Five Phase III Trials with a Noninduction Control Arm

Three of the five trials closed before the target accrual goal was met. The NCI trial was halted due to slow accrual, whereas the M.D. Anderson and Spanish studies were stopped early by data monitoring committees due to large survival differences (Table 44.11). The NCI investigators found no statistical difference between the two arms, but the p-value decreased with longer follow-up to 0.11 in favor of the chemotherapy arm. [44] There were differences in recurrence patterns by arm in the NCI trial, in that less distant but more local disease was observed in the induction chemotherapy group. The group with preoperative chemoRT had a survival rate identical to the surgery-alone arm in the Japanese study. [45] However, only clinical staging was required in this small phase III trial, resulting in stage and disease bulk imbalances.

The two small randomized trials were stopped early due to strongly positive results in favor of the induction chemotherapy arms, as shown in Table 44.11. [46,47] With additional follow-up of the M.D. Anderson trial cohort (median follow-up, 81 months), 32% of patients were alive in the induction chemotherapy group versus 16% in the surgery-alone arm (p = 0.06). [49] The p-value became significant if only deaths due to cancer were considered. The Spanish trial was updated in a meeting presentation at the 1997 World Lung Cancer Congress. No patients survived in the surgery group, whereas 16% were long-term survivors in the induction chemotherapy arm.

These M.D. Anderson and Spanish trials continue to generate discussion and debate. The consensus is that these results were provocative but not definitive. There are aspects of the design and outcome of the studies that call for confirmatory trials. The major concern is the marked substage heterogeneity within these two trials. It is not clear if early-stopping rules for these very small trials accounted for the strong potential influence of even slight substage or molecular prognostic factor imbalances between the two arms. Minor shifts of these factors between arms would have a major impact on the survival differences due to the small sample sizes. Furthermore, the surgical control arms fared poorly, possibly due to substage imbalances. There was a large number of unexpected stage IIIB/IV disease at time of surgery in the control arm of the M.D. Anderson trial. The Spanish trial control arm had 37% patients with N0 or N1 disease, but this arm contained more tumors with K-*ras* mutations and aneuploid DNA, both potential adverse prognostic factors. Small differences in unstratified prognostic factors such as K- *ras* could potentially affect the results.

The results of the FTCG trial in 355 eligible patients were presented at the 1999 meeting of the American Society of Clinical Oncology. [48] There were two treatment-related deaths during induction chemotherapy. Eight postoperative deaths (4.5%), six due to pneumonia, occurred in the surgical control arm. There were 14 postoperative deaths (8%) following induction chemotherapy, six due to fistula or empyema and seven from pneumonia. The overall survival rate favored the induction chemotherapy arm but did not reach statistical significance at a median follow-up of 59 months (p = 0.09). The hazards were not proportional over time, with later emergence of superiority in the cohort that received induction chemotherapy. The median survivals were 37 and 26 months, and the three-year survivals were 52% and 41% in the induction and surgery-alone arms, respectively. The lack of pathologic staging and wide range of stage subsets were problematic, but a Cox multivariate model adjusted for stage and N status revealed a p-value of 0.053 in favor of induction chemotherapy. The benefit of induction chemotherapy was statistically significant for those patients with N0 or N1 disease, but not for N2, although this is a subset analysis. Induction therapy also significantly decreased distant relapses (p = 0.009), but there was no difference between arms in the local relapse rates.

Despite the specific concerns regarding each of them raised in the preceding discussion, these five trials, provide encouragement regarding the potential role of induction therapy in earlier-stage disease. The large ongoing phase III trials worldwide (discussed later in this chapter) that are designed to minimize stage-mix and bulk-of-disease biases will definitively address the value of induction therapy in resectable disease. These trials also include ancillary biomarker and PET imaging substudies that will analyze characteristics to predict the best candidates for induction therapy approaches and those who will derive the most benefit from postinduction surgery.

PHASE III INDUCTION TRIALS THAT ADDRESSED OTHER IMPORTANT QUESTIONS

Radiotherapy as a Component of the Induction Regimen

The only randomized trial to date that addressed the need for RT in the induction regimen was conducted in Brazil and published as a meeting abstract. [50] Ninety-six patients with either clinically bulky or biopsy-proven stage IIIA(N2) and T4 IIIB disease were randomized between chemoRT followed by surgery versus chemotherapy alone followed by surgery (Table 44.12). Two programs commonly employed at the time were compared: cisplatin and 5-fluorouracil plus RT versus the MVP regimen. At the 1994 abstract presentation, survival was significantly better in the chemoRT arm. More neutropenia and neurologic toxicity were observed in the MVP arm, whereas there was a higher rate of mucositis in the chemoRT group. Updated results were provided during a 1997 meeting presentation but are not published at this writing. The five-year survival was 31% in the chemoRT arm but only 15% in the MVP arm (p = 0.05). However, this study enrolled mixed bulk disease with some but not all cases pathologically staged.

TABLE 44.12. COMPLETED PHASE III INDUCTION TRIALS FOR NSCLC THAT ASKED OTHER QUESTIONS

To determine definitively the worth of induction RT, additional study is needed in a homogeneously staged population with identical induction chemotherapy on both arms. A major concern for the group of patients with advanced stage disease is that induction chemotherapy alone may not be enough to deal with bulky local disease. One other lead regarding the necessity of RT was provided in a Japanese trial that did not include surgery. [51] Patients with stage III disease without progression after two cycles of cisplatin-containing chemotherapy were randomized to RT with 60 Gy (2 Gy per day) or to no additional therapy. The three-year survival rate was 29% versus 3% in favor of the addition of RT. An ongoing phase III trial in Germany tests the contribution of hyperfractionated RT to induction chemotherapy versus induction chemotherapy alone. [52] Radiotherapy is given after surgery in the arm without induction RT, so it is not a pure test of the question. However, this study will determine if induction chemoRT yields a higher rate of pCR, complete resection, and nodal downstaging (all important variables for long-term survival, as discussed above) than induction chemotherapy alone. Japanese investigators plan to conduct a phase III trial of induction chemoRT versus induction chemotherapy. But for now, the role of RT as an induction modality is still debated, especially questioned in the subset with low-bulk, early-stage disease.

Radiotherapy Timing and Fractionation in Induction Trials

If the added value of RT is accepted in multimodality trials that include surgical resection, controversy also exists regarding the optimal timing of RT with respect to chemotherapy and surgery. The debate has been that concurrent induction chemoRT is more toxic than sequential and that no data exist to support its use over sequential therapy for unresectable disease. [8] No trials have been completed with postinduction surgery to address the question of concurrent versus sequential chemoRT. However, a Japanese study without surgery was conducted regarding this issue in unresectable, stage III disease. [53] There was a significant long-term survival advantage to the concurrent over the sequenced regimen. An ongoing RTOG trial directly tests this question in locally advanced disease (but without surgical resection). The phase III German trial compares induction chemotherapy followed by concurrent chemoRT (hyperfractionated) followed by surgery with induction chemotherapy followed by surgery followed by standard RT. This is the only induction trial planned at this writing to address the "position" of RT in the multimodality treatment program, although the RT fractionation is different in each arm.

Because there are no completed studies that directly address the radiation timing question, it is difficult to determine if there is added excessive morbidity from concurrent chemoRT induction compared with chemotherapy alone. The toxicity profiles reported in the various second- and third-generation phase II studies reviewed herein were similar regardless of when the RT was given, although concurrent chemoRT regimens perhaps resulted in a higher rate of esophagitis. The overall operative mortality and pulmonary complication rates were not significantly different between the two approaches, even when hyperfractionated RT regimens were employed (discussed later in this chapter). The CALGB investigators had difficulty completing the planned RT that was prescribed in the trial "posterior" to the surgery because of patient compliance and dropout because of toxicity. [29]

Whether induction chemoRT with hyperfractionation is better than standard, once-daily dosing is another important question. The safety profile and efficacy of preoperative hyperfractionated RT combined with chemotherapy followed by surgery were defined in two recent trials. [41,42] A randomized study of single versus twice-daily fractionation combined with chemotherapy (but with no subsequent surgery) is ongoing by the RTOG, but no trial that compares the type of induction fractionation with the addition of surgery is in progress at this writing.

Surgery versus Radiation after Induction Chemotherapy

Which modality—surgery or RT—provides optimal local control after induction chemotherapy is another critical question. Prior study results were mixed regarding whether achievement of a complete resection was a favorable predictor of long-term survival. For example, the CALGB I study update reported that many of the long-term survivors did not undergo a complete resection, and the Memorial Sloan-Kettering Cancer Center investigators did not find this to be a major discriminant like pCR. [25,40] However, the SWOG and Toronto investigators found prolonged five to six-year survival if complete resection was accomplished. [27,38]

Two randomized studies were designed directly to address the worth of postinduction surgery versus postinduction RT: one by the NCI Canada (n = 31) and the other by the RTOG (n = 71). [54,55] These phase III trials are described in Table 44.12. Both protocols randomized the study population to induction chemotherapy followed by either surgical resection or definitive RT. The studies required biopsy proof of mediastinal nodal involvement, and only patients with stage IIIA(N2) disease were eligible. Both studies closed prematurely because of impaired accrual but were recently reported with mature follow-up. The survival curves overlap in both studies. The four-year survival was 13% in the surgery arm and 20% for the RT group in the RTOG study. These findings are intriguing, but do not answer the question due to lack of statistical power. Large, ongoing phase III studies by the North American Intergroup and the European Organization for the Research and Treatment of Cancer (EORTC) are designed to answer the question regarding definitive RT versus surgical resection, and both should meet their accrual goals (described later in this chapter).

Chemotherapy or Radiation as the Sole Induction Modality

Only one phase III trial has been designed directly to compare induction chemotherapy with induction RT. [56] This trial of the CALGB in patients with biopsy-proven N2 disease is described in Table 44.12. One arm had both induction and posterior RT ("best local-regional therapy"), whereas the other arm had induction chemotherapy and adjuvant chemotherapy followed by posterior RT. The study closed prematurely because of poor accrual, with only 47 patients enrolled. At last report, the survival curves were identical. However, this one incomplete study should not be used to argue against proceeding with other randomized trials of induction chemotherapy.

OLDER VERSUS NEWER CHEMOTHERAPY REGIMENS WITHIN INDUCTION PROGRAMS

Many chemotherapy regimens are effective in the induction setting, and response rates in general are higher than observed with the same combinations in stage IV disease. However, no one regimen can currently be recommended as superior to the others, and no phase III trials asked or plan to address this question. All protocols with published safety data and long-term follow-up employed second-generation cisplatin-based combinations, either alone as induction therapy or in sequence or concurrent with RT. Mature data are lacking on trimodality approaches that incorporate new agents, and only a few pilot studies in early stage disease assessed the role of new agent-based induction chemotherapy. It is too early to determine if these programs will be at least as safe and effective as the studies reviewed in this chapter. Prior to recommending new agent combinations for presurgery induction programs, the feasibility and superiority (either in terms of survival or patient tolerance or both) of adding new agents within a chemoRT approach with no surgery in locally advanced disease must first be proven.

Pilot studies of induction chemotherapy or induction chemoRT that used one of the newer agents, such as a taxane, gemcitabine, or vinorelbine, in combination with cisplatin or carboplatin, or as doublets without a platin, have been initiated. To date these are reported in meeting summaries or in abstract form only, and follow-up is short. One example is the phase II study of the Bimodality Lung Oncology Team (BLOT). [57] Ninety-eight patients with early stage, minimal disease burden and a negative mediastinoscopy (T2N0, T3N0, T1–3N1) were treated with two to three cycles of carboplatin plus paclitaxel, followed by surgery and an additional two to three cycles of chemotherapy. Patients with unresectable disease, positive margins, or N2 nodes were taken off the study. The response rate was 54%, the complete resection rate was 82%, and there were four pCRs. There were two postoperative deaths. This was a well-tolerated induction regimen, but so far, with short follow-up, the results are not superior to the standard second-generation induction regimens. Thus ongoing phase III trials in early-stage disease that employ second-generation

induction chemotherapy regimens should not be critiqued on this issue.

Many of these ongoing studies incorporate etoposide in the induction regimen, but its role is often questioned. The Avignon, France, group conducted two successive phase II trials for patients with mixed stage III disease, with identical staging criteria in each trial, in which the addition of etoposide was the only difference between studies. Superior five-year survival was achieved with concurrent cisplatin, etoposide, and RT (26%), compared with cisplatin and RT (12%, p = 0.008). [58] The addition of etoposide was an independent favorable predictor of survival in a multivariate analysis, and local control was significantly improved.

Another concern regarding ongoing studies with second-generation induction chemotherapy or chemoRT is that, based on current practice patterns in stage IV NSCLC, new drug combinations should replace the old. This recommendation is premature for several reasons. So far, no regimen has emerged as superior to second-generation regimens in the stage IV setting. [59,60] Furthermore, numerous phase II pilot studies of a taxane, or a platin plus a taxane, (usually paclitaxel) in combination with RT but without subsequent surgery were recently reported in stage III disease, with encouraging early results. [61,62,63 and 64] However, none of these newer programs tested in carefully staged subsets have to date reported superior efficacy or long-term survival over second-generation programs. Response rates in four successive trials of paclitaxel and RT with or without carboplatin were 73% to 77%, very similar to the response rates of the second- and third-generation induction chemoRT programs reviewed herein. [62,65] The three-year survivals of 15.5% and 19% reported in two of these trials and the two-year survival of 38% from a third study are comparable to those reported in the past for second-generation cisplatin-containing chemoRT bimodality regimens without surgery. For example, the two- and three-year survivals after the combination of cisplatin, etoposide, and concurrent RT without surgical resection in the SWOG 9019 stage IIIB study were 33% and 26%, respectively. [35] Overall response and one-year survival rates were also no different from the SWOG 9019 findings in a recent randomized phase II study conducted by the CALGB. [66] This bimodality study for patients with clinical stage III disease tested chemoRT with cisplatin plus either paclitaxel, gemcitabine, or vinorelbine. Longer follow-up is needed to determine if the "tail" on the survival curves is better than seen to date with second-generation chemotherapy plus RT. Until then, completion of ongoing phase III randomized studies that employ second-generation chemotherapy in combination with RT prior to surgery can be justified.

Safety and tolerability data reported to date from new agent-based approaches with bimodality chemoRT regimens (either sequenced or concurrent with no surgery) and trimodality studies (with surgery) raise concern. Severe esophagitis, neutropenic fever, hospital admissions, stump insufficiency, and other serious problems were reported at rates as high as 49%. [62,64,66,67 and 68] Given these early observations of significant toxicity, more data is needed before routine use of new agents as part of induction regimens can be recommended. Ideally, ongoing trials of chemoRT alone should mature with complete safety analyses before making the leap to incorporate surgery. With all new trials involving new agents, it will be critical to monitor the stage subset mix and methods of substage documentation in order to determine if the anticipated reports of superiority can be attributed solely to the change in chemotherapy.

TREATMENT-RELATED MORBIDITY AND MORTALITY IN COMBINED MODALITY INDUCTION TRIALS

The morbidity from combined modality therapy that includes surgery is not insignificant. It is often difficult to attribute a particular toxicity to just one modality, because the entire "package " effects patient tolerance and the treatment-related mortality. All combined modality induction programs were tested in the "fittest" patients, who were fully ambulatory and had general medical conditions that permitted the rigors of this therapy. Eligibility criteria were of necessity quite strict in these trials. It may be dangerous to offer this type of treatment outside a clinical trial, especially to patients who have a poor performance status and/or major comorbidities, because the literature will underestimate the extent of morbidity and mortality in this group. Clinical trials designed for the large group of patients ineligible for these aggressive approaches are needed. But for patients who match the eligibility criteria of published studies, the literature provides some information on the expected morbidity and mortality during induction therapy, the postoperative period, the late or posterior chemotherapy and/or RT, and after all treatment is completed.

During Induction Therapy

The most common toxicity reported among all trials during the presurgery induction phase is myelosuppression from chemotherapy. This is usually short-lived and in most studies did not result in admissions for neutropenic fever. Other drug-specific side effects, such as nausea and emesis, diarrhea, mucositis, and cisplatin-related malaise, are variably reported. In fact, nausea and emesis are now quite infrequent compared to the rates reported in the initial trials because of the expanded number of compounds effective against this toxicity. Esophagitis is more often observed after induction chemoRT than chemotherapy alone, although severe events occurred in less than 10% of patients in most series with single fractionation RT. [30,31,32,33 and 34] The two third-generation trials with hyperfractionated RT reported severe esophagitis rates of 6% and 14%. [41,42] Pneumonitis during induction therapy is quite rare, except that the risk of septic deaths from postobstructive pneumonia may have been greater with the MVP regimen in one large series. [27] Overall, most second-generation induction regimens were fully managed in an outpatient setting. A significant proportion of patients who enter induction therapy with symptoms related to bulk disease in the chest report a gradual improvement in sense of well-being and performance status as treatment is ongoing. However, formal quality-of-life studies have not been conducted for this group of patients.

During the 30-Day Postoperative Time Period

Despite the wealth of clinical trials that follow algorithms leading to eventual exploration and resection after induction therapy, there is no consensus as to what constitutes expected or acceptable postinduction surgical morbidity and mortality. This lack of consensus is due to the marked heterogeneity of induction regimens (as reviewed in preceding sections); the lack of consistency across trials in the adequate reporting of surgical complications; different criteria for preoperative eligibility regarding pulmonary function, comorbidities and conditioning (see section to follow); and variable experience of the surgeon in dealing with postinduction surgical scenarios at the time of thoracotomy and in providing the required supportive care during the postoperative time period.

A number of publications document the risk of pulmonary resection in the noninduction situation. The modern 30-day mortality for pneumonectomy is 3% to 6.2% and the mortality of a standard lobectomy is 1% to 2%. [69,70 and 71] As detailed in Chapter 41, the most frequent complications after pulmonary resection include supraventricular arrhythmias (16% to 18%), atelectasis (7%) and air leak lasting longer than seven days (5%). These rates are rarely provided in the induction therapy literature. However, in a large series involving multiple institutions, the SWOG investigators observed a similar spectrum of perioperative complications. [30,37] Acute surgical morbidities appear to be similar regardless of the type of induction, unless RT is given and too much time is allowed to elapse so that extensive fibrosis is encountered. Whether drugs that rarely cause pulmonary reactions during induction therapy increase the rates of these types of postoperative complications is not clear. However, the incorporation of drugs such as mitomycin C in the induction regimen often leads to higher rates of major pulmonary morbidity (13% in the Memorial Sloan-Kettering Cancer Center series). [25]

Pulmonary complications and deaths due to pulmonary causes during the postoperative time period are the greatest concern after induction therapy, and collectively rates are probably greater than reported in the literature after surgery alone. In particular, events such as extensive pneumonitis (usually culture-negative), ARDS, and bronchopleural fistula have a high mortality in the postoperative period. Pulmonary morbidity and mortality rates are often quoted to be greater after induction regimens with chemoRT than after induction chemotherapy alone. However, a careful review of all the literature available (detailed in preceding sections) discloses great variability. Postoperative mortality rates from 3.1% to 17% (including some cases of ARDS) were reported after MVP- or VP-containing induction chemotherapy, from 4% to 15% after second-generation induction chemoRT, and from 5% to 7% after induction chemoRT with hyperfractionation.

The specific type of mortal postoperative event may differ according to whether RT was included with induction chemotherapy or not, although this issue is not fully resolved. For example, complicated stump insufficiency was the most common cause of postoperative death in the WGCC experience with twice-daily RT in the induction[42], whereas ARDS may be the most common cause of postoperative deaths after single fractionation chemoRT in multiple series. The presence of RT in the induction regimen, however, may not be the sole explanation for greater pulmonary-related mortality, especially ARDS, after certain induction regimens. For the most part, many of the patients treated with concurrent chemoRT induction approaches had advanced, central disease that required a pneumonectomy after induction. Pulmonary-related postoperative mortality rates are expected to be much higher in this population with advanced disease. [30,32,42] So far, there has been no difference in overall postoperative mortality rates compared to the surgery-alone control arms in trials with induction chemotherapy for early, more minimal bulk disease. [46,47 and 48] Complete data regarding pulmonary-related complications after pneumonectomy is needed from these three trials.

It is too soon to know the true mortality rates and cause after incorporation of the newer chemotherapy agents into the induction regimen. The BLOT investigators reported a reassuringly low postoperative mortality rate after induction carboplatin plus paclitaxel. [57] However, other reports are worrisome. The Vanderbilt investigators observed life-threatening complications after induction carboplatin plus paclitaxel in 32% of 25 patients, with an 8% postoperative mortality. [68] The Rush Presbyterian St. Lukes group reported an increased incidence of ARDS and bronchopleural fistulae using preoperative paclitaxel-containing chemotherapy with concurrent RT. [67]

Serious pulmonary complications in the postoperative period clearly result from a combination of causes in addition to the type of induction therapy. [72,73,74 and 75] Although doses of RT higher than 45 Gy have been implicated, [74] the occurrence of ARDS in trials with no induction RT and the lack of an excess rate of ARDS in other trials with higher-dose RT or altered fraction RT [34,41,42] underscore that the tolerance of lymphatic sump disruption and postpneumonectomy shunts is variable after both induction chemotherapy and induction chemoRT. The type of complication may also vary based on the schedule of the RT, with perhaps more events of serious stump insufficiency but less ARDS after hyperfractionated versus single-fraction RT. The preoperative DLCO may be the most important screen for the risk of serious postoperative pulmonary complications, an hypothesis that is being studied prospectively in the current North American Intergroup phase III trial in N2 disease (see Table 44.13).

TABLE 44.13. ONGOING OR PLANNED PHASE III STUDIES THAT ADDRESS THE ROLE OF SURGERY FOR BIOPSY-PROVEN STAGE IIIA(N2) NSCLC

After the Postoperative Time Period

Many induction program algorithms recommend additional chemotherapy with or without RT after the patient has recovered from surgery. Usually the spectrum of toxicities from posterior chemotherapy are similar to those observed during induction, [30] although it may be more difficult to complete a boost dose of RT. [29] Patients are at greater risk for pneumonitis, either from prior RT or due to infectious causes, beyond the postoperative time period, especially if the prior surgery was a pneumonectomy. Data on this issue are rarely reported in the induction therapy literature. [30] Prompt attention to symptoms of infection with broad-spectrum antibiotic coverage is critical to minimize the risk of mortality.

The other major morbidity experienced by many patients after induction therapy followed by surgery is a posttreatment constitutional syndrome. This consists of a constellation of symptoms including thoracotomy pain, malaise, anorexia, and poor pulmonary reserve. This syndrome probably occurs at a greater frequency than with radiation or surgery alone, but its rate is grossly underreported. [3C] It often resolves within a year after treatment, although its lingering presence is clearly discouraging to the patient and caregiver. Prospective quality-of-life analyses and active rehabilitation protocols for this population are needed. Patients also continue to experience problems from their comorbid diseases long after treatment is completed, especially cardiovascular disease and noncancer pulmonary events. Competing cause-of-death reporting is rare, and death certificates often attribute cause to "lung cancer" even when the disease has never recurred. The SWOG investigators categorized cause of death via a review of flow sheets for the patients without disease progression, rather than assume all were cancer-related. Although cancer accounted for 64% of all deaths, 20% were due to various other causes, such as late pneumonia long after the end of treatment, myocardial infarction, pulmonary embolus, cerebrovascular accidents, trauma, ulcer, or second primaries. [30]

OTHER IMPORTANT CONSIDERATIONS REGARDING THE INDUCTION THERAPY APPROACH

Several areas more relevant to the treatment of patients with induction therapy followed by surgery than other aspects of lung cancer care merit special mention. These include the importance of a multidisciplinary patient evaluation, management, and follow-up; assessment of the functional status of the patient before and after induction; various radiotherapy issues; and special surgical considerations such as the extent of resection, the timing of surgery, and technical issues during the operation.

Evaluation and Management by a Multidisciplinary Team

A multidisciplinary team approach is mandatory from the time of diagnosis. This team should include a thoracic surgeon with expertise in the technical demands of postinduction surgery and postoperative care, medical and radiation oncologists, a pulmonologist, a pathologist and a radiologist. The team discusses details of both the anatomic and functional workup, the patient's performance status and comorbid illnesses, the extent of staging workup needed, and whether the patient is eligible for a clinical trial (or if not, whether he or she fits the eligibility criteria for a published trial that reported a favorable risk-benefit ratio). The role for special staging procedures is also reviewed, including whether MRI or PET scanning would add to the information provided by the standard CT-scan-based approach.

During this initial multidisciplinary case review, the surgeon must specifically address issues related to the chest wall and mediastinum, including nodal status and the presence of chest wall or mediastinal invasion (T3 or T4 descriptors from the radiology review). This thoracic surgical evaluation will determine if a simple mediastinoscopy or mediastinotomy can provide all the necessary nodal sampling to establish fully the substage designation, or whether thoracoscopy or thoracotomy is needed to provide more data regarding N2 or T3–4 status. This comprehensive evaluation will also enable proper planning for the extent of operation that might be needed after induction therapy is complete. The pathologist's contribution regarding histologic subtype may influence the use of additional invasive staging of the mediastinum in the absence of suspicion on the CT scan (for example, undifferentiated tumors or large, central adenocarcinomas).

Airway assessment is also critical and can be obtained jointly by the pulmonary and thoracic surgery components of the team. A proximal obstruction might be cleared by laser or nonlaser techniques to provide better assessment of the airway for special surgical approaches such as bronchial sleeve resection. Moreover, as a patient enters an induction program, establishment of an adequate, nonobstructed airway lessens the chance for obstructive pneumonia or other airway complications such as hemoptysis during the hematologic nadir from chemotherapy. If the patient presents with a *de novo* pleural effusion that is large enough to access at the bedside or under radiographic guidance, cytologic examination of the fluid is mandatory to rule out pleural metastases that would make the patient ineligible for an induction approach.

Multidisciplinary team management is also necessary during induction and at the reevaluation point after induction therapy is completed. All specialists involved should see the patient at this time and discuss results of the restaging tests. New pleural or pericardial effusions are most often due to the intervening induction therapy if small, but should not be dismissed without evaluation if large enough to access. The functional status of the patient and degree of recovery from the induction therapy, along with any serious complications experienced up to that point, should also be reviewed jointly. A decision about whether to proceed to surgery is made, and if so, the optimal time for surgery is determined. The degree of radiographic response, together with anatomic location, functional evaluation (see below), and type and tolerance of induction therapy, will dictate the extent of resection needed and whether it is feasible and safe. The role of the nonsurgical members of the team is also important during the postoperative period to assist in the management of treatment-related morbidity.

Functional Evaluation of the Patient

In parallel with the important pretherapy anatomic evaluation of disease reviewed above, a thorough assessment of the patient's physiologic and functional status is critical before an induction approach is selected. This evaluation must be repeated after induction is completed but before surgery is attempted. The treatment of comorbid illnesses should be optimized, and a full cardiovascular and pulmonary assessment must be conducted. If there is a history of angina, hypertension, arrhythmia, or congestive heart failure, active medical therapy should be optimized, and prior catheterization or echocardiographic data should be retrieved and reviewed. A stress test to evaluate myocardial reserve is often indicated, along with other invasive cardiac testing as necessary. Right heart function must be considered, especially if a pneumonectomy is planned or possible.

Complete pulmonary function testing (PFT) that includes spirometry and lung volumes, an arterial blood gas measurement, and a DLCO is mandatory before induction and also before surgery. Special attention should be paid to the DLCO, since it may be the most important predictor of risk of subsequent serious pulmonary morbidity or mortality. Quantitative (split-function) perfusion studies should be added to the standard PFTs if the FEV1 is marginal for the planned lobectomy or pneumonectomy. Active pulmonary rehabilitation and general reconditioning directed by the pulmonologist and others is often needed during the entire course of the induction program. The latter includes nutritional support, functional conditioning, smoking cessation assistance, and application of appropriate bronchodilator, antibiotic, and steroid therapy as needed (see also Chapter 36).

Radiotherapy Considerations

If RT is given as part of the induction, careful joint evaluation of the patient by the radiation and medical oncologists is necessary. Close attention to the granulocyte count and hemoglobin as well as early indicators of esophagitis will minimize serious complications. This careful follow-up must be tailored to the regimen and the patient's specific needs, and requires experience on the part of both disciplines. For most chemoRT induction regimens, there is a clear "learning curve," so the expertise of those familiar with a given approach should be tapped when embarking upon a program for the first time. When to hold the RT in the face of emerging toxicity versus the importance of continuing with full supportive care to maximize benefit is an important issue to balance in most chemoRT induction programs.

In addition to these practical matters, a number of theoretical concerns remain unresolved regarding the role of RT. One issue is the definition of the proper margin of normal lung. Radiation oncologists with experience in concurrent chemoRT induction recommend closer margins than usually employed in regimens without surgery. Tightening of the margin may decrease the risk of postoperative pulmonary complications. [30] Another important outstanding issue is the need to define the optimal target volume and dose within induction regimens. Clinical trials must be conducted to address how conformal RT approaches could be applied to minimize toxicity and fibrosis and to maximize the dose to the tumor.

Special Surgical Issues after Induction Therapy

An attempt at surgical resection is recommended even if disease remains stable on postinduction radiographic evaluation. Thus, mandating a formal response assessment beyond documentation of lack of progression may not be necessary. Patients with stable disease on CT scans of the chest after the induction is completed are often found to have either minimal or no tumor in the pathology specimen, and should also be offered resection. For example, in the SWOG 8805 study, there were 37 patients who had stable disease after induction. Thirty of these underwent thoracotomy, of whom 26 were resected. Of these, 12 (46%) had no residual tumor or only rare microscopic foci of disease. [30]

The timing of the resection after induction therapy will be defined in the clinical trial if a patient is enrolled in one. If not, the usual recommendation is to proceed with surgery three to six weeks after completion of the induction. A delay longer than six weeks may result in greater fibrosis if RT was used as part of induction. This finding adds major technical difficulty and risk of complications to the often already-complex resection. Even when the timing of surgery is optimal, the technical aspects of pulmonary resection after induction therapy can be quite demanding. Vascular planes may be obliterated by fibrosis, and the scarring at sites of previous tumor invasion can be unyielding to the standard maneuvers of pulmonary resection. The degree of fibrosis cannot be predicted, so operative time must be planned accordingly.

Guidelines for intraoperative assessment of resectability have not been standardized for the patient who has received an induction regimen. Bronchoscopy just before the resection often yields valuable information on the extent of the proximal margin and should be compared with the preinduction results, if one was done. General principles of operative conduct include the use of double-lumen endotracheal intubation, fluid restriction, and low concentration of inspired oxygen. The use of right-heart (Swan Ganz) monitoring should be selective, and pulmonary embolism prophylaxis should be considered.

The type of surgical resection required is to a large degree determined by the initial extent and bulk of disease, together with the predicted functional reserve of the patient. At least for approaches delivered to patients with advanced stage III disease, complex operations were often found to be necessary and the technical experience of the thoracic surgeon in postinduction surgery was critical to a favorable outcome. [2] Of the resections performed in the SWOG 8805 trimodality trial, 43% were standard lobectomies, 15% were complex lobectomies (extrapleural, spine, chest wall or sleeve resections), 13% were pneumonectomies, and 29% were intrapericardial pneumonectomies. [36,37] Resection criteria may also extend to atrial and caval resections, which is justified if the T4N0–1 designation remains true during intraoperative assessment of the mediastinal nodes. [38] However, there is no data yet to support similar extensive resections when N2 or N3 involvement persists.

The thoracic surgeon is often forced to deal with theoretical issues as induction regimens become more innovative and aggressive. In particular, what should define a "complete resection" after a major response to induction therapy? Should the margins of resection encompass the original extent of disease, or only what remains? Should a complete assessment be made of potential contralateral nodal disease, or should only the initially involved stations be resampled? Is a complete resection contraindicated if there is viable tumor in the nodes and lung, or is this the situation for which surgery would have the greatest impact on long-term survival? If the most aggressive course is favored, then extended approaches using median sternotomy or the clamshell incision to allow for bilateral dissection may be justified. The ultimate question, however, that will dictate replies to all these other issues is whether the surgery is needed "simply" for optimal local control, or if it truly impacts on long-term survival. Fortunately, ongoing phase III trials that address the role of surgery, with careful assessment of pathology variables in the chest and mediastinum at time of surgery and a full analysis of patterns of recurrence, will provide answers to these questions.

ONGOING PHASE III TRIALS WORLDWIDE

It is clear that an optimal induction approach cannot be recommended, since none has emerged as superior to date. Lack of consensus exists because: (a) no large randomized trial addressed a single question in a homogeneously staged, subset-restricted group of patients; (b) inconsistent application of careful staging methods resulted in marked variability in T and N subset groupings; (c) there was often a mix of extent of disease bulk within trials; and (d) many trials lacked a reproducible definition of what constituted "resectable " versus "unresectable" disease upfront. Therefore the ongoing phase III trials around the world are most welcome, in that most of these problems are addressed in the study protocols. These trials are designed to either address the role of postinduction surgery or induction radiation in more advanced disease or question the value of induction chemotherapy in early stage disease.

Phase III Trials for Advanced Stage IIIA(N2) Disease

There are two large phase III trials ongoing worldwide to address the role of surgery and a third study is planned for patients with biopsy-proven stage IIIA(N2) disease (and selected IIIB in the third study). The trial designs are shown in Table 44.13. The current High Priority North American Intergroup Trial 0139 (RTOG, SWOG, ECOG, CALGB, NCCTG, and NCI Canada) compares the trimodality program developed by the SWOG [30] with the same induction chemoRT with full-dose RT but no surgery in pathologically documented, bulky, N2 disease. [76] Two cycles of posterior chemotherapy are given to all patients, but no posterior "boost" RT is used in the surgical arm. The trial is accruing well and planned analyses of toxicity and outcome by the Data and Safety Monitoring Committee permit completion of accrual. No unexpected toxicities or excess postoperative mortality were observed in the first 200 patients accrued by this broad North American consortium. The second trial is ongoing within the European Intergroup (Table 44.13). It asks whether surgical resection or RT is the optimal local control after three cycles of induction chemotherapy with any cisplatin-containing regimen. [77] At the point of accrual of 179 patients, an interim analysis showed a resection rate of 89%, three treatment-related deaths, and downstaging in 42%. Patients were able to complete the postchemotherapy RT. The third phase III trial also addresses the role of surgery after induction therapy and is planned at this writing. It is a follow-up study to the phase II West German Cancer Center trial [42] and will also include the stage IIIB subsets of T4 and N3 (contralateral mediastinal nodes only). This study will test the worth of surgery after induction chemotherapy plus concurrent, hyperfractionated RT versus, instead of surgery, continuing the RT to 66 to 75 Gy using a conformal approach.

Phase III Trials that Ask a Radiotherapy Question in Stage III Disease

An ongoing study in Germany for patients with stage IIIA and IIIB disease is designed to test whether hyperfractionated RT as part of induction is better than induction chemotherapy alone. Its design is outlined in Table 44.14, and so far, this approach appears feasible and safe. [52] However, this study does not provide a pure test of the RT question, because those patients assigned to induction chemotherapy alone will receive single daily fraction RT after surgery. But this trial will provide important information regarding the contribution of RT to the achievement of pCR, complete resection, and nodal downstaging. A planned trial by Japanese investigators for patients with IIIA(N2) disease will test the important RT question. The only variable is the presence or absence of RT in the induction regimen (Table

Investigators	Stage Subsets	Design
North American Intergroup (Chair: SWOG)	IB, IIA, IIB	Carbo/T × 3 → surgery vs surgery alone
Germany[]	IIIA and IIIB	PE × 3 → HfRT + Carbo Vd → surgery* vs PE × 3 → surgery → RT
German Krebshilfe	Central T3N0-1 Minimal N2 (1 or 2 nodes)	PE × 3 → HfRT + PE → surgery vs surgery → RT
Netherlands	T2N0, N1, T3N0	EP × 2–4 (to maximum response) → surgery vs surgery alone
England	"Early stage"	Cisplatin-containing CsT × 3 → surgery vs surgery alone
EORTC[]	IB, II	Carbo/T, PG or PN × 3 (choice) → surgery vs surgery alone
Japan**	ISA(N2)	MRP × 2 → RT 45Gy (split) → surgery vs MRP × 2 → surgery

SWOG, Southwest Oncology Group; EORTC, European Organization for Research and Treatment of Cancer; E, etoposide; P, cisplatin; Carbo, carboplatin; T, paclitaxel; Vd, vindesine; G, gemcitabine; N, navelbine; CsT, chemotherapy; HfRT, twice-daily radiotherapy.
* Additional HfRT after surgery if no complete resection.
** Planned to open at this writing.

TABLE 44.14. ONGOING PHASE III TRIALS THAT QUESTION THE ROLE FOR INDUCTION CHEMOTHERAPY OR RADIOTHERAPY

Phase III Trials that Address the Role of Chemotherapy in Early-Stage Disease

The remainder of the trials described in Table 44.14 consider whether or not chemotherapy is indicated before surgery in patients with early-stage, nonbulky disease. These trials are all large enough, with careful restriction of the eligible stage subsets, that the critiques of the completed trials discussed previously will be addressed.[46,47,48] The German Krebshilfe trial is ongoing for patients with central T3N0–1 or very minimal N2 disease (one or two positive nodes only). The designs of the trials from the North American Intergroup (follow-up of the BLOT phase II study, at this writing soon to open), EORTC (planned), Netherlands, and England are similar, differing primarily in the use or not of newer chemotherapy regimens.

INDUCTION THERAPY BEFORE SURGERY: THE TWO DEBATES, REVISITED

The questions posed in Table 44.1 can now be revisited, informed by the worldwide data reviewed herein on induction therapy followed by surgery. Can standard-of-care recommendations be made at this time in both categories of disease burden? That is, for patients with advanced stage or bulky disease, does subsequent resection improve survival, and if so, for which subsets? And should preoperative chemotherapy with or without RT be given routinely in patients with early stage or nonbulky disease who are candidates for resection? Many practitioners, especially in North America, have concluded "yes" to both debates and routinely prescribe such treatments outside a clinical trial setting for many stage subsets. However, the majority Consensus Statement of the International Association for the Study of Lung Cancer (IASLC) emphasized that the data argue it is premature to reach these conclusions in either disease group and that completion of the ongoing trials is needed to establish new practice guidelines.[7] Trials completed since this consensus statement do little to change this position.

The First Debate in Advanced, Bulky Disease Subsets

The IASLC Consensus Statement pointed out that feasibility and safety were demonstrated for postinduction surgery and that some provocative outcome data were reported for patients with advanced stage III disease. But postinduction surgery has not yet been proven to be superior to chemoRT or chemotherapy alone in this subgroup, even when phase II trials reported since publication of the position paper are considered. Thus this approach should not be routinely applied to initially unresectable or marginally resectable, bulky, N2 or stage IIIB disease, for which chemoRT remains the standard of care. Outside a clinical trial, exceptions might be considered for the special circumstances of either T4N0–1 disease or if all initial N2 and N3 disease is eradicated by the induction therapy. However, practice guidelines cannot be based solely on these subset analyses of phase II trials, so validation of the observations in the ongoing phase III trials is needed.

The Second Debate in Early, Nonbulky Disease Subsets

At the time of the IASLC Consensus Statement, data was available from four small randomized trials regarding the role of induction chemotherapy in early-stage, resectable disease. The position paper concluded that surgery alone was still the standard (versus preoperative chemoRT or chemotherapy) for these patients. This issue was unsettled at that time because of the concern over stage subset biases in the two randomized trials with positive results.[46,47] Since then, the superimposition of survival curves was reported in the two other (albeit incomplete) trials that tested surgery versus RT after induction chemotherapy,[54,55] thus keeping the debate alive. However, 1999 brought the first presentation of the results of the first large phase III trial, the French Thoracic Cooperative Group Study. The results were in favor of induction CT but as yet do not reach statistical significance.[46] Stage subset imbalances and the use of only clinical staging contribute to the uncertainty regarding the findings, but longer follow-up is needed. Thus there is justification to continue trials with surgery-alone control arms and complete accrual.

Resolution of the Debates

It is hoped that the two debates will be resolved with definitive answers via completion of the phase III trials outlined in Table 44.13 and Table 44.14. Yet there are growing trends to attempt resection of disease in all patients following chemotherapy with or without RT, to add new agents to induction RT ahead of published pilot safety and efficacy data in clearly defined subsets, and routinely to give third-generation chemotherapy prior to resection in those patients with early-stage disease. These practice trends may jeopardize the worldwide accrual to the randomized trials, and if so, this debate will remain the most controversial area in the management of NSCLC. All medical and radiation oncologists and thoracic surgeons involved in the care of these patients must support these studies, which in turn will resolve these two debates and establish new practice standards for a large subset of patients with NSCLC.

CURRENT AND FUTURE CHALLENGES

Apart from the critical questions addressed by the ongoing clinical trials (Table 44.13 and Table 44.14), a number of other areas must be addressed in parallel to achieve the next level of improvement in survival for these patients. Perhaps the most critical area for study is novel approaches for the treatment of residual distant microscopic disease after completion of a standard induction program.Even the newer chemotherapy regimens, when merged into induction programs, are not expected to result in "quantum" improvements in long-term survival. Many types of approaches are available for testing as "consolidation," including matrix metalloproteinases, angiogenesis inhibitors, antibodies to growth factor receptors, gene therapy, and vaccines. At the same time, however, new approaches to achieve better local control are needed. The role for the PET scan and functional imaging approaches within induction therapy programs must be defined, as well as optimal use of molecular markers and other variables to predict better which patients benefit from surgery after induction therapy.

Concurrent with this research, studies are needed on how to maximize quality of life and functional reserve (especially pulmonary, via active rehabilitation programs) during combined modality induction therapy, and how to minimize treatment-related pulmonary morbidity and mortality. Brain metastases must be prevented, since they are the major site of first distant relapse in this population. Chemoprevention of second primary cancers, smoking cessation initiatives, and aggressive treatment of comorbid conditions will lengthen the survival time of the patients who are free of recurrence after completion of combined modality induction programs.

RADIOTHERAPY FOR LOCALLY ADVANCED LUNG CANCER: AN OVERVIEW

WALTER J. CURRAN, JR

WHAT IS LOCALLY ADVANCED NON–SMALL CELL LUNG CANCER?

The term locally advanced non–small cell lung cancer (LA-NSCLC) is used to describe disease that is too extensive for primary surgical resection, is limited to the thorax, and technically allows the inclusion of the entire tumor within a reasonable radiation field. This definition typically includes patients with bulky inoperable stage IIIA and stage IIIB lesions, usually with the exclusion of patients with a malignant pleural effusion. In the most recent revision of the staging system for lung cancer, [1] T3N0 tumors were assigned to stage IIB because of their distinctively more favorable prognosis when compared to lymph node–positive subgroups of stage IIIA. Although controversy exists regarding the selection of clinically stage IIIA patients for surgery as a component of their initial management, the following discussion addresses issues related to the management of patients whose treatment excludes surgery.

EFFECT OF THORACIC RT ON LOCAL CONTROL

Patients with LA-NSCLC comprised 25% to 40% of 178,100 new lung cancer patients diagnosed in 1997 in the United States. [2] Until recently, the standard treatment administered to those patients has been a six-week course of fractionated external beam thoracic radiation therapy (RT) to 60.0 Gray (Gy). The dose of photon irradiation has been investigated by trials conducted by the Radiation Therapy Oncology Group (RTOG). RTOG 73-01 [3] randomized 551 patients to four arms of thoracic RT: 40.0 Gy delivered in a continuous fashion (2.0 Gy daily, 5 days a week, for 4 weeks) versus 40.0 Gy in a split course, versus 50.0 Gy continuous versus 60.0 Gy continuous. The highest treatment response rate (55%), the lowest rate of local tumor failures at 3 years (36% versus 63%), and the best three-year survival rate (20% versus 10%) were observed among patients assigned to the 60.0 Gy arm. Unfortunately, these tumor control and survival advantages were lost by 5 years, with identical estimated local failures and survival rates in the 60.0 and 40.0 Gy arms of 70% and 7%, respectively. The dose 60.0 Gy over 6 weeks was adopted as the standard dose for definitive RT of patients with LA-NSCLC despite a six-year survival of only 5%. Lack of benefit of standard thoracic RT on survival was the main conclusion of a randomized Southeastern Cancer Study Group trial, [4] where 319 patients with LA-NSCLC received either thoracic RT, or single-agent vindesine, or both combined. The overall response rate was superior in both RT arms (30% versus 10%, p = 0.001), but median survival time (MST) was 8.4 months for patients receiving RT alone, 9.4 months for those receiving RT+vindesine and 10.1 months for those receiving vindesine (p = 0.58). The study reported a large (37%) proportion of patients on the vindesine arm receiving delayed RT, therefore making it a study of immediate versus delayed thoracic RT.

Reports on the ability of any nonoperative therapy to locally control LA-NSCLC vary markedly, depending on the nature of the assessment and the time interval since therapy. Furthermore, short survival and varying methods of assessing for local and distant failure compounds this problem. When posterior-anterior and lateral chest radiographs were used in RTOG 73-01 [5] and a cross-section of the tumor or the pulmonary shadow is recorded, a complete response was reported in 24% of patients treated to 60.0 Gy, and a partial response in 32%. Another 35% had stable disease, and only 9% progressive disease. One has to note that those two-dimensional data may not reflect the true volumetric responses. When a complete response was defined rigorously as absence of tumor by the clinical, radiographic, and bronchoscopic examinations, with a negative endoscopic biopsy, [6] and the evaluation of a response repeated every 6 months, only 16% to 20% of patients had a complete response, 15% a partial response, 16% to 20% stable disease, and 45% to 53% progressive disease at 3 months after the completion of radiotherapy; however, at 3 years local control was only 7% to 8%. More recently, an impressive bronchoscopically verified local control of 71% at 2 years has been reported by King et al., [7] with a higher dose, chemotherapy-assisted novel hyperfractionated accelerated RT to a total dose of 73.6 Gy, directed to the primary tumor and adjacent enlarged lymph nodes.

The tumor control probability for bronchogenic carcinoma can be estimated to be 10% for tumors of more than 4 cm at a dose of 80.0 Gy, with an assumption that an average sized lung cancer may require doses beyond 100.0 Gy to control tumor with a 50% to 80% probability. [8] Therefore, if the local tumor control is a prerequisite for improved survival, one may expect to start seeing the impact of a local control on survival only, when eradication of the tumor will be possible in more than 50% of treated patients.

MEDICALLY INOPERABLE STAGE I NSCLC AND LOCAL CONTROL

Radiotherapy can effectively control small lung tumors. There are several reports of a durable intrathoracic control achieved in patients with clinical stage I (T1 or T2) tumors.[9,10,11,12,13,14 and 15] Precise data on the relationship between tumor size (or volume) and the degree of local control are lacking in the radiotherapy literature, but it appears that the rate of local failure with standard thoracic RT increases sharply with the largest tumor diameter exceeding 3 or 4 cm. For example, the intrathoracic failure rate at 3 years was only 4% (1/24) in medically inoperable stage I patients whose tumors measured no more than 4 cm, but increased to 47.8% (11/23) in patients with larger tumors, treated with a hypofractionated course of RT to a dose of 48 or 56 Gy. [9] Similarly, Kupelian et al. [15] quote a local failure at 3 years of 11% for T1 lesions and 39% for T2 tumors, with significant favorable prognostic factors for local control being tumor size of less than or equal to 4 cm, no chest wall invasion, a radiation dose of at least 60 Gy, and a complete response at 6 months after RT. It appears, however, that with longer follow-up, local failure rates increase significantly, even for those small tumors. [11] Nevertheless, definitive RT can provide three-year cause-specific survivals of 30% to 49% [11,13,15] for patients with small tumors and no radiographic evidence of lymph node involvement, and serve as a noninvasive equivalent of wedge resection. A clear-cut dependence of local control and disease-free survival (DFS) of T1 tumors on RT dose is evident in several reports, [10,11,15] with DFS of 90% at 3 years when doses of 65 Gy or higher are used, compared to 29% if doses between 60–65 Gy are delivered (p = 0.0611). [10] Overall, it appears that the dose-response relationship in NSCLC is evident only for tumors 3 cm or smaller, at least within the range of doses of 60–65 Gy. In those patients with larger tumors, doses much higher than 65 Gy would likely have to be delivered to expect local control. This dose is difficult to achieve with larger tumors because of the constraints of toxicity to the surrounding normal tissues, mostly lung, spinal cord and heart.

Results of definitive RT cannot be directly compared to those of surgical resection because the pathologic status of regional lymph nodes is not routinely investigated prior to initiating RT, and patients often do not undergo as rigorous of a systemic staging before RT as they would before surgery. [13]

ALTERED FRACTIONATION RT IN THE TREATMENT OF LOCALLY ADVANCED NSCLC (SEE ALSO CHAPTER 47)

The realization that local control of lung cancer with conventional RT (2.0 Gy daily, 5 days per week) remains unsatisfactory has led to various efforts at optimizing RT, including the altering RT fractionation schedule. One such alteration, called *hyperfractionation* (HF), or delivery of a larger number of smaller fractions, may potentially allow a higher total dose to be delivered to the tumor and result in improved local control, with the same probability of late effects to surrounding normal tissues. Although the MST (13 months) and two-year survival rates (29%) in the 69.6 Gy arm appeared superior to the benchmark standard fractionation results, there was no apparent improvement in five-year survival results, ranging between 6% to 8% in all dose levels. [16] In a phase III study coordinated by the RTOG (RTOG 88-08/Eastern Cooperative Oncology Group [4588]) (discussed in detail in the following section), the 69.6 Gy hyperfractionated dose was tested against two other arms, standard once-daily RT or induction chemotherapy/standard RT, [17] with HF RT producing an early survival result intermediate between the combined modality

arm and standard RT, with one-year survival rates of 59% versus 51% versus 46%, respectively.

Continuous hyperfractionated accelerated radiation therapy (CHART) is a regimen that tested the hypothesis that tumor cell repopulation is an important cause of failure in conventional RT. To counteract repopulation, a continuous treatment regimen was designed, delivering 1.5 Gy three times per day on every day, including Saturday and Sunday, to a total dose of 54.0 Gy. An interval of at least 6 hours was maintained between RT fractions to avoid late toxicity in slowly repairing tissue, such as spinal cord. Preliminary results of a randomized trial [18] comparing CHART versus standard RT to 66.0 Gy in 563 patients with good performance LA-NSCLC has been published recently. With a minimum potential follow-up of 2 years, there was a significant improvement in survival for the CHART-treated patients over conventionally treated patients (30% versus 20%, p = 0.006). The incidence of acute esophagitis was higher in the CHART arm (49% versus 19%), but it subsided quickly in both arms and without apparent chronic sequelae. Although these results are exciting, longer observation is necessary before drawing final conclusions.

In the United States, thrice-daily RT was tested in the RTOG 92-05 trial (1.1 Gy TID, 5 days a week, to 79.2 Gy). Results of this study are pending. An ECOG pilot study was also completed,[19] in which 1.5 Gy was delivered three times daily to a total dose of 57.6 Gy in 30 patients, with a one-year survival rate of 63%, which has provided the basis for a larger trial to assess the true efficacy of such a regimen.

ROLE OF RT IN SYMPTOMATIC CONTROL

For patients with known extrathoracic metastases, poor performance status, or intrathoracic disease not amenable to aggressive, full-dose irradiation, thoracic RT can still provide rapid and durable relief of several life-threatening or distressing symptoms. Intrathoracic symptoms palliated by thoracic RT in more than 80% of patients include hemoptysis, tumor-related pain, and superior vena cava obstruction. Cough and dyspnea are palliated in about two-thirds of patients, and atelectasis and vocal cord paralysis are improved in a smaller number of cases (23% and 6%, respectively).[20,21 and 22] A total symptomatic relief can be accomplished in 61% of patients.[20] It is important to note that comparative information regarding the ability of multiagent chemotherapy to palliate these symptoms is limited.

The optimal RT dose/fractionation schedule for palliation of intrathoracic symptoms is unsettled. Although most practicing radiation oncologists would agree that a six-week course of treatment is unnecessarily protracted for patients with known distant metastases, there is also concern that more accelerated courses may produce more severe treatment-related esophagitis. A randomized trial conducted by the Medical Research Council compared two RT fractionation schemes for 509 such patients: 39 Gy in thirteen daily fractions versus 17 Gy in two weekly 8.5 Gy fractions.[23] The symptoms were more rapidly palliated by the shorter regimen, and esophagitis was shorter lasting (6.5 days) in the two-fraction regimen than in the 13-fraction regimen (14 days).

PATIENT SELECTION

One of the observations derived from the RTOG 73-01[3] was a better treatment outcome (at 2 years) for patients with a favorable performance status (Karnofsky index of more than 70). Since then a body of evidence has been accumulated, attesting to the need to identify different prognostic groups within all patients with LA-NSCLC. A large group of patients (1,052) with locally advanced or metastatic NSCLC treated with cisplatinum-based chemotherapy by the European Lung Cancer Working Party was analyzed with regard to the prognostic factors for survival, using univariate and multivariate methods.[24] Among 16 pretreatment variables, a limited disease extent, good Karnofsky performance status, normal leukocyte and neutrophil counts, normal serum calcium, absence of skin metastases, age less than 60, and female gender were all associated with a significantly improved survival. After application of recursive partitioning algorithm and amalgation algorithm, four subgroups of patients were identified, heterogeneous for survival. The best group included limited-disease females with Karnofsky index of at least 80, and these women had an MST of 14.1 months. The least favorable group were those patients with disseminated disease, abnormal leukocyte count, and poor Karnofsky index, and they had an MST of 3.3 months. A thorough knowledge of differences in outcome is essential for the proper design of therapeutic trials because an effective treatment applied to the *a priori* unfavorable group of patients may result in an erronous conclusion regarding the likelihood of treatment benefit.

COMBINED MODALITY STUDIES: CHEMOTHERAPY AND STANDARD FRACTIONATED RT

Because most patients with LA-NSCLC have metastatic disease at the time of their death,[3] the testing of systemic therapy in their management was a logical step. Several prospective randomized trials have been conducted to examine the role of chemotherapy in NSCLC, in addition to thoracic RT, with varying conclusions. Dillman et al. [Cancer and Leukemia Group B (CALGB) 8433][25] reported an MST of 13.7 months for patients receiving sequential treatment: induction chemotherapy with vinblastine/cisplatin for two cycles followed by 60.0 Gy standard fractionated RT, in comparison to 9.6 months for those receiving 60.0 Gy alone (p = 0.012). A seven-year follow-up report[26] confirmed a long-term improved survival rate for chemotherapy/RT-treated patients. It is crucial to emphasize that only favorable prognosis patients were eligible for the CALGB study; that is, those with minimal, if any, weight loss (maximum of 5%) and a Karnofsky score of at least 70.

Schaake-Koning et al. [European Organization of Research in the Treatment of Cancer (EORTC) 08844] [27] reported that concurrent chemoradiation provides a statistically significant survival benefit over RT alone using a schedule of low-dose daily cisplatin or weekly cisplatin during RT. Although a survival benefit over TRT alone was observed in the low-dose daily cisplatin arm advantage (three-year survival rate of 16% versus 2%; p = 0.009), the weekly schedule did not provide a statistically significant benefit. The survival benefit of daily combined treatment appeared to be caused by improved control of local disease (p = 0.003).

LeChevalier et al. [French Multicenter Trial, CEBI 138][6] reported results similar to those of the Dillman trial but in 353 patients: 12-months MST for chemoradiotherapy versus 10 months for TRT alone. The relative risk of death was 1.2 for the radiotherapy arm compared to that of the chemoradiation arm. The metastasis rate was significantly lower in the combined modality arm (p < 0.001). Despite employing an RT dose of 65.0 Gy in both treatment arms, local tumor control rates, as evaluated at 3 months, were disappointingly low (15% to 17%). Complete remission was indicated in this study by the complete disappearance of all objective tumor shown by chest radiograph, and no evidence of new disease shown by optical and histologic examination during fiberoptic bronchoscopy.

In RTOG 88-04,[17] 30 patients received both induction vinblastine and cisplatin as well as concomitant cisplatin during a standard RT course. Although nearly 30% of enrolled patients did not meet the good performance status and minimal weight loss criteria, the survival results were encouraging, with an MST of 16.1 months and two-year survival rate of 34%.

Two metaanalyses using data extracted from all published randomized trials comparing RT to RT and cisplatin-based chemotherapy in LA-NSCLC were performed.[28,29] Although they differ with regard to the methodology used[30] (analysis based on published data versus based on the updated individual patient data), they both report a small improvement in survival (absolute benefit of 4% at 2 years and 2% at 5 years, or a lengthening of life by 4 months, or a 13% reduction in the risk of death).

In summary, although the observed benefits of chemotherapy in addition to thoracic RT are modest, they offer hope for progress and demonstrate that the role of chemotherapy should be further investigated.

COMBINED MODALITY STUDIES: CHEMOTHERAPY AND ALTERED FRACTIONATION RT

The RTOG has completed three phase II trials evaluating concomitant delivery of high-dose cisplatin-based chemotherapy and HF thoracic RT for LA-NSCLC. RTOG 90-15 enrolled 42 patients to receive immediate hyperfractionated RT (69.6 Gy) and cisplatin/vinblastine.[16] Toxic reactions were primarily hematologic, and MST was 12.1 months in this unfavorable patient population. Among the 10 most favorable patients in this protocol, the MST was 16 months. In RTOG 91-06,[31] 76 patients received immediate HF thoracic RT and concomitant cisplatin and oral etoposide. As recently analyzed, the estimated one-year survival rate is 67%, and MST is 19 months. Grade 4 hematologic toxic reactions in RTOG 91-06 were 43% and 57%, respectively, and were comparable to the 48% rate seen in the induction chemotherapy arm of RTOG 88-08; however, grade 3 or worse esophagitis was substantially worse, with a rate of 36% versus 4% in RTOG 88-08. A third phase II trial (RTOG 92-04) confirmed the encouraging results of RTOG 91-06 and RTOG 88-04.

Further evidence in support of improved survival with the addition of chemotherapy to HF RT came from the randomized Yugoslavian/Japanese study [32] of 131 patients, reporting an MST of 14 months for HF RT alone (69.6 Gy) versus 22 months for HF RT and carboplatinum/etoposide chemotherapy, with four-year survival rates of 9% versus 23%, respectively. Survival was probably improved as a result of improved local control, which may suggest a radiosensitizing effect of daily chemotherapy dosing in that study.

An ongoing RTOG study (94-10) attempts to define the optimal sequencing of chemotherapy in those patients, comparing sequential chemotherapy/RT to concurrent

chemotherapy/RT and concurrent chemotherapy with HF RT. Using the MST of 13–14 months seen in both the RTOG and CALGB trials with sequential cisplatin-based chemoradiation, this trial is powered to detect a 43% improvement in MST based on the 19-month MST in the phase II RTOG trial of concurrent oral etoposide, cisplatin, and hyperfractionated RT.

CONFORMAL RADIOTHERAPY

Because the established pathways of the primary lung tumor spread follow the lymphatic flow from the tumor to the hilum, mediastinum, and supraclavicular lymph nodes, traditional radiation volumes include the primary lesion, ipsilateral hilum, bilateral mediastinum, and often ipsilateral supraclavicular region. Elective nodal irradiation has been commonplace since it was demonstrated that survival of patients treated on RTOG 73-01 who did not receive elective nodal RT was inferior to those who did.[33] However, there is a recent movement to limit the size of the RT fields to include gross primary and only known nodal disease, as defined by thoracic computerized tomography (CT) scans. Because larger RT field sizes have limited total dose and have been related to increased acute and late toxicity, [34,35 and 36] several investigators have delivered thoracic RT to the gross tumor only, reporting no compromise in locoregional control or survival. [15,37,38 and 39] Although there is interest in treating smaller RT volumes in lung cancer, this concept remains a project without firmly established benefits and risks (see also Chapter 48).

Tumor volume definition is improved with three-dimensional (3-D) planning, and doses to critical structures can often be reduced, especially if multiple noncoplanar beams are used.[40] An ongoing RTOG study is evaluating the feasibility of dose escalation for patients with LA-NSCLC, treated with 3D conformal RT to the gross tumor only, without elective nodal irradiation. Maximum doses as high as 77.4–90.3 Gy are being planned, depending on the percentage of the total lung receiving more than 20.0 Gy. Such dose escalation is based on pilot experience, [41] correlating the incidence of grade 3 or higher radiation pneumonitis with the percentage volume of normal lung to doses exceeding 20.0 Gy. There is also a prospective trial ongoing at the University of Michigan in which total RT doses are also partitioned according to the percentage of the entire lung volume receiving 20.0 Gy. Among patients with the lowest percentage of lung receiving 20.0 Gy, the current prescribed doses are more than 100.0 Gy.[39]

FUTURE DIRECTIONS

The prognosis of the vast majority of patients with LA-NSCLC remains poor, and more effective therapeutic approaches need to be investigated, including RT dose escalation and novel chemotherapy agents. Identification of prognostic factors may facilitate the design of clinical trials, allowing physicians to limit more aggressive and more toxic approaches to the subgroups of patients who may derive benefit from them.

Development of improved staging methods, based not only on radiographic evidence of anatomic organ enlargements (CXR, CT), but also on functional and immunologic or molecular techniques, such as immunohistochemical assessment of individual tumor cells in lymph nodes, [42] functional scans (labeled monoclonal antibodies; thallium-201 or PET scans), [43,44 and 45] may allow definition of more uniform patient populations with predictable treatment outcomes.

Finally, an international effort to increase participation of adult patients in clinical trials from the current 2% of all patients with cancer to larger percentages would allow for a more effective investigation of new therapeutic modalities and a faster establishment of new standards of care.

RESECTABLE NON—SMALL CELL LUNG CANCER IN THE MEDICALLY INOPERABLE PATIENT: CURATIVE MANAGEMENT WITH RADIATION THERAPY

HENRY WAGNER, Jr

Surgery produces better survival than radiotherapy. In 1963, Morrison and colleagues published the results of a prospective trial, conducted between 1954 and 1958 by the Medical Research Council (MRC), which randomized 58 patients with clinically operable carcinoma of the lung to surgery or radical radiation therapy. [1] Survival at four years was seven of 30 (23%) for the surgery patients versus two of 28 (7%) for the radiation therapy patients, which was "almost significant" at the 5% level. When only patients with squamous cell carcinoma were considered, excluding cases with anaplastic carcinoma (ten surgery, nine radiation therapy) and two otherwise unclassified cases in the radiation therapy group, the survival differences were more pronounced (30% versus 6% at four years) and significant at the p = 0.05 level. These superior results for surgery were obtained despite the fact that only 17 of the 30 cases randomized to surgery were able to undergo potentially curative resections and there were three postoperative deaths in this group, very low resectability, and high postoperative mortality by present standards. "Under the conditions in which this trial has been conducted it appears that surgery is the better method for treatment for operable cases of squamous carcinoma of the lung." Some incorrectly assume that radical radiation therapy was of little if any value in the treatment of patients with lung cancer. Equally unsupported is the assertion that unresected disease was incurable disease.

Not all patients with resectable tumors, however, are fit candidates for surgery. Other patients adamantly refuse surgery despite its appropriateness as the treatment most likely to cure them. Since chronic tobacco abuse ravages the physiologic function of the cardiopulmonary system, and the median age for lung cancer in the United States is about 65, many patients with early-stage lung cancers, whose tumors are suitable for resection, are poor operative candidates. Despite marked improvements in operative and postoperative management of patients with limited cardiopulmonary reserve, some patients pose too high a risk of immediate postoperative complications or chronic respiratory insufficiency for surgery to be feasible.

Over the past several decades many institutions have reported their results using radical radiation therapy for patients with clinically operable non–small cell lung cancer (NSCLC). Generally these conclude that radiotherapy represents a valid treatment option for patients medically inoperable or refusing surgery. Some results have been sufficiently positive to suggest that thoracic radiotherapy might equal surgery for lung cancer, particularly for elderly patients, warranting a modern direct prospective comparative trial. This chapter reviews these series and discusses several points critical to assessment of the proper role of radical radiation therapy for patients with stage I-II NSCLC. These include patient selection, patterns of failure, radiation therapy technique, treatment volumes, treatment dose and fractionation, and investigational approaches to improved local and systemic control appropriate for this population.

While surgical resection remains the present standard of care for these patients, all standards shift. At the time of the original MRC trial, pneumonectomy was considered the appropriate operation for most patients, even those with early-stage disease. Now most of these patients would be treated with lobectomy and even less aggressive resections, such as segmentectomy or wedge resection, particularly for patients with compromised cardiopulmonary function. However, a prospective trial by the Lung Cancer Study Group, which randomized patients with T1N0M0 NSCLC to lobectomy or lung conserving resection (segmentectomy or nonanatomic wedge resection), showed that the more conservative resections were associated with significantly higher rates of overall and local recurrence, and a 50% increase in the rate of death with cancer (p=.10). [2] The conservative resections did not reduce acute or late pulmonary morbidity, and thus could not be recommended.

SURGICAL MORTALITY

As shown in Table 46.1, operative mortality rises with both the age of the patient and the extent of resection performed, from 1.3% for patients less than 60 years old to 8.1% for patients over 80, and from 1.4% for limited resections to 6.2% for pneumonectomy. [3] The greater mortality for older patients, particularly since these were selected as fit for surgery, must be weighed with other factors in the choice of their optimal treatment (see also Chapter 41). Furthermore, these data represent results obtained by thoracic surgeons with particular interest and expertise in the management of lung cancer. One might anticipate poorer results for either general or cardiothoracic surgeons without special training or experience in lung surger. In one series, 1,538 resections were analyzed; one half of lobectomies and nearly 60% of pneumonectomies were performed by general surgeons. Mortality was significantly higher for lobectomies performed by general surgeons rather than thoracic surgeons (5.3% versus 3.0%; p less than 0.05), in patients with major comorbidity (43.6% versus 25.4%; p = 0.03) or age over 65 years (7.4% versus 3.5% p less than 0.05). The number of resections performed differed strikingly, with 70% of general surgeons performing fewer than ten resections per year and 75% of thoracic surgeons performing more than ten cases per year. [4] and [5]

Type of Resection and Age of Patient	Number of Resections	30-Day Mortality (%)
All resections	2,220	3.7
Pneumonectomy	569	6.2
Lobectomy	1,508	2.9
Segmentectomy or wedge resection	143	1.4
<50	230	1.3
50–59	617	1.3
60–69 years	920	4.1
70–79	416	7.0
≥80	37	8.1

TABLE 46.1. MORBIDITY OF RESECTION IN PATIENTS WITH LUNG CANCER

Several strategies may be effective in reducing postoperative pulmonary complications in patients at risk. [6] Preoperatively patients should undergo optimization of lung function, including smoking cessation for several weeks, treatment of airflow obstruction and infection, when present, and education regarding postoperative lung expansion maneuvers. Good postoperative pain control and vigorous attention to lung expansion by methods including deep breathing exercises, incentive spirometry, or continuous positive airway pressure are also important. Attention to such details may make the difference between an uncomplicated resection and a

complicated one, or a patient deemed medically inoperable and one at acceptable risk for resection.

RESULTS OF SURGICAL THERAPY:STAGING BIAS

In comparing the results of surgical and nonsurgical therapy, it is essential to be aware of the potential biases in comparing clinically versus surgically staged patients. Patients who receive nonsurgical therapy for stage I-II disease have clinical rather than surgical staging. Ideally, we would want to compare the results of radical radiation therapy with the results of radical surgery in a population of similar age, and compare clinical stage to clinical stage rather than clinical stage to pathological stage. Such a direct comparison cannot be made without accurate assessment of mediastinal nodes.

Mountain, in his 1986 article describing the data for 3,753 patients on which the International Staging System was based, reported five-year survivals by both clinical and surgical stage. The results were markedly better for the surgically staged patients in most TNM subgroups. [7] Despite detailed imaging of the hila and mediastinum by CT or MRI, the ability to distinguish between reactively enlarged and metastatic nodes is imperfect, as is the ability to detect metastatic disease in nodes of normal size. Inaccuracy results in false-positive and -negative rates of 20% to 30%. While radiographic upstaging does occur, more commonly occult microscopic N1 or N2 disease occurs, resulting in the surgical upstaging of patients clinically classified as N0. Oda and colleagues have reported a series of patients with peripheral T1 NSCLC and normal mediastinal nodes by CT. [8] However, microscopic involvement of N1 or N2 nodes occurred in about 15% of patients with squamous cell carcinoma and about 25% with adenocarcinoma. These frequencies of occult nodal involvement and surgical upstaging have implications both for attempts to compare surgically and nonsurgically staged and treated patients and in determining appropriate target volumes for radiation therapy.

Positron emission tomography (PET) with [18]fluorodeoxyglucose (FDG) has been reported to improve the sensitivity and specificity when combined with CT scanning, with some investigators reporting better than 90% for these parameters. [9],[10],[11],[12],[13] and [14] It remains to be seen how well these results will stand up with more general availability of this technology outside of specialized centers. If its accuracy is corroborated, FDG scanning may provide comparability of surgical and nonsurgical staging and may obviate the benefit of invasive staging procedures for some patients.

In choosing treatment, it is important to consider both the physician's and the patient's assessment of relative risk and evaluation of short-term and long-term survival. McNeil and associates reported a study of 14 patients with operable (stage I-II) NSCLC who had recently undergone treatment (surgery in six, radiation therapy in eight). [15] Through a structured interview technique, they attempted to elicit preferences for a guarantee of survival at an early date as compared with the likelihood of survival at some later time. Their survival model, based on surgical data and the radiation therapy data of Hilton and Smart, [16] was that radiation therapy would yield a greater probability of short-term survival, while surgery was more likely to obtain long-term survival. The actual probabilities of survival with surgical and nonsurgical therapy, as well as the perioperative mortality used in this study are based on series from the 1950s through the 1970s, and do not reflect results of current treatment. Within the limitations of these data, however, the analysis suggested that, while surgery was more likely to be curative for almost all age groups of patients, the preference of most patients for early versus later survival probability would lead them to favor radiation therapy. The authors speculated that the phenomenon of patients being more risk-averse than their (generally younger and healthier) physicians may be common. The concept that patients may well have different preferences regarding early versus late utilities of differing modes of therapy is probably valid, and should be taken into account in making recommendations for the individual patient. An updated study using prospective rather than retrospective interviews and using modern estimates of operative mortality and survival with surgery or radiation therapy would provide useful information. As lung cancer becomes increasingly a disease of former rather than active smokers and with an increasing incidence in women, there may well be shifts in patient preferences for more or less aggressive risks of treatments balanced against potentials for long-term survival. In practice, it is essential to introduce the concept of early versus late risks to the patient and help them to make an individually appropriate decision.

OVERVIEW OF TREATMENT RESULTS

Table 46.2 summarizes the results of published series describing results of radical radiation therapy for patients with early-stage NSCLC. There is considerable variation in the clinical stages of the patients treated (as well as the techniques used for ascertaining stage), characteristics of the patients (Table 46.3), and details of radiation therapy technique (Table 46.4). With these cautions, however, several clear conclusions may be reached from these data, which span four decades.

1. Radiation therapy can produce long-term survival in a proportion of these patients, ranging from 6% for ill-staged patients to 42% for patients with T1N0M0 disease. The variability of staging and treatment technique limit confidence about the exact five-year survival rates.

TABLE 46.2. RADIATION THERAPY FOR PATIENTS WITH CLINICALLY RESECTABLE NSCLC

TABLE 46.3. RADIATION THERAPY FOR PATIENTS WITH CLINICALLY RESECTABLE NSCLC: CLINICAL CHARACTERISTICS

2. Survival of patients treated with radical radiation therapy is inferior to that of patients with similar clinical stage selected for surgical resection by either open thoracotomy or thoracoscopy.
3. Local failure within the irradiated volume is frequent, with the best series reporting 30% local failure for T1 lesions, and rising to 70% for T2 lesions. Local failure rates following surgery, even with limited resections, are less than 20%. These high local failure rates suggest that the difference in survival between the surgical and radiotherapeutic series is not due solely to stage imbalance but reflects in part the inferior local control achieved with the technique and doses of radiation therapy used. Improved radiation therapy techniques for target volume delineation, dose delivery, and fractionation may improve local control and survival.

PATTERNS OF FAILURE

Determining patterns of failure in patients with lung cancer treated with radiation therapy is essential to improvement of treatment, but these data are frustratingly difficult to obtain. Accurate distinction between tumor recurrence and postradiation can be difficult. Patients who develop systemic disease will usually die rapidly, often before local recurrence can become apparent. Differing statistical methodologies for reporting failure rates (crude ratio, actuarial risk, competing risk models) can produce different apparent rates for the same data. With these caveats in mind, Table 46.5 summarizes the reported patterns of failure for published series treating patients with clinical stage I-II NSCLC with irradiation alone. It must be cautioned that these series did not generally specify either how (clinical, radiographic for symptomatic sites only, thorough restaging) or when (first failure, site of any failure during the patient's life, autopsy distribution of disease) these failure patterns were reported. In the following sections we consider treatment and patient factors that relate to treatment outcome.

TABLE 46.5. RADIATION THERAPY FOR PATIENTS WITH CLINICALLY RESECTABLE NSCLC: PATTERNS OF FAILURE

OPTIMAL DOSE AND FRACTIONATION

A detailed analysis of failure patterns as a function of both stage and radiation dose is found in the series reported by Dosoretz and colleagues. [17] These are valuable data, but note that the series was retrospective, spanned a period of eight years, and a wide range of radiation doses was used (from less than 50 to over 70 Gy, although the majority of patients (91 of 152) received doses between 60 and 69 Gy). They reported a decrease in local failure with increasing dose; however, this decrease is seen only at the highest dose level (over 70 Gy), which was given to fewer than ten patients. Considering all patients in the series, the actuarial risk of local failure was 50% for patients receiving under 50 Gy, 57.8% for 50 to 59 Gy, 60.2% for 60 to 69 Gy, and 33.3% for over 70 Gy (p = 0.13). [18] However, only four patients were in each of the highest and lowest dose groups. Disease-free survival at 30 months was better for patients receiving doses under 65 Gy, compared with 60 to 65 Gy both for patients with tumors over 3 cm (90% versus 29%, p = 0.06) and under 5 cm (39% versus 20%, p = 0.02), but not for tumors of intermediate size (p = 0.35). With the multiple analyses performed in this study, the likelihood of finding some reasonable correlations by chance is high. In any case, the arguments made regarding dose-control relations are more desired than established by the data.

Zhang and associates also reported improved local control and survival with higher radiation doses. [19] Patients receiving 55 to 61 Gy had five-year survival of 27% (six of 22) versus 36% (eight of 22) for those receiving 69 to 70 Gy (significance not stated). Local recurrence was seen in eight of 22 (36%) of the low-dose group versus four of 22 (18%) of the high-dose group. While the trends are in line with expectation, these numbers are very small. In Ono's and colleagues' series, the number of five-year survivors was three of five (60%) for doses over 60 Gy, four of 11 (36%) for 60 to 69 Gy, and ten of 22 (45%) for 70 Gy. [20] Both series are too small for establishing either reliable survival or local control rates.

Hayakawa reported slightly better two-year survival for patients receiving ³80 Gy (54%) than for those receiving doses of ³70 Gy (37%) or ³60 Gy, but this apparent advantage was lost over the next several years, and the best five-year survival was seen for the 60 to 69 Gy group, which had a five-year survival of 24% versus 8% for the ³80 Gy group.[21] There was no suggestion of superiority of the 70 to 79 Gy group over the 60 to 69 Gy group at any time interval. The poor late results for the high-dose group were attributed to a high incidence (four of 13) of fatal bronchial stenoses in this group. [22] These results correlating dose and survival were for all patients in the series, about half of whom had stage IIIA or IIIB disease, and were not reported separately for the stage I and II patients. Kaskowitz and associates reported trends favoring improved local control and survival for patients receiving ³65 Gy, but these did not reach statistical significance. [23]

Hafty and colleagues reported that, in their series of 43 patients, local control and survival was superior for the 11 patients receiving continuous-course RT than for the 32 receiving split-course treatment. [24] Overall five-year survival for the entire patient group was 21%, while it was 45% for the patients receiving continuous-course RT versus 12% for those treated with split course. There was, however, an imbalance in prognostic factors between the two groups, with a higher percentage of patients with T1 tumors (36% versus 25%) in the group receiving continuous course radiation therapy. Several other series which have reported excellent survival, including those of Noordijk and colleagues and Ono and colleagues, have used split-course treatment for all patients. [20,25] In the U.S., the bias against split-course treatment may have resulted in assignment of this technique for patients with poorer expected outcome.

TREATMENT VOLUME

Hayakawa and associates noted a strong inverse correlation between portal size and survival. [21] For patients treated to portals 100 cm^2 or less, five-year survival was 22%, compared to 6% for those with larger portals. These data, however, include patients with stage III disease (78 of the 142) and it is entirely possible that this negative correlation simply reflects the use of larger portals for patients with higher-stage disease. Review of other series, however, also shows that some of the most favorable results have been obtained with the use of small fields, with the intent to treat the primary tumor but not electively irradiate regional nodes.

In Hafty's and colleagues' series of patients with clinical stage I disease, the mediastinum was treated in about 90% of patients, and the five-year survival was 21%. [24] By contrast, in Noordijk's and colleagues' series, the mediastinum was not treated, and the five-year survival was 16%. [25] This clinical experience was expanded and reported with longer follow-up by Krols and associates, with a similar conclusion questioning the value of elective nodal irradiation. [26] Ono and associates used a policy of only local treatment for patients with peripheral tumors, but inclusion of the hilum and mediastinum for patients with "hilar type lung cancer." [20] The five-year survivals for these two groups were five of 12 (42%) for the hilar lesions and 12 of 26 (46%) for the peripheral ones. This may be interpreted as showing either a lack of need for elective nodal irradiation or its appropriate benefit for that subgroup requiring it. Of concern, however, was a five of 12 (41%) incidence of fatal radiation pneumonitis in the patients treated to the larger fields.

Morita and colleagues reported results somewhat at variance with the other authors, noting a significantly superior rate of complete response and five-year survival for patients who received elective hilar/mediastinal irradiation (five-year survival 31.3% versus 14.9%; p = 0.022). [27] The choice of whether or not to give elective irradiation was dictated by the patient's cardiopulmonary status and location of the tumor, with elective irradiation more commonly given for upper lobe tumors. The

authors do not comment whether there was an correlation between tumor size and elective nodal treatment. If elective nodal radiation were more commonly given to smaller upper lobe tumors, it could well correlate with better outcome without being its cause.

Sibley has recently reviewed nine published series through 1996 as well as his own data from 1998. [26] Beneficial outcomes, either local control or survival, correlated with tumor dose but *not* with volume treated in the majority of these series. He observed that although treatment only to local fields might be predicted to miss disease in about 25% of cases, the observed rate of regional progression after local-only treatment is only about 3% to 7%, suggesting that distant failure, local failure, and intercurrent death reduce the clinical magnitude of regional failure and need for regional treatment.

In summary, there are now reasons to suggest that treatment of patients with T1–2N0 lesions to small volumes encompassing the primary tumor without elective nodal irradiation may be an appropriate option. It should be recognized that this represents a choice between leaving possible microscopic nodal disease rather than undertreating known disease at the primary site. Success of such a strategy will rely on there being a steep dose-control relation in the range of dose escalation facilitated by elimination of nodal irradiation. So long as local failure rates are high, the survival benefits to be gained by increasing the treatment volume to include suspected subclinical mediastinal disease are likely to be small. The ability of 3D treatment planning to devise effective plans for the delivery of high doses to the target volume is hampered as the target volume increases, and a reasonable research strategy will be to escalate doses to a limited target volume. [29,30] and [31] For patients with clinical T1–2N1 disease, there are no good data supporting treatment of restricted volumes, and the mediastinum should probably be irradiated in these patients.

CONFOUNDING OF SELECTION AND TREATMENT EFFECTS IN CORRELATING DOSE, TREATMENT VOLUME, AND OUTCOME, PARTICULARLY LOCAL CONTROL

The attempt to correlate radiation dose and volume with treatment outcomes, particularly local control, must be viewed critically. On basic physics and radiobiologic principles, one would expect several correlations:

1. For a tumor of given size, local control will increase with total radiation dose, at least for most of the dose-control curve. There will be little change in control with dose at very high or very low rates of local control.
2. For a given tumor dose, control should decrease as tumor size increases.
3. Local control requires adequate margins around the tumor volume to account for errors in planned tumor volume, microscopic extensions of tumor, daily variation in patient positioning, changes in tumor position with respiration, and patient movement during treatment.

There are, however a number of nonradiobiologic factors which will tend to skew the distribution of tumor doses in patients not randomly assigned to dose, which may result in similar apparent correlations without requiring a radiobiologic mechanism:

1. For a tumor of given size, higher doses will tend to be given to patients appearing to have a favorable response to treatment and tolerating treatment well, rather than to those who clinically deteriorate during the initial weeks of treatment. Such a policy of higher doses for "good" patients was explicit in the series of Hayakawa and may also have been operative in others. [21]
2. In clinically similar patients with tumors of varying size, it is expected that the most aggressive treatment would be given to the patients expected to have a chance at a good outcome. With a bias favoring a good outcome for patients with smaller tumors (perhaps also because of their better performance status), they would be more likely to receive higher doses.
3. In this group of patients, selected in part because of their poor pulmonary function, there is a natural desire to spare as much normal lung as possible. Treating a small tumor (e.g., a 2 by 2 cm T1 lesion) with a reasonable margin may still result in a tolerable overall field size. As the lesion increases, so does the volume of normal lung treated, and, with the lower expectation of control of the large lesion, there may be a tendency to skimp on margins. Thus even for similar nominal central axis or 100% isodose line prescribed doses, it is more likely that there will be underdose at the margins of larger rather than smaller tumors.

It is not clear to what extent any of these potential biases occurred in any of these trials, but it is likely that some of the apparent variation in dose-control and treatment volume–survival correlations is due to differences in such decisions about treatment. This in no way negates the importance of the radiobiologic principles that have been well substantiated in other tumor sites better suited for dose-control analysis (e.g., head and neck).

Martel and colleagues have reviewed the effects of tumor volume on local control and survival in patients with NSCLC treated with definitive radiotherapy using three-dimensional treatment planning in a dose escalation trial. [30] For patients with positive lymph nodes, there was no clear correlation between tumor size and outcome. For node-negative patients, however, there was a significant survival advantage for patients with tumor volumes less than 200 cc. This volume corresponds to a sphere of radius 3.6 cm, that is, a T2 tumor. However T staging poorly reflects the tumor volume, as demonstrated in this study. Within a given T-stage, there were wide (more than tenfold) variations in tumor volume. For example, a 2 cm diameter tumor (volume 4.2 cc) involving visceral pleura and a 8 cm tumor (volume 268 cc) in the lower lobe, without chest wall or mediastinal invasion, would both be considered T2 lesions by the TNM classification, including its most recent modifications. [7,32,33] For nonsurgical treatments (radiation alone or combined with chemotherapy), a staging system based more explicitly on volume might well be superior to the present system, based primarily on surgical therapy. [34] Sculier and associates have analyzed results of a trial, conducted by the European Lung Cancer Working Party, of induction chemotherapy followed by either irradiation or further chemotherapy for patients with stage III NSCLC, and found that patients with several subgroups of stage group IIIB (T1–2N3 and T4N0–1) had survival similar to that of patients with stage IIIA disease. [35] Their best discriminant of survival came from classifying patients as stage IIIB (T3–4N3) or IIIA (all other subgroups of stages IIIA and IIIB), with median survivals of 29 versus 45 weeks (p less than 0.0001). These results are intriguing but will require prospective validation in other trials. The major importance of clinical factors other than anatomic stage, such as age, weight loss, and performance status must also be kept in mind in comparing series from different institutions. [36]

THE MYTH OF ORGAN PRESERVATION—OR, WHY THE LUNG IS NOT LIKE THE BREAST

It has been suggested that the efficacy of radiation therapy in controlling microscopic disease in NSCLC should prompt attempts to conduct lung-conserving therapy which would consist of a local excision, by wedge or bronchopulmonary segment, followed by radiation therapy (interstitial or external beam) to the tumor bed. Such conservative local surgery would be combined with surgical staging of hilar and mediastinal nodes. The Cancer and Leukemia Group B (CALGB), with the participation of the Eastern Cooperative Oncology Group (ECOG), has instituted a phase I-II evaluation of the feasibility of such an approach in patients with T1–2N0 NSCLC whose cardiac and/or pulmonary function is so poor as to contraindicate lobectomy. If it is shown that such an approach is feasible, the plan is to compare this strategy with lung-conserving surgery alone, omitting radiotherapy to the tumor bed (L. Kohman, 1993, personal communication). Such considerations fail to take into account that the success of organ conservation therapy, whether of the breast or of the rectum, lies in the ability of the organ in question to tolerate the doses of radiation needed to control the suspected microscopic residual disease while maintaining organ function. There is no strong reason to expect that this will hold true for the lung. The portion of the lung treated to doses of 50 Gy or so expected to be required to control microscopic residual disease will lose function. Even with careful treatment planning and the use of multiple non-coplanar beams, it is not possible to avoid treating some volume of entirely normal lung to doses well above the 30 Gy or so which is the limit of lung tolerance.

COMPLICATIONS

Most series have reported good tolerance to radiation therapy in this population (Table 46.6). The report by Ono and colleagues is an exception. [20] They note that, of 38 patients, seven developed radiation pneumonitis (diagnostic criteria not specified) which was fatal. This complication was seen in five of 12 (42%) of patients whose fields included the primary tumor, hilum, and mediastinum but in only two of 26 (8%) of patients whose treatment volume encompassed only the primary tumor. Other series have reported occasional problems with late pulmonary fibrosis, pericarditis, or esophageal stricture, but these have occurred in only about 5% of cases. As with surgery, improvements in radiation therapy technique over the years should lead to a reduction in such complications. One review of the toxicity of postoperative radiation therapy following pneumonectomy has noted a reduction in complication rates from 18% to 4% and of lethal complications from 12% to 4% with a shift from treatment planning with orthogonal radiographs and treatment with ^{60}Co beams to CT based treatment planning and treatment on linear accelerators. [37]

Author	Complications
Morrison[5]	7% fatal late fibrosis (1 lung, 1 esophageal stricture, patient died after attempted dilation)
Smart[6a]	n.q. patients were seen daily during radiation therapy and dose and fractionation adjusted according to acute toxicity
Coy[6b]	not reported
Cooper[7a]	not reported
Haffty[8]	5% worsening pulmonary symptoms, 2% worsening CHF
Noordijk[9]	no serious early or late complications, radiation fibrosis was seen radiographically but was asymptomatic
Zhang[10]	2% radiation myelitis
Talton[11]	frequent transient symptoms of radiation pneumonitis, occasional symptomatic radiation fibrosis
Sandler[12]	"rarely reported", none fatal
Dosoretz[13]	3.08 (18%) fatal radiation pneumonitis, 5/13 in patients with mediastinal and hilar RT, 2/26 in patients treated by primary tumor only
Dosoretz[13]	No major complications, no mortality associated with radiation
Hayakawa[14]	2.5% fatal bronchial stenosis (all 4 patients received <80 Gy), includes data on patients with stage II disease
Rosenthal[15]	not reported
Kaskowitz[16]	6% chronic pneumonitis, 6% pericarditis
Graham[17]	1% grade 3 pneumonitis, 2% grade 2 pneumonitis
Gauden[18]	none requiring hospitalization or causing death
Kupelian[19]	no treatment-related deaths; symptomatic pneumonitis in 7%, no difference in complications between patients treated to primary tumor only or with regional nodes
Morita[20]	no major complications reported
Slotey[21]	1.5% grade 3–5 complications, both pneumonitis

[*] Includes some patients with small cell carcinoma.
[†] Includes some patients with unresectable proximal T3 lesions.

TABLE 46.6. RADIATION THERAPY FOR PATIENTS WITH CLINICALLY RESECTABLE NSCLC: COMPLICATIONS

In planning radiation therapy for these patients, it is important to recognize some of the present deficiencies in our database on dose and volume effects on lung tolerance to radiation. Tolerance values derived from data on younger patients treated to partial lung volumes for Hodgkin's disease are not likely to be very applicable to this population. The presence of substantial chronic obstructive lung disease in these patients, often with loss of much functioning lung parenchyma, will perturb dose distributions. Most reported series have reported dose calculations without correction for lung density, even by a nominal "healthy" lung tissue density value such as 0.23 to 0.33. When one considers the often lower actual lung density in these patients, the doses reported, based on no density correction, are likely 10% to 20% lower than the actual received dose to the tumor. Institutions routinely doing planning using either nominal or individualized lung density corrections should keep this in mind and increase their prescribed doses appropriately.

Recent clinical data also suggest that, even when treatment technique and dose are standardized, there is considerable individual variation in the susceptibility to radiation-induced lung damage which may have a genetic basis. [38] In animal systems, such genetic differences between strains of mice with low or high incidences of fibrosis following radiation or drugs such as bleomycin have been well described and appear to be mediated by different levels of induction of fibrogenic cytokines such as TGFb.[39,40] (see also Chapter 13).

Another theoretic technical physical consideration comes from the lack of electronic equilibrium in the transition region between low-density tissue such as emphysematous lung and a solid tumor nodule or mediastinal lymph node. The result of such disequilibrium is underdosing of the first several millimeters of the tumor mass. Attention to this theoretic problem, with phantom modeling studies, has led to the suggestion that high-energy photons (e.g. over 12 MV) should be avoided in treatment plans where there will be lung-tumor interfaces. The clinical impact of this factor is that treating patients with bulky stage IIIA and IIIB disease has been difficult to measure, and the one study which has examined survival as a function of beam energy has failed to find such a relation. [41] One would not expect this review of patients with advanced-stage disease to be a particularly sensitive test, however, and the impact of such dose inhomogeneity would likely be greater in the scenario of treating small peripheral lesions surrounded by low-density lung parenchyma. While a general recommendation is difficult to make, it would seem wise to use multiple-beam techniques with lower- or moderate-energy photons, if these are available, rather than parallel opposed treatments with higher-energy beams.

Radiation toxicity to the lung depends on the dose and the volume of lung treated. Clinical and radiographic changes appear at doses of 18 to 20 Gy (with 1.8 to 2.0 Gy fractions) to the whole lung. Higher doses to smaller volumes will produce more severe changes, which appear earlier with higher doses. The precise shape of the curve relating irradiated volume, dose, and complication probability is not presently known. Attempts to model this, as well as the more complex yet realistic situation wherein differing lung volumes receive differing doses, are essential to the practical implementation of 3D treatment planning systems. [31]

In conjunction with the development of more accurate models of dose-volume-complication effects, we need better understanding of the effects of various "standard" treatment volumes (e.g. tumor only, tumor plus hilar and/or mediastinal nodes, etc.) on pulmonary function. (see also Chapter 36.) Several groups have attempted to do this by measuring baseline pulmonary function by routine flow and volume measurements, and in the case of the Fox Chase group, lung perfusion scans. Curran and colleagues reported on measurements made of 165 nonoperative patients (of unspecified stage) and reported that the percent of functioning lung irradiated increased from 11.3% ± 4.9% for treatment of the primary tumor plus a 2 cm margin to 31.2% ± 10.2% when the ipsilateral hilum and mediastinum were irradiated as well.[42] Choi and associates noted relatively small and transient changes in pulmonary function in patients receiving postoperative radiation therapy to the mediastinum; however, this may not predict the effects of treatment of parenchymal lesions in patients with marginal pulmonary function. [43] Marks and colleagues have developed image correlation methods for combining nuclear medicine delineation of lung function by ventilation and perfusion and CT delineation of lung anatomy, and thus quantitate predicted functional loss for various treatment plans. [44,45] Such techniques have not been widely used in choosing beam arrangements for patients with stage I and II lesions but have the potential to maximize sparing of functional lung on an individualized basis.

AVENUES FOR IMPROVEMENT

It is unrealistic to expect that randomized trials will be conducted to define the role of altered radiation fractionation or the addition of chemotherapy to radiation therapy in patients with clinical stage I–II NSCLC who are treated with radical radiation therapy. Use of such techniques must be guided by reasonable extrapolation from their results in other tumor sites and an understanding of patterns of failure for patients with stage I–II treated with present conventional irradiation.

While systemic failure due to occult metastatic disease is a major problem even in patients with clinical stage I NSCLC, as it is in all of lung cancer, local control has also been frustratingly difficult to achieve in these patients. They, more than patients with more advanced disease, are most likely to have a good correlation between local control and survival.[46]

Altered Fractionation

The RTOG conducted several phase II trials in patients with unresectable NSCLC, investigating both dose response and the role of altered fraction—either BID treatment with small fractions and escalating the total dose, or accelerated fractionation with a concomitant boost. The most promising development of these was a regimen of 1.2 Gy fractions given twice a day to a total dose of 69.5 Gy (see also Chapter 47). In a sequential phase II trial, this gave a survival which was significantly better than standard fractionation for patients with favorable clinical characteristics of minimal weight loss and good performance status. [47] A confirmatory phase III trial conducted by the RTOG and ECOG directly compared this regimen with standard daily fractionation to a dose of 60 Gy in 30 fractions over six weeks.[48,49] The hyperfractionated regimen appeared slightly better than the standard one, but this difference did not reach statistical significance. When local control was analyzed, a significant benefit was seen only for peripheral T3 tumors without nodal involvement. A metaanalysis of three randomized trials of hyperfractionated RT for NSCLC has suggested a significant improvement in survival, although the total number of patients in these trials was relatively small. [50]

In the UK, Saunders and associates have reported promising results with a regimen incorporating TID fractionation and treatment without weekend interruptions (continuous hyperfractionated accelerated radiation therapy or CHART) to a dose of 54 Gy in two weeks. [51] On the basis of favorable phase II data, patients with unresectable NSCLC, of whom about 80% had squamous histology and about one quarter had early-stage but medically inoperable disease (criteria not specified) were randomized to either CHART or conventional once-daily radiation therapy to 60 Gy in six weeks. Results have shown statistically significant improvements in local control and survival, at least to four years, favoring the CHART regimen. [52,53]

It is likely that further improvement in local control and survival can be achieved by strict attention to completing treatment without undue interruptions. Cox and colleagues have analyzed data from three separate RTOG trials and reported that, for the favorable subset of patients described above, survival was significantly compromised by delays of overall treatment time. [54] No effect was seen in less-favorable patients or in patients receiving total doses less than 69.6 Gy. While it is difficult to separate treatment interruption as a cause of bad outcome from treatment interruption as an index of poor patient performance status and underlying tumor burden, the results are in line with radiobiologic prediction that even short treatment interruptions may allow significant proliferation of remaining tumor and greatly reduce local control. The use of agents which are cytostatic but not particularly cytotoxic (e.g., DMFO or inhibitors of *ras* prenylation) may be of use in ameliorating the harmful effects of treatment protraction.

Combining Radiation and Chemotherapy

The addition of chemotherapy to radiation therapy for patients with NSCLC could improve survival through improvement in local control or reduction in distant metastases. While the series which have reported improved survival for patients with stage III disease by treating with induction chemotherapy followed by radiation have reported a reduction in distant failure but no improvement in local control, the use of concurrent daily cisplatin during radiation therapy has been reported to improve local control and survival in one study, although another study of similar design showed no benefit. [55] The effectiveness of present chemotherapy appears restricted to prognostically favorable patients with excellent performance status and minimal weight loss, [56] so its role in the treatment of elderly patients, or patients with significant medical problems other than cancer, with medically inoperable stage I–II NSCLC should be explored with some caution. However, several newer, less-toxic agents such as vinorelbine can be used even in older and sicker patients, and one recent trial in such a group, the ELVIS (Elderly Lung Vinorelbine Italian Study) trial, showed a survival benefit for single-agent chemotherapy when compared with best supportive care. Several trials combining weekly or daily chemotherapy with BID radiation for patients with stage III NSCLC have shown significant improvements in local control and survival not limited to favorable performance status patients[57,58] (see also Chapter 52).

To date, the role of induction chemotherapy has only been tested in some studies in patients with resectable stage I–II NSCLC. However, based on favorable results of induction chemotherapy for patients with resectable stage III NSCLC, [59,60 and 61] trials have recently been conducted to demonstrate the feasibility of such management of patients with stage Ib, IIa, IIb, and selected IIIa (T3N0) NSCLC prior to a phase III trial which will compare immediate surgery to surgery following induction chemotherapy. Based on the results of trials of radiation therapy alone or preceded by induction chemotherapy for patients with stage IIIA/B NSCLC showing survival benefits for the combined modality approach, [49,62,63 and 64] it is reasonable (though of unproven benefit) to consider such a sequence in patients with medically inoperable stage I and II disease so long as they able to tolerate chemotherapy.

CONCLUSIONS

Surgery remains the preferred treatment for patients with clinical stage I-II NSCLC who are or can be made to be of reasonable operative risk. The role of radiation therapy in the management of patients with clinical stage I and II NSCLC is a secondary one. There is little reason to expect radiation alone, or a combination of limited surgery and radiation, to replace surgical management for the patient without significant contraindications to surgery. Based on current data, there is little reason to consider mounting a trial comparing lobectomy versus limited resection plus radiation for the good-risk patient.

The situation is quite different when we consider the patient whose physiologic age, concurrent medical problems, or preference make him or her a poor surgical candidate. Present data lead to the following recommendations:

1. Radical radiation therapy is curative in a worthwhile proportion of these patients, with five-year survivals as high as 40% for patients with clinical stage I disease, and should be offered as the present standard of care for patients with medically inoperable stage I-II NSCLC.
2. While there are no prospective trials that address issues of optimal radiation dose, fractionation, and volume, data would suggest the following guidelines:
2.1 The primary tumor should receive a dose of at least 65 Gy (as calculated without correction for lung density; make appropriate adjustments if lung corrections are used) if conventional fractionation of one daily fraction of 1.8 to 2.0 Gy is used. Exploration of higher total doses and alternatives to once-daily fractionation has shown promise and should be continued.
2.2 Good results have been reported with both split-course and continuous-fractionation schemes. Some retrospective comparisons have suggested superiority of continuous regimens, but such analysis is confounded by the frequent practice of selecting better patients for continuous treatment. In either case, undue protraction of treatment time, either by a long-planned split or by frequent or long treatment interruptions for bothersome but not life-threatening acute toxicities such as esophagitis is likely to decrease local control. Reduction of target volumes to the known tumor without elective nodal radiation should largely prevent significant acute esophagitis and other toxicities, and thus remove the impetus for split-course treatment.,
