Systolic function was also a topic for the echocardiographic substudy analysis.⁵⁴ In this study, LV mass was the strongest correlate of impaired endocardial shortening and midwall shortening. In patients characterized with eccentric LVH, depressed endocardial shortening was most common, whereas patients with concentric remodeling or hypertrophy demonstrated impaired midwall shortening. As a follow-up to this study, it was later demonstrated in blinded treatment analyses that 3 years of antihypertensive therapy improved systolic LV performance, associated with decreases in LV mass, relative wall thickness, and BP and an increase in stroke volume.⁵⁵ In a separate analysis that addressed those participants with ISH versus those with combined hypertension, relative wall thickness was independently associated with ISH, supporting the concept that SBP is a stronger determinant of target organ damage than DBP.⁵⁶

Because atrial fibrillation is strongly associated with stroke, correlates of left atrial size were also determined. It was found that 56% of women and 38% of men had enlarged left atria. Left atrial enlargement was found in multiple logistic regression to be related to LVH and eccentric geometry, increased BMI, SBP, age, mitral regurgitation, female gender, and atrial fibrillation.⁵⁷ Repolarization electrocardiogram correlates of ventricular arrhythmias, namely the QT interval and QT dispersion, were found to be significantly related to the LV mass index and LVH.⁵⁸

Insulin Carotids United States Scandinavia (ICARUS) Study

A small subset of LIFE participants (99, with 11 excluded from the analysis because of DM) underwent isoglycemic hyperinsulinemic clamp studies, forearm venous plethysmographic studies, and ultrasonic examination of the common carotid arteries during the placebo phase of the LIFE study.⁵⁹ The main finding from this examination was that high SBP was associated with common carotid vascular hypertrophy. Hyperinsulinemia and insulin resistance were related to carotid vascular distensibility, while minimal forearm vascular resistance was correlated with SBP and pulse pressure only in men.

Other smaller substudies have investigated issues surrounding insulin sensitivity, blood viscosity, and vascular changes, as well. In unmedicated LIFE-ICARUS participants, fasting insulin independently explained 12% of the variation in blood viscosity at high shear rate, whereas at low shear rates, baseline adrenaline independently explained 17% of the variance in

blood viscosity.⁶⁰ Elevated DBP and serum low-density lipoprotein were found to be related to impaired acetylcholine-induced vasodilation independently from nitroprusside-induced vasodilation in small resistance arteries. These results suggested that, in 41 patients in the ICARUS study with previously treated hypertension, endothelial dysfunction was unrelated to structural changes in the vasculature.⁶¹ In 43 patients, a low exercise capacity was documented and found to be related to increased LV mass (measured by magnetic resonance imaging), lower systemic vascular compliance, and higher minimal forearm vascular resistance.⁶² Thus patients with longstanding hypertension had reduced exercise capacity perhaps due to cardiovascular hypertrophy and reduced systemic vascular compliance.

SUMMARY

The LIFE study demonstrated that a treatment regimen based on losartan was superior to one based on atenolol in preventing cardiovascular endpoints in patients with hypertension and LVH, despite similar BP control during the 4.8 years of average follow-up. These effects were generally observed in the subsets of the LIFE cohort with higher risk, namely patients with ISH and DM, but also in those patients with no previous clinical history of CVD. The most profound treatment effect of losartan was on fatal and nonfatal stroke, whereas no significant differences between treatments were demonstrated for fatal and nonfatal MI.

Regression of ECG LVH was also greater in the group randomized to losartan, providing a possible mechanism for its protective action in comparison with atenolol. Reduction in endpoints in the losartan group could be related to blunting of the age-related increase in SUA. Furthermore, losartan reduced albuminuria to a greater extent than did atenolol.

In the future, we can expect to see a continuing flow of medical knowledge made possible by the persons who volunteered to participate in the LIFE study. The findings of this study have verified the importance of treatment with losartan in patients with hypertension and echocardiographic evidence of LVH.

The VALUE Trial

Stevo Julius, Sverre E. Kjeldsen, Hans Brunner, Steffan Enkman, John H. Laragh, Pelle Stolt, Gordon T. McInnes, Beverly A. Smith, Francis Plat, M. Anthony Schork, Michael A. Weber, Alberto Zanchetti

The benefits of antihypertensive treatment in terms of reduced morbidity and mortality are well established. However, the question whether there are differences between blood pressure (BP)-lowering agents beyond their direct antihypertensive effects remains undecided. Several large-scale hypertension trials have failed to show significant outcome differences when comparing different types of treatment (i.e., diuretics, β -blockers, calcium channel blockers, angiotensin-converting enzyme [ACE] inhibitors, or α -blockers), with respect to primary cardiovascular outcomes (Figure 32-1).¹⁻⁴ However, a growing number of trials have shown indications of benefits beyond BP lowering as a result of inhibiting the renin-angiotensin system (RAS). Two studies, CAPP (the Captopril Prevention Project)¹ and HOPE (the Heart Outcomes Prevention Evaluation Study),⁵ reported that treatment with ACE inhibitors conferred greater cardiovascular protection than other treatments, albeit the results relied on secondary analyses. In CAPP, where patients were randomly assigned to captopril or to diuretic, β -blocker, or diuretic plus β -blocker, the incidence of diabetes was lower in the captopril group than in the conventional group (.86; $p = .039$). However, in many cases captopril (50-100 mg daily) was given once a day, which is contrary to the usual recommendation of two or three daily doses.⁶ Another important point is that there were differences between the two treatment groups in prerandomization height, weight, BP, and the presence of diabetes. Furthermore, the higher (2 mm Hg) diastolic blood pressure (DBP) in the captopril group at baseline seemed to persist throughout the study and may have influenced outcomes.

In the HOPE study, 9297 men and women ≥ 55 years of age were eligible if they had a history of coronary disease, stroke, peripheral vascular disease, or diabetes mellitus, plus at least one other cardiovascular risk factor (smoking, hypertension, hyperlipidemia, or microalbuminuria). The eligible patients were randomized to either ramipril 10 mg daily or matching placebo.

The ramipril patients had lower rates of the primary composite endpoint of myocardial infarction (MI), stroke, or death from cardiovascular causes (relative risk, .78; $p < .001$). Risk reductions were also reported for death from cardiovascular causes (relative risk, .74; $p < .001$), MI (relative risk, .80; $p < .001$), stroke (relative risk, .68; $p < .001$), heart failure (relative risk, .77; $p < .001$), and complications related to diabetes (relative risk, .84; $p = .03$).

However, HOPE was not primarily directed at patients with hypertension and was not actively controlled. Ramipril was reported to have a small effect ($-3/2$ mm Hg) on BP, but this small difference between treatment groups has been questioned. The reported differences refer to office BP, whereas a

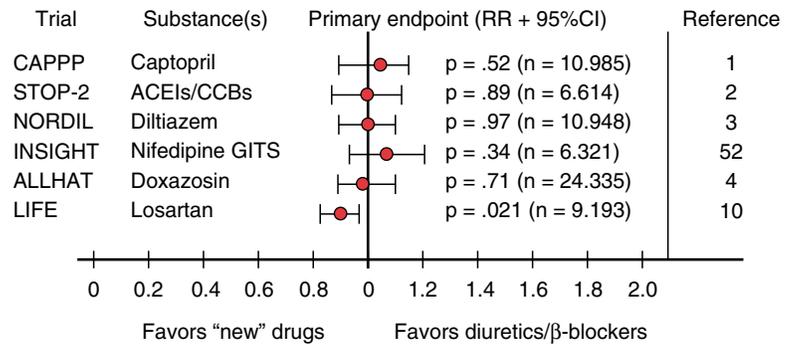

substudy of HOPE showed a 15/6-mm Hg difference from placebo in 24-hour ambulatory BP.⁷ If expressed as the reduction in cardiovascular events per mm Hg difference in BP, the benefits in HOPE were no greater than those seen in other high-risk populations treated with other forms of antihypertensive therapy.⁸

The Second Australian National Blood Pressure Study (ANBP2) reported reduced risk for cardiovascular events or death from any cause in elderly (65-84 years) hypertensive subjects treated with ACE inhibitors than with diuretics. A mean decrease of 26/12 mm Hg in the 6083 participants led to a risk ratio of .89 with borderline significance ($p = .05$).⁹ However, this was an open-label study in family practices and thus not directly comparable with randomized double-blind controlled trials. The Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Trial (ALLHAT) failed to show outcome differences between the ACE inhibitor lisinopril and the thiazide-like diuretic chlorthalidone,⁴ which may have been due to inadequate dose levels or to differences in systolic blood pressure (SBP) in disfavor of the ACE inhibitor throughout.

The strongest evidence for differences between antihypertensive therapies has come from trials with angiotensin receptor blockers (ARBs). The LIFE study (Losartan Intervention for Endpoint Reduction in Hypertension) compared the ARB losartan with the β -blocker atenolol in 9194 hypertensive patients with left ventricular hypertrophy (LVH).¹⁰ The trial reported 13% reduction in the primary composite endpoint of death, MI, or stroke; 25% reduction in risk of stroke; and 25% reduction in new-onset diabetes in hypertensive patients treated with losartan compared with atenolol, for the same degree of BP reduction. The risk reduction was most prominent in patients with isolated systolic hypertension (ISH) (25% reduction in primary composite endpoint).¹¹ The equal BP reduction in both treatment groups in LIFE has not been challenged and the results were widely recognized as the first demonstration of BP independent differences between antihypertensive therapies. Mean BPs at the last visit were 144.1/81.3 mm Hg in the losartan group and 145.4/80.9 mm Hg in the atenolol group.¹⁰

Further support for the conclusions from LIFE came from SCOPE (Study on Cognition and Prognosis in the Elderly), which focused on elderly populations (70-89 years) with mild hypertension. In SCOPE, there was a statistically significant 28% reduction in stroke and a nonsignificant trend toward reduced rates of new-onset diabetes with the ARB candesartan compared with a non-ARB-based antihypertensive regimen.¹² However, the trial design was changed from the planned placebo-controlled to active-controlled for ethical reasons, and BP reductions at the end of study were not equal between

Figure 32-1 Large hypertension trials with “new” versus “old” drugs. (Adapted from Kjeldsen SE, Westheim AS, Os I. INSIGHT and NORDIL. International Nifedipine GITS study: Intervention as a goal in hypertension treatment. Nordic Diltiazem Study. *Lancet* 356:1929-1930, 2000. © Elsevier Ltd; used with permission.)

the treatment groups (3.2/1.6 mm Hg greater reduction with candesartan). These two factors reduced the power and weakened the interpretation of SCOPE results.

Thus, to date, we have two trials indicating that ARBs confer cardiovascular protection, most dramatically against stroke, beyond that of lowering BP alone. This is a highly intriguing finding. Although traditionally hypertension has been associated with a higher incidence of coronary heart disease (CHD) than of stroke, an analysis of 11 major randomized antihypertensive intervention trials recently revealed stroke to be the more common event.¹³ This strong association was seen not only for elderly patients, who tend to be more stroke-prone than younger people, but also in other age groups.^{1,3,8} It is still possible that some of the differences in LIFE were due to negative effects of atenolol rather than to benefits from losartan, but this explanation is less plausible for the SCOPE results, in which the use of β -blockers was limited.¹² Atenolol and other β -blockers are reported to increase insulin resistance.¹⁴ Other trials are needed to clarify this issue, as well as the mechanism of the possible beneficial effect of ARBs.

As to the stroke effects, there are data supporting the contention that the effects in LIFE and SCOPE are indeed due to positive actions of the ARBs. ARBs are known to have benefits on endothelial function. Losartan has been shown to improve maximal acetylcholine response as compared with atenolol.¹⁵ A small crossover study with irbesartan and atenolol has shown that the media width:lumen ratio in resistance arteries decreased when hypertensive patients whose BP was controlled after 1 year of atenolol treatment were switched to the ARB irbesartan for 1 year.¹⁶ Because these studies were comparisons with β -blocker treatment, a negative effect of the comparator drugs such as peripheral vasoconstriction cannot be excluded, but there are data showing that the ARB valsartan improves the vasodilator response to acetylcholine in hypertensive patients, whereas the effects of the calcium channel blocker amlodipine were neutral.¹⁷ However, it needs to be established whether such data translate into clinical outcome benefits.

Furthermore, we still need data on the cardiac effects of angiotensin receptor blockade. The similar cardiac outcomes in both arms in LIFE are an interesting issue, because losartan reduced LVH to a significantly greater extent than atenolol, an effect that would have been expected to translate into cardiac protection. However, it is important to remember that the comparison in LIFE was against an active agent with proven cardiac benefits. A hypothesis is that the cardioprotective effects of the two treatments used

in LIFE were balanced; the reduced stroke work and antiarrhythmic effects conferred by atenolol may have compensated for the benefits from the LVH reduction in the losartan group.

Such unanswered questions and more raise high expectations of the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) Trial of Cardiovascular Events in Hypertension,¹⁸ one of the largest intervention studies in essential hypertension. VALUE is a multicenter, double-blind, randomized, prospective, active-controlled parallel group trial designed to compare the effects of valsartan with those of the calcium channel blocker amlodipine, in doses of 80 to 160 mg and 5 to 10 mg once daily, respectively, on coronary morbidity and mortality in patients with essential hypertension and at high risk for CHD. All primary endpoints in VALUE are cardiac endpoints, with the hypothesis that for the same level of BP control, valsartan will be significantly more effective than amlodipine in decreasing acute MI, congestive heart failure (CHF), and cardiac mortality.¹⁸

The choice of amlodipine as comparator in VALUE is highly appropriate, because calcium channel blockers are considered to have stroke-protective and possible cardioprotective effects. Recently, ALLHAT found similar stroke-protective effects from amlodipine as from a diuretic,⁴ and thus there is a need for adequately designed trials addressing the issue. In contrast to the effects of valsartan or the ACE inhibitor enalapril, amlodipine has been shown to increase sympathetic activity.^{19,20} Furthermore, amlodipine has a neutral effect on insulin resistance,²¹ in contrast to atenolol. Such metabolic effects, possible confounders in LIFE, are unlikely in VALUE.

The stroke protection from calcium channel blockers has been attributed to direct effects on the structural integrity of the blood-brain barrier from reduced endothelial permeability²² or to amelioration in the abnormal sensitivity of arterial smooth muscle cells to Ca^{2+} .²³ Other possible effects are inhibition of detrimental effects of oxygen radicals.²⁴ Among cardioprotective effects, amlodipine has been reported to improve myocardial function, to reduce the size of the myocardial infarct following ischemia-reperfusion,²⁵⁻²⁷ and to protect against the postischemic impairment of coronary endothelium-dependent relaxation.²⁸ The mechanisms of some of these effects remain to be established.

The VALUE trial will provide important information on cardiac effects of valsartan and amlodipine, and is expected to resolve the issue of whether the lower rates of stroke with losartan in LIFE were due to negative effects of atenolol or positive effects of angiotensin receptor blockade.

VALUE TRIAL DESIGN

VALUE is a prospective, multinational, multicenter, double-blind, randomized, active, controlled two-arm parallel group comparison trial with a response-dependent dose titration scheme. Eligible patients were men and women 50 years of age or older with essential hypertension previously untreated or treated. To be included, previously untreated patients had to have mean sitting SBP of 160 to 210 mm Hg (inclusive) and a mean DBP \leq 115 mm Hg, or a mean sitting DBP of 95 to 115 mm Hg and SBP \leq 210 mm Hg. For patients already taking antihypertensive treatment, there were no lower limits of BPs, but upper limits of \leq 210/115 mm Hg. Exclusion criteria included cardiovascular conditions and obvious non-cardiac diseases that may limit long-term survival or increase the likelihood of nonadherence to study medication. Patients already receiving antihypertensive treatment were directly rolled over to one of the two VALUE arms, discontinuing previous drugs and starting on the treatment drug, without a placebo run-in period.

Patients were randomized to either valsartan 80 mg once daily or amlodipine 5 mg once daily. The BP target is 140/90 mm Hg. After 4 weeks on the initial dose, patients were titrated to a dose of valsartan 160 mg or amlodipine 10 mg once daily (Figure 32–2). If the BP target was still not achieved, hydrochlorothiazide could be added at 12.5- or 25-mg doses. A fifth step of the protocol allowed for free add-on of antihypertensive drugs, with the exception of ACE inhibitors, calcium channel blockers, ARBs, or diuretics other than hydrochlorothiazide; however, in patients with impaired renal function or with CHF, thiazide diuretics could be replaced or supplemented by loop diuretics. The usual dose titration period of 4 weeks could be shortened if it was considered in the patient's best interest.

VALUE is endpoint driven and will run until 1450 patients have experienced a primary cardiac event. The primary endpoint is defined as composite sudden cardiac death, fatal MI, death during or following percutaneous transluminal coronary angioplasty (PTCA) or coronary artery graft bypass (CABG), death due to heart failure, MI on autopsy, new-onset heart failure or chronic heart failure requiring hospital management, nonfatal MI, emergency PTCA/CABG, or thrombolytic/fibrinolytic treatment to avoid MI. It was calculated that 14,400 enrolled patients were needed to give the study 90% power at a significance level of $p < .05$ to detect a 15% reduction in the primary endpoint rate from 12.5% in the amlodipine group to 10.6% in the valsartan group over an average of 5 years of treatment. As a comparison, LIFE had 80% power to detect differences in the primary endpoint rates. Altogether, 15,314 eligible patients in 31 countries were randomized by December 31, 1999.

Overall, BP reduction was similar with both treatments. However, the mean differences throughout the study were not consistent. The differences in BP between drug regimens were 4.0/2.1, 4.3/2.5, 3.0/2.0, 2.4/1.7, 2.1/1.6, and 2.0/1.5 mm Hg after months 1, 2, 3, 4, 6, and 12, respectively, and stabilized at 1.5/1.3 mm Hg thereafter. The target BP ($<$ 140/90 mm Hg) was achieved in 56% of the valsartan group and 62% of the amlodipine group. The cardiovascular event rate was 25.5 per 1000 patient-years in the valsartan group and 24.7 per 1000 patient-years in the amlodipine group. Cardiac mortality and morbidity were not significantly different in

the two treatment groups (4.0% vs. 4.0% and 7.7% vs. 7.6%, respectively). Heart failure, stroke, and all-cause death were similar between valsartan- and amlodipine-randomized groups (4.6% vs. 5.3% $p = .12$; 4.2% vs. 3.7% $p = .08$; 11.0% vs. 10.8% $p = .45$, respectively). However, fatal and nonfatal MI were reduced with amlodipine compared with valsartan (4.8% vs. 4.1% $p = .02$, respectively), whereas new-onset diabetes was significantly reduced with valsartan compared with amlodipine (13.1% vs. 16.4% $p < .0001$). The VALUE study highlights the importance of BP lowering in a prompt manner. The early BP differences limit the ability to assess the BP-independent effects between these two drug treatments. Furthermore, achieving adequate BP control in high-risk patients often requires combination therapy early in the treatment period.

Risk Stratification

A unique feature of VALUE is the use of a specially designed algorithm that takes into account risk factors and disease factors, to assess cardiovascular risk.¹⁸ The risk factors include diabetes mellitus, cigarette smoking, hypercholesterolemia, LVH without strain diagnosed on ECG, proteinuria, and serum creatinine above 1.7 mg/dl. Disease factors include a documented history of MI, peripheral vascular disease, stroke or transient ischemic attack, or the presence of LVH with strain on ECG (Box 32–1). This combination of risk factors and disease factors, together with age and sex, makes it uniquely possible to assess the predictive power of an up-to-date cardiovascular risk scale in a large international population of treated hypertensive patients traditionally considered to be at high risk of a cardiovascular event.

The age/risk stratification criteria vary between patient groups according to age. For men aged 50 to 59 years, there is a requirement for at least three additional risk factors or one additional disease factor to be eligible for enrollment. Because of the lower risk profile of women of perimenopausal age, women between 50 and 59 years need to present with a minimum of two risk factors and one additional disease factor to qualify for enrollment. For patients \geq 60 years of age, sex is not considered a factor influencing cardiovascular risk, and thus the requirements are identical for both sexes. Patients aged 60 to 69 years need at least two risk factors or one disease factor, whereas only one risk or one disease factor is required for patients \geq 70 years. The requirements for this last group are based on the significantly increased predictive value of increasing age.

Endpoints

As noted, all primary endpoints in VALUE are cardiac endpoints. The primary variable to be assessed is the time to the first cardiac morbidity or mortality event. Cardiac mortality was defined previously; cardiac morbidity is defined as new or chronic CHF requiring hospitalization, nonfatal acute MI, emergency thrombolysis, or any other interventional procedure performed to prevent a full-blown MI. Important secondary variables are all-cause mortality, cardiac mortality and cardiac morbidity (both defined as for the primary endpoint), stroke, cardiac morbidity plus stroke, worsening of chronic stable angina or unstable angina, routine cardiac interventional procedures, potentially lethal arrhythmias, syncope or near-syncope, silent MI, and end-stage renal disease.

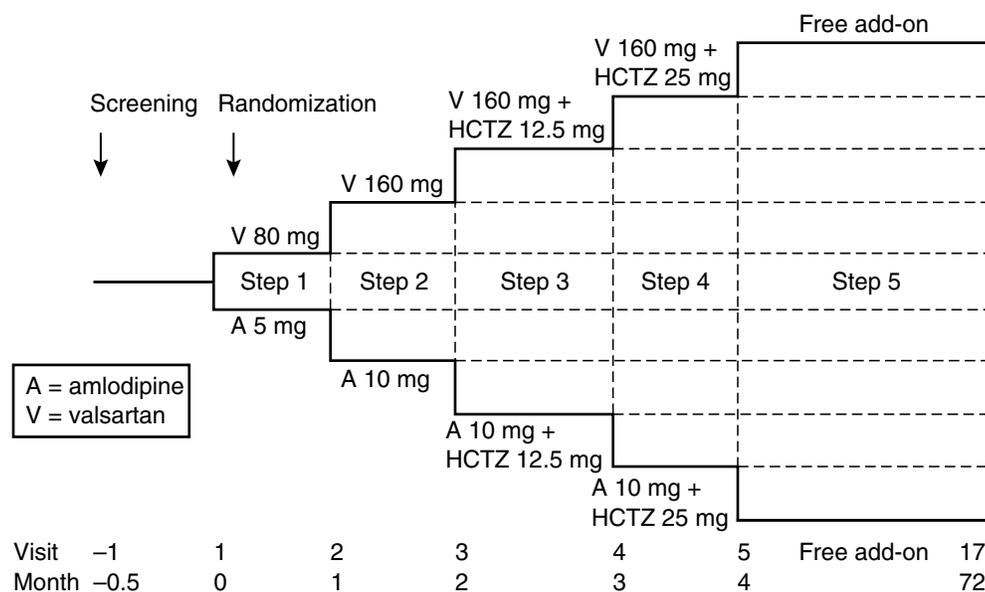

Figure 32-2 VALUE trial design. (After Mann J, Julius S. The Valsartan Antihypertensive Long-Term Use Evaluation [VALUE] trial of cardiovascular events in hypertension. Rationale and design. *Blood Press* 7:176-183, 1998. © Taylor & Francis; used with permission.) HCTZ, hydrochlorothiazide.

Box 32-1 Risk Factors and Disease Factors in the VALUE Trial

Risk Factors

- Diabetes mellitus (defined as overnight fasting plasma glucose concentration >7.8 mmol/L [140 mg/dl] on at least two separate occasions or as chronic intake of hypoglycemic agents with or without occasional intake of insulin)
- Current smoking (defined as smoking at least 10 cigarettes/day on a regular basis for at least 5 years before inclusion in the study; if the patient has quit smoking, he or she will be considered a smoker if he or she stopped less than 12 months before inclusion)
- High total cholesterol (>6.2 mmol/L or >240 mg/dl); left ventricular hypertrophy (LVH) as per ECG (Sokolow-Lyon criteria or Cornell criteria); proteinuria (1+ or more on dipstick in a morning urine specimen)
- Serum creatinine >150 μ mol/L (>1.7 mg/dl)

Disease Factors

- History of MI verified by Q-wave ECG and/or hospital records, and/or cardiovascular revascularization; coronary heart disease (CHD) verified by angiography and/or hospital records
- History of peripheral arterial occlusive disease, verified by angiography or Doppler or hospital records or statement of angiologist
- History of stroke, transient ischemic attack (TIA), verified by angiography or Doppler or PET or CT scan or persistent hemiparesis (stroke) or hospital records
- LVH with strain pattern (ST-segment depression)

ECG, electrocardiogram; MI; myocardial infarction; PET, positron emission tomography; CT, computed tomography.

VALUE BASELINE DATA

VALUE enrolled a total of 15,314 patients at 947 centers in 31 countries, with the largest numbers of patients randomized in the United States ($n = 3676$), Germany ($n = 1557$), Italy ($n = 1095$), United Kingdom ($n = 887$), and France ($n = 841$).³⁰ The average age at randomization was 67.2 years, and more than 80% of patients were older than the age of 60.

There are a large number of women (6496) in the trial population, although the majority of patients (57.6%) are men. Some significant differences in baseline characteristics exist between the sexes: Women were on average 3.7 years older than the men ($p < .0001$) and had higher levels of SBP ($p < .0001$) and DBP ($p < .0001$). Average SBP was 3.9 mm Hg higher in the female group. Women also had lower serum creatinine levels (Table 32-1). Rates of diabetes mellitus were higher in women ($p < .0001$), but the rates of CHD were higher in the male population ($p < .0001$; Table 32-2).

The population was slightly overweight at randomization, with an average body mass index of 28.6 kg/m². Most patients ($>92\%$) were taking antihypertensive medication at the time of randomization and were started on the treatment drug without a placebo run-in period. Hence, BP at the time of randomization was only moderately elevated, averaging 154.7/87.5 mm Hg. The high rate of patients already on treatment is in contrast to the populations in large-scale trials such as the Hypertension Optimal Treatment (HOT) study⁸ or the Nordic Diltiazem (NORDIL) study,³ in which 48% and 56%, respectively, of participants were untreated at the time of enrollment. Elevated SBP tended to be more prevalent than elevated DBP: 37.5% of patients had SBP >160 mm Hg but only 10.4% had DBP >100 mm Hg.

As seen in Table 32-2, the prevalence of CHD (45.8%), high cholesterol (33.0%), type 2 diabetes mellitus (31.7%), smoking (24.0%), proteinuria (22.5%), cerebrovascular disease (19.8%), LVH including bundle branch block and strain (18.3%), and peripheral arterial disease (13.9%) were high in

Table 32-1 Demographic and Biochemical Characteristics at Randomization of Patients in the VALUE Trial*

Variable	Men (n = 8816)	Women (n = 6497)	Total (n = 15,314)
Age (years)	65.7 ± 8.1	69.4 ± 7.6	67.2 ± 8.1
Body mass index (kg/m ²)	28.5 ± 4.5	28.8 ± 5.6	28.6 ± 5.0
Previously treated (%)	92.2	92.6	92.3
SBP (mm Hg)	153.0 ± 18.9	156.9 ± 18.9	154.7 ± 19.0
DBP (mm Hg)	87.8 ± 10.7	87.1 ± 10.9	87.5 ± 10.8
Heart rate (beats/min)	71.4 ± 10.9	73.7 ± 10.3	72.4 ± 10.7

the VALUE population. The high number of patients with diabetes is notable. This is a consequence of the use of diabetes as qualifying risk factor in VALUE, which was not the case for the LIFE trial (12% diabetic patients).³¹ The number of patients with diabetes in VALUE (4854) is greater than the total number enrolled into the four trials that established ARBs as first-line treatment in diabetic hypertensive patients: Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL; n = 1513),³² Irbesartan Diabetic Nephropathy Trial (IDNT; n = 1715),³³ Irbesartan Microalbuminuria Type 2 (IRMA-2; n = 690),³⁴ and

Microalbuminuria Reduction with Valsartan (MARVAL; n = 332).³⁵ However, reduced renal function is of low frequency in VALUE (3.6%), indicating that patients are at earlier stages of the disease than the patients enrolled into the diabetes trials. This may well affect the benefits from treatment. In contrast to LIFE, in which there was a major reduction in mortality in the diabetic subgroup,³⁶ neither IRMA-2, IDNT, nor RENAAL showed mortality benefits from ARB treatment.³⁷ This has been attributed to the less advanced stages of renal disease in LIFE,³⁸ similar to the population in VALUE, as well as limited power of the diabetes trials related to small patient numbers.

The proportion of patients with LVH in VALUE is smaller than in LIFE, in which LVH was an inclusion criterion. There is a relatively high proportion of smokers (24%). Cross-sectional studies of the population indicate that the percentage of smokers is lower among patients with higher BP.³⁹ This can be interpreted as a greater success with smoking cessation attempts in patients with higher BP,⁴⁰ or alternatively, that smoking is particularly lethal in this population.⁴¹

An estimate of the total cardiovascular risk in the VALUE trial population puts patients at a similar risk level to the populations in the Swedish Trial in Old Patients with Hypertension (STOP),⁴² or HOPE.⁵ The main risk factors in the two STOP trials were age and hypertension, and there was a low proportion of CHD events. In contrast, the main risk in HOPE was due to history of CHD in about 80% of patients, almost half with treated hypertension, and one third with type 2 diabetes. Against these differences, it will be interesting to analyze the effects of the VALUE algorithm on the number of CHD events in VALUE.

An important issue in evaluating the trial results and their impact on future antihypertensive treatment patterns is to what extent the VALUE population is representative of patients at high cardiovascular risk in general.⁴³ Only the risk profile, but not the demographic characteristics, differed between the patients enrolled in VALUE and those who were

screened but who did not meet the criteria for high risk of CHD.³⁰ From the data available it seems reasonable to consider the randomized patients in the trial to reflect the risk profile of other hypertensive populations at high coronary risk.

BLOOD PRESSURE CONTROL IN VALUE

VALUE is primarily an antihypertensive prevention trial, and thus it is important to achieve adequate BP reduction in both treatment arms and to ensure that there are no relevant differences between the degree of BP lowering between the patients receiving different treatments. Such differences between the treatment arms were responsible for the doubts about the possible BP-independent effects of ramipril in HOPE⁷ and for the limited analysis that could be made from the SCOPE data.¹²

Because the VALUE trial is ongoing at the point of writing, there is no information on differences between the treatment arms. Data are currently available on BP control in 13,449 patients for whom there are complete BP records at baseline, who had in-study BP measurements at each point up to 24 months and for whom information about treatment status at 24 months is available. Similar data for BP control at 30 months are available for 12,570 patients,⁴⁴ but no analysis of the

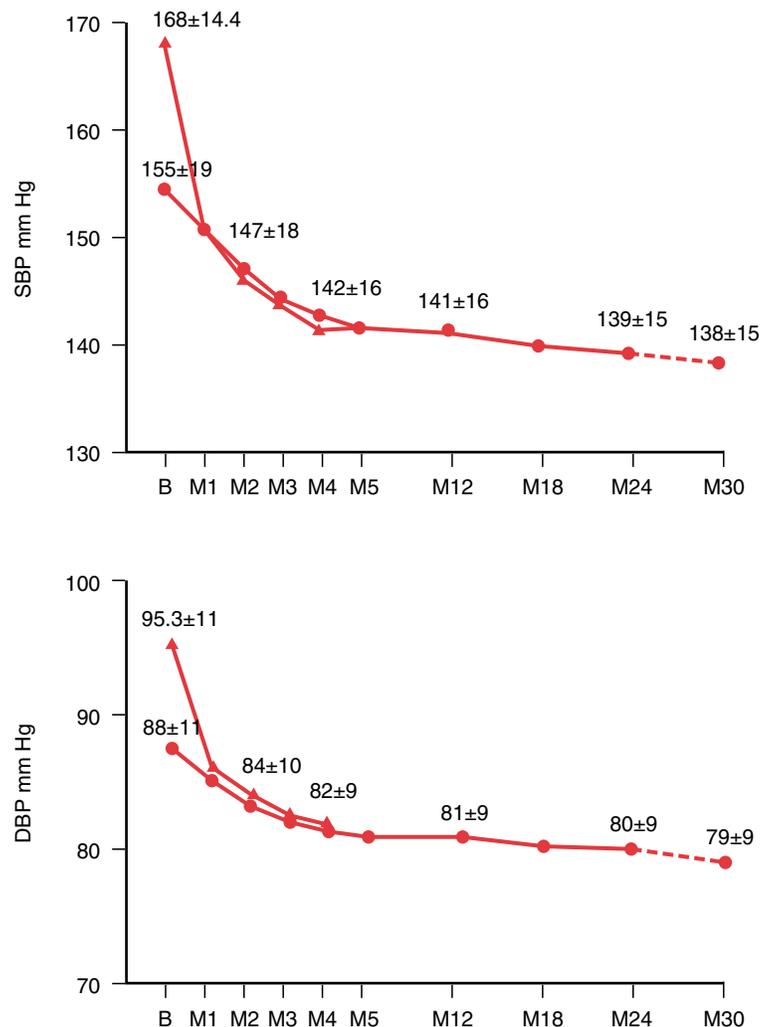

Figure 32-3 Blood pressure trends in the cohort of 13,449 patients who had baseline and 24-month data (dots) and in 12,570 patients who also had 30-month data (broken line). Triangles denote the pressures in 1051 patients who were not receiving antihypertensive treatment before the enrollment. (From Julius S, Kjeldsen SE, Brunner H, et al. VALUE trial: Long-term blood pressure trends in 13,449 patients with hypertension and high cardiovascular risk. *Am J Hypertens* 16:544-548, 2003. © Elsevier Ltd; used with permission.)

utilization of blinded drugs at 30 months has been published. Of the total of 15,314 patients, 1864 were not included in the 24-month report, mostly because of discontinuation for reasons other than death (n = 1012) and because of death (n = 524).

A majority of patients with 24-month BP data (n = 12,398, 92.2%) received antihypertensive drugs prior to enrollment and were rolled over directly to study drugs. The baseline status of these patients gives an insight into how hypertension is treated in routine clinical practice. Among these patients, only 21.9% subjects had controlled (<140 mm Hg) SBP at baseline compared with a DBP control (<90 mm Hg) rate of 54.2%. These findings confirm other observations that practicing physicians are more attuned to controlling the diastolic than SBP.^{6,45-49}

The baseline BP of the 1051 patients who were not receiving treatment prior to enrollment was 14.6/8.4 mm Hg higher than in the patients previously treated. However, both the treated and untreated groups achieved similar BP levels as early as at month 4, and by month 6 the BP readings of both groups were identical (Figure 32-3).

BP was rapidly reduced in the VALUE population during the initial medication up-titration phase over the first 6 months of the trial, but there was very little additional reduction between months 6 and 12, particularly in SBP. The response to this situation was a strong concerted effort at all organizational levels of the trial to improve control of BP, SBP in particular. Through an extensive information and monitoring effort, emphasizing the BP goals and the simple algorithm to achieve these goals, major reductions in SBP were achieved over the next 18 months. Between months 12 and 24, the reduction in SBP/DBP was 1.3/1.0 mm Hg (p <.0001/.0001). A further reduction of 1.0/1.0 mm Hg was achieved between months 24 and 30 (p <.0001/.0001; see Figure 32-3).

The percentage of patients with controlled SBP (<140 mm Hg) at baseline was 21.9%, rising to 59.5% at month 24 and to 62.2% at month 30. In addition to the 62.2% with controlled SBP, an additional 20.6% had “nearly controlled” (≥140 to <150 mm Hg) SBP and 9.3% had “inadequate” SBP control (≥150 to <160 mm Hg; Figure 32-4). Only 7.9% had “uncontrolled” systolic hypertension (≥160 mm Hg). The DBP con-

trol increased from 54.2% at baseline to 88.6% at month 24 and 90.2% at month 30. An additional 6.5% had “near control” values (≥90 to <95 mm Hg), and only 1.3% of patients had “inadequate” (≥95 to <100 mm Hg) or “uncontrolled” DBP (≥100 mm Hg; see Figure 32-4).

A comparison with other hypertension trials further illuminates the success of the SBP initiative. VALUE has achieved substantially greater reductions in BP than most published studies. The average achieved SBP level in VALUE is 16 mm Hg lower than in the STOP 2² and NORDIL³ studies, 12 mm Hg lower than in Syst-Eur,⁵⁰ and 11 mm Hg lower than in CAPPP.¹ A comparison of the 30-month BP reduction rates in VALUE with final results of the Systolic Hypertension in the Elderly Program (SHEP)⁵¹ and HOT⁸ studies shows the rates in VALUE to be a couple of mm Hg lower than in the other two trials and similar to values reported at the end of the INSIGHT (Intervention as a Goal in Hypertension Treatment) study.⁵² Finally, in perhaps the most relevant trial, LIFE, average SBPs at study end were 6 mm Hg higher in the losartan and 7.3 mm Hg higher in the atenolol group than the average SBP achieved at the 30-month point in VALUE.¹⁰ The SBP control rate in the LIFE study was 48%, compared with a control rate of 62.2% in VALUE at 30 months. This is in spite of the use of a stricter definition of control in VALUE than in LIFE (<140 mm Hg vs ≤140 mm Hg).

At first glance, the BP reductions in the ALLHAT trial appear greater than in VALUE: In ALLHAT, SBP in the chlorthalidone, amlodipine, and lisinopril groups, were 135.9, 137.1, and 138.4 mm Hg, respectively, at study end.⁴ However, if the higher baseline SBPs in VALUE are taken into account (155.2 vs. 146.2 mm Hg in ALLHAT), the BP reduction from baseline even in the most successful patient group in ALLHAT, the chlorthalidone group, was 10.3 mm Hg compared with a 16-mm Hg decrease at month 30 in the VALUE study. Thus, VALUE is on track to become one of the most successful trials ever conducted in terms of achieved reductions in BP.

The VALUE titration scheme aimed to achieve BP control by titrating to the maximum dose of monotherapy before adding hydrochlorothiazide and other medications. This is in contrast to LIFE, in which hydrochlorothiazide was added as a second step, before increasing doses of losartan or atenolol.⁵³ Such differences in trial design limit the comparisons of treatment status to BP control between trials. The number of patients still on monotherapy at month 24 in VALUE was

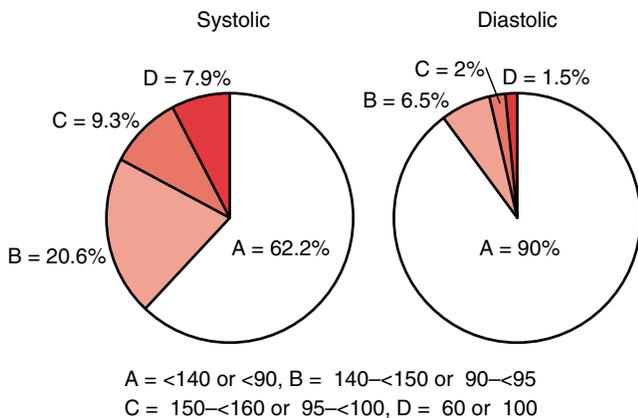

Figure 32-4 Proportion of patients reaching different blood pressure targets in VALUE at 30 months. (After Julius S, Kjeldsen SE, Brunner H, et al. VALUE trial: Long-term blood pressure trends in 13,449 patients with hypertension and high cardiovascular risk. *Am J Hypertens* 16:544-548, 2003. © Elsevier Ltd; used with permission.)

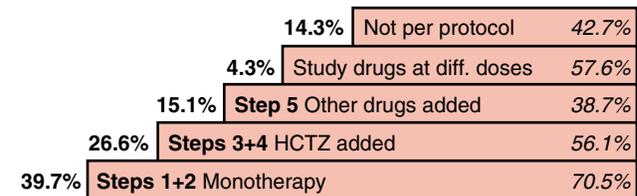

Figure 32-5 Drug utilization and blood pressure control at 24 months in the VALUE study (n = 13,449). Numbers in **bold** are percentages of all patients at various drug steps. Numbers in *italics* are the percentages of patients whose blood pressure was controlled (<140/90 mm Hg) within each category. (After Julius S, Kjeldsen SE, Brunner H, et al. VALUE trial: Long-term blood pressure trends in 13,449 patients with hypertension and high cardiovascular risk. *Am J Hypertens* 16:544-548, 2003. © Elsevier Ltd; used with permission.)

5342 or 39.7% (Figure 32–5).⁴⁴ This is higher than in the differently designed LIFE trial, where only 9% to 10% of patients were on monotherapy at the end of the trial, but comparable with other large-scale trials. In the ALLHAT trial, 49.6% of patients were still receiving monotherapy at year 3,⁵⁴ and 37% of participants were still on single drug at the 5-year visit.⁵⁴ The corresponding figure at the end (median treatment period 4.1 years) of ANBP2 was 66%.⁹ In national surveys, the proportion of treated hypertensive patients that receive monotherapy is typically 60% to 70%.⁴⁷

A majority of the VALUE patients on monotherapy (70.5%) had their BP controlled, but almost one third of the patient group had inadequate BP control ($\geq 140/90$ mm Hg). Most of these inadequately controlled patients had acceptable DBP but elevated SBP, further illustrating the greater difficulties with controlling SBP than DBP.

The VALUE study protocol stipulated hydrochlorothiazide as the first added-on medication, and at month 24, 66.3% of patients were receiving either this combination or monotherapy. Further permitted add-on drugs were used in 15.1% of the population. In an additional 4.3% of patients, the physicians used drugs defined by the protocol but in different doses from those stipulated. A small number of patients (6.3%) received added drugs not foreseen by the protocol.

At the time of the analysis, there was clearly room for further improvement in the utilization of study medications. The control rates in the monotherapy group indicate that diuretics should be added to the regimens for a substantial percentage of patients. In the diuretics-added group, approximately 44% of patients had BP above the treatment goals, indicating that the fifth step of the protocol should be used (see Figure 32–5). Despite these options for further efficacy increases, in all probability some study subjects will have systolic hypertension refractory to treatment. An indication of this is that although the group receiving additional therapy in addition to full doses of treatment drugs and diuretics (step 5) comprised a rather low (15.1%) percentage of the VALUE population, this group had a relatively high percentage of patients (61.3%) with BP still above target. However, the true proportion and the clinical characteristics of patients whose SBP is resistant to treatment will be known only after all therapeutic options for controlling BP provided by the VALUE protocol have been exhausted.

SUMMARY

VALUE is expected to be one of the most important hypertension trials. After the LIFE study showed differences between the ARB losartan and the β -blocker atenolol beyond that which could be attributed to lowering of BP, VALUE is expected to resolve several outstanding issues and to establish whether such benefits are due to vascular and cardiac effects of angiotensin receptor blockade or whether the reduction in outcomes in LIFE can be attributed to negative effects in the β -blocker group. In selecting the calcium channel blocker amlodipine as the comparator in VALUE, the design has ensured a substance with neutral effects on insulin resistance and with reported stroke-protective and cardioprotective actions, as well as beneficial effects on ISH. This sets the scene for a trial designed to decide the issues of whether ARBs are stroke-protective and cardioprotective beyond their effects on BP.

It should be reemphasized that VALUE is a BP trial and as such has already been very successful. The impressive rates of BP control achieved at months 24 and 30 demonstrate what is possible when practitioners work in a structured environment, with the help of explicit BP goals, a simple algorithm to achieve these goals, and education of both patients and practitioners on the importance of achieving stringent BP control.

Main Results from VALUE

Sverre E. Kjeldsen, Stevo Julius, Michael A. Weber, Pelle Stolt

The first results of the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) were reported in mid-2004 and are summarized here.^{1,2} The rationale of the trial and design were discussed in the previous chapter, together with details of baseline characteristics of the enrolled patients. Because the main results of VALUE were published so recently, no subgroup analyses or further details are available at the time of writing. The data are presented here in a brief format.

A total of 15,245 randomized patients were included in the analysis, and 68 patients in nine centers were excluded because of good clinical practice deficiencies. Only 90 patients (0.6%) were lost to follow-up. The mean duration of exposure to study medication was 3.6 years in both treatment groups. The median daily doses were 151.7 mg of valsartan and 8.5 mg of amlodipine. As indicated in the 30-month analysis, the majority of patients in both groups were on combination treatment by the end of the trial. Fewer patients in the valsartan-based group (27.0%) than in the amlodipine group (35.3%) remained on monotherapy during the course of the study.

Blood pressure control rates in VALUE were among the highest reported for an outcome trial: 56% of patients in the valsartan group and 62% of patients in the amlodipine group reached target blood pressure levels below 140/90 mm Hg. These numbers should be viewed in light of the fact that although 92% of patients were being treated for hypertension at baseline and most were receiving more than one drug, only 22% had their blood pressures controlled at that time.

MAJOR OUTCOMES

However, particularly during the first 6 months' treatment-adjustment period, the effects of the amlodipine-based regimen in VALUE were more pronounced than those of the valsartan-based regimen (Figure 33–1). Differences in systolic blood pressure were 4.0/2.1 mm Hg after 1 month and were reduced to 1.5/1.3 mm Hg after 1 year ($p < .001$ between groups). Despite these differences, there was no difference in the primary outcome of composite cardiac endpoints between the valsartan and amlodipine groups (Figure 33–2).

The primary endpoint occurred in 10.6% of patients in the valsartan arm and in 10.4% of patients in the amlodipine arm: hazard ratio 1.04, 95% confidence interval (CI) .94–1.15, $p = .49$. Rates of all-cause death were not different between the groups: hazard ratio 1.04, 95% CI 0.94–1.14, $p = .45$. Of the secondary endpoints, fatal and nonfatal myocardial infarction occurred in more patients on valsartan-based therapy (hazard ratio 1.19, 95% CI 1.02–1.38, $p = .02$), although it should be noted that this was due to lower rates of nonfatal events with amlodipine (hazard ratio 1.22, 95% CI 1.04–1.44, $p = .02$) and that the rates of fatal events were not different between the treatment groups (hazard ratio 1.04, 95% CI 0.74–1.47, $p = .81$). There was a trend

toward fewer heart failure hospitalizations in the valsartan group (hazard ratio 0.89, 95% CI 0.77–1.03, $p = .12$). Stroke rates were not significantly different between the groups (hazard ratio 1.15, 95% CI 0.98–1.35, $p = .08$).

Notably, new-onset diabetes developed in 690 patients on valsartan-based and in 845 patients on amlodipine-based regimens (odds ratio 0.77; 95% CI 0.69–0.86, $p < .0001$ (Figure 33–2). This is the first demonstration of benefits in the prevention of diabetes with an angiotensin receptor blocker as compared with a metabolically neutral antihypertensive agent.

The early differences in blood pressure appeared to have influenced the overall outcomes. During the treatment-adjustment period of the first 6 months, odds ratios tended to favor amlodipine-based treatment for all endpoints. This corresponded to the time of greatest differences in blood pressure between treatments. As blood pressure differences diminished during the following months, there was attenuation in odds ratios (Figure 33–3). For the endpoint of hospital admission for heart failure, there was a trend in favor of valsartan during the last 4 years.

ADVERSE EVENTS

Tolerability was good in both groups, but the most common adverse event, edema, including peripheral edema, was twice as common in amlodipine-treated patients as in valsartan-treated patients. Hypokalemia was more common in the amlodipine group. Although they occurred with low frequency, dizziness, headache, and diarrhea were more frequently reported in patients on valsartan-based regimens. Discontinuation rates from adverse events were significantly lower with valsartan-based treatment (13.4% compared with 14.5%, $p = .045$). It should be noted that the rates of adverse events were somewhat higher than those reported previously for these drugs, almost certainly reflecting the influence of the agents that were added to the primary treatments.

THE ROLE OF BLOOD PRESSURE

VALUE emphasizes the importance of prompt blood pressure control in hypertensive patients at high cardiovascular risk. This was reinforced by further analyses of the correlation between early blood pressure response and outcomes.² By 1 month of treatment, 32.6% of 7543 valsartan patients had systolic blood pressure higher than 160 mm Hg, a significantly greater proportion ($p < .0001$) than the 23.0% of 7504 taking amlodipine; at 6 months, the corresponding proportions (13.2% vs. 8.3%) were also different ($p < .0001$). Event rates in these uncontrolled patients in the valsartan and amlodipine groups, respectively, were as follows: at 1 month, 12.1% of 2456 and 12.3% of 1725 for the combined cardiac endpoints, 5.4% and 5.0% for stroke, and 12.7% and 13.7% for death; at

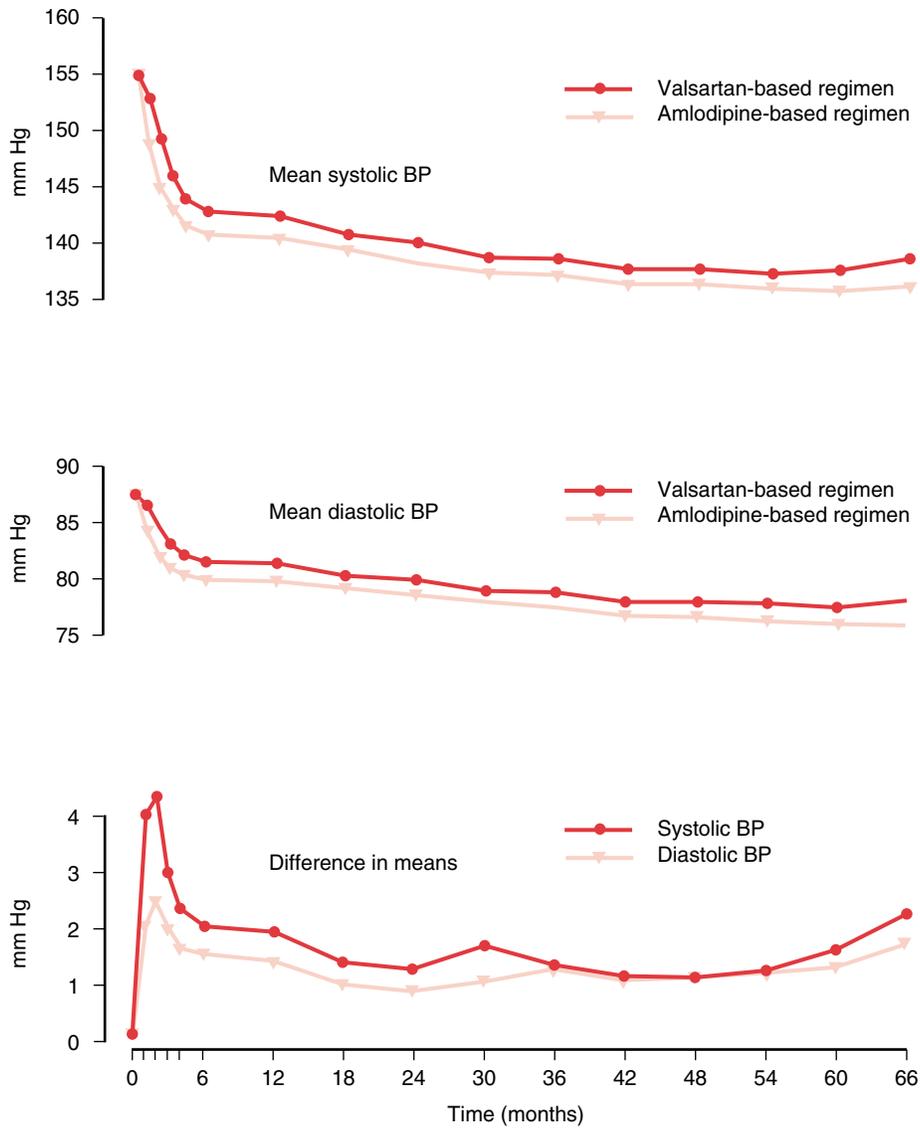

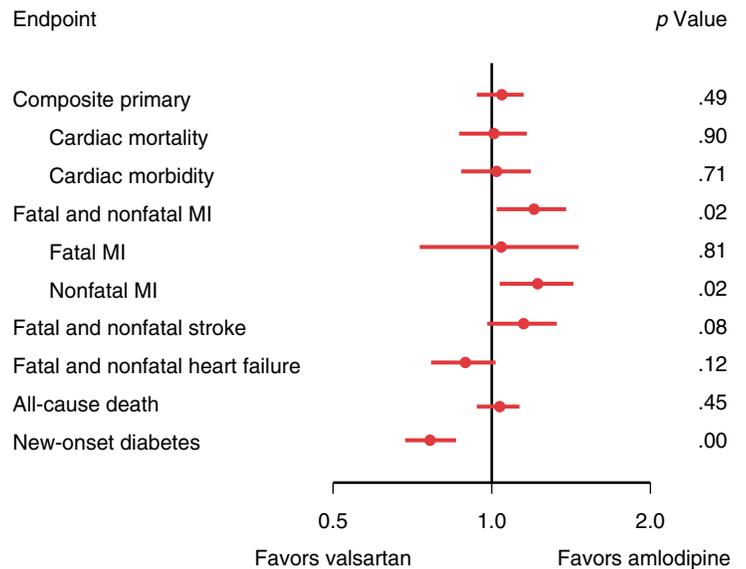

Figure 33-1 Systolic and diastolic blood pressure (BP) and differences (valsartan-amlodipine) in blood pressure between the treatment groups during follow-up. (From Julius S, et al., *Lancet* 363:2022-2031, 2004.)

Figure 33-2 Hazard ratios (odds ratio for new-onset diabetes) and 95% confidence intervals for the primary and secondary endpoints in VALUE, as well as for all-cause death and new-onset diabetes. MI, myocardial infarction.

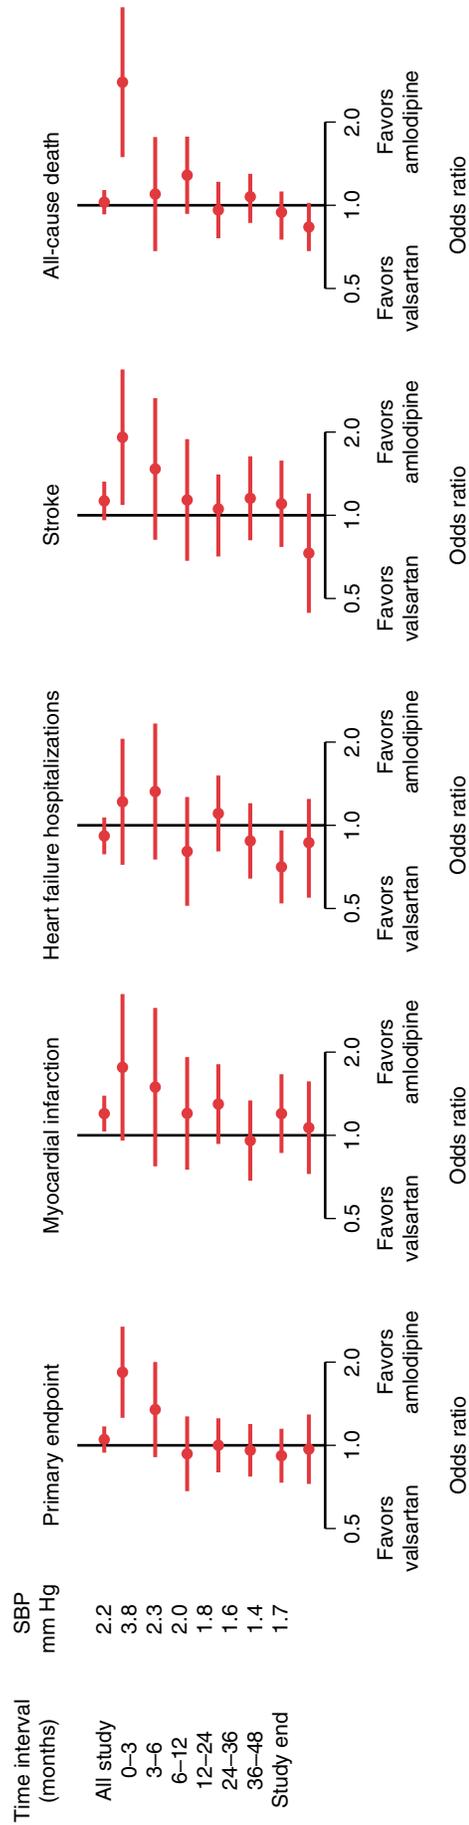

Figure 33-3 Blood pressure differences between the treatment groups together with odds ratios and 95% confidence intervals for valsartan or amlodipine during consecutive time periods in the study. Data are presented for the primary endpoint, the secondary endpoints, and all-cause death. (From Julius S, et al., Lancet 363:2022-2031, 2004.)

6 months, 11.7% of 951 and 11.5% of 601 for the combined cardiac endpoints, 5.9% of 953 and 7.0% of 603 for stroke, and 12.4% of 964 and 15.5% of 606 for death. Event rates during the remainder of the study for patients in this hypertensive stratum were closely similar in the valsartan and amlodipine arms. These numbers indicate that achieved blood pressure rather than drug type was the main determinant of event rates in this high-risk population.

ACHIEVING CONTROL

Because the aim of VALUE was to achieve control of blood pressure by 6 months, it was assessed whether reaching this goal affected outcomes for each of the drug groups. Hazard ratios for subsequent clinical events in patients with systolic blood pressure <140 mm Hg at 6 months were compared with those whose systolic blood pressure was not controlled, within each treatment group. Control of blood pressure was a powerful determinant for the primary and secondary endpoints (except myocardial infarction), as well as for all-cause death. The differences between the two groups were so minor that the data could be pooled to show the overall role of blood pressure control in optimizing outcomes independent of drug type (Table 33–1). These findings provide evidence to validate the target recommendations (140/90 mm Hg) in hypertension guidelines from both Europe and the United States for this high-risk population.

TESTING THE HYPOTHESIS: SERIAL MEDIAN MATCHING

The early blood pressure differences between treatment groups in VALUE made the overall results difficult to interpret. In an attempt to test the hypothesis in a controlled population, the technique of serial median matching was applied to the dataset at 6 months. Although a posthoc analysis, this method should be considered in plans for new studies and perhaps even tested in previously reported studies with substantial blood pressure inequalities. The method selected the most

Table 33–1 Controlled Compared with Noncontrolled Patients: Endpoint

Endpoint	Hazard Ratio (95% CI)
Fatal and nonfatal cardiac events	0.75 (0.67–0.83)*
Fatal and nonfatal stroke	0.55 (0.46–0.64)*
All-cause death	0.79 (0.71–0.88)*
Myocardial infarction	0.86 (0.73–1.01)
Heart failure hospitalizations	0.64 (0.55–0.74)*

After Weber MA, et al., Lancet 363:2047-2049, 2004.

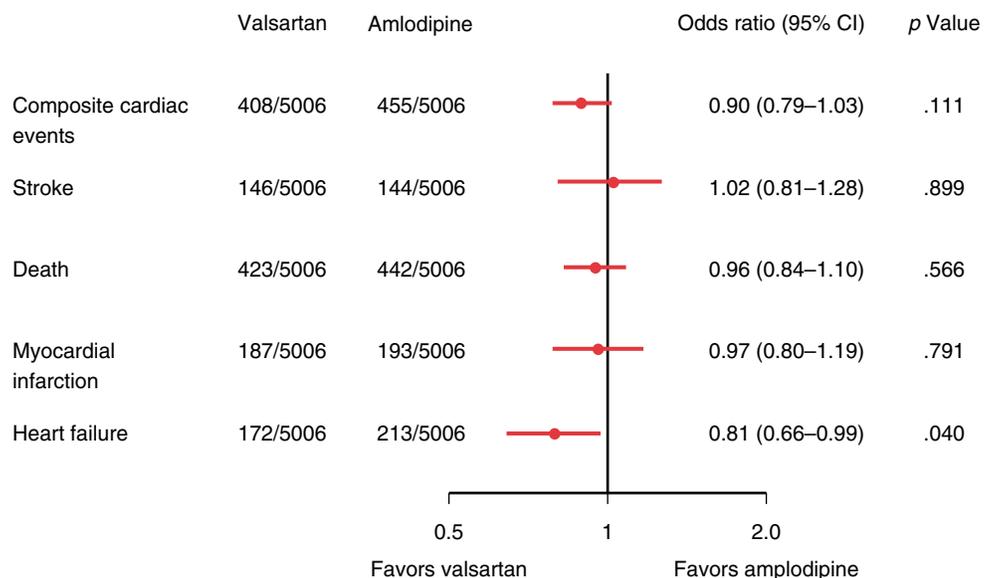

*Hazard ratios for events in controlled compared with noncontrolled patients. After Weber MA, et al., Lancet 363:2047-2049, 2004.

median patient (based on systolic blood pressure) within the valsartan group and paired this patient with one from the amlodipine group matched for systolic blood pressure (within 2 mm Hg); age; sex; and the presence or absence of previous coronary disease, stroke, and diabetes. The process was repeated until all eligible patients were included. In this way, 5006 comprehensively matched valsartan/amlodipine cohort pairs (a total of 10,012 patients) were created, with a mean systolic blood pressure of 139.9 mm Hg in each drug group. The analysis of this patient population, where essentially patients at the high and low extremes of achieved blood pressure were excluded, showed a nonsignificant trend in favor of valsartan for the combined cardiac endpoint. The rates of fatal and nonfatal myocardial infarction, stroke, and mortality were close to identical in both treatment groups. However, admission to hospital for heart failure was significantly ($p = 0.040$) lower with valsartan (Figure 33–4).

SUMMARY

The results from VALUE underscore that in hypertensive patients at high risk for cardiac events, achieving blood pressure targets is a highly important determinant of outcomes. Most of these patients should be on combination therapies. If blood pressure is controlled, VALUE indicated that valsartan-

Figure 33–4 Hazard ratios for major study endpoints in patients on valsartan- or amlodipine-based therapies for events occurring after a baseline translocated to the 6-month point of the trial and after treatment adjustment designed to achieve blood pressure control. Data are shown for 5006 treatment cohort pairs matched by systolic blood pressure; age; sex; and the presence or absence of prior coronary disease, stroke, and diabetes. (From Weber MA, et al., Lancet 363:2047-2049, 2004.)

based therapy is associated with a reduced risk for heart failure hospitalizations and is otherwise closely similar to amlodipine for other cardiovascular endpoints. Furthermore, regardless of blood pressure, valsartan-based treatment was associated with a significantly reduced number of cases of new-onset diabetes. These data were obtained with a valsartan dose range of 80 to 160 mg, which is less than the 160 to 320 mg now recommended in the United States and is associated with the more complete blockade of the renin-angiotensin system. The findings of VALUE are likely to influence future guidelines for blood pressure control and drug selection in high-risk patients.

Clinical Outcome Trials of Hypertension with Angiotensin Receptor Blockers

Shawna D. Nesbitt, Stevo Julius

Recent basic science research has revealed that the renin-angiotensin system (RAS) plays an integral role in the development and propagation of hypertension and related to target organ damage. Agents that block the deleterious effects of the RAS on the vasculature have the potential to ameliorate the cardiovascular consequences of hypertension. Angiotensin receptor blockers (ARBs) are the most recently developed class of antihypertensive agents. They are distinguished by their high tolerability without compromising efficacy in blood pressure (BP) reduction. Another class of closely related agents, angiotensin-converting enzyme (ACE) inhibitors, has been shown to protect against renal, cardiac, and cerebrovascular morbidity and mortality associated with hypertension. Although ACE inhibitors are effective in blocking the RAS through limiting the conversion of angiotensin I to angiotensin II, ARBs may be even more selective in blocking the effects of angiotensin on the vasculature and target organs because they act directly on the angiotensin receptors. In this chapter we review the important completed and ongoing clinical outcome trials of ARBs in hypertension (Table 34-1).

CARDIOVASCULAR OUTCOME TRIALS

The effect of lowering BP on cardiovascular mortality has been demonstrated with various antihypertensive agents. Meta-analysis of the early studies, including primarily β -blockers and diuretics, showed a 25% reduction in stroke and 14% reduction in coronary heart disease (CHD).¹ As newer therapies become available, it is necessary to study their effects on cardiovascular outcomes. Every agent in the ARB class has been shown to be efficacious in lowering BP but there is only one completed trial of cardiovascular outcomes with an ARB. Other important studies are in progress.

LIFE Study

The Losartan Intervention for Endpoint Reduction in Hypertension Study (LIFE) is the only completed hypertension trial of an ARB to assess cardiovascular outcomes.² This landmark study was designed to establish whether the ARB losartan reduces cardiovascular morbidity and death to a greater extent than the β -blocker atenolol despite equal BP reduction. In this double-blinded, randomized, parallel group trial, 9193 participants aged 55 to 80 years with essential hypertension and left ventricular hypertrophy (LVH) by electrocardiographic criteria were assigned to losartan-based or atenolol-based antihypertensive treatment and followed for 4 years. BP was decreased by 30.2/16.6 (\pm standard deviation 18.5/10.1) mm Hg and 29.1/16.8 (\pm 19.2/10.1) mm Hg in the losartan and atenolol groups, respectively.

The cardiovascular event rate was 23.8 per 1000 patient-years in the losartan group and 27.9 per 1000 patient-years in the atenolol group, resulting in a 13% reduction in the losartan group. Assignment to losartan was associated with a 25% reduction in stroke and a 25% reduction in new-onset diabetes. These results were equally robust in the subset of participants who had no clinical evidence of vascular disease. Among the 1195 diabetics in the LIFE study, losartan reduced the primary endpoint by 24%, cardiovascular mortality by 37%, congestive heart failure (CHF) by 41%, and total mortality by 39% compared with atenolol.³ In a subsequent analysis of the 533 African American participants in the LIFE study, although BP reduction was similar in both treatment groups, the greater reduction in cardiovascular endpoints was seen in the atenolol group, not the losartan group. This finding must be viewed with caution because the sample size was small.⁴ Nevertheless, the LIFE study suggests that with equivalent BP control, treatment with losartan prevents more cardiovascular morbidity and death than atenolol, thus conferring benefits beyond BP reduction alone.

The largest ongoing outcome trials of ARBs are the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) and the Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET).⁵⁻⁷ They have different foci, and their results will be instrumental in determining future standards of hypertension care.

VALUE Study

The VALUE study is a multinational, multicenter, double-blind, randomized, prospective, active-controlled parallel group trial comparing the effects of two treatment modalities on BP and cardiovascular endpoints in hypertension.^{5,6} The ARB valsartan at doses of 80 or 160 mg/day is compared with a calcium antagonist amlodipine at doses of 5 or 10 mg/day. Additional treatment may be given as open-label hydrochlorothiazide, 12.5 or 25 mg/day. If needed, additional antihypertensive agents may be added, with the exception of calcium antagonists, ACE inhibitors, or other ARBs, to reach a target BP of <140/90 mm Hg.

Patients are randomized to one of the treatment regimens and followed for 4 to 6 years or until 1450 primary events occur. The study is an endpoint-driven trial, and it has been calculated that 14,400 enrolled patients are needed to detect a 15% between-group difference in cardiovascular outcomes with a 90% power and a significance level of $p < .05$ during an average treatment period of 5 years.

VALUE includes men and women ≥ 50 years of age from 31 countries of any racial background with high-risk cardiovascular profile and systolic and/or diastolic hypertension. Those who were previously untreated must have seated systolic blood pressure (SBP) of 160 to 210 mm Hg and diastolic

Table 34-1 Clinical Trials of Angiotensin Receptor Blockers

Trial	Expected Completed	Agents Used in Trial	Sample Size	Study Group	Length of Study (years)	Primary? Endpoint	% Reduction ARB vs. Comparator Drug
LIFE	2002	Losartan vs. atenolol	9193	HTN + LVH	4	CVD mortality and morbidity	13%
VALUE	2004	Valsartan vs. amlodipine	15,314	HTN	5	CVD morbidity and mortality	No difference in CV events
ONTARGET	2007	Telmisartan vs. ramipril vs. telmisartan + ramipril	23,400	High CV risk	4	CVD mortality and morbidity	In progress
TRANSCEND	2007	Telmisartan vs. placebo	6000	ACE intolerant, high CV risk	4	CVD mortality and morbidity	In progress
HOMED-BP	2009	ARB vs. ACE vs. CCB	9000	HTN	7	Fatal/nonfatal MI, fatal/nonfatal stroke, CVD death	In progress
TROPHY	2005	Candesartan vs. placebo	809	Prehypertension	4	Incidence of HTN	In progress
SCOPE	2002	Candesartan vs. placebo	4964	Elderly HTN	2.5	CV events, cognitive decline, dementia	No difference in CV events; stroke reduced by 23%; no difference in cognition
PRoFESS	2007	Telmisartan + ASA/dipyridamole vs. telmisartan + ASA + clopidogrel vs. placebo + dipyridamole/ASA vs. placebo + clopidogrel + ASA	15,500	Recent ischemic stroke, ≥55 years old	4	Recurrent stroke	In progress
IRMA	2001	Irbesartan 150 mg vs. irbesartan 300 mg vs. placebo	590	DM type 2, HTN	2	Diabetic nephropathy	44% with irbesartan 150 mg; 68% with irbesartan 300 mg
RENAAL	2001	Losartan vs. placebo	1513	HTN, DM type 2	3.5	Doubling serum creatinine, ESRD, and death	16% by intent-to-treat analysis; 22% by per protocol analysis; 25% reduction in doubling serum creatinine; 28% reduction in ESRD
IDNT	2001	Irbesartan vs. amlodipine vs. placebo	1713	HTN, renal disease + proteinuria, DM type 2	2.6	Doubling serum creatinine, ESRD, and death	20% reduction with irbesartan compared with placebo; 23% reduction with irbesartan amlodipine

ARB, angiotensin receptor blocker; HTN, hypertension; LVH, left ventricular hypertrophy; CVD, cardiovascular disease; CV, cardiovascular; ACE, angiotensin-converting enzyme; CCB, calcium channel blocker; MI, myocardial infarction; ASA, acetylsalicylic acid (aspirin); DM, diabetes mellitus; ESRD, end-stage renal disease.

blood pressure (DBP) <115 mm Hg; or SBP <210 mm Hg and DBP 95 to 115 mm Hg. For those patients already on antihypertensive treatment, the SBP should be <210 mm Hg and DBP <115 mm Hg; there is no lower BP limit for entry. These patients are then rolled over to one of the two treatment arms without a placebo run-in period, while discontinuing previous drugs.

The primary outcome in this study is time to first cardiac morbid or mortal event. Cardiac mortality is defined as sudden cardiac death, fatal acute myocardial infarction (MI), death during or post-percutaneous transluminal coronary angioplasty (PTCA) or post-coronary artery bypass graft (CABG), death due to CHF, and evidence of recent acute MI on autopsy. Cardiac morbidity is defined as new or chronic CHF requiring hospitalization, nonfatal acute MI, emergency thrombolysis, or any other interventional procedure performed to prevent a full-blown MI. Secondary outcomes include all-cause mortality, cardiac mortality or morbidity, cardiac morbidity with worsening of chronic stable angina or unstable angina, routine interventional procedures, potentially lethal arrhythmias, syncope or near-syncope, stroke, silent MI, and end-stage renal failure.

A total of 15,313 patients were randomized into the study at the close of recruitment in November 1999. The key feature of the VALUE study is that it is the first to directly compare these two vastly different classes of antihypertensives on cardiac mortality and morbidity.

ONTARGET Study

ONTARGET is designed to compare the effects of the ARB telmisartan, the ACE inhibitor ramipril, and the combination of ramipril and telmisartan on cardiovascular morbidity and mortality in high-risk patients similar to the Heart Outcomes Prevention Evaluation (HOPE) study participants.⁷ This international, multicenter study of 23,400 participants is intended to include 35% diabetics and to have a significant recruitment from Asian countries. The study participants are aged ≥ 55 years and have a history of coronary artery disease, stroke or recent transient ischemic attack, peripheral vascular disease or diabetes mellitus with target organ damage, ankle brachial index of <0.8, or LVH. The study drugs are given in addition to other antihypertensive medications, thus the baseline BP <140/90 mm Hg. Recruitment was completed in June 2003 and the trial will be completed in 2007. ONTARGET is not a "classical" hypertension trial because the participants are not all hypertensive and stage 2 hypertensives (BP >160/100 mm Hg) will be excluded. Rather, this trial is more specifically designed to study the benefit of reducing the activity of the RAS on cardiovascular disease in high-risk patients, including stage 1 hypertensives. As in the HOPE study, BP will likely be lowered in these individuals regardless of hypertensive status. ONTARGET will attempt to discern the difference between the benefits of ACE inhibitors alone and those seen with ARBs alone and whether there is an advantage to combining of the two drug classes.

The related Telmisartan Randomized Assessment Study in ACE-I Intolerant Patients with cardiovascular disease (TRANSCEND) study will assess the effects of telmisartan compared with placebo on cardiovascular events in 6000 high-risk patients who are intolerant of ACE inhibitors.⁷

HOMED-BP Study

The only completed trial that attempted to define an optimal BP goal for patients was the Hypertension Optimal Treatment (HOT) trial, which utilized a dihydropyridine calcium channel blocker-based therapy in all treatment groups.^{8,9} The Hypertension Objective Treatment based on Measurement by Electrical Devices of Blood Pressure (HOMED-BP) study is a Japanese study of 9000 untreated essential hypertensives aged 40 to 78 years with home BPs of $\geq 135/85$ mm Hg. HOMED-BP is designed to determine an optimal target BP level based on home self-measured BPs and the optimal initial antihypertensive agent to prevent cardiovascular events. It is a 2 \times 3 factorial randomized controlled trial conducted with a prospective randomized open-blinded endpoint (PROBE) design. The participants will be randomized to an antihypertensive regimen based on a calcium antagonist, ACE, or ARB and to one of two levels of target home BP: 125 to 134/80 to 84 mm Hg or $\leq 125/80$ mm Hg. Any drug within a randomized class of agents may be prescribed by the physician. Thus this trial is a study of class effect, rather than a specific drug. When the data are collected in the outpatient clinics, they will be transmitted to a host computer, which will determine the necessity for additional therapy or dose increments to reduce the bias in the study. The home BPs in this trial will be collected using an automated device. The primary outcome is a composite of nonfatal stroke, nonfatal MI, and cardiovascular death. The planned average follow-up is 7 years.

TROPHY Study

The Trial of Preventing Hypertension (TROPHY) study is a randomized, placebo-controlled trial designed to assess the effects of treatment with the ARB candesartan cilexetil on the progression to hypertension in individuals with high-normal BP.¹⁰ Between June 1999 and June 2001, 809 individuals were randomized to placebo or low-dose candesartan for 2 years followed by 2 years of placebo. They were qualified for the study by the average of three seated BP measurements taken on three separate clinic visits by an automated device (OMRON 706). Untreated individuals with SBPs between 130 and 139 mm Hg and DBPs between 85 and 89 mm Hg were included in the study. The primary outcome of the trial is the incidence of hypertension determined by clinic SBP >140 mm Hg and/or DBP >90 mm Hg on three visits during the study follow-up or SBP >160 mm Hg systolic and/or DBP >100 mm Hg on one occasion; secondary outcomes include the development of target organ damage requiring BP treatment.

CEREBROVASCULAR OUTCOME TRIALS

In the LIFE study, the greatest benefit of losartan compared with atenolol in hypertensives with LVH was in stroke. Thus there is evidence that ARBs offer a benefit beyond BP reduction in cerebrovascular disease.

The Study on Cognition and Prognosis in the Elderly (SCOPE) is a prospective, double-blind, randomized, parallel group study designed to assess whether candesartan-based therapy in elderly hypertensives confers a reduction in cardiovascular events, cognitive decline, and dementia.¹¹ SCOPE included 4964 patients aged 70 to 89 years with SBP of 160 to

179 mm Hg and/or DBP 90 to 99 mm Hg with a Mini Mental State Examination (MMSE) score ≥ 24 . Patients were assigned to candesartan or placebo in addition to other open label antihypertensive medications. The BP reduction in the study was 21.7/10.8 mm Hg in the candesartan group and 18.5/9.2 mm Hg in the control group, a net difference of 3.2/1.6 mm Hg. The MMSE score was equally well maintained in both the candesartan and placebo groups. The reduction in cardiovascular events was not statistically significant, but the reduction in nonfatal stroke was 27.8% ($p = .04$) and in overall stroke 23.6% ($p = .056$) with candesartan-based therapy compared with placebo.

The benefit of ACE inhibitors in the reduction of secondary stroke has been demonstrated in the Perindopril Protection against Recurrent Stroke Study (PROGRESS) utilizing perindopril in combination with indapamide.^{12,13} However the individuals in this study were not all hypertensive. Another trial that may have further implications regarding the use of ARBs in the prevention of secondary stroke is the Prevention Regimen for Effectively Avoiding Second Strokes (PROFESS) trial. In this trial telmisartan in combination with antiplatelet agents is compared with placebo with antiplatelet agents to assess the most effective regimen for preventing recurrent stroke. This is a randomized, parallel group, multinational, double-blind, double-dummy, active, and placebo-controlled study, which has a 2x2 factorial design with a target enrollment of 15,500 patients. The study arms include (1) dipyridamole extended-release/aspirin + telmisartan; (2) clopidogrel + aspirin + telmisartan; (3) dipyridamole extended-release/aspirin + placebo; and (4) clopidogrel + aspirin + placebo. The only entry criteria are that the individual must be male or female ≥ 55 years of age and have had an ischemic stroke within the previous 90 days. Thus the population will not be restricted to hypertensives, but it is likely that many of the participants will be hypertensive. The primary endpoint of PROFESS is time to the first recurrent stroke. The secondary endpoints are composite endpoint of "vascular events" defined as time to first recurrent stroke (fatal or nonfatal), MI (fatal or nonfatal), or vascular death; major hemorrhagic events; and composite outcome of first occurrence of recurrent stroke or major hemorrhagic event. The study launched in 2003 and will be completed in 2007.

RENAL OUTCOME TRIALS

The effectiveness of ARB treatment in renal disease has been demonstrated in several trials. Losartan, irbesartan, and valsartan have all been shown to reduce the progression of renal disease in type 2 diabetic hypertensives. In the Irbesartan for MicroAlbuminuria in type 2 Diabetes study (IRMA-2), 590 patients with 20 to 200 $\mu\text{g}/\text{min}$ albuminuria, normal serum creatinine, hypertension (BP $>135/85$ mm Hg), and type 2 diabetes were randomized to placebo or irbesartan 150 or 300 mg daily for 2 years.¹⁴ The participants were all Caucasian, 70% male, with mean age 58 years, mean baseline BP 153/90 mm Hg, baseline albuminuria 55 $\mu\text{g}/\text{min}$, glomerular filtration rate (GFR) 110 ml/min, and HgBA_{1c} 7.2%. The 24-hour trough BP was 145/84, 143/84, and 142/84 mm Hg on placebo; 150 mg irbesartan; and 300 mg irbesartan, respectively. After adjustment for baseline microalbuminuria and the BP achieved during the study, the risk reduction for diabetic nephropathy was 44% in the 150-mg irbesartan group

and 68% in the 300-mg irbesartan group compared with placebo. In the placebo group, albuminuria decreased 2%, whereas it decreased 24% with the 150-mg irbesartan group and 38% with the 300-mg irbesartan group. Although the difference was not statistically significant, the rate of nonfatal cardiovascular disease was 8.7% in the placebo and 4.5% in the 300-mg irbesartan groups.

In the Reduction in Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) trial of 1513 participants with type 2 diabetes and nephropathy, the study participants were randomized with losartan (50-100 mg) or placebo and treated with other antihypertensive agents to lower BP to $<140/90$ mm Hg.¹⁵ This 4.5-year planned study was discontinued 1 year early because of the mounting evidence that blockade of the RAS conferred cardioprotective benefits in patients with renal disease. The study participants had a mean age of 60 years, 38% were female, and 48% were Caucasian. In the losartan group, 27% were taking 50 mg, whereas while 71% were taking 100 mg. BP was lowered from 152/82 versus 153/82 mm Hg at baseline to 140/74 versus 142/74 mm Hg at the study endpoint with losartan and placebo, respectively. The primary endpoint of doubling of serum creatinine, progression to end-stage renal disease (ESRD) or death was reduced in the losartan group by 16% in the intention-to-treat analysis and by 22% in the patients on treatment analysis. There was a 25% reduction in doubling of serum creatinine and 28% reduction in ESRD with losartan. Despite the $-4/-2$ -mm Hg BP difference at the end of year 1 favoring losartan, the results remained statistically significant even after adjustment. Of note, 87% to 90% of the participants in the losartan group were also treated with a calcium channel blocker, which did not appear to adversely affect the benefits of the ARB treatment. Losartan prevented one case of ESRD for every 16 patients treated during the 3.5 years of the study.¹⁶

In RENAAL there were no significant differences between the groups in the composite endpoints of cardiovascular mortality and morbidity. However, first hospitalization for CHF was significantly reduced with losartan, and the number of MIs was less in the losartan group although not statistically significant.

The Irbesartan Diabetic Nephropathy Trial (IDNT) included 1713 participants age 30 to 70 years with type 2 diabetes; proteinuria (>900 mg/day); creatinine 1.0 to 3.0 mg/dl (women) and 1.2 to 3.0 mg/dl (men); hypertension (SBP >135 mm Hg or DBP >85 mm Hg or taking antihypertensives); and no recent active cardiovascular disease.^{17,18} Participants were randomized to irbesartan 300 mg, amlodipine 10 mg, or placebo and followed for a mean of 2.6 years. Baseline mean age was 59 years; baseline BP was 160/87 mm Hg; creatinine was 1.7 mg/dl; proteinuria was 4 g/24 hours; and 30% had experienced at least one cardiovascular disease event >6 months before entering the study. The BP goal was 135/85 mm Hg. However, the mean achieved BP was 140/77 mm Hg in the placebo group. The relative risk of the primary endpoint, including doubling of serum creatinine, progression to ESRD or death, was reduced by 20% in the irbesartan group relative to the placebo group and by 23% relative to the amlodipine group. There was no significant difference between the amlodipine and placebo groups. The unadjusted relative risk of doubling serum creatinine in the irbesartan group was 33% lower than placebo and 37% lower than the amlodipine

group. The unadjusted relative risk of ESRD was 23% lower in the irbesartan group than in the other groups. The effects of irbesartan remain significant after adjustment for BP differences between the groups. Based on this study, over 3 years, to prevent one patient from having a primary event, it is necessary to treat 15 patients with irbesartan 300 mg or 10 patients to prevent one patient from doubling serum creatinine.

There was no difference in all-cause mortality or composite cardiovascular disease endpoints among the study groups in IDNT. However, there were some differences in individual cardiovascular outcomes. Irbesartan reduced CHF 35% compared with amlodipine and 27% compared with placebo, whereas amlodipine compared with placebo showed no difference in CHF. Interestingly amlodipine significantly reduced nonfatal MI compared with placebo, yet irbesartan did not show the same effect. There were no differences in stroke between the treatment groups.¹⁹ Small trials of other ARBs demonstrate similar effects on microalbuminuria, thus this may well be a class effect.²⁰

An extensive series of clinical trials is being conducted to compare telmisartan with valsartan, losartan, amlodipine, and ramipril in patients at increased risk of target organ damage. Nine clinical studies will examine the effects of telmisartan in 5000 hypertensive patients with isolated systolic hypertension, type 2 diabetes, obesity, LVH, or renal disease. All of the studies will be conducted using state-of-the-art technology, including such techniques as ambulatory BP monitoring and magnetic resonance imaging.²¹ This program will also investigate the effects of an ARB on key surrogate markers of target organ damage.

The earliest outcome trials of ARBs have shown an emerging role for this new class of antihypertensives in preventing cardiovascular, cerebrovascular, and renal outcomes in hypertension. The trials currently in progress may further expand the role of ARBs in hypertensive therapy.

ACE Inhibitor Trials: Effects in Hypertension

Irene Gavras, Haralambos Gavras

The relationship between blood pressure (BP) levels and increased cardiovascular morbidity/mortality was recognized long ago. Oral antihypertensive drugs for chronic treatment of hypertension first became available in the 1950s with the appearance of reserpine, hydralazine, and methyldopa. A major advance was the introduction of thiazides in 1958, followed by the β -adrenergic blockers in the 1960s in the United Kingdom and the 1970s in the United States. As antihypertensive therapy became widespread, the benefits and adverse effects of various agents became a matter of debate: Although the treatment of malignant hypertension undoubtedly prolonged survival, the benefits of treating “benign” essential hypertension were less readily apparent, and there was a lingering notion that the age-related BP rise may be necessary to ensure adequate perfusion of vital organs. The Veterans Administration studies in 1967 and 1970^{1,2} finally proved beyond doubt that successful BP lowering in essential hypertension could significantly decrease the rates of morbidity and mortality from heart failure, renal failure, stroke, and progression to malignant hypertension, although the rates of coronary events seemed to be less affected.

Several theories were proposed to explain this discrepancy between cardioprotection and protection of other target organs, including the fact that hypertension is one of several coronary risk factors and some antihypertensives tend to exacerbate other risk factors, offsetting the benefit of BP lowering. For example, thiazides and β -blockers tend to accentuate insulin resistance,^{3,4} the defining feature of the metabolic syndrome, whose components are independent coronary risk factors.⁵ Diuretics and direct vasodilators (including the dihydropyridine calcium channel blockers) also tend to trigger neurohormonal stimulation, and there is evidence that an activation of the renin-angiotensin system (RAS) increases cardiovascular risk.⁶

The angiotensin-converting enzyme (ACE) inhibitors that became available in the 1980s held the promise of overcoming this handicap. They were shown to be as effective as any other antihypertensive class in terms of BP-lowering capacity, with the added advantages of inhibiting the RAS and improving insulin sensitivity—the latter most likely attributable to their bradykinin-mediated actions.⁷ Theoretically, the ACE inhibitors should be cardioprotective and nephroprotective, and both animal studies and clinical studies confirmed this.⁸ It was noted that Black patients, who tend to have suppressed RAS and kinin systems, are less responsive to ACE inhibition in terms of both BP lowering and cardioprotection. Nevertheless, because of the mechanistic considerations indicated previously, it was postulated that most hypertensives would benefit from ACE inhibitors, at least to the same extent as, if not more than, from other antihypertensive drug classes.

Twenty years and several large controlled outcome trials later, this issue is still under debate. Many of these trials have shown better protection of target organs with an ACE inhibitor-based regimen than other antihypertensives, yet

others, including the largest one, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), found either no difference or a better protection with a thiazide-based regimen.⁹ The value of attaining BP control is well established and drugs from all antihypertensive classes are generally equally effective in lowering BP. It has been estimated that a 10- to 15-mm Hg decrease in systolic BP should lead to a relative risk (RR) reduction of 15% for myocardial infarction (MI) and 40% for stroke.¹⁰ Ideally, the magnitude of BP decrease and the level of BP attained should be identical in the ACE inhibitor-based arm and the comparator arm of each trial to permit a fair comparison of regimens, because a 3- to 4-mm Hg difference may translate into a 5% and 13% difference in RR of MI and stroke, respectively. In fact, small BP differences between treatment arms in outcome trials are common and may contribute to the results.

Following is a brief overview of some of the trials comparing ACE inhibitors with conventional therapies and an attempt to reconcile the discrepant results. Of note, several earlier trials in patients with congestive heart failure (CHF), cardiomyopathy, or post-MI, showed 20% to 25% reductions in RR of recurrent coronary events or hospitalizations for CHF. These trials, including the Survival and Ventricular Enlargement (SAVE) trial (testing captopril post-MI),¹¹ the Studies of Left Ventricular Dysfunction (SOLVD) trial (enalapril in CHF),¹² the Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS) (enalapril in CHF),¹³ the Acute Infarction Ramipril Efficacy (AIRE/AIREX) trial (ramipril in CHF),¹⁴ and the Quinapril Ischemic Event Trial (QUIET) (quinapril in coronary disease)¹⁵ enrolled patients selected for preexisting coronary disease or CHF. These trials are not included in this overview because the issue in question is whether ACE inhibitors have advantages over other drug classes in the treatment of hypertensive patients. Specifically, we evaluate studies testing whether antihypertensive treatment based on ACE inhibition compared with conventional therapies results in decreases in morbidity and mortality beyond those attributable to BP lowering per se (Box 35-1).

THE HYPERTENSION TRIALS

The earliest prospective randomized outcome trials comparing ACE inhibitor-based antihypertensive therapy with therapy based on other drug classes were the Appropriate Blood Pressure Control in Diabetes (ABCD) trial¹⁶ the Fosinopril versus Amlodipine Cardiovascular Events Trial (FACET),¹⁷ and the UK Prospective Diabetes Study (UKPDS).¹⁸ All three are small trials comprising a few hundred patients selected for the presence of type 2 diabetes and hypertension, a combination known to increase the risk of cardiovascular events and hence permit the detection of significant treatment-related differences with smaller numbers and in a shorter follow-up period.

Box 35-1 Alphabetic List of Randomized Outcome Trials Comparing Morbidity/Mortality Reduction from BP Lowering with ACE Inhibitors Vs. Other Drug Classes (Year of Publication)

AASK (2002)—African American Study of Kidney Disease and Hypertension
 ABCD (1998)—Appropriate Blood Pressure Control in Diabetics
 ALLHAT (2002)—Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial
 ANBP2 (2003)—Second Australian National Blood Pressure Trial
 BPLT (2000)—Blood Pressure Lowering Treatment Trialists' Collaboration
 CAPP (1999)—Captopril Prevention Project
 FACET (1998)—Fosinopril versus Amlodipine Cardiovascular Events Trial
 HOPE (2000)—Heart Outcomes Prevention Evaluation
 PROGRESS (2001)—Perindopril Protection Against Recurrent Stroke Study
 STOP-2 (1999)—Swedish Trial in Old Patients with Hypertension, Part 2
 UKPDS (1998)—United Kingdom Prospective Diabetes Study

The ABCD¹⁶ compared enalapril with nisoldipine in 470 hypertensive diabetics. The nisoldipine arm was terminated early, when an interim evaluation revealed a risk ratio of 7.0 for MI in the nisoldipine arm compared with the enalapril arm. Although more detailed evaluation of additional cases in the next 2 years decreased this risk ratio to 4.2,¹⁹ the conclusion remained the same (i.e., overall cardiovascular mortality was not statistically different), but the rate of MI was significantly lower with ACE inhibition. FACET¹⁷ compared fosinopril with amlodipine in 380 hypertensive diabetics. Over the 3.5 years of follow-up, twice as many amlodipine patients experienced the combined cardiovascular endpoint of stroke, MI, or hospitalization for angina (27/191 vs. 14/189 on fosinopril, $p = .03$).

The UKPDS,¹⁸ in contrast, showed no advantage of captopril compared with atenolol in preventing cardiovascular complications in diabetics. In a subset of 758 diabetic hypertensives allocated to "tight control" of BP with an average follow-up of 9 years, all cardiovascular endpoints, including total cardiovascular mortality (48/400 vs. 32/358, respectively), tended to be higher in the captopril than in the atenolol group, although none of the differences was statistically significant. What was highly significant was the overall 24% reduction in total endpoints in the group assigned to "tight control" (BP $\leq 150/85$ mm Hg), which, by today's standards, seems inadequate. These results support the notion that the degree of BP control is the deciding factor for target organ protection, regardless of how it is achieved.

Subsequent trials, whose results are more directly applicable to the general population, comprised much larger numbers of hypertensive patients. The Scandinavian Captopril Prevention Project (CAPP)²⁰ assigned 5492 patients to captopril and 5493 to a diuretic, β -blocker, or both. Overall, there

was no significant difference in the primary endpoints, including MI, although the rate of cardiovascular mortality tended to be lower with captopril (RR 23%, not significant) and the rate of stroke was higher (RR 25%, $p = .044$). In this, as in all subsequent large trials, the incidence of new-onset type 2 diabetes was significantly lower in the ACE inhibitor arm (RR 22%, $p = .04$). This trial has been criticized because the short-acting ACE inhibitor captopril was administered once daily, and the captopril arm had an average 2-mm higher systolic and diastolic BP throughout.

The Swedish Trial in Old Patients with Hypertension-2 (STOP-2)²¹ comprised 6614 patients aged 70 to 84 years assigned to either an ACE inhibitor, a dihydropyridine calcium channel blocker, or a conventional (β -blocker and/or diuretic) arm. There was no difference in endpoints among the three arms, leading to the conclusion that the only important factor for the prevention of cardiovascular events was a decrease in BP.

In contrast, the Heart Outcomes Prevention Evaluation (HOPE) study,²² which included 9297 persons older than age 55 with evidence of atherosclerotic cardiovascular disease (of whom 47% were nonhypertensives, but with other cardiovascular risk factors), found that treatment with ramipril decreased by 22% ($p < .001$) the combined RR of MI, stroke, or cardiovascular death, compared with placebo added to standard therapy. RR of stroke was decreased by 32%, of MI by 20%, of heart failure by 23%, of new-onset diabetes by 34%, of death from cardiovascular causes by 24%, and from any cause by 16% (all highly significant with $p < .001$).

Furthermore, a meta-analysis of 15 studies carried out by the Blood Pressure Lowering Treatment Trialists' Collaboration that collectively included 74,696 patients²³ compared treatment regimens based on different drug classes, including ACE inhibitors, as well as treatments of different intensity. Studies of ACE inhibitors and comparator regimens included more than 12,000 patients and revealed reductions in stroke by 30%, coronary heart disease (CHD) by 20%, and cardiovascular death by 26% with ACE inhibitors versus placebo. Both ACE inhibitors and placebo were added to standard therapy in these studies. In the same meta-analysis, treatment with calcium channel blockers was associated with a 19% higher risk of CHD and 18% higher risk of heart failure when compared with treatment with ACE inhibitors, both statistically significant. In this as in other meta-analyses,²⁴ calcium channel blockers seemed to have a small, nonstatistically significant advantage over other treatments in terms of protection from stroke.

The Perindopril Protection against Recurrent Stroke Study (PROGRESS)²⁵ was designed to evaluate the effect of the ACE inhibitor perindopril, alone or in combination with indapamide, on recurrence of stroke in 6105 patients who had suffered an ischemic or hemorrhagic stroke within the past 5 years. Of those, only half were hypertensive and all were receiving standard protective therapy, including antiplatelet agents, statins, and antihypertensives (other than ACE inhibitors) as needed. Patients were assigned to either perindopril alone, perindopril plus diuretic, or placebo; added to standard therapy; and followed for an average 3.9 years. Those on perindopril-based therapy had a 28% RR reduction in the primary outcome endpoint (i.e., total stroke), but this reduction was driven by the results in the perindopril plus diuretic group, who had a more pronounced

BP fall (12/5 mm Hg, compared with 5/3 mm Hg on the ACE inhibitor alone). It is also notable that among patients who did experience recurrent strokes, those taking perindopril were reported to have significantly lesser cognitive decline and dementia compared with those on standard therapy.²⁶

Every RAS-inhibiting drug (whether ACE inhibitor or angiotensin II receptor blocker [ARB]), when first introduced, was compared for antihypertensive efficacy with a thiazide. The aforementioned large outcome trials were multinational collaborative studies conducted mostly in Europe and the Far East and comprising mainly Caucasian or Asian populations, who respond equally well or better to the RAS-inhibiting agent than to a diuretic. However, in Black patients the RAS-inhibiting drugs were found to be less effective for reasons that have remained largely elusive. An obvious explanation is that Blacks generally have a suppressed RAS. However, the same is true for elderly hypertensives, yet older patients respond readily to RAS-inhibiting treatment and, in fact, require on average lower doses of these drugs (as with most other drugs) than younger hypertensives.²⁷ Trials of the effects of RAS inhibition on the heart, such as SOLVD¹² and the Losartan Intervention For Endpoint Reduction in Hypertension (LIFE) trial,²⁸ have suggested that Black patients might not get the same degree of cardioprotection with these agents as Caucasian patients. However, the numbers of Black participants in these trials were not large enough to produce conclusive results, and the issue requires further study (see Chapter 56 for a discussion of hypertension in Blacks).

The National Institutes of Health (NIH)–sponsored African American Study of Kidney Disease and Hypertension (AASK)²⁹ was designed to evaluate the effects of BP lowering and of choice of antihypertensive drug on the rate of decline of renal function in African Americans (Blacks) with mild hypertensive (nondiabetic) renal disease. It evaluated 1094 patients randomized according to a 3×2 fractional design comparing higher (102–107 mm Hg) with lower (≤92 mm Hg) BP goals, as well as therapy based on ramipril, metoprolol, or amlodipine, with add-ons as needed to achieve goal BP. Surprisingly and contrary to previous experience, the level of BP attained did not affect rate of decline of renal function. However, the choice of antihypertensive class did: The ramipril group manifested reduced risk for the clinical composite outcome (reduction of GFR by ≥50% from baseline, end-stage renal disease, or death over 3 to 6 years of follow-up) by 22% versus metoprolol and by 38% versus amlodipine, both highly significant.

The ALLHAT trial,⁹ also an NIH-sponsored outcome study, enrolled 42,416 hypertensives older than 55 years of age, of whom 35% were African Americans, making it the largest outcome study of antihypertensive treatment ever, and clearly the largest hypertension study involving African Americans. ALLHAT was designed to compare four drug classes—the diuretic chlorthalidone against the ACE inhibitor lisinopril, the calcium channel blocker amlodipine, and the peripheral α_1 -adrenoceptor blocker doxazosin. The α -blocker arm was interrupted prematurely, when an interim evaluation found that patients randomized to it had twice the rate of heart failure as the other three arms and because the probability of finding benefit beyond diuretic therapy was vanishingly small (a futility indication). After an average 4.9 years of follow-up, there was no difference between ACE inhibitor and calcium channel blocker versus diuretic treatments in the rate of primary outcome (CHD or MI) or of all-cause mortality.

Consistent with previous trials, there was a 30% lesser incidence of new-onset type 2 diabetes in the lisinopril group compared with the chlorthalidone group. However, the lisinopril group had a 20% higher RR of heart failure and 15% of stroke—the latter driven by a 40% higher RR in African Americans, who also had an average 4–mm Hg higher systolic BP throughout. Although subgroup analyses by age, race, and other clinical characteristics may help explain some of these results, the discrepancy between these findings and those of most previous trials will surely be debated for a long time.

The Second Australian National Blood Pressure Study (ANBP2)³⁰ enrolled an unselected hypertensive population of 6083 patients aged 65 to 84 years attending family practices throughout Australia. Comparison of ACE inhibitor–based or diuretic-based therapy over an average of 4.1 years, with add-on drugs as needed to normalize BP, revealed an advantage of the ACE inhibitor (any drug of this class) in overall reduction of the incidence of cardiovascular events or death by a modest, but statistically significant 11%, despite a slightly higher incidence of fatal strokes. For reasons difficult to explain, this result was driven by the 17% decrease in RR in men, whereas there was no discernible difference in women. The study population was mostly Caucasian.

COMMENTARY AND SUMMARY

In spite of their disparate results, these trials have some things in common. One is that morbidity and mortality were affected first and foremost by the degree of BP reduction, and therefore insufficient BP lowering in one arm of a comparative trial would adversely affect the outcomes in that arm (e.g., the once-daily captopril dosing in CAPPP was probably inadequate for 24-hour BP control). A related issue is that of salt sensitivity and its impact on the reciprocal relationship between sodium retention and reactivity of the RAS.³¹ The prevalence of salt-sensitive hypertension has been estimated at between 30% to 75%, depending on the population studied, with the higher percentages found in Black persons and in older individuals, because it is known to increase with age.³² Hypertension in such patients is characterized by a suppressed RAS that is less reactive to salt depletion.

Clinical and experimental animal studies have established that a reciprocal relationship exists between the contributions of the RAS and sodium to the maintenance of a given BP level: When sodium intake is high, the RAS is suppressed and BP is maintained via salt-dependent mechanisms, whereas when sodium is removed, the RAS becomes activated and BP is maintained to a larger extent via angiotensin-induced vasoconstriction. Therefore, normotensive persons and normal- or high-renin hypertensive patients, when treated with diuretics and/or a low-salt diet, respond with activation of the RAS, which tends to limit the BP-lowering effect of salt depletion. Low-renin and salt-sensitive hypertensives are usually less responsive to treatment with RAS inhibition, but with vigorous diuresis to effectively remove a substantial proportion of their exchangeable sodium, these patients respond with a reactive hyperreninemia and exhibit a marked BP fall after blockade of the RAS.²⁷ This particularly efficacious combination of a diuretic with an RAS blocker has been used in many outcome trials that have demonstrated the target organ protection with ACE inhibitors or ARBs.

Existing knowledge of the pathophysiology of hypertension and its cardiovascular complications can thus reconcile some seemingly conflicting results: The STOP-2 trial in elderly Scandinavians used small doses of diuretics, which would fail to produce much reactive hyperreninemia—and the same would be true for amlodipine. Hence, these patients were not exposed to the detrimental influence of an activated RAS and were equally responsive to ACE inhibitors as to calcium channel blocker or diuretic/ β -blocker treatment. On the other hand, Black patients in the ALLHAT trial had a poor BP response to lisinopril monotherapy. Combination with a diuretic, which would have enhanced the benefits of the ACE inhibitor, was not permissible on this protocol. A more detailed analysis and comparison of subgroups may explain some of these findings.

In general, trials in populations in whom the RAS is expected to contribute to high BP and target organ damage (younger, Caucasians, diabetics, or prediabetics) are more likely to show advantages of ACE inhibitors in protection against cardiovascular mortality, morbidity, and target organ damage. Populations with a suppressed and less reactive RAS seem to do as well or better on diuretic-based regimens. It is important to keep in mind that the best regimen is one that ensures optimal BP control with the least neurohormonal activation.

Critical Assessment of Hypertension Guidelines

Gordon T. McInnes

INTRODUCTION

The delivery of care for individuals with hypertension is variable and often poor.¹ In the United States, control rates are much less than 50%, with a particular shortfall in the control of systolic blood pressure. Furthermore, 30% of those with high blood pressure are unaware that they have hypertension, and awareness has not changed in the last decade. As a consequence of the ageing population in most developed countries, the total number of stroke and coronary heart disease events is increasing or remains static. Also, a “second wave” epidemic of cardiovascular disease is flowing through developing countries and the former socialist republics. Thus, hypertension is an emerging public health problem on a global scale.

There is no shortage of well-meaning advice for clinicians treating hypertension. In 2003 alone, five major organizations published guidelines,¹⁻⁵ and revised British recommendations appeared early in 2004.⁶ Authors of guidelines are quick to offer justification. More than 50% of countries lack formal guidelines for the management of hypertension,⁷ and many lack the resources to make significant impact. Rather surprisingly, the recent World Health Organization–International Society of Hypertension (WHO-ISH) Guidelines⁵ overlap substantially with those of the Joint National Committee (JNC)¹ and the European Society of Hypertension–European Society of Cardiology (ESH-ESC)³ recommendations, which are aimed primarily at a North American or European audience, with little acknowledgment of problems in the developing countries that make up the vast bulk of the world population.

The guidelines essentially address three issues—when (or whom) to treat, what the target of treatment should be and how to treat. Discrepancies in detail are readily apparent, but the concordance of opinion is impressive. All guidelines emphasize the need for careful assessment before diagnosis and treatment, the early treatment of severe and accelerated hypertension, rigorous targets particularly in high-risk individuals, and the role of nonpharmacologic management. The choice of drugs for treatment of hypertension is perhaps the area where uniformity is least.

The need for advice on the management of hypertension is evident, but the dangers are seldom recognized. When an authoritative body makes specific recommendations, it is easy for deviation from the guidelines to be regarded as suboptimal or even negligent practice.

WHEN (OR WHOM) TO TREAT

Traditionally, the threshold for treatment of hypertension has been based on blood pressure levels. “Hypertension should be defined in terms of a blood pressure level above which inves-

tigation and treatment do more good than harm.”⁸ The threshold has to be set to select the individuals most likely to benefit. Reduction in risk is valuable only if it is appreciable in magnitude and in absolute terms.

Both systolic and diastolic blood pressure are recommended for guidance on treatment thresholds. Although the benefit of treating elevated systolic blood pressure is restricted to the elderly, the same systolic threshold is recommended at all ages. Some recent guidelines^{1,5} recommend a treatment threshold for systolic blood pressure of 140 mm Hg and/or for diastolic blood pressure of 90 mm Hg, even in low-risk individuals. The evidence in support of this advice comes from observational data.^{9,10}

Recommendations have been extended to those with high-normal blood pressure (130-139/85-89 mm Hg).¹⁻⁶ Because experimental support for blood pressure reduction in such individuals is so far limited to those with diabetes mellitus,¹¹⁻¹⁴ coronary heart disease,¹² and stroke,^{15,16} antihypertensive drug treatment can be advised only for patients with high risk.³

JNC 7¹ has gone further by including a category termed prehypertension (120-139/80-89 mm Hg) because such individuals have twice the risk of developing hypertension as compared with those with lower blood pressures.¹⁰ Prehypertension is intended to identify those in whom early adoption of healthy lifestyle could reduce blood pressure, decrease the rate of progression of blood pressure elevation to hypertension with age, or prevent hypertension entirely.¹ JNC 7 claims that prehypertension is not a disease category but that drug treatment is recommended when there is concomitant diabetes or renal disease if lifestyle intervention fails to reduce blood pressure to 130/80 mm Hg or less.¹

Contemporary guidelines further extend the definition of threshold for intervention by advising ambulatory blood pressure monitoring (ABPM) or home blood pressure monitoring (HBPM) in some circumstances.¹⁻⁶ There is uncertainty about definitions and implications. Measurement of blood pressure outside the clinician’s office (ABPM or HBPM) may have a role in some patients but should not be used indiscriminately in the routine evaluation of patients with hypertension. Although all guidelines provide considerable detail on how to use ABPM or HBPM to diagnose white coat (isolated office or clinic) hypertension, little practical advice is given on how such individuals should be managed. These approaches are not available in many developing countries.⁴

With successive guidelines, the blood pressure threshold has been reduced, often without trial evidence of benefit and without consideration for the practical issues of implementation. Small changes in thresholds can have a profound effect on the proportion of adults who will be given drug treatment. Even when using the cheapest antihypertensive drugs, current blood pressure thresholds have a massive economic impact on

the healthcare system when additional labor costs are included in the equation.

Although there may be divergence about the appropriate blood pressure thresholds, there is unanimity that the presence of other cardiovascular risk factors (e.g., dyslipidemia, diabetes, smoking), target organ damage (e.g., left ventricular hypertrophy), and associated clinical conditions^{1,3,5,6} should result in a lowering of the threshold for intervention (Table 36–1). It may be reasonable to delay drug treatment in individuals with mild hypertension unless there are other risk factors.^{3,5} This recommendation is sensitive to circumstances where resources are limited.⁴

Guidelines for hypertension^{1–6} and cardiovascular risk prevention¹⁷ endorse the concept of risk stratification, but not all provide precise advice. Intuitive estimates of cardiovascular risk are crude and indiscriminate.¹⁸ Risk stratification is more accurate when major risk factors are estimated and weighted by using risk functions derived from epidemiologic studies.¹⁹ The categorical method recommended by WHO-ISH⁵ and ESH-ESC³ is less accurate than those using continuous variables such as British Hypertension Society (BHS),⁶ based on the Framingham risk equation,¹⁹ which has been shown to apply to U.S. and North European populations, although it is less predictive in other ethnic groups.

Although management based on a precise estimation of cardiovascular risk is logical, it requires consultation of relevant computer programs, charts, or tables before a decision is made about treatment. This approach determines short-term (10-year) risk and therefore favors treatment of the elderly (men) rather than the young (women). Restricting treatment to high- or very high-risk persons may be cost-saving for the practitioner but less than optimal for the patient. In some cases, strict adherence to these approaches would result in drug treatment being denied when blood pressure exceeds

conventional thresholds. Although short-term risk of cardiovascular and renal morbidity and mortality may be low in younger patients with risk factors of only moderate severity, long-term risk can be unacceptably high. A decision not to treat should be reviewed regularly, because risk increases with age and may in time become sufficient to justify intervention.

When resources are limited, priority should be given to hypertensive patients with high and then moderate cardiovascular risk. In those with low cardiovascular risk, decisions should be based on estimated cardiovascular risk and patient choice.

The JNC 7 guidelines have largely abandoned the risk stratification approach and provide treatment recommendations primarily based on blood pressure levels.¹ The simplicity of this method may be useful for the busy clinician, but there are confusing inconsistencies. Treatment of all patients with mild hypertension is advised if either risk factors, target organ damage, or both are present. Furthermore, the Framingham risk score¹⁹ is suggested as an aid to doctors and patients in demonstrating the benefits of treatment. The strategy advocated by JNC 7 is less logical than others but is also less expensive. It may provide a better service for countries where every penny counts.

TARGET BLOOD PRESSURE

Until recently, detailed discussion about the threshold for treatment was not often matched by detailed consideration of the target for treatment—that is, the level of blood pressure that should be achieved. There is very good epidemiologic evidence that, within the usual range of systolic and diastolic blood pressure, the lower the pressure, the lower the risk of both stroke and coronary events.²⁰ However, there has been persistent concern that normalization of diastolic blood pres-

Table 36–1 Factors Influencing Prognosis

sure (80–85 mm Hg) may increase the risk of coronary death in patients with established coronary artery disease.²¹

The findings from the Hypertension Optimal Treatment (HOT) study²² have been hugely influential in determining target blood pressure. Despite limitations, the HOT study provides reasonable support for contemporary recommendations that blood pressure should be reduced to less than 140/90 mm Hg in all treated individuals.^{1–6} In the HOT study,²² there was little additional benefit from reducing systolic blood pressure to below 150 mm Hg. Therefore, this systolic blood pressure target is an acceptable fall-back position^{3,5,6} and is particularly appropriate when resources are limited.⁵

The evidence for more-rigorous blood pressure control is most robust for diastolic blood pressure in type 2 diabetes^{22–25} but is extrapolated to include systolic blood pressure and patients with type 1 diabetes and other high-risk individuals including those with established cardiovascular disease where a target blood pressure of less than 130/80 mm Hg is recommended.^{1,3,5,6} Even tighter blood pressure control is advised in diabetic patients with nephropathy and in nondiabetic renal disease. However, the quality of data in support of rigorous targets becomes weaker the lower the achieved blood pressure. Clinical trial evidence²⁶ questions the desirability of pressing below conventional levels even in patients at high risk of cardiovascular events and renal failure.

Despite best practice, blood pressure targets may be difficult to achieve. Particularly in the elderly, rigorous control of systolic blood pressure may prove impossible without severe detrimental influences on the individual's quality of life. Occasionally, there is no alternative to accepting poor blood pressure control. Under these circumstances, it is vitally important that the physician does not convey to the patient an impression of therapeutic failure or despair. Both the physician and the patient should recognize that partial blood pressure control reduces the risk posed by hypertension. Guidelines should pay more attention to this difficult but not infrequent clinical problem.

The primary goal of management is to obtain maximum reduction in total risk of cardiovascular and renal morbidity and mortality. Effective treatment requires management of all identified reversible risk factors and associated clinical conditions, as well as blood pressure. The burden of lifestyle modification and drug therapy can be overwhelming for the patient and the practitioner.

HOW TO TREAT

There is universal agreement about the role of lifestyle modification in the management of hypertension, including those with high-normal blood pressure, particularly where there is a strong family history^{1–6} (Box 36–1 and Table 36–2). Lifestyle modifications can be difficult to apply in the population at large and in the long-term, and the ability of nonpharmacologic interventions to reduce mortality and morbidity in hypertension has not been shown directly. Application of lifestyle intervention should not delay the introduction of drug therapy, especially in high-risk patients.

Practitioners who advocate rigorous lifestyle modifications can be considered by the recipient of advice as “warriors against pleasure.” An individual's lifestyle is driven by personal performance and economic realities. Although the person

may accept that habits are harmful and should be improved, change is always difficult, and undue pressure may be resented. The consequence may be poor concordance with management plans. Overzealous lifestyle advice without immediate benefit can result in the individual declining further contact with the perceived persecutor.

Advocated lifestyle changes are chiefly of value in more-prosperous communities, although even then, success may be elusive. These lifestyle changes may not always be relevant to poorer countries where dietary approaches may be unaffordable. The most helpful approach for poorer areas⁵ may be trying to influence the policies of government agencies and food manufacturers to reduce sodium consumption in these communities.

There is general agreement that lowering blood pressure is the main determinant of benefit and is more important than specific drug selection.^{1–6} The major classes of antihypertensive agents—diuretics, β -blockers, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers—are suitable for initiation and maintenance of therapy. The emphasis on identifying the first class of drugs to be used has probably been superseded by the recognition that two or more drugs in combination are needed to achieve the goal blood pressure.

Despite these considerations, two influential recent guidelines^{1,5} advocate therapy based on a specific drug class, thiazide, or thiazide-like diuretics, for all hypertensive patients unless there are compelling indications for another class. Findings from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)²⁷ are used to justify this policy, despite misgivings about the validity of its interpretation.²⁸ Diuretics are undoubtedly underused, enhance blood pressure lowering in multidrug regimens, and are often more affordable than other drugs.²⁹ It is probable that the last factor is decisive in determining the advice from JNC 7¹ and WHO-ISH.⁵

In settings where cost is the overriding consideration, this approach may not be unreasonable. This is particularly true in African countries,⁴ because diuretics have strong blood pres-

Box 36–1 Lifestyle Measures That Lower Blood Pressure and Cardiovascular Disease

Lifestyle measures that lower blood pressure

- Weight reduction
- Reduced salt intake
- Limitation of alcohol consumption
- Increased physical activity
- Increased fruit and vegetable consumption
- Reduced total fat and saturated fat intake

Measures to reduce cardiovascular disease risk

- Cessation of smoking
- Reduced total fat and saturated fat intake
- Replacement of saturated fats with mono-unsaturated fats
- Increased oily fish consumption

†The effects of implementing these modifications are dose- and time-dependent and could be greater for some individuals.

sure lowering effects in Blacks.³⁰ In low-risk patients, treatment may not be cost-effective unless the cheapest drugs are used, but in high-risk patients who gain large benefits from treatment, expensive drugs may be more cost-effective.³¹ Because the focus of most recent guidelines is on identification and treatment of patients at high risk, a more-relaxed approach to treatment regimens may be more logical.

The average blood pressure fall induced by each of the different drug classes is similar, but there is considerable heterogeneity among patients. The appropriate choice for a patient may be determined by the individual's other characteristics, such as ethnicity and age. Diuretics and calcium channel blockers are particularly effective in Blacks and the elderly.^{30,32} This is emphasized by the WHO-ISH guidelines,⁵ but it is not pointed out that other drugs, such as ACE inhibitors and angiotensin receptor blockers, may be more efficacious in non-Blacks and younger individuals. Furthermore, certain high-risk conditions provide compelling indications for particular drugs (Table 36-3). In certain individuals there are contraindications and cautions for all classes of drugs (see Table 36-3).

If the first-choice therapy is well tolerated but blood pressure remains above target, all guidelines¹⁻⁶ give the option of switching to a different class of drugs (substitution) in mild and uncomplicated hypertension. Whether this should be continued if the second choice fails to control blood pressure is controversial. Rotational monotherapy is laborious and frustrating for doctors and patients and may reduce compliance. Moving to combination therapy achieves blood pressure control more efficiently.¹⁻⁶ Drugs can be added in a stepwise manner until blood pressure is controlled.

Simple algorithms can aid the prescriber in choosing the most appropriate sequence of drug combinations.^{3,4,6} The most recent BHS guidelines⁶ endorse the ABCD algorithm. This is based on the categorization of hypertensive patients into high- and low-renin groups. Younger patients (younger

than 55 years) and Caucasians tend to have high-renin hypertension and respond well to A (ACE inhibitors or angiotensin receptor blockers) or B (β -blockers), which block the renin-angiotensin system,³³ whereas older patients and Blacks respond well to C (calcium channel blockers) or D (diuretics),^{30,34-37} predicting responsiveness to first-line therapy. If control is not achieved, A (or B) can be combined with C or D with favorable effectiveness.^{38,39} When there is no compelling indication for a particular drug class, the cheapest available drugs should be used. β -Blockers (B) in combination with diuretics (D) should be avoided in patients at high risk of diabetes^{40,41}—that is, those with a strong family history of type 2 diabetes, obesity, impaired glucose tolerance, and/or the metabolic syndrome, and certain ethnic groups such as South Asians. The ABCD algorithm appears logical, but its utility needs to be tested in clinical practice.

Combination therapy is needed by most patients to achieve optimal blood pressure control. The most innovative recommendation of the recent guidelines¹⁻³ is to consider initiating therapy with combinations of two agents in those whose blood pressure is substantially elevated or where target organ damage or other risk factors demand an aggressive approach. In JNC 7,¹ combination therapy from the outset is an option if blood pressure is 160/100 mm Hg or greater. Thus, if baseline blood pressure is 20/10 mm Hg above target, prescribers might initiate therapy with two agents. This should help dispel the myth that most patients can be controlled with one agent.

The prompt initiation of combination therapy enhances efficacy, facilitates more-rapid achievement of goals, requires fewer visits to clinicians, and is particularly desirable in communities that lack adequate healthcare provisions. A disadvantage is the possible exposure to an unnecessary drug. There is also an increased risk of orthostatic hypotension, particularly in diabetics and older people. However, for the majority, combination therapy is an efficient approach to management.

Table 36-3 Compelling and Possible Indications, Contraindications, and Cautions for the Major Classes of Antihypertensive Drugs

Class of Drug	Compelling Indications	Possible Indications	Caution	Compelling Contraindications
α-Blockers	Benign prostatic hypertrophy		Postural hypotension heart failure ^a	Urinary incontinence
ACE inhibitors	Heart failure, LV dysfunction, post-MI, type 1 diabetic nephropathy, 2° stroke prevention ^e	Chronic renal disease, ^b type 2 diabetic nephropathy, proteinuric renal disease	Renal impairment, ^b PVD ^c	Pregnancy, renovascular disease ^d
ARBs	ACE inhibitor intolerance, type 2 diabetic nephropathy, hypertension with LVH, heart failure in ACE-intolerant patients, post-MI	LV dysfunction post-MI, intolerance of other antihypertensive drugs, proteinuric renal disease, chronic renal disease ^b	Renal impairment, ^b PVD ^c	Pregnancy, renovascular disease ^d
β-Blockers	MI, angina	Heart failure ^f	Heart failure, ^f PVD, diabetes (except with CHD)	Asthma/COPD, heart block
CCBs (dihydropyridine)	Elderly, ISH	Elderly, angina	—	—
CCBs (rate limiting)	Angina	MI	Combination with β-blockade	Heart block, heart failure
Thiazide/thiazide-like diuretics	Elderly, ISH heart failure			Gout ^g

From Williams B, Poulter NR, Brown MJ, et al. Guidelines for management of hypertension: Report of the fourth working party of the British Hypertension Society, 2004–BHS IV. *J Human Hypertension* 18:139-185, 2004.

^aHF when used as monotherapy.

^bACE inhibitors or ARBs may be beneficial in chronic renal failure but should only be used with caution, close supervision, and specialist advice when there is established and significant renal impairment.

^cCaution with ACE inhibitors and ARBs in peripheral vascular disease because of association with renovascular disease.

^dACE inhibitors and ARBs are sometimes used in patients with renovascular disease under specialist supervision.

^eIn combination with a thiazide/thiazide-like diuretic.

^fβ-Blockers are increasingly used to treat stable heart failure. However, β-blockers may worsen heart failure.

^gThiazide/thiazide-like diuretics may sometimes be necessary to control blood pressure in people with a history of gout, ideally used in combination with allopurinol.

COPD, chronic obstructive pulmonary disease; ISH, isolated systolic hypertension; PVD, peripheral vascular disease; LVH, left ventricular hypertrophy; ACE, angiotensin-converting enzyme; ARBs, angiotensin II receptor blockers; MI, myocardial infarction; CCBs, calcium channel blockers.

For reasons of convenience and increased patient compliance, preparations that contain two or more drugs in a single tablet or capsule may be appropriate if there are no cost disadvantages. The availability and cost of fixed-dose combinations vary greatly around the world. Optimal strategies should take into consideration local circumstances and needs.

When blood pressure is at goal and stable, follow-up every 3 months is reasonable.¹ If therapeutic goals are not achieved in 6 months, referral to a specialist is advised.³ In many settings, this resource may not be available.

When appropriate, step-down of therapy is generally recommended.^{1,3} This should be undertaken only after blood pressure has been controlled effectively for at least 1 year. Careful monitoring is required, and success is minimal if the initial diagnosis of hypertension was accurate.

Treatment of all other reversible risk factors for cardiovascular disease should be considered as an integral part of

hypertension management. Recommended strategies include lifestyle modification, lipid lowering, glycemic control, and antiplatelet therapy.¹⁻⁶ Aspirin should be included only when blood pressure is controlled because of the increased risk of intracerebral bleeding in uncontrolled hypertension.

SPECIAL CONSIDERATIONS

Diabetes Mellitus

The main focus of treatment is generally considered to be systolic blood pressure, although it is not yet firmly established by clinical trial evidence. The systolic blood pressure target (<130 mm Hg) is particularly difficult to achieve.⁴² Most trials have failed to reduce systolic blood pressure to 140 mm Hg or below.⁴³

The choice of drugs is an area of great controversy, myths, and misconceptions.⁴⁴ ACE inhibitors are generally recommended as first-line treatment,³ but the supporting evidence is weak. Findings from ALLHAT²⁴ and other trials^{41,45,46} provide little indication that ACE inhibitor–based therapy offers advantages over other regimens. It is uncertain whether the renoprotective effect of ACE inhibitors in type 1 diabetes and of angiotensin receptor blockers in type 2 diabetes makes such agents first-line therapy in all patients with diabetes, as suggested by ESH.³ JNC 7¹ and BHS⁶ advise use of these agents only where there is established nephropathy or target organ damage, in line with existing evidence.^{11,13,14,47-49}

Statins are recommended regardless of lipid levels. Aspirin should be used when reasonable blood pressure control has been achieved. Glycemic control should be optimized. Thus, hypertensive patients with diabetes can expect to be prescribed seven or more drugs, as well as strict lifestyle changes. It is little wonder that compliance is often poor.

Chronic Kidney Disease

Strict blood pressure control is essential to retard progression of renal impairment, but the precise blood pressure goal for optimal renoprotection is uncertain.^{26,50,51} The evidence for preferential use of drugs that block the renin-angiotensin system³ in patients with chronic kidney disease is restricted to trials in African Americans.^{51,52} In patients with overt proteinuria, the data in favor of blockade of the renin-angiotensin system is more compelling.^{6,53-54} Because of high cardiovascular risk, statins and aspirin are usually indicated.^{3,6}

Cardiovascular Disease

In these high-risk individuals, antihypertensive therapy is indicated even if blood pressure is only marginally elevated. Tight blood pressure control is critical. The guidelines provide advice on appropriate agents.

Cerebrovascular Disease

In the absence of evidence, it is reasonable to recommend a cautious approach after acute stroke until the patient and the blood pressure are stabilized.¹ Little additional advice is provided despite recent findings that strongly support rigorous control of blood pressure beyond the acute phase of stroke or transient ischemic attack.¹⁶

Age

The guidelines give special consideration to hypertension in the elderly, because absolute risk is much greater than in younger people. Initiation of therapy beyond 80 years of age depends on the presence of comorbidities. If the individual is generally fit and especially if there are hypertensive complications or target organ damage, treatment should not be denied.⁵⁵ JNC 7 recommends treatment of systolic blood pressures of 140 to 159 mm Hg.¹ No consideration is given to the relative benefits and resource implications of treating all those older than 60 years of age with systolic blood pressure in this range. To avoid cognitive dysfunction, the optimal blood pressure appears to be particularly low (135-150/70-79 mm Hg).^{56,57} Posthoc analysis of the Systolic Hypertension in the

Elderly Program (SHEP)⁵⁸ suggests that it is advisable to avoid reducing diastolic blood pressure below 70 mm Hg or 60 mm Hg at the lowest.

In contrast, very little guidance is provided about management of hypertension in young individuals. Secondary hypertension is more common in the young but is still rare. In the absence of clinical clues or very high blood pressure, management should follow the usual protocol with further investigation if there is a poor response to therapy. Guidelines that advocate treatment based on short-term (usually 10-year) cardiovascular risk^{3,5,6} lead to undertreatment of the young, who are left to develop increasing blood pressure and a lifetime risk of cardiovascular events far greater than that in the elderly.

Minority Groups

Blacks respond particularly well to diuretics and calcium channel blockers that should form the basis of drug therapy. However, there is evidence of preferential renal protection with drugs that block the renin-angiotensin system in Black patients with renal impairment.⁵¹ Individuals of South Asian origin are at high risk of the metabolic syndrome and require an aggressive multifactorial approach.⁶ In ethnic subgroups, socioeconomic and lifestyle factors may be barriers to acceptance of treatment. People from African and South Asian communities are less willing to accept the disease label of hypertension, and the cost of management can be a disincentive.

Resistant Hypertension

The guidelines do not deal adequately with the frequent clinical problem of the patient whose blood pressure falls short of the accepted target. More-complex treatment and specialist referral is suggested,^{1,3,56} without indicating how the specialist should deal with the issue.

SUMMARY

Current guidelines emphasize the importance of risk assessment in identifying individuals who merit antihypertensive treatment. Patients with established cardiovascular disease readily identify themselves to medical services, are at high risk, and gain considerable benefit from treatment. However, doctors are very poor at identifying high-risk individuals from clinical clues in the general “healthy” population, as can be seen from the continued failure to recognize and treat those at high risk.

A staged approach may be appropriate where resources are scarce. Priority is given to those with established vascular disease. Thereafter, intervention focuses on those with high cardiovascular risk, including patients with diabetes, target organ damage, and absolute cardiovascular risk above an agreed threshold.

Algorithms to initiate treatment on the basis of the level of risk rather than the level of blood pressure in individuals with the mildest hypertension represent an important new direction. This approach will require evaluation because it alters fundamentally the way in which doctors are encouraged to think about the treatment of hypertension. The future cannot be predicted with any real certainty for asymptomatic indi-

viduals. For 1000 persons with 20% cardiovascular risk, neither the 200 potential losers nor the 800 potential winners can be anticipated.

Short-term risk assessment favors treatment of older individuals, but older individuals without symptomatic disease can be classified among the winners, because they have tolerated risk factors for many years. Younger people with risk factors have relatively low short-term absolute risk yet stand to gain the most benefit in the long-term and are at increased risk of premature disease.

Costs of treatment are assuming greater importance as larger populations are being treated in healthcare systems that work within limited budgets. Even nonpharmacologic management may carry a heavy cost in advice and monitoring and may actually prove more expensive than drug therapy.⁵⁹ Thoughtful drug selection, even when the cost at first may seem painfully high, makes economic sense when compared with the expense of hospitalization or other major interventions for the serious consequences of inadequate management.

In developing countries, costs may make it difficult to afford diagnostic procedures and drug therapies. Some might be considered a luxury when healthcare systems are inadequate. For instance, countries in sub-Saharan Africa may spend only USD 10 per citizen annually on health. Despite those deficiencies, key recommendations of international guidelines^{1,3,5} are accepted. However, concepts such as prehypertension are of questionable significance when healthcare is tightly constrained. The obstacles facing practitioners in developing countries should not be underestimated. These challenges appear beyond the capacity of authors of international guidelines.

The impact of guidelines in changing practice has been small.⁶⁰ There is little evidence that clinical practice has improved based on guidelines that are widely acknowledged but largely ignored. Most practitioners can hardly keep pace with advances in healthcare. They would have to read 20 articles every day to maintain present knowledge.⁶¹ Although guidelines reduce the need to read original papers, it is still difficult to keep up.⁶² Even if practitioners are aware and willing, change is difficult, particularly if the environment is nonconducive to improving standards of care.

To date, it may be argued that the major beneficiaries of guidelines are their authors, administrators/managers, and lawyers. The authors gain prestige, administrators and managers gain control over practitioners, and lawyers can sue those who do not follow the guidelines. Benefits do not necessarily extend to clinicians or, most importantly, to patients.

Management guidelines presume a simple algorithm in which clinical evidence is distilled into guidelines that will filter down into clinical practice. However, the flow is unlikely to be successful without efforts to improve implementation. Traditional approaches have focused on improving availability and presentation by producing “glossy” summary guidelines, reviews in clinical journals, and continuing medical education (conferences). Practitioners value management guidelines but consider those available to be too scientific, excessively demanding on resources and of impractical complexity, of limited local applicability, and also having a short shelf-life. Revised guidelines may be published before the generalist has come to terms with the earlier version. Guidelines appear to be updated every few years to follow contemporary fashion rather than to reflect important new evidence. Often,

the data supporting the revision appear marginal at most and may simply reflect expert opinion qualified by prejudice.

In addressing the problems of implementation, most guidelines are long on rhetoric but short on practical advice. Various strategies are needed to target obstacles to change.^{63,64} Change in practice is only partially within the doctor’s control.

Hypertension guidelines are unlikely to be successful unless concerted efforts are made to address public health issues.⁷ The American Public Health Association has led the way in its resolution that food manufacturers and restaurants should reduce sodium in food by 50%. This important primary prevention initiative is endorsed by JNC 7¹ and echoed in other guidelines.^{3,5,6}

Current Prescribing Practices

J. Jaime Caro, Krista A. Payne

That clinical decisions should be rational and based on the best evidence possible is the keystone of modern scientific medicine. Finding reality wanting, however, opinion leaders have increasingly called for a more determined effort to ensure that actual practice meets this standard. Criteria that have been proposed for the selection of studies that will provide this evidence emphasize the randomized clinical trial as a gold standard.^{1,2} A physician faced with a common—and very well studied—condition such as hypertension is expected to turn to randomized trials (or corresponding meta-analyses), and the guidelines based on these, for information on which to base treatment choices.³⁻⁹

The sixth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI), published in 1997,³ recommended that a diuretic or β -blocker be selected as first line pharmacologic therapy in the absence of special patient characteristics that indicate use of a specific drug. Moreover, it was suggested that a series of steps be followed, including adding or switching medications, if the response to the initial treatment was insufficient.³ Published in December 2002, results of the landmark Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),¹⁰ the first and only trial to compare, longitudinally, three classes of antihypertensive drug therapies with conventional thiazide therapy, validated the recommendation to initiate antihypertensive therapy with older versus newer medications. More specifically, in a clinical trial of 33,357 patients over a mean follow-up period of 4.9 years, it was observed that although each class of medication substantially reduced blood pressure (BP) and served equally well to decrease the risk of combined fatal coronary heart disease (CHD) or nonfatal myocardial infarction (MI; the primary trial endpoint), thiazide-type diuretics, the least expensive of the antihypertensives, were superior to either angiotensin-converting enzyme (ACE) inhibitors or α -blockers in the prevention of one or more major forms of cardiovascular disease (CVD). Although these results appear to have achieved mainstream acceptance, many have publicly refuted these findings, citing design-related biases that may be associated with better outcomes for the diuretic group, an apparent lack of concern on the part of the ALLHAT investigators for the higher rate of diuretic-related adverse events observed in the trial and the potential long-term clinical and economic sequelae of these events.¹¹⁻¹⁴ Given the flurry of editorials and publications related to both the merits and weaknesses of ALLHAT, it is anticipated that debate will continue for quite some time. One wonders if the ALLHAT trial raises more questions than it answers.¹⁴

Primarily as a result of the ALLHAT trial¹⁰ and a published meta-analysis of clinical trials of antihypertensive treatments,¹⁵ a seventh set of guidelines by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) has been issued.¹⁶

Consequently, it is now recommended that pharmacologic treatment for uncomplicated hypertension *always* begin with a thiazide-type diuretic with the addition of a second drug from a different class if the BP goal is not achieved. Marking a major change from previous guidelines, β -blockers have now been relegated to second-line therapy. In contrast, the most recent set of European Society of Hypertension guidelines¹⁷ do not recommend a specific class of antihypertensive drug as first-line therapy for uncomplicated hypertension. These guidelines, instead, encourage the practitioner to consider, at his or her own discretion, each patient and his/her optimal therapy on a case-by-case basis.

Although it will take some time before the full impact of studies like the ALLHAT trial and recent guidelines on physician prescribing practices can be observed, in this chapter we review recent hypertension treatment patterns from actual practice in several countries and examine how they have accorded with earlier guidelines. We also provide comment on the generalizability of clinical trial results, the gold standard upon which treatment guidelines are based, to the real world and reasons to start treatment for uncomplicated hypertension with drugs other than diuretics or β -blockers (in this chapter, referred to as *group 1* to connote “older” drugs). Only data from articles published since 1988 are included.

INITIAL TREATMENT CHOICES

United States

In the United States, antihypertensive treatment practice appears quite varied. For example, in a study of 377 newly diagnosed patients carried out in the Midwest over an 18-month period (1991-1992),¹⁸ 55% received monotherapy, but only about a third started on a diuretic or β -blocker. The most common initial therapy was a calcium channel blocker given to 30%, followed by an ACE inhibitor in 22%. Sequential monotherapy was used in 18% of the patients, and stepped therapy (with more than one class of drug given at some point) in 22%; 5% were started on more than one drug. The picture was very different in patients beginning antihypertensive therapy who were part of a cohort of approximately 1700 patients examined annually between 1989 and 1993.¹⁹ Consistently, about half started with regimens that incorporated a group 1 drug (55% of the 157 patients seen in 1989-1991; 49% of the 142 seen in 1990-1992; and 56% of the 120 seen in 1991-1993). Calcium channel blockers slightly led ACE inhibitors among the rest.

In contrast to these studies of actual practice, surveys of U.S. physicians find that they report much greater adherence to published treatment guidelines. For example, 69% of 128 family physicians and primary care internists in Iowa in 1988 reported choosing a group 1 drug as initial therapy for

patients younger than 40 years of age.²⁰ Most of the rest (27%) would choose an ACE inhibitor. Similar results were obtained for older patients in a survey of more than 1000 New Jersey physicians in 1985: 78% reported choosing a group 1 drug as the initial treatment for patients older than 60 years with isolated systolic hypertension (ISH).²¹ Even greater adherence to official guidelines was reported in a survey of 274 physicians in Minnesota in 1987,²² where 91% stated that a group 1 drug was their first choice of medication.

Factors such as age and gender of the patient can influence the choice of antihypertensive treatment in the United States. Among 183 Minnesota physicians surveyed about initial therapy in 1992,²³ no drug class predominated as first choice, but group 1 drugs were more frequently selected for a 48-year-old man (30%) than for a 65-year-old (25%). Choice of a calcium channel blocker was much less common for the younger man (16% vs. 36%), whereas ACE inhibitors were more common (44% vs. 37%). For older women, however, the preferences were evenly distributed.

Studies have revealed changes in the level of adherence to the guidelines over time. A review of 8428 people aged 65 years and older, whose records were in the New Jersey Medicaid and Medicare databases from 1982 to 1988, found that the proportion starting treatment with a group 1 drug dropped from about 70% to 45%—most of the decline occurring in diuretic prescriptions.²⁴ Use of a calcium channel blocker increased from 7% to 28%, and of an ACE inhibitor from 0.3% to 16%, during the same 6-year period. Diuretic use was more common in patients older than 85 years, women, and African Americans.

Similar declines in preference for group 1 drugs were found among 241 primary care physicians in the Midwest surveyed in 1987 and again in 1989²⁵—from 90% to 62%. In the latter survey, 30% chose an ACE inhibitor and the rest, a calcium channel blocker or other class. Physicians were also asked for their preferences for a group 2 medication. In 1987, 84% stayed within group 1, whereas only 60% did so by 1989, with ACE inhibitors chosen by about one quarter of physicians.

In a structured care setting, changes in preferences appear to parallel treatment guidelines more closely. This is evident in a study of 550 union members during the first year of a union-sponsored hypertension screening and follow-up program carried out between 1986 and 1992.²⁶ In the period before JNC IV guidelines, physicians treated 87% of their patients with group 1 drugs. After JNC IV (which recommended all four classes), 90% of patients were started with a calcium channel blocker or an ACE inhibitor, whereas publication of JNC V (which recommended group 1 drugs for initial treatment) saw practice even out to about 25% for each major class.

Canada

Evidence from Canada also reveals much variation in antihypertensive prescribing practices and a tendency to disregard practice guidelines. In a review of the medical records of 711 newly diagnosed hypertensive patients seen in Edmonton, Alberta, between 1993 and 1995,²⁷ less than one third (31%) of those receiving medicines (531) were started on a group 1 drug. This remained less than 50% even when patients with a documented contraindication to one of these drugs were excluded. ACE inhibitors were the most common first choice (44%), whereas only 23% used a calcium channel blocker.

These prescribing patterns were reported to be very similar among physicians in many different types of practice. However, family physicians were found to choose the recommended classes of medication more often than did internists.

In a study of the records of more than 27,000 new patients in the neighboring province of Saskatchewan, carried out from 1990 through 1994,²⁸ nearly half (48%) were found to have started on a group 1 drug. Indeed, among the 24 different drugs prescribed initially to at least 100 patients each, the combination of triamterene and hydrochlorothiazide in a single tablet was more than three times more common than any given ACE inhibitor or calcium channel blocker. ACE inhibitors, however, were the second most frequent initial drug class, whereas only 13% of new patients began on a calcium channel blocker. The initial choice of drug among new patients varied according to the age and gender of the patient (Table 37-1). In females and older males, group 1 drugs remained the most common choice, with diuretics predominating. By contrast, in younger men, an ACE inhibitor was as common as a group 1 drug. Although choice of a β -blocker was infrequent in all groups, it was relatively more common in younger patients.

There was little variation over the 5 years of the study, however, with group 1 drugs consistently representing the initial choice in about 45% of new patients. ACE inhibitors also remained the second most common initial choice throughout the study period. Use of calcium channel blockers, other single drugs, combination drugs, and multiple drugs also remained stable during the study period.

These data on actual practice confirm the results of a Canadian survey of physicians' preferences in the province of Alberta in 1995.²⁹ In that study, physicians were asked for their choice of initial therapy for several hypothetical cases. In the case of a lower-risk patient, group 1 drugs were prescribed by 44% of physicians, ACE inhibitors by 46%, and calcium channel blockers by 5%. As risk factors increased, group 1 drugs dropped to 20%, ACE inhibitors increased to 67%, and calcium channel blockers increased to 10%. Only in the case of a patient with target organ damage, left ventricular hypertrophy (LVH), and previous MI did the preference shift to group 1 drugs (62%), primary β -blockers (56%).

The choice of medication can vary, as expected, with the clinical condition.³⁰ When ISH was the issue, the majority of 281 physicians surveyed in 1995 in Edmonton, Alberta, reported their choice of antihypertensive treatment to be a diuretic—74% among internists and 58% among family physicians; only 10% of internists and 26% of family physicians would choose an ACE inhibitor first in this situation.

New Zealand

Physicians in New Zealand also reported less preference for group 1 drugs. In a 1992 survey of 100 physicians, only 48% would choose a group 1 drug for a 60-year-old man with essential hypertension and no contraindications.³¹ Most of the remainder (39%) would choose an ACE inhibitor (9% chose a calcium channel blocker).

Actual practice data do not clearly address the issue of initial treatment choices, because they do not distinguish between new and established patients. For example, a 1988 survey of 37 general practitioners that included information on 2 months of prescriptions³² found that nearly half of patients (44%) were receiving more than one drug. Thus,

Table 37-1 Distribution of Initial Drug Regimens in Newly Diagnosed Hypertensives*

Drug Class	Male (%)		Female (%)		Overall (%) (n = 27,364)
	Younger than 60 years (n = 5262)	60+ years (n = 6653)	Younger than 60 years (n = 6046)	60+ years (n=9403)	
Diuretics	23	36	41	45	38
β-Blockers	15	8	13	8	10
ACE inhibitors	38	28	25	25	29
Calcium channel blockers	14	16	11	13	13
Other single agent	3	4	5	3	4
Combinations	3	3	3	2	3
Multiples	4	5	3	4	4

*Differences in distribution within gender and age group $p < .001$.

although diuretics were used in 47% and β-blockers in 48%, it is uncertain what their first prescription was. This problem applies as well to surveys in 1982 and 1987,³³ in which the use of diuretics was high initially but dropped between surveys (64%-47%), whereas β-blocker use remained constant (52%-55%), and use of calcium channel blockers (3%-13%) and ACE inhibitors increased (0%-13%).

United Kingdom

In the United Kingdom, actual practice has conformed to guidelines—at least, according to surveys of physicians' opinions. In one survey of 360 general practitioners in Leicestershire, England, in 1991,³⁴ 62% reported they would start treatment with a thiazide diuretic in a 70-year-old hypertensive patient without target organ damage. Among the remainder, 17% reported they would use nonpharmacologic treatment. Another survey of 200 physicians in England (East Anglia) in 1993 found similar results: 85% of the respondents indicated that in the absence of contraindications, they would start therapy with a group 1 drug—nearly two thirds of these with a diuretic. Only 10% chose an ACE inhibitor and 5% a calcium channel blocker.³⁵ The tendency to favor a diuretic was even more pronounced among 92 physicians surveyed in Northamptonshire in 1993³⁶: 83% reported that a thiazide diuretic would be their initial choice for a 70-year-old patient with no end-organ damage; another 5% reported choosing a β-blocker first.

Although there are some differences according to the type of physician, the preference for group 1 drugs persists. For example, a 1992 survey of 214 general practitioners and 127 hospital physicians in the northern region of England found that the former would choose a group 1 drug for an otherwise well, 75-year-old male nonsmoker 79% of the time, whereas the latter would do so only 62% of the time.³⁷ For the remainder, the split was similar, with a calcium channel blocker chosen almost three times as often as an ACE inhibitor.

These reported preferences for group 1 drugs are supported by actual practice data, although they are not specific to new patients. In a review of the database records of more than 37,000 hypertensive patients seen in 1992 to 1993, new courses of treatment were analyzed.³⁸ Among the 10,222

patients starting a new type of treatment, 86% received a group 1 drug, 32% a calcium channel blocker, and 27% an ACE inhibitor. The numbers add to more than 100%, because more than a third of patients received multiple new drugs.

Australia

Survey data published in 1992 on 132 randomly selected general practitioners in South Australia indicate similarly high adherence to the guidelines: About three quarters would choose a group 1 drug for treating an uncomplicated moderately hypertensive patient.³⁹ Although this preference varied little with the age of the hypothetical patient, the balance between diuretics and β-blockers did. In a 75-year-old patient, the diuretics were heavily favored (68% vs. 9%) compared with a more even distribution for a 45-year-old patient (41% vs. 31%). Most of the physicians surveyed in Australia (80%) also indicated that if they failed to achieve control with the initial therapy, they would add another drug rather than switch therapies.

These reported preferences differ from the findings of an analysis over an 11-year period of the Commonwealth Department of Community Services and Health database, which covers 80% of community prescriptions (not including hospital dispensings or those paid by private insurance). According to these data, the use of diuretics decreased by nearly one third from 1982 to 1987, whereas the use of ACE inhibitors increased dramatically.⁴⁰ Unfortunately, as in the United Kingdom, the analysis did not distinguish new from established patients, and thus it is impossible to say whether this change in prescription patterns reflects a shift in the choice of initial medication or in the drugs used subsequently.

In an analysis of the Australian Pharmaceutical Benefits Scheme (PBS) and Repatriation Pharmaceutical Benefits Scheme (RPBS) data from 1994 to 1998, it was observed that in 1998, the most frequently prescribed antihypertensive medications were those acting on the renin-angiotensin system (RAS), followed by calcium channel blockers, and then group 1 drugs.⁴¹ Results show a trend of decreasing rates of prescriptions to group 1 medications over this 5-year period, and the opposite for RAS agents and calcium channel blockers. Authors also note

that this lack of adherence to guidelines has cost the Australian government \$1.45 million annually due to the significantly higher cost of the newer medications.

Germany

Physicians in Germany also reported remarkable adherence to published guidelines in the choice of initial therapy. In a 1988 survey of 315 general practitioners, 93% reported choosing a group 1 drug for a 45-year-old man; in contrast to the United Kingdom and Australia, nearly all (92%) would select a β -blocker.⁴² Only 3% chose a calcium channel blocker and 1% an ACE inhibitor. For a 65-year-old man, a group 1 drug was chosen 71% of the time; most, however, chose a diuretic. A calcium channel blocker was chosen by 21%; an ACE inhibitor by 2%. The overall pattern of prescribing was very similar for internists and was not affected by the physician's age.

Again, these reported preferences are somewhat at odds with actual data—this time gathered in the Monitoring of Trends and Determinants of Cardiovascular Disease (MONICA) Augsburg project, which surveyed 3324 hypertensive men and women in 1984 to 1985 and again in 1987 to 1988.⁴³ There were 167 patients treated for hypertension in the second survey who were untreated in the first. Although these patients were considered “newly treated” by the authors, it is unlikely that the prescription information obtained consistently represented the first medication used. Thus, by the time they were surveyed, only 25% of these patients were on a β -blocker and just as many were on triple-agent therapy. Among men, calcium channel blockers, singly or in combination with another agent, accounted for one third of prescriptions, whereas among women, diuretics and diuretic combinations accounted for one third of prescriptions reported.

Sweden

β -Blockers were reported to be the favorite in a survey of 126 general practitioners and specialists in the Uppsala-Orebro region in 1991.⁴⁴ The physicians were asked for their first choice of therapy for each of six hypothetical hypertensive patients. For a healthy, nonsmoking, 44-year-old man with a family history of diabetes and BP of 180/100 mm Hg, 40% indicated that they would choose a β -blocker, whereas less than 1% chose a diuretic. ACE inhibitors were the second most common choice (24%), but more so among specialists (34% vs. 18%). Calcium channel blockers were the choice of 18%, and 17% would not choose pharmacotherapy. In only two of the six hypothetical cases did diuretics account for more than 10% of the choices, and neither of these was a new patient.

This preference for β -blockers was reported to be even stronger in a 1991 survey of 236 physicians.²³ For an otherwise healthy 48-year-old man, 72% chose a β -blocker. The preference for a β -blocker was less pronounced for older patients and women: 57% of physicians chose a β -blocker for a 65-year-old man, but only 52% did for a 65-year-old woman. Preference for diuretics increased from less than 5% for a 48-year-old man to 20% for a 65-year-old man and 27% for older women. Physicians were surveyed about the hypothetical 48-year-old man again in 1993, and treatment preferences were found to have changed little.⁴⁵

More data from Swedish actual practice⁴⁶ reveal that from 1981 to 1998 in patients who attended their annual follow-up visit to an outpatient hypertension clinic, rates of prescriptions of thiazides declined from 61% to 10%, whereas prescriptions of calcium channel blockers increased from 4% to 30% and ACE inhibitors from 0% to 23%. It was also reported that prescriptions of both calcium channel blockers and ACE inhibitors increased during 1990 to 1995, but that the former decreased significantly from 1996 to 1998 when concerns related to their safety emerged.

Norway

Preferences for β -blockers did not hold in Norway. A 1989 survey of 235 Oslo physicians found that 51% would choose diuretics for an asymptomatic 75-year-old hypertensive man⁴⁷; calcium channel blockers were a second choice at 25%. ACE inhibitors accounted for only 13%, and β -blockers and others accounted for the remaining 11%. Physicians older than 50 years of age were more apt to prescribe a diuretic, whereas a calcium channel blocker was more commonly chosen by physicians younger than age 40 years and by specialists. Female physicians were significantly less apt to choose an ACE inhibitor than were males.

Italy

A physician preference for newer antihypertensive medications instead of group 1 drugs was observed in an Italian database analysis of data from 5061 elderly patients with hypertension from 1988 to 1997.⁴⁸ Group 1 drugs were prescribed to a minority of patients despite a significant increase in their use over time. ACE inhibitor prescriptions also increased over time and by 1997 became the most common class of antihypertensive prescribed (50%). With respect to diuretics, their use dipped between 1988 (3%) and 1991 (3%) following publication of the JNC IV guidelines,⁴⁹ but over time reached rates of 4% in 1997, second only to ACE inhibitors. According to these authors, evidence-based medicine has had little impact on the hypertension management practices of Italian physicians.

India

Two studies conducted in India^{50,51} suggest that physician practice is more in accord with guideline recommendations than most other countries. In the first,⁵⁰ survey data of 1076 prescriptions written to patients attending an outpatient hypertension clinic (validated by medical records and patient interviews) revealed that β -blockers were the most frequently prescribed (51%), followed by calcium channel blockers (47%), and ACE inhibitors (46%). This study did not differentiate between patients with new versus chronic hypertension nor single and combination therapies.

The same pattern emerged in a second study⁵¹ of 300 patients attending an internal medicine clinic: β -Blockers were the most frequently prescribed (46.7%), followed by calcium channel blockers (34.3%), and then ACE inhibitors (30%). Diuretics were prescribed only 13.2% of the time, which prompted a call by the authors for more frequent use of these agents given their low relative cost.

Other Countries

Marked differences between countries were reported in a 1992 survey of general practitioners in Indonesia, Italy, United Kingdom, Croatia, Panama, France, and Belgium (each represented by at least 18 physicians).⁵² Asked for their first choice for treating mild hypertension in the absence of contraindications, 63% of Italian physicians and 93% of Croatian physicians chose diuretics, compared with Indonesia and Belgium, where 40% and 94%, respectively, chose β -blockers.

EFFECTS OF INITIAL TREATMENT CHOICES

The recommendations to choose group 1 drugs as initial therapy depend, at least in part, on two key assumptions: One is that at the start of therapy there is *no reason to expect that any one therapy will do better than others*. The second is that the initial treatment choice is not so important because, if it is not successful, changes can be made to optimize the regimen for a given patient and these *modifications will have no detrimental effects*. If these two assumptions hold, it makes sense to choose a drug from a class proven to reduce cardiovascular risk and with a lower acquisition cost. If they prove untenable, however, the appropriate first choice might turn out to be quite different. This might be the case if the likelihood of patients remaining compliant—and, thus, benefiting from treatment—differs according to the class of drug chosen initially. This could happen if the side effect profile of a class were less well tolerated by patients who, in the context of an otherwise asymptomatic condition, tend to stop treatment or if the therapeutic “turbulence” generated by changes in the regimen to deal with side effects or to achieve BP control bothers the patient in excess of the perceived benefits. The patient may ask, why put up with what appears to be troublesome trial and error to treat a condition with nebulous menace?

The assumptions underlying the choice of group 1 drugs as initial therapy for uncomplicated hypertension may seem reasonable to the physician, but they have been implemented virtually without testing in routine actual practice. The evidence for equivalent expectations has been based on controlled clinical trials and the evidence that treatment modifications, or therapeutic turbulence, will have no detrimental effects is actually quite scant. Even clinical trials as high profile as the ALLHAT study, which was designed to assess efficacy, are unable to address these assumptions because the very procedures implemented to ensure valid efficacy data so alter compliance that the trial no longer reflects true routine practice.

The essence of these two assumptions—that the drug classes are equivalent in the proportion of patients who can be expected to stay on therapy and thus achieve BP control—was tested in a study using the healthcare databases of Saskatchewan.^{28,53} Saskatchewan Health funds the healthcare system of the province, including a prescription drug plan.⁵⁴ The records were examined of 27,364 Saskatchewan residents with a diagnosis of essential hypertension who received at least one antihypertensive agent listed in the Saskatchewan formulary between November 1, 1989, and December 31, 1994, but had no record of treatment in the preceding year. Men and women older than age 40 years without a diagnosis

of malignant hypertension of hepatic, renal, or cardiovascular diseases other than hypertension were eligible.

The outpatient prescription drug plan database yielded all dispensings of an antihypertensive drug identified by its generic name, as well as the dispensing date, quantity, strength, and drug form. The database did not include information on the actual prescription nor on BP. A patient was considered persistent with therapy if it was estimated, based on a priori algorithm used to assess the dispensing records that he or she still had antihypertensive medication to take on the last day of follow-up. Whether the patient actually took the medication, or if it had been discontinued following physician's advice, could not be determined.

Persistence was analyzed for the 22,918 patients who were observed in the database for at least 6 months and who began treatment with one of the four major classes of medication. Almost one quarter of patients had discontinued all antihypertensive therapy within a year of starting it. The rate of persistence varied with class of drug: 74% of patients who started treatment with a diuretic were persistent at 1 year; the persistence rate among patients starting on a β -blocker was 78%, 81% for those starting on a calcium channel blocker, and 84% for those starting on an ACE inhibitor. At 2 years, persistence rates were even lower: 64% for a diuretic, 69% for a β -blocker, 71% for a calcium channel blocker, and 74% for an ACE inhibitor. Four years after starting antihypertensive therapy, only 46% of those starting on a diuretic were still on antihypertensive therapy; this figure was 54% for a β -blocker, 53% for a calcium channel blocker, and 58% for an ACE inhibitor. The increased persistence over time associated with ACE inhibitors compared with group 1 drugs remains significant, even when controlling for differences in age, gender, and use of healthcare resources in the prior year.

A higher frequency of changes in the therapeutic regimen was also significantly associated with decreasing persistence in each of the first 3 years of therapy ($p = .05$). For example, subjects who had two or more changes to their therapeutic regimen in any 6-month interval were 25% less likely to persist with medication in the next 6 months, and even a single change decreased persistence by 7%. These data indicate that the choice of first antihypertensive agent is an important determinant of the likelihood that the patient will continue with therapy.

These results from actual practice have been replicated. A comprehensive review that included the Saskatchewan analyses⁵³ and other similar database studies revealed that *all* studies of initial hypertension treatment in newly diagnosed patients reported very poor adherence in actual practice with observed rates of nonadherence ranging from 12% to 57% depending on the definition of nonadherence and time horizon employed.⁵⁵ It was also evident from this same review that initial treatment with newer classes of drugs in newly diagnosed hypertension patients was a significant factor favoring treatment adherence. More specifically, when the results by initial drug class for each of the 10 studies reviewed were rank ordered (i.e., lowest to highest rate of nonadherence), the following pattern emerged without exception: Adherence in the first year was greatest for patients initially prescribed ACE inhibitors, followed in descending order by those treated with calcium channel blockers, β -blockers, and diuretics. Results of more actual practice database studies, which include adherence profiles for the newest class of antihypertensives, the

angiotensin II (Ang II) receptor antagonists, are consistent with earlier studies and reveal even higher rates of persistence for this class.⁵⁶⁻⁵⁹

The interpretation of these persistence data from actual practice has been hotly debated, with critics citing selection bias and effective marketing as factors to explain the observed results.^{60,61} Although it is not possible to determine the validity of these arguments, in light of the international scope and replicability of these studies, at the very least this evidence from actual practice should not so easily be dismissed. The underlying premise of therapeutic guidelines, which suggests that drug classes are equivalent in terms of *effectiveness* outcomes and that changes in medication can be made without detriment, therefore, must be questioned. Evidence from actual practice also suggests that side effects associated with diuretics and other older drugs can lead to therapeutic inefficiency and nonpersistence, which dramatically diminish differences in treatment costs between older and newer agents.⁶² The issue is not that observational data should replace data from clinical trials, but simply that results from studies in actual practice are also worth considering when weighing all of the evidence for the selection of a first-line therapy.⁶⁰ Curiously, neither JNC VI nor 7 make reference to this growing volume of data from actual practice.^{3,17}

SUMMARY

When physicians are surveyed about their hypertension treatment practices, adherence to guidelines is typically reported. Consistently, however, data from actual practice in numerous countries with diverse healthcare systems reveal that drugs other than diuretics or β -blockers are nevertheless being prescribed as first-line therapy in the majority of newly diagnosed cases of elevated BP. Whereas in some countries, such as Germany, India, and the United Kingdom, a diuretic or β -blocker is frequently used; an ACE inhibitor or calcium channel blocker is more common in others (United States, Canada, Sweden, and Italy). The choice of initial medication for treatment of hypertension in actual practice varies by country and by practitioner.

Although a general discussion of the full range of possible reasons why physicians do not adhere to guidelines is outside of the scope of this chapter,⁶³⁻⁶⁵ some potential guideline-related barriers to such adherence have been hypothesized.⁶⁴ In a published critique of three current guidelines for hypertension treatment,^{3,4,65} numerous shortcomings are highlighted that could account for the limited impact on physician practice that has been observed. The most significant of these reported were dissidence among guidelines, failure to address clinically relevant issues, format deficiencies, lack of implementation strategies, poor methodologic quality, and failure to incorporate patient-clinician values.

Generally, for patients without comorbidities, known drug sensitivity, or other factors that drive the decision, results from key clinical trials¹⁰ and current guidelines suggest that treatment be started with a diuretic and that changes be made thereafter as needed. Data from actual practice studies, such as the Saskatchewan analysis,^{28,53} indicate that there may be disadvantages to this process.⁵⁵ Although the interpretation of these data have been debated^{60,61} and largely excluded from the pool of evidence drawn upon for the creation of treatment

guidelines, physicians, nevertheless, should weigh all the evidence. An increased probability of achieving BP control by ensuring that patients remain on medication could justify the initial choice of one of the newer agents, such as an ACE inhibitor Ang II receptor blocker.

Calcium Channel Blockers: Controversies, Lessons, and Outcomes

Lionel H. Opie

Calcium channel blockers (CCBs) are powerful antihypertensive agents. Until relatively recently, however, there have been no trials showing long-term efficacy and safety of CCBs in reducing outcome measures such as stroke and heart disease. Efficacy of any group of drugs does not necessarily equal safety. The latter may be defined as the absence of significant adverse effects when the drug is used with due regard for its known contraindications.¹ In the case of CCBs, concerns have been expressed that these agents may have inherent safety problems, such as increases in myocardial infarction (MI), cancer, and gastrointestinal bleeding. The latter two fears have largely been discounted,¹ but the possible relationship of CCB use to acute myocardial infarction (AMI) has remained controversial² until recently. Results of three medium-sized (between 1000 and 10,000 participants) randomized controlled trials, STOP-2,³ NORDIL,⁴ and INSIGHT,⁵ and three mega-trials, ALLHAT, CONVINCENCE, and INVEST (Table 38–1), have swollen the total number of subjects persons studied to more than 100,000 to allow an objective reappraisal of the role of CCBs in hypertension therapy based on solid trial data in more than 100,000 hypertensives. These extensive trial data weaken the conclusions of an earlier negative meta-analysis.⁶ As summarized in Table 38–2, AMI is not increased with CCB treatment.⁷ This chapter reevaluates the safety and efficacy of CCBs as antihypertensives with special emphasis on the randomized controlled trials and updates the information in the author's previous meta-analysis⁸ and review.⁹

HISTORICAL BACKGROUND TO CONTROVERSY

CCBs were initially hailed as very effective antianginal agents at a time when the coronary spasm theory of unstable angina held sway. The HINT (Holland Inter-university Nifedipine Trial) study was one of the first to test the safety and efficacy of a CCB in this condition.¹⁰ Patients with unstable angina were allocated to one of several groups: placebo, CCB (short-acting nifedipine), β -blocker (metoprolol), or the combination (nifedipine plus metoprolol). The trial was stopped because nifedipine capsules doubled the rate of AMI within 48 hours of beginning therapy, the mechanism presumably being adrenergic activation because the addition of the CCB to preexisting β -blocker therapy gave benefit. By combining a number of trials using very high doses of short-acting nifedipine given to patients with largely unstable coronary disease, Furberg linked use of this agent to increased mortality in a widely cited meta-analysis.¹¹ Although his results have been

disputed by many, including myself and Messerli,¹² and although there were serious errors in the calculations, nonetheless Furberg correctly pointed out the need for large randomized controlled trials with the CCBs. In the case of hypertension, many adequate trials have now been undertaken, all with long-acting rather than short-acting CCBs, which is important because sustained blood levels of an antihypertensive agent are required for maximal antihypertensive effects over 24 hours. The results of these trials indicate that CCBs can be used in hypertension with reductions in cardiovascular mortality similar to those with conventional agents such as diuretics and β -blockers, and without evidence of increased cardiovascular risk (see Table 38–1). Going back to 1995,¹³ observational studies have pointed to potential negative effects of CCBs, specifically the short-acting dihydropyridines (DHPs). The claimed adverse events included increased mortality, cardiovascular events, gastrointestinal bleeding, and cancer. These have often been reported in major U.S. newspapers, magazines, and even leading medical journals. Many other articles denied these claims. The result has been confusion that should now be dispelled by outcome and safety data on more than 100,000 patients. This chapter evaluates the controversies, the lessons that can be learned, and the outcomes.

CONTROVERSY 1: DO CALCIUM CHANNEL BLOCKERS DECREASE MORTALITY IN HYPERTENSION?

To achieve a decrease in mortality with any antihypertensive requires either a very large trial, a very high-risk population, or a meta-analysis of several trials.¹⁴ A number of nonrandomized cohort studies, available in the year 2000, tested the hypothesis that CCB therapy could increase mortality.¹ There was suggestive evidence for a mortality increase related to short-acting agents, chiefly nifedipine. However, in 13 placebo-controlled trials, there was a trend to reduced mortality rates. Currently there is much stronger evidence for the hypothesis that CCBs can reduce mortality in hypertension. Proof of this supposition comes from four trials—STOP-2,³ NORDIL,⁴ INSIGHT,⁵ and ALLHAT¹⁵ (see Table 38–1). In each case, the mortality in the CCB group equaled that of conventional therapy. When considering the elderly population, in the only trial that gave a clear-cut mortality reduction vs. placebo,¹⁶ two thirds of the patients received combined β -blocker plus diuretic therapy after starting on one of these agents. The conventional therapy group in STOP-2 and NORDIL was similarly treated. In INSIGHT and ALLHAT, the CCB group gave similar mortality results to diuretic-based therapy. If conventional antihypertensive therapy reduces mortality,¹⁶ then CCBs do likewise.

Table 38-1 Key Features of Recent Large Outcome Trials, Each in More than 10,000 Persons, Comparing Calcium Channel Blockers (CCBs) with Other Agents in 82,355 Hypertensives

	ALLHAT ¹⁵	CONVINCE ⁴⁹	INVEST ⁴⁰	ASCOT ⁵⁰
Comparators	CCB (amlodipine); diuretic	CCB (verapamil); diuretic or β -B	CCB (verapamil \pm ACEi); β -B \pm diuretic	CCB (amlodipine \pm ACEi); β -B \pm diuretic
Numbers in trial, CCBs vs. non-CCBs	9048; 15,255 respectively	8179; 8297 respectively	11,267; 11,309 respectively	>19,000
Mean age at start	67 years	66 years	66 years	To come
Trial design	Double-blind, randomized	Double-blind, randomized	PROBE, randomized open; blinded for endpoint	PROBE; randomized open; blinded for endpoint
Strong points of study	Patients at high risk for MI	Older than 55 years, high risk including obesity	100% of patients had CAD	1, 2, and 3 endpoints; event driven
Weak points of study	Low initial BP; practice-based endpoints	Stopped after 3 years instead of planned 5	Not blinded for drugs	Not blinded for drugs
Mean initial BP	146/84 mm Hg	150/87 mm Hg;	150/86 mm Hg;	Not known
Mean final BP	135/75 mm Hg; 134/75 mm Hg;	137/79; mm Hg; 137/78 mm Hg;	131/76 mm Hg;	Not known
Duration (approximate)	4 to 8 years	5 years; forced early stop	Mean, 2.7 years	Up to 5 years
Primary endpoint(s)	Combined fatal CHD or nonfatal MI	Nonfatal MI, nonfatal stroke, CV-related death	All cause mortality, nonfatal MI, nonfatal stroke	Nonfatal MI, fatal CHF
Major results	Similar	Similar	Similar	Not known

ALLHAT, Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial; CONVINCE, Controlled Onset Verapamil Investigation of Cardiovascular Endpoints; INVEST, International Verapamil SR/Trandolapril Study; ASCOT, Anglo-Saxon Cardiac Outcomes Trial; β -B, beta-blocker; MI, myocardial infarction; BP, blood pressure; CAD, coronary artery disease; CHD, coronary heart disease; CV, cardiovascular.

CONTROVERSY 2: ARE CALCIUM CHANNEL BLOCKERS SAFE?

In a comprehensive review of 100 studies available in the year 2000, the safety and efficacy of CCBs were evaluated in evidence coming from a variety of types of studies, including case series, case control studies, cohort studies (both prospective and retrospective), randomized controlled trials, and meta-analyses.¹ Eighty-four of these studies gave enough detail to allow evaluation of adverse or beneficial effects. Of these, 25 studies claimed adverse effects, 37 studies showed a lack of adverse effects, and 22 showed beneficial effects. Two additional epidemiologic studies, one with 3511 participants followed for 6 years¹⁷ and the other with 11,663 participants followed for 16 years,¹⁸ showed no impact of CCBs on cancer. In the case of hypertensives treated with CCBs, data from randomized controlled trials show no increase in AMI, cancer, GI bleeding, or depression. Only increased heart failure remains a problem, as will be discussed.

Overall safety does not mean that CCBs can be used with impunity. Clear contraindications such as the use of dihydropyridines (DHPs) without β -blockers in acute coronary

syndromes (unstable angina), cannot be ignored. In the case of the non-DHPs, sinus bradycardia and/or an excessively prolonged PR-interval are relative contraindications, and combined therapy with β -blockers is generally contraindicated.

LESSONS FROM META-ANALYSES

Blood Pressure Lowering Treatment Trialists' Collaboration (BPLTTC)

This meta-analysis compared results of treatment with different antihypertensives in 162,341 patients in 29 trials (see Table 38-2).⁷ Trials comparing ACE inhibitors and CCBs with placebo, included much smaller numbers: 18,229 in five ACE inhibitor trials and only 6656 in four CCB trials. Nevertheless, this analysis provides strong evidence of benefits of each type of drug on stroke and major cardiovascular events, including coronary heart disease (CHD). When compared with placebo, CCBs reduced stroke by 38% (confidence intervals [CI], 0.47-0.82), and major cardiovascular events by 18% (CI, 0.71-0.93). Furthermore, CCBs, when compared

with “conventional” (diuretic- or β -blocker-based) therapy, gave the same incidence of coronary mortality, cardiovascular death, and total mortality. However, as will be discussed, heart failure increased by 33% (CI, 1.21-1.47) with CCB treatment. The specific virtue of this meta-analysis is that it was prospectively started in 1995 by the principal investigators of the major trials then in progress. This procedure avoided one of the major problems of a retrospective meta-analysis, namely selection bias, resulting from the subjective judgment of which trials to include and which to exclude. This study also has the support of the World Health Organization–International Society of Hypertension. The major defect of the analysis is the grouping together of trials with totally different cardiovascular inclusion criteria, for example hypertension and coronary artery disease or diabetic nephropathy. This incongruity does not affect the comparison of CCBs with conventional agents in hypertension.

Pahor-Furberg Meta-Analysis

The Pahor-Furberg meta-analysis of 27,743 individuals in nine trials compares longer acting CCBs with all other antihypertensive drugs, not only in the three major trials shown in Table 38–1, but also in several smaller trials.⁶ Strength of this analysis include its comprehensive nature and the viewpoint

of a group experienced in meta-analytic techniques. Several important points emerge. First, this meta-analysis agrees with that of the BPLTTC in that CCBs as a group do not alter total mortality when compared with other agents (see Table 38–2). This conclusion is in contrast to the influential meta-analysis of Furberg in 1995 that linked short-acting nifedipine to increased mortality in patients with CHD.¹¹ Second, when compared with all other agents, including ACE inhibitors, CCBs give a 26% (CI, 1.11-1.43) increase in AMI and very similar increase in heart failure.

There are also some problems with this meta-analysis. The first, as in any other retrospective study, is the difficulty of eliminating selection bias. Second, as Psaty and Furberg emphasize elsewhere,¹⁹ the quality of a meta-analysis critically depends on the quality of the studies deemed to be eligible for that meta-analysis. “Trials with major design flaws carry little or no weight.” If the major issue is the effect of different anti-hypertensives on outcome measures, then it is crucial that these should be clearly defined. In STOP-2,³ NORDIL,⁴ and INSIGHT⁵ there were exact and detailed definitions of stroke, AMI, and heart failure. In INSIGHT, an independent critical events committee assessed all endpoints according to prespecified criteria. These therefore become the major studies, constituting a total of 21,611 patients versus 27,743 in the Pahor meta-analysis. The minor studies included by Pahor⁶ cover

Table 38–2 Major Differences Between Four Meta-Analyses Comparing Calcium Channel Blockers (CCBs) with Other Therapies in Hypertension

	Pahor et al., 2000 ⁶	Opie and Schall, 2002 ⁸	BPLTTC, 2003 ⁷	Staessen, 2003 ²⁴
Authors	Seven academics from three U.S. universities	Dual authorship	Committee of 48 under the aegis of the WHO-International Society of Hypertension	Three academics from one Belgian center
Type of study	Retrospective	Retrospective	Prospective	Retrospective
Entry point	All trials on hypertension meeting criteria	All high-quality trials on hypertension	All trials from initiation of study	All BP-lowering trials with no heart failure at start
Comparators	All non-CCB results taken together	CCBs with conventional; separate comparison with ACEi in diabetics	Separate comparisons of CCBs with placebo, conventional therapy, and ACEi	New (CCBs, ACEi or ARB) vs. old drugs (diuretics, β -blockers)
Number of trials	9	6	18	7
CCB numbers in study	12,699 vs. non-CCBs	12,116 CCBs vs. conventional; 1965 vs. ACEi in diabetics	31,031 CCBs vs. conventional; 12,541 CCBs vs. ACEi	32,864 CCBs vs. conventional
Major result	Mortality unchanged	Mortality unchanged	Mortality unchanged	Mortality unchanged
CV outcomes vs. conventional	\uparrow MI 26% (CI = 1.11-1.43); \uparrow CHF 25% (CI = 1.07-1.46); stroke unchanged	\downarrow stroke 12.7% (CI = 0.77-0.99); \uparrow MI 18% (CI = 1.04-1.35); NS \uparrow CHF 15% (CI = 0.97-1.36)	CV mortality and MI unchanged; CHF \uparrow 33% (CI = 1.21-1.47)	\downarrow stroke 10%; CV mortality, MI unchanged; CHF \uparrow 33%

MI, myocardial infarction; CHF, congestive heart failure; CV, cardiovascular; NS, nonsignificant; CI, confidence intervals; \uparrow , increase; \downarrow , decrease; ACEi, ACE inhibitor; ARB, angiotensin type 1 receptor blocker.

6132 individuals. In MIDAS (Multicenter Isradipine Diuretic Atherosclerosis Study)²⁰ clinical endpoints were not predefined. In CASTEL (Cardiovascular Study in the Elderly)²¹ the only predefined endpoints were total and cardiovascular mortality, with others not listed in the trial protocol. The outcome results of these other endpoints were not published. CASTEL has other defects. According to data given to the present author, nifedipine tablets were given once daily (correct dosage interval twice daily) and compared with two other agents given together, namely high-dose atenolol plus a diuretic. Thus it is inevitable that 24-hour blood pressure (BP) reduction would have been better in the double-dosed patients, thereby explaining the better outcome.

The Pahor meta-analysis⁶ also relies on ABCD (Appropriate Blood Pressure Control in Diabetes), in which the outcome data have had to be revised²² and on FACET (Fosinopril versus Amlodipine Cardiovascular Events Trial),²³ an open-label study without clearly predetermined outcome endpoints. This meta-analysis also includes clonidine in the non-CCB drugs, although clonidine was used only in the small CASTEL study (61 patients given clonidine of a total of 27,743 in the meta-analysis as a whole).²¹

Opie-Schall Meta-Analysis

Based on the same data as the other meta-analyses, the Opie-Schall⁸ approach differed in that the primary studies were subjected to quality control and divided into grade A (such as those in Table 38–1) and others. The statistical quality was increased by introducing the Bonferroni criteria for multiple comparisons. As the other meta-analyses had concluded that total and cardiovascular mortality was unchanged by CCBs compared with conventional treatment, we reasoned that the prime differences must lie in nonfatal events. We proposed that diabetics treated by ACE inhibitors were likely to be different from nondiabetics, because of the known hemodynamic effects of ACE inhibitors on the kidneys. The study concluded that CCBs balanced a relatively small increase in AMI by a very similar decrease in stroke.

Staessen Meta-Analysis

Using virtually the same studies as the other meta-analyses, but updated to March 2003, Staessen et al.²⁴ set out to compare the “old” agents, diuretics and β -blockers, with the “new” therapy, namely ACE inhibitors and CCBs. They proposed that all the agents had roughly similar effects for the same BP reduction and outcomes, and that most of the benefit came with a fall of about 5 mm Hg in systolic blood pressure (SBP). The CCBs reduced stroke by 10%, whereas heart failure increased by 33%. The latter value is heavily dependent on the large numbers in ALLHAT, in which the criteria for heart failure were one symptom and one sign, hence open to criticism.²⁴

Pstay Meta-Analysis

In the Pstay meta-analysis²⁵ a network system was used to incorporate both direct comparisons and indirect evidence from trials that had one treatment in common. This meta-analysis showed that low-dose diuretics reduced heart failure by 26% versus CCBs. Although the indirect methodology is

open to question, this effect on heart failure is in accord with direct comparisons as in ALLHAT¹⁵ and INSIGHT.⁵

LESSONS TO BE LEARNED FROM META-ANALYSES

Four major lessons may be learned from these meta-analyses. First, the much-publicized large percentage increase in AMI found in the CCB group by Pahor and Furberg could not be confirmed in the better and larger mega-trials with CHD as a primary endpoint (see Table 38–1). Due caution must be exercised in interpreting any meta-analysis, especially when it is at least in part based on imperfect trial data. Although the result of a meta-analysis may look very impressive, more and better trial data can and do change the picture. Second, all the meta-analyses showed that there are no differences in mortality between CCB and conventional therapy, by far the most important endpoint. This point of concordance, which is very seldom emphasized, means that it is BP reduction and little else that determines mortality,²⁴ apart from some special situations to be considered later. Third, it is very important to publicize both the relative and absolute changes thought to be due to any specific therapy. Percentage changes make small absolute changes seem much larger. Last, a meta-analysis is not infallible. There have been obvious statistical mistakes in at least two of meta-analyses.^{8,11}

BENEFITS AND DEFECTS OF CALCIUM CHANNEL BLOCKER THERAPY

Benefits of Calcium Channel Blocker Therapy

CCB therapy has several benefits in addition to favorable effects on outcome. First, CCBs act within hours or days, which is useful to convince the patient that the BP can be controlled, thereby gaining the patient’s confidence. Second, they often bring down the BP in otherwise refractory patients. Third, they may be used as initial therapy in salt-sensitive Black patients²⁶ who may not respond to initial therapy with a β -blocker or ACE inhibitor (for reservations emanating from the AASK study, see later). Fourth, CCBs may be especially useful in selected patients with stable effort angina, often giving a better quality of life than β -blockers.²⁷ Fifth, they are often required in combination therapy to reduce BP to the new goals now being suggested,²⁸ especially in diabetics.^{29,30} Sixth, they have antihypertensive effects that are less influenced by indomethacin than in those of ACE inhibitors.³¹ Seventh, they lessen the risk of new diabetes when compared with diuretic/ β -blocker therapy.^{15,32}

Known Defects of Calcium Channel Blockers

What are the disadvantages of CCB therapy? These agents, especially the DHP group when given in high doses, often have nuisance side effects such as headache and ankle swelling that make it relatively common for patients to discontinue

them. Nonetheless, in the Treatment of Mild Hypertension Study³³ amlodipine in a low dose of 5 mg was the best tolerated of the five types of agents used, including a β -blocker and a diuretic.³³ There are some important situations in which CCBs *should not be used* as initial antihypertensive therapy. In post-MI patients, there are no trials favoring the use of DHPs. Non-DHPs may be different, with good data for verapamil³⁴ and lesser data for diltiazem. In heart failure, there are no data favoring CCBs. In fact, in INSIGHT⁵ and ALLHAT¹⁵ the long-acting DHP used increased heart failure, as will be discussed. In renal disease and in diabetics with nephropathy, ACE inhibitors or angiotensin receptor blockers (ARBs) are generally preferred as initial therapy (see next section).

OUTCOMES: CALCIUM CHANNEL BLOCKERS IN SPECIFIC SUBGROUPS OF PATIENTS

Isolated Systolic Hypertension

There have been only a few trials with clearly defined isolated systolic hypertension (ISH) as the entry criterion. A long-acting CCB, nitrendipine, was used in the Syst-Eur study, a placebo-controlled double-blinded trial in the elderly that was stopped early because of the marked reduction in stroke.³⁵ Although very similar results were obtained in a diuretic-based trial, Systolic Hypertension in the Elderly Program (SHEP),³⁶ it is often forgotten that hypokalemia was relatively frequent in SHEP and, when it occurred, took away the cardiovascular benefit of treatment.³⁷ In the diabetic subgroups of these studies, the CCB was overall more effective (e.g., with a reduction in total mortality).³⁸ In the Syst-Eur study, the development of dementia was lessened by the CCB.²⁴ Furthermore, in the Systolic Hypertension in China (Syst-China) study,³⁹ nifedipine tablets gave a clear reduction in overall mortality, again in an elderly population.

Coronary Heart Disease

Although earlier meta-analyses suggested increased CHD with CCB therapy,^{6,8} two large trials with this primary endpoint showed no difference between CCB and diuretic or β -blocker therapy.^{15,40} The updated meta-analysis of the BPLTTC⁷ and Staessen²⁴ also showed no differences.

Renal Disease

Regarding hypertensives with overt proteinuria, there is a caution in African Americans (and probably Black patients elsewhere) on the basis of results of the AASK Study (African-American Study of Kidney Disease and Hypertension).⁴¹ The amlodipine arm of this study was stopped because of worsening renal function, but the ACE inhibitor and β -blocker arms continued in those with proteinuria >1 g per day. Here there is a pathophysiologic basis for preferring ACE inhibitors, which reduce both afferent and efferent arteriolar tone, whereas the DHPs tend to reduce only afferent arteriolar tone, with risk of increasing intraglomerular hypertension and worsening proteinuria. Nonetheless, there is no evidence for a blanket contraindication to DHPs in hypertensives with proteinuria. Of note, in INSIGHT, proteinuria of 0.5 g or more

per 24 hours was one the possible entry criteria to the trial.⁵ It was the diuretic group rather than the CCB group that had the greater withdrawal rate because of impaired renal function (4.6% withdrawal in the diuretic group, 1.8% in the CCB group, $p < .0001$). CCBs are often combined with other antihypertensive agents such as ARBs or ACE inhibitors in the treatment of advanced renal disease, including diabetic nephropathy,⁴² with the aim of achieving current standards for optimal BP reduction.

Diabetic Hypertensives

In diabetic hypertensives with nephropathy, similar hemodynamic arguments indicate a preference for the use of ACE inhibitors or ARBs. A direct comparative study of the CCB amlodipine versus the ARB, irbesartan and a placebo has been carried out in patients with diabetic nephropathy.⁴³ The ARB gave better renoprotection than the CCB or placebo, without, however, altering overall mortality. In elderly diabetics without overt nephropathy, CCB and conventional therapy could not be distinguished in STOP-2.⁴⁴ Likewise, in the diabetic subgroups of the NORDIL and INSIGHT studies, no significant differences emerged between CCBs and conventional or diuretic-only therapy.⁴⁵ With new BP goals as low as 128/75 mm Hg³⁰ or even 120 mm Hg SBP emerging,²⁹ combination therapy including a CCB will almost always be required.

FEWER NEW DIABETICS THAN WITH DIURETICS, BUT MORE HEART FAILURE

The INSIGHT study⁵ compared long-acting nifedipine in an initial dose of 30 mg daily with a thiazide-potassium retaining combination diuretic in an initial dose of 25 mg hydrochlorothiazide plus 5 mg amiloride daily (equivalent to *half* a tablet of Moduretic [amiloride and hydrochlorothiazide]). Doses could be doubled if needed. The diuretic group showed increased blood sugar and uric acid, matched by increased development of diabetes and gout. In INSIGHT, the diuretic treatment group also had more hypokalemia, hyponatremia, hyperuricemia, hypoglycemia, and renal impairment than the CCB group. Hypokalemia occurred in 6.2% of the diuretic-treated group and 1.9% of the nifedipine group, even though a potassium-retaining agent was used. Even mild hypokalemia may be more serious than previously thought. In the INSIGHT study the thiazide dose was allowed to go up to 50 mg, "high" by current standards. In the meta-analysis that separately considered low-dose and high-dose diuretic versus β -blocker therapy, only low-dose diuretics clearly reduced mortality.⁴⁵ Thus, the metabolic advantages of the CCB versus the diuretic found in INSIGHT would probably be less obvious if the thiazide dose had been limited to 25 mg daily or lower.

In the ALLHAT study, the diuretic chlorthalidone, started in a low dose of 12.5 mg daily and titrated up to 25 mg had similar effects as amlodipine on total mortality and AMI, but with a small advantage to the diuretic in heart failure, a secondary endpoint. Concern remains about adverse metabolic effects of the diuretic, especially on potassium and blood sugar. In ALLHAT 12.7% and 8.5% of participants randomized to chlorthalidone developed low potassium values ($K < 3.5$ mmol/L) after 2 and 4 years, respectively. Furthermore,

other metabolic changes in ALLHAT were in the same direction as in INSIGHT, with increased blood glucose and cholesterol levels in the chlorthalidone group. Particularly serious in ALLHAT was the increase in new diabetes from 9.8% at 4 years with the CCB to 11.6% with the diuretic. Because antihypertensive therapy is often lifelong, these metabolic changes cannot be ignored. On the contrary, and perhaps unexpectedly, the CCB nifedipine may improve insulin sensitivity.^{46,47} Overall, four studies in 25,529 patients show that CCBs reduce new diabetes by 16% (CI, 0.78-0.91) versus conventional therapy.³²

Heart Failure

Compared with diuretics, DHPs increase heart failure. In the INSIGHT study heart failure was carefully defined and experienced observers individually confirmed each case.⁵ The incidence was low (0.82% in the CCB group) and the absolute increase only 0.38%, although the relative increase was large (220%) compared with the diuretic. Diuretic therapy is known to benefit heart failure, whereas CCBs are contraindicated, in part because of their negative inotropic effects. Therefore, incipient heart failure is less likely to develop in a patient treated with a diuretic. In ALLHAT, the incidence of heart failure was inexplicably much higher in both the diuretic (5.7%) and the CCB (7.8%) groups. There are several other points of concern. First, ACE inhibitors, agents known to be effective in the treatment of all stages of heart failure, increased heart failure in ALLHAT by 19% ($p < 0.001$) compared with the diuretic. Second, the diagnosis of heart failure was chiefly made by primary care physicians, and it is not sure how the ankle edema, known to be a side effect of DHP therapy, was dealt with diagnostically. Therefore, while noting the findings of ALLHAT, those of INSIGHT seem to be based on more reliable clinical observations and data. Nonetheless, both studies showed increased heart failure with a DHP. To prevent heart failure, combination of a CCB with an ACE inhibitor is likely to be successful.⁴⁰

INDIVIDUALIZED AND PATIENT-GUIDED CHOICE

Although the diuretic appeared to be the clear winner in ALLHAT, in reality there was overall equality of the primary outcome, fatal CHD and nonfatal AMI, between the CCB and the diuretic. Apart from the problematic heart failure issues, the CCB has advantages. In contrast to the diuretic, there are no metabolic side effects. Furthermore, an earlier Veterans Affairs study showed little or no BP response to diuretics in whites aged younger than 60 years.⁴⁸ In ALLHAT, the initial mean age (67 years) was well into the elderly category. The choice between CCBs and conventional treatment with a β -blocker or diuretic or other therapies such as ACE inhibitors should be carefully considered for each individual patient. In the elderly, a low-dose diuretic may be the first choice,²⁵ but a CCB has equally strong arguments.²⁴ A small reduction in stroke and a better metabolic profile with CCBs may be balanced by an increase in heart failure when compared with the diuretics. In many patients, combination therapy must be used to achieve current low BP goals, especially in diabetics and those with renal disease. In some cases CCBs are contraindicated, in oth-

ers they will be among the agents of first choice. The latter category includes those with effort angina or more severe hypertension, or the elderly with ISH.^{35,38}

SUMMARY

This chapter evaluates the current position of CCBs in antihypertensive treatment in the light of three mega-trials and five extensive meta-analyses. CCBs are equivalent to conventional (initial diuretic, diuretic/ β -blocker, or β -blocker) therapy when total and cardiovascular mortality are the endpoints. With the mega-trial data, increased AMI can with confidence be eliminated as an unwanted effect of CCB therapy. Prior findings, largely from observational studies and mostly focused on short-acting capsular nifedipine, suggesting increases in cancer, gastrointestinal bleeding, and suicide can now be discounted by the results of randomized trials. When evaluating a CCB versus conventional treatment for first line therapy, β -blockers are preferred in postinfarct patients or in those with heart failure or unstable angina (a contraindication to DHPs in the absence of β -blockade). (See Chapter 54 for complete discussion of antihypertensives in the patient with ischemic heart disease.) CCBs are particularly useful when hypertension is accompanied by effort angina or when β -blockade is not likely to work well, as in African Americans or the elderly. Reductions in new-onset diabetes (by 16%) and stroke (by about 10%) with CCBs balance the increase in heart failure (versus thiazides). This increased risk of heart failure can probably be avoided by combining the CCB with an ACE inhibitor. Such choices should be individualized for each patient. Thus an open mind should be kept about the place of CCBs in current hypertension therapy. CCBs are neither better nor worse than conventional therapy, but act differently to achieve combined vasodilation and antianginal effects. CCBs remain a very valuable component of the antihypertensive armamentarium.

Acknowledgment

This study was supported by (1) the Medical Research Council of South Africa by a grant to the Hatter Institute of the Cape Heart Center as part of the program of the Interuniversity Heart Research Group; (2) the Chris Barnard Fund of the Faculty of Health Sciences of the University of Cape Town; and (3) an educational grant from Servier Laboratories, Paris.

Nursing Clinics in the Management of Hypertension

Nancy Houston Miller, Martha N. Hill

Nearly one in four Americans has hypertension. It is the single most common reason for a medical office visit.¹ While awareness and treatment of hypertension have improved over the past two decades, control rates have lagged far behind, leaving only one third of hypertensive patients achieving blood pressures (BPs) of less than 140/90 mm Hg.²

As we move into the twenty-first century, several important insights compel us to recognize the importance of hypertension as a major public health and medical problem. First, the lifetime risk of developing hypertension is very large. Investigators from the Framingham Heart Study³ have reported the lifetime risk of hypertension to be 90% for men and women normotensive at 55 or 65 years, who survive to age 80 to 85. Moreover, there is a linear risk of ischemic heart disease and stroke mortality associated with increasing BP beginning at 115 systolic (SBP) and 75 mm Hg diastolic (DBP).⁴ A doubling of mortality occurs for every 20-mm Hg and 10-mm Hg increase in systolic and diastolic pressures, respectively. Secondly, environmental factors associated with high BP in the United States and globally require us to acknowledge the impact of this public health problem. These include an obese population (50% are overweight or obese),⁵ a high-sodium intake of 4100 mg/day for men and 2750 mg/day for women,⁶ fewer than 20% of the population engaging in recommended physical activity of 30 min/day,⁷ and less than a quarter of the population consuming five or more fruits and vegetables per day.⁸ In addition to traditional clinical care of ambulatory patients with hypertension, population strategies may help to reduce BP in the population. These strategies include health education, professional education, and partnerships with national organizations, such as the food industry. Finally, important at-risk and high-risk populations, including those with multiple risk factors, diabetes, older age, and renal impairment, require meticulous BP control to lower risk of morbidity and mortality and the associated economic costs of hypertension care.

During the past three decades, nurses and other health-care providers have played important roles in screening and managing patients with hypertension in inner-city areas, academic and community centers, multicenter research trials, and hypertension care management programs. Recognizing the enormity of the problems associated with hypertension today, their efforts to screen, identify cases, refer, follow-up, and educate patients is paramount. Moreover, their success in following protocols to achieve more timely and persistent BP control is significant. This chapter will focus on the success of nurses managing hypertension in a variety of healthcare settings.

IMPLEMENTATION OF NURSE-RUN CLINICS

Management of an asymptomatic condition such as hypertension is challenging. Once individuals with hypertension are aware of their high BP, the first challenge is having them enter into and remain in treatment after initial screening and diagnosis. Many patients never make a first appointment after elevated BP is identified with screening or return for follow-up appointments after the initial diagnosis is made. Others do not undertake the lifestyle changes that could improve BP control or remain on medications. Moreover, it is well known that lifestyle changes cannot be adequately achieved without ongoing support during both the adoption and maintenance of these behaviors. The reasons for these patterns of medical care are many and discussed in other chapters.

Early efforts to involve nurses in hypertension management sought to offer more convenient options for supporting individuals with hypertension by bringing hypertension care to the home, local community, and work environment. In a landmark study by Runyan,⁹ patients with hypertension, diabetes, or cardiac disease could choose to be followed by specially trained nurses in decentralized clinics close to their homes or in a hospital outpatient clinic for chronic disease staffed by internists. Patients in both groups were similar with regard to sociodemographic and clinical characteristics. At the end of 2 years, patients treated by nurses had lower BPs in all age groups except those aged 30 to 39 and older than 80 years of age. Moreover, by the end of the treatment period, patients treated in the nurse clinics had utilized approximately 50% fewer hospital admission days, while those treated in the outpatient clinics staffed by physicians showed an increase in hospital days for each of the disease categories. The authors attributed the success of the nurse-run clinics to the greater follow-up and greater time devoted by nurses to helping patients manage their condition.

In another study by Alderman et al.,¹⁰ nurses played the central role in the screening and follow-up of patients in a worksite setting in New York City. In this successful program, nurses performed screening and enrollment in a New York department store. Hypertensive individuals who elected to participate in the program were followed by a nurse for 1 year. Nurses were responsible for taking the initial medical history, drawing preliminary laboratory data, and obtaining an electrocardiogram (ECG) upon entrance into the program. Approximately 1 week later, the medical director obtained a history, performed a physical exam, and reviewed laboratory data. Working closely with the medical director and using treatment algorithms, nurses initiated drug therapy and increased treatment in a step-wise fashion until the BP was <140/90 mm Hg. Diuretics were used

as first-line therapy. The number and frequency of follow-up visits to the nurse were individualized based on patient's needs and control of BP. At these visits, which decreased in frequency to one every 3 months once BP was controlled, nurses monitored the BP, reviewed therapy and potential complications, checked medication and diet compliance, and helped to motivate patients to assume greater participation in and responsibility for their care. At the end of 1 year, the nurses' provision of care did not compromise program acceptability. In this worksite, 84% of the 1850 employees were screened, two thirds of those eligible for the hypertension treatment program sought care through the nurse program, and 97% of accepted patients remained in therapy, with 81% achieving acceptable BP reduction. Moreover, the direct annual per patient cost of \$100 offset the costs associated with hypertension, including time lost from work, and allowed the health payer to offer this program as a union membership benefit.

In a study similar to that of Alderman, Logan et al.¹¹ found that hypertensive patients who were randomly allocated to receive care at work compared with those receiving standard care were significantly more likely to be put on antihypertensive medications (94.7% vs. 62.7%), to reach goal BP in the first 6 months of therapy (48.5% vs. 27.5%), and to take prescribed medications (67.6% vs. 49.1%). The authors claimed that the improvement in BP control was due to the fact that long-term care was more convenient, therapy was more vigorously applied, and compliance with therapy was more strongly encouraged by nurses.

Nurses have also made a major contribution to the management of hypertensive patients in national multisite clinical trials, many of which began in the late 1970s. The Hypertension Detection and Follow-up Program (HDFP)¹² and the Systolic Hypertension in the Elderly Program (SHEP)¹³ are just two examples of large clinical trials conducted in the United States in which nurses provided screening, counseling, and medication management of hypertensive individuals. Most recently, nurses were part of the intervention team of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) study.¹⁴

Evaluations of nurse-run clinics in which nurses saw patients alone or in collaboration with physicians show a level of BP control comparable with that achieved by physicians.¹⁵ Similar results are seen where case-mix adjustment indicates nurses care for patients as complex as those seen by physicians.¹⁶ Pheley et al.¹⁷ reported on the screening, outcomes, and management of patients enrolled in a nurse-run hypertension management program in a large multispecialty practice in Minnesota. One year after entry into this program the proportion of patients who had their BP controlled to 140/90 mm Hg or less increased from 17% to 44%.

Nursing case management involving the use of telecommunication holds promise as an application for managing hypertensive individuals. In a study by Miller,¹⁸ 78 patients were managed in a single face-to-face encounter and then systematically followed by telephone. During the initial encounter patients were educated about lifestyle changes and taught to measure BP using a home device. This session was followed by biweekly nurse-initiated telephone encounters of 10 minutes duration over a 6-month period, at which time SBPs and DBPs had declined by 10% and 8%, respectively, or 15 mm Hg and 7 mm Hg in absolute terms. The proportion of patients reach-

ing a goal BP increased from 22% to 48%. Importantly, the mean weight loss of patients enrolled in the study was 3.5 kg.

A similar pilot study conducted by Artenian et al.¹⁹ highlights the value of a nurse-managed home telemonitoring system. Using a telephonic management system (Lifeline Monitoring, Inc.) to download BPs taken three times weekly at home by patients, nurses followed up with patients weekly through telephone calls to provide feedback on BP and counsel about lifestyle modification and adherence to medication regimens. This home-based nurse treatment intervention was compared with usual care and an intervention consisting of home BP measurement three times per week in a community center and feedback about lifestyle education by nurses. At the end of 3 months those in the home-based nurse treatment arm had the greatest improvement in BP.

More recently, Hill et al.^{20,21} showed the benefit of incorporating a multidisciplinary team including a nurse-practitioner, community health worker, and physician in controlling BP in a high-risk population. Three hundred nine hypertensive African American males, mean age 41 ± 6 years, were randomly allocated to an intensive intervention consisting of nurse practitioner visits every 1 to 3 months for medications, and at least an annual visit by a community health worker versus a less intensive intervention. For those assigned to the intensive intervention, a community health worker provided referrals to social services, and offered job training and local housing resources. The physician offered consultation to the nurse practitioner about management and participated in case consultation. Those randomized to the less intensive intervention received education about the benefits of hypertension control, and referrals to hypertension care in the community. Men in both groups received an annual hypertension evaluation and a 6-month telephone call to assess health status and healthcare utilization. At 36 months, the mean change in SBP and DBP was $-7.5/-10$ mm Hg for the more intensive group, compared with $+3.4/-3.7$ mm Hg for the less intensive group ($p = .01$ and $.005$ for SBP and DBP, respectively). Moreover, the proportion of men reaching a controlled BP of $<140/90$ mm Hg was 44% in the intensive group compared with 31% in the less intensive group ($p = .45$), figures surpassing the national control rate. The authors suggest that, especially in high-risk populations, the traditional one-on-one physician-patient visit in an office practice setting needs to be supplanted by a more systematic patient-centered team approach.²¹

NURSE MANAGEMENT—CLINICAL SETTINGS

Roles and Responsibilities

The goals of managing hypertensive individuals are the same, whether the care is given in specialty clinics, private practice offices, worksite settings, primary care clinics, or neighborhood clinics. A team approach, bringing together physicians and nurses as well as community health workers, often produces better outcomes than a traditional medical approach. If nurse practitioners are caring for the patients, they practice quite independently, using protocols based upon guidelines and modified jointly with the physicians with whom they collaborate.²² In settings in which the nurses do not have advanced

practice credentials, physicians are responsible for making the diagnosis of hypertension and for determining secondary causes and comorbidities, which may influence decisions about appropriate treatment. Physicians help to formulate a treatment plan and provide consultation to nurses in managing complex cases. This shared collaborative practice arrangement allows physicians to use their time caring for sicker patients.

Nurses have shown that they can demonstrate critical clinical judgment in the management of patients within a hypertension clinic. In the worksite setting, they are often responsible for conducting screening programs to identify and refer hypertensive individuals. In programs to verify sustained elevated BP, nurses are responsible for determining the appropriateness of patients' ongoing management. For example, in the hypertension management program described by Pheley et al.,¹⁷ more than three quarters of all patients referred for management of hypertension were deemed normotensive on the basis of a BP readings <140/90 mm Hg documented over three consecutive weekly screenings. Within this program nurses were responsible for seeing patients weekly to determine their level of BP and to provide the appropriate education for individuals with or at risk for hypertension. Screening and verification programs conducted by nurses enable them to identify individuals with sustained hypertension using standardized BP measurement techniques and to establish a database of individuals who can be followed for appropriate rescreening, as necessary. Such programs also help nurses identify patients who, based upon the multiple BP measurements, need lifestyle modification to lower high-normal pressures. By having nurses measure BP on multiple occasions, false positive diagnoses of hypertension and unnecessary treatment can be avoided.²³ This is important because previous studies have shown that physicians may base their treatment on a single measurement rather than making the diagnosis on at least two occasions with the appropriate attention to technique.²⁴ Moreover, having nurses use home BP measures taken by the patient or multiple measures more frequently in the clinic may obviate the "white coat" hypertension effect found by the physicians in office settings.²³

In managing a cohort of patients within a hypertension clinic the nurse is responsible for taking a thorough medical history and for ordering appropriate blood chemistry tests such as sodium, potassium, creatinine, blood urea nitrogen, cholesterol, and a complete blood cell count; a urinalysis; and an electrocardiogram. This preliminary data collection allows physicians to devote their efforts either later in the visit or during a subsequent visit to performing the physical exam and formulating an appropriate treatment plan based upon the information and laboratory data provided by the nurse.

In the majority of hypertension clinics, nurses provide the education and counseling necessary to ensure that individuals are undertaking lifestyle changes that may favorably influence BP. Weight loss, the most successful nonpharmacologic technique to lower BP, requires behavior change for both eating and physical activity patterns. In addition, patients need help to limit calorie and sodium intake (to 100 Mmol/day) and alcohol consumption (to 1-2 drinks* per day).²² In addition,

many hypertensive individuals present to the clinic with multiple risk factors for cardiovascular disease. The nurse can provide education and counseling for smoking cessation and dyslipidemia to help patients lower their overall risk of cardiovascular disease.

Why is the nurse's role so critical? Modifying lifestyle behaviors requires many clinical interventions: assessment of an individual's baseline behaviors, education about how to make the appropriate changes, counseling to develop strategies such as setting short-term goals and self-monitoring that will ensure the maintenance of the changes, constant rechecking with the individual to determine whether compliance is a problem and to resolve barriers, and reinforcement about progress toward the goal of change in behavior.²⁵ Success with any of these changes requires frequent interaction with the patient. Additional exchange of information to assess progress toward goals and provide feedback and reinforcement can be done by telephone, facsimile, e-mail, home visit, and face-to-face clinic visits. This is often best accomplished by a healthcare provider, such as the nurse, who has the requisite time for the education and counseling necessary to change behavior. Moreover, it has been shown that individuals who receive education and counseling on hypertension management exhibit increased adherence.²⁶ The important aspects of education and counseling that should be incorporated into the management of individuals with hypertension are noted in Box 39-1.

In many settings, nurses are also responsible for the pharmacologic aspects of hypertension management. Using well-defined protocols based upon national guidelines such as the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7),² advanced practice nurses and specially trained nurse case managers can prescribe and titrate medications and help patients to manage the numerous steps in taking medications required for BP control. The ability to attain greater control of BP than is achieved with standard care has been demonstrated in numerous settings.^{9,11,17,20} In many cases the improved outcomes have resulted from nurses placing a greater number of patients on medications, altering drug regimens more frequently in response to inadequate BP control, and prescribing more effectively. In some studies nurses have also been noted to place a higher proportion of patients on multiple drug regimens to achieve greater BP control.^{16,27} Although changes may produce higher costs initially, as noted by Logan,²⁸ obtaining the best regimen for the patient must be paramount if patients are to remain in treatment and achieve greater adherence and BP control rates.

The effective development and implementation of protocols for medication management allow achievement of BP control, a significant factor in helping to offset some of the costs of providing a clinic. For example, more than 20 years ago more than 6000 treated patients within the Veterans Affairs Clinics,²⁷ were managed by nurses who used a successful combination of a thiazide diuretic and other agents, such as methyldopa and reserpine. At the end of five treatment visits, half of all patients had DBPs below 90 mm Hg, and two thirds of those who began treatment remained in treatment for at least 2.5 years. The total yearly cost for treating one patient was \$221. Nurses have been shown to effectively manage other risk factors, such as dyslipidemia, using multiple drugs at lower cost than usual care.²⁹

*A drink is defined as 1 oz of ethanol (e.g., 24 oz of beer, 10 oz of wine, or 2 oz of 100-proof whiskey).

Box 39-1 Strategies for Patient Education**Identify knowledge, attitudes, beliefs, and experience**

- Assess readiness to achieve blood pressure (BP) control
- Correct misinterpretations

Educate about condition and treatment

- Inform patient of his or her BP level
- Identify alternative treatment plans
- Provide simple oral and written information
- Teach self-monitoring skills

Tailor the regimen to the patient

- Include patient in decision making
- Agree on BP goal
- Incorporate treatment into patient's daily lifestyle
- Simplify the regimen
- Prioritize critical aspects of the regimen
- Implement the treatment plan in stages
- Encourage self-monitoring of BP in selected patients
- Encourage discussion of medication, side effects, and concerns
- Modify dosages or change medications to avoid side effects
- Minimize cost of therapy
- Schedule frequent visits for nonadherent patients

Provide reinforcement

- Hold exit interviews
- Arrange home visits
- Use appointment reminders
- Contact patients who miss appointments
- Consider clinician-patient contracts

Promote social support

- Include family and others in care
- Suggest group sessions

Collaborate with other professionals

- Recognize shared practice goals
- Draw upon the skills and knowledge of other providers

From Hill MH. Strategies for patient education. *Clin Exp Hypertens* A11(5&6):1187-1201, 1989. Courtesy of Marcel Dekker, Inc.

Another role of the nurse is to direct and coordinate the efforts of other team members who provide consultation or are practicing in the clinic. Whereas collaborative teams of physicians and nurses provide care in a typical outpatient setting, other healthcare providers such as nutritionists, pharmacists, and community healthcare workers also practice in some clinics. The role of community healthcare workers involved in underserved communities is discussed in Chapter 40. The nurse may also be responsible for training and supervising office personnel such as office assistants and the receptionists. The ability of office assistants to take BPs accurately can be helpful in screening and can also decrease costs. Receptionists also play a very helpful role by scheduling appointments, making reminder telephone calls, obtaining laboratory results, entering data to support evaluation of clinical outcomes, and ensuring that referring physicians receive timely correspondence about their patient's management.

Clinic Needs and Setup

Most ambulatory settings, whether physician offices or clinics, in which nurses may provide hypertension management require no additional specialized equipment or space. An examination room and/or clinic office can be used to see patients and their families for education and counseling as well as patient care, thus avoiding additional space costs. Setting up neighborhood clinics, especially in underserved communities, minimizes the burdens of transportation, enabling many individuals to remain in care who might not otherwise do so. Although this may require additional resources for rental space in a neighborhood, improved hypertension care in high-risk individuals reduces hospitalizations and chronic illness management for heart failure, stroke, and renal failure.

Clinic staff must use equipment that is appropriately calibrated to ensure adequate measurement of BP. The clinic must be structured with a variety of cuff sizes and furniture that permits taking BPs appropriately. In addition, if a clinic provides patients with BP monitors for home use or access to a service for home monitoring, patients whose BP needs tighter control will benefit. Computers are necessary to track appointments and telephone contacts; collect medical, demographic, and billing information; and generate reports to physicians, payers, and patients. Moreover, documentation of clinical outcomes is increasingly important and necessary. Tracking the frequency of visits, medications, compliance, hospitalizations, and BPs through a computer program enables rapid evaluation of clinical outcomes and the costs incurred in providing antihypertensive treatment. A simple checklist for use in starting up a hypertension clinic is shown in Box 39-2.

Caseload Size

Several factors influence the capability of nurses and others to manage a caseload of patients within a clinic setting. Caseload size is strongly influenced by the characteristics of the patient population. Patients with more severe hypertension often require more frequent and/or longer visits to regulate medications and manage target organ complications. Those with mild hypertension may require less frequent monitoring and reinforcement of education and counseling. Experience of a large clinic in Glasgow suggests that a single nurse practitioner working with a physician can manage up to 700 to 900 patients per year.³⁰ Within a worksite clinic, Alderman et al. observed that a nurse can see an average of 16 patients per day.¹⁰ Nurses and other personnel may be able to shorten the length of clinic visits by increasing office efficiency. Efficiency also can be increased if staff order fewer unnecessary blood chemistry tests, lower the cost of medications, and provide education creatively within the clinic by offering education and counseling through videotapes, written materials, and other vehicles in the waiting rooms. Additional support can also be obtained by using volunteers to provide services that do not require the expertise of the nurse or physician.

Reimbursement for Services

Reimbursement issues need to be understood by nurses and physicians wanting to establish a collaborative hypertension management program. Much of what has been learned in the

Box 39–2 Outpatient Hypertension Clinic Start-up Checklist

1. Establish need and cost benefits
 2. Assess and establish staff support and qualifications
 3. Designate physician medical director and coordinator
 4. Ensure efficient assessment and educational physical space
 5. Develop written policies and procedures
 - Entry and referral criteria
 - Treatment algorithms
 - Exit criteria
 - Laboratory standards
 - Pricing
 - Fee-for-service schedule
 - Compute capitation rate or contribution to global rate for managed care contracts
 - Billing and corrections policy
 - Operational budget and proforma outcomes measures (JNC 7 goals)
 6. Develop standard forms
 - Patient information (medical history, lifestyle)
 - Initial assessment and treatment plan
 - Return visit and progress report
 - Drug descriptions and patient administration instructions
 - Individual lifestyle counseling prescription (dietary, exercise, stress management)
 - Dietary and body fat assessment (BMI)
 7. Determine sequence and pathway of patient visit flow
 - Schedule for new and return visit
 - Physician consultation schedule with new patients
 8. Develop patient data storage and tracking system
 - Assess existing patient tracking software packages
 - Determine relevant patient data
 - Develop protocol for monitoring clinical events and associated costs
 9. Acquire and maintain patient education materials
 - Pharmacologic information
 - Lifestyle information
- Other resources
10. Marketing and promotion plan
 - Internal marketing and promotion: medical and ancillary staff
 - Patients
 - Referring physicians, PPOs, and HMOs
 - Business and industry
 - Alliances with hospitals, PPOs, and drug companies to form organized and efficient disease management programs
 11. Develop continuing education schedule for clinic staff
 - New research funding
 - New reimbursement guidelines and legislation
 12. Develop link and network with national hypertension organizations

Revised and adapted with permission from LaForge R, Thomas T. Outpatient management of lipid disorders. *J Cardiovasc Nurs* 11(1):39-53, 1996.

JNC 7, the seventh report of the Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; BMI, body mass index; PPOs, preferred provider organizations; HMOs, health maintenance organizations; BMI, body mass index.

establishment of lipid clinics, anticoagulation monitoring services, and diabetic education programs applies to obtaining coverage for services provided within a hypertension clinic.³¹ Although a hypertension management clinic is not a covered service per se, many of the services provided within the clinic are covered under the Medicare and Medicaid guidelines set forth by the Centers for Medicare and Medicaid Services (CMS), formerly called the Health Care Finance Administration (HCFA), under Medicare. Hypertension clinic personnel should establish a fee structure using guidelines set forth by the CMS in Health Care Finance Administration Medicare Carriers Manual, Section 2050.³² Because the “incident to” guidelines under Medicare are nationally recognized, many insurance carriers follow the rules developed by CMS. The guidelines indicate that nurses and other licensed personnel may provide follow-up services such as conducting physical examinations, taking medical histories, and providing medical decision making as long as the service is provided under the direct supervision of a physician or nurse practitioner. The physician or nurse practitioner must be in the same office setting, and must be immediately available to provide assistance. In these instances, the physician employs or contracts with the nurse and directly supervises the healthcare professional who provides the services. Some of the important issues that should be noted about

following the “incident to” ruling under Medicare are noted in Box 39–3. Clinic personnel should recognize that each CMS representative within a state may interpret the guidelines differently; therefore obtaining clarification through written guidelines is important to ensure that rules are followed and adequate coverage is obtained. When the registered nurse or other licensed personnel bills under the physician provider or nurse practitioner, the maximum billing code that may be used is a level I (99211).³²

Several innovative mechanisms of payment may also provide a way to cover the costs incurred in running a hypertension clinic. Contracting to provide these services with a managed care organization may be a viable option. Developing relationships with pharmaceutical companies (e.g., to conduct small research projects) may offset some of the costs. Providing multiple services for cardiovascular disease management for patients with heart failure, lipid disorders, hypertension, and diabetes may also expand the scope and opportunities for success of specialized clinics. Additionally, if physicians or nurse practitioners spend more than half of their time in the visit educating or coordinating care, they may bill for a higher level of service even if a physical examination is not performed. This time must be actual time spent face-to-face with the patient and provider.³³

Box 39-3 Medicare “Incident To” Billings (What Is Important)

Service must be

- Integral part of physician’s professional service
- Commonly included in physician’s bill
- Furnished in physician’s office or clinic under direct supervision
- Furnished by individual qualifying as an “employee” acting under scope of state licensure laws

Services are billed

- Under supervising physician’s provider number using same CPT codes
- As one service per patient per day unless there is documentation of need

Documentation in the patient record to support level of service/coding is absolutely essential.

CPT, Current Procedural Terminology.

MODIFICATION OF GLOBAL RISK AS PART OF NURSE MANAGEMENT OF HYPERTENSION

The magnitude and significance of multiple risk factors in the American population and globally is noteworthy. Treating hypertension is especially critical in the diabetic population, who are at high risk for coronary heart disease (CHD) and kidney failure. Importantly, a BP goal of <130/80 mm Hg for the diabetic population has been shown to be more difficult to achieve than a BP goal of <140/90 mm Hg.³³ Nurses can have a major impact on this population and positively influence their risk. In a study conducted in the United Kingdom where nurses have gained widespread acknowledgement for their efforts to reduce CVD risk, Denver et al.³⁴ followed 120 hypertensive men and women with type 2 diabetes and a BP >140/90 mm Hg, 71% of whom had increased urinary albumin excretion (UAE). Patients were randomized to conventional primary care whereby physicians received a letter stating the measured and target BP as well as recommendations for treatment according to guidelines or to a nurse-led hypertension clinic. Patients assigned to the nurse clinics saw nurses monthly for 3 months and then every 6 weeks for 3 months. At these visits BP was measured, compliance was reviewed, nonpharmacologic therapies were discussed, and medication changes were initiated based on physician orders through standing protocols. At 6 months of follow-up, the proportion of treatment changes was 88% in the nurse-led group compared with 15% in primary care; $p = .000$. While SBP and DBP fell in both groups, the fall in SBP was far greater (12.6 mm Hg, $p = .000$) in those assigned to the nurse clinics. No changes in CHD or stroke risk were noted in those assigned to primary care, while the reductions in 10-year CHD and stroke risk were significant in the nurse-led group ($p = .004$ and $.000$). These risk reductions were entirely due to the six times greater changes in medications in the nurse clinics compared with conventional care. Further studies are needed to support the approach of nurse-managed clinics and case management for populations at greatest risk of morbidity and mortality from CHD and stroke.

SUMMARY

In two separate editorials in the mid-1970s,^{35,36} Finnerty suggested that asymptomatic patients would not remain under care and on medication without proper motivation. He noted that once the initial diagnosis of hypertension was made, the care of the patient was an issue primarily of education. He further suggested that we should recognize the value of specially trained nurses in managing hypertension, just as we have relied on nurses’ expertise in the coronary care unit. His suggestion was based on the reality that most physicians have been trained as diagnosticians responsible for managing complicated illness or treating the patient in an emergent situation. Today, recognizing that close to one third of hypertensive patients drop out of care and that only a third of all patients treated with hypertension achieve a goal BP of <140/90 mm Hg,² we should focus on the need for what Finnerty advocated and what we know improves patient care and outcomes. In a system that is highly focused on medical care of acute illness and on reducing costs, nurses practicing collaboratively with physicians in the outpatient setting can benefit large numbers of patients with hypertension and other chronic asymptomatic conditions, as well as the healthcare provider and the healthcare system.

Community Outreach

Martha N. Hill, Lee R. Bone, David M. Levine

Community outreach is an essential component of comprehensive programs to promote health, as well as prevent and/or control disease and related risk factors. It complements other strategies and is especially effective in reaching individuals and populations who do not have access to healthcare and related human services and those who have discontinued care. Community outreach improves care and outcomes by providing state-of-the-art prevention and treatment interventions to the populations, as well as to individuals and families. Outreach has been utilized successfully to impact positively on a wide variety of health problems, including prenatal care, immunizations, hypertension, HIV/AIDS, tuberculosis, chronic obstructive pulmonary disease (COPD), asthma, diabetes, and mental health.

Effective hypertension control requires a comprehensive approach that integrates social, psychological, behavioral, and economic, as well as medical, strategies. Community outreach improves hypertension control by linking health professionals, healthcare organizations, and current or potential patients with resources in patients' communities. Clinical hypertension care and control programs, which include community outreach provide three important lessons:

1. Clinicians can use resources in the community to directly enhance their care of patients, thus improving long-term control of hypertension and reducing associated target organ damage.
2. Community programs provide reinforcement of the clinician's recommendations and teaching efforts.
3. Physicians, nurse practitioners, and other clinicians can provide community service and leadership by accepting referrals, promoting outreach programs, and acting as consultants.

DEFINITION OF COMMUNITY OUTREACH

Community outreach is a health services, health education, and health promotion strategy directed to entire populations, as well as to specific high risk and underserved groups and individuals. It is an activity at the interface of medicine and public health, an area that is the focus of community nursing. It seeks to mobilize health and human resources at local, state, and national levels. Outreach can be defined differently depending on a program's purpose. Its goal, however, is to reach those who are not reached by usual methods for the purpose of increasing knowledge, information, and access to and utilization of health services. It inevitably has to address

issues of health services availability, accessibility, acceptability, and affordability focusing on removing geographic, cultural, linguistic, administrative, and financial barriers to health-care.¹ Outreach has been an integral part of public health for more than the past century. Traditionally, it has targeted meeting the needs of the underserved. In the past few decades, however, hospitals and academic health centers have begun to extend of medical and nursing care to patients' homes and communities, in part to respond to needs identified by surrounding communities. Outreach has thus become a way of providing community service to meet patient and population needs, health promotion and disease prevention objectives and marketing and public relations goals.

Key principles of community outreach are active community participation and/or partnership, careful diagnosis and planning program implementation, and evaluation. A needs assessment and definition of goals, aims, strategies, and resources are essential for success. The types of outreach programs vary widely and include screening, case finding, referral, education, and monitoring. Effective interventions combine persuasive communications, interpersonal relationships, skills training, and community organizing. Mass media can be used to deliver informative messages through local radio, television, and newspaper public service announcements; talk shows; celebrity guest features; and other methods. Additional outreach strategies include person-person contact, mailed postcards and letters, telephone calls, street contact, home visits, mobile units, and hot or warm lines. Outreach also can be provided at community events such as health fairs or in sites such as churches and recreation centers.²

Community participation and partnership are essential ingredients for productive sustained outreach programs. Organizing a group of respected community leaders as an advisory or coordinating committee can be constructive. Community organizers, politicians, physicians, clergy, and others with an interest can help design, implement, evaluate, and sustain an outreach program that will be acceptable and responsive to the community and directed at meeting their needs. Uncommon partners (e.g., dental school faculty) have joined outreach collaborations to help reduce health disparities.³ Community involvement is invaluable in deciding who should participate, what they should do, and how they should be recognized for their contributions. While the good will and community service produced by many outreach activities is evident, it is important to evaluate the efficiency and cost effectiveness of such activities to compare various approaches prior to replication. Particularly in a time of scarce resources, outreach programs need to demonstrate achievement of objectives and impact on clinical outcomes.

HISTORY OF OUTREACH PROGRAMS TO CONTROL HYPERTENSION

During the 1960s and the War on Poverty, outreach services became an integral part of many health and social service programs.⁴ Grass roots organizing, community development and, more recently, economic development were seen as mechanisms to improve quality of life including social, emotional, and physical well-being. In an effort to reduce disparities in health status and outcomes, many hypertension outreach programs targeted African Americans whose high blood pressure (BP) was detected, treated, and controlled at rates that lagged behind rates of whites.⁵⁻⁸

The value of finding undetected cases of hypertension through community outreach was first demonstrated in the late 1960s. The purpose of these outreach programs was to motivate people to have their BP measured at a familiar and convenient site for little or no cost. Organized BP screenings found that an accessible location, community participation, referrals to care, and follow-up of referred people contributed to improved care and control of hypertension. Community-based screening programs became common place at sites where people congregate and space was available for staff or volunteers to measure BP and provide education and counseling. Firehouses, churches, barbershops, and work sites were frequently used.

In the early 1970s, household, community, and clinic surveys documented low rates of hypertension awareness, treatment, and control in Georgia, Virginia, Maryland, and Washington, DC.⁹⁻¹³ In an effort to screen for undetected hypertension in inner city Washington, D.C., Finnerty et al. found house-to-house canvassing by trained interviewers to be ineffective, time consuming, and dangerous. Encouraged by civic leaders, trained allied personnel held screenings in churches and supermarkets, identified large numbers of hypertensive individuals, and referred them to care. In several care settings, low rates of appointment attendance and BP control and high rates of clinic dropouts were documented. Interviews with patients revealed three key findings affecting patients' attitudes about remaining in care: amount of time expended to receive care (transportation and waiting), understanding of all aspects of the disease, and "doctor/paramedical/patient" relationship. A new patient-centered hypertension care program was designed, including health aides trained to (1) serve as patient advocates; (2) deliver preappointment reminders by telephone, mail or in person (which led to a doubling of attendance); and (3) help resolve difficulties affecting compliance with visits and medication.^{12,13}

The Hypertension Detection and Follow-up Program (HDFP) was designed to test the effectiveness of a comprehensive treatment program to control high BP and reduce its complications compared with usual care in the community.^{14,15} Clinic-based care, community outreach, free transportation and medication, a multidisciplinary team approach to care, and a very committed staff, in addition to pharmacologic benefits of hypertension control, were demonstrated to be very effective in improving BP control, as well as morbidity and mortality rates. These methods, which were first published in the 1970s, have been generalized to the community and incorporated into all major multisite hypertension treatment and

prevention clinical trials since the conclusion of, for example, MRFIT, TOHMS, and TOPH.¹⁶⁻¹⁹ In a classic health education clinical trial designed to develop ways to improve physician care of hypertension, Green, Levine, and colleagues used a factorial design to test three supplementary interventions: physician visit exit interview with the nurse, home visits to a person identified by the patient as a source of social support with health matters, and group classes.^{20,21} The home visits, which were found to be an effective outreach strategy, were conducted by nurse-supervised high school students from the community. Work-site programs—an additional type of outreach—were found to be very successful in improving rates of hypertension care and control. Schoenbaum et al., working with a labor union for department store employees, documented the high standard of care provided on site by nurse practitioners²²; Foote and Erfurt documented the value of work-site interventions at Ford Motor Company.²³

A broad definition of community outreach encompasses many of the efforts of the National Heart, Lung, and Blood Institute's (NHLBI) National High Blood Pressure Education Program founded in 1972. These outreach activities were directed to the public (through mass media campaigns), healthcare practitioners, professional societies, voluntary health organizations, industry, and individual patients. In the 1970s and early 1980s, seven state programs supported by NHLBI demonstrated the value of mobilizing and coordinating community-wide resources to increase the rates of hypertension awareness, treatment, and control.²⁴⁻²⁷ In Maryland, a coordinating council served as the hub for the collaboration of professional groups, academic health centers, voluntary nonprofit organizations, and others who wanted to improve hypertension care and control. Committees were formed to carry out the project aims of the NHLBI funded program by providing outreach into many communities. The projects were numerous, varied, and included professional education; public information and communication; screening and monitoring at health departments, work sites, churches, and barbershops; and demonstration projects in inner city and rural areas of the state.^{28,29,30} Professional education, which can disseminate consensus recommendations to improve practice and patient care, has been a national priority since the High Blood Pressure Education Program began. Over the following decades, the Joint National Committee reports have focused increasingly on diagnosis, evaluation, and initial medical treatment of hypertension and other risk factors with lessening emphasis on community programs, multidisciplinary approaches, and adherence strategies.³¹ Outreach information is available in separate documents that have been disseminated primarily to the public health community.³²

In the 1980s, the following comprehensive community-based cardiovascular risk reduction studies were conducted: The Stanford Five-Cities Project,³³ The Minnesota Heart Health Program,³⁴ and The Pawtucket Heart Health Program.³⁵ These major community-based programs to reduce cardiovascular and stroke risk utilized state-of-the-art communication and education strategies in combination with community organization, outreach, and social support.³⁶ This application of knowledge drew from the social and behavioral sciences complementing and supplementing knowledge from the biomedical sciences.³⁷ These programs demonstrated the complex challenges in improving outcomes through risk reduction at the community level.

Today, telecommunication technologies, including hand-held and personal computers, telephone, facsimile (FAX), and electronic mail (e-mail) are being used to collect, transmit, and store data. These technologies provide opportunities for creative models of outreach for diagnosis and treatment. These tools facilitate patient self-monitoring of BP and communication of information among patients in their homes, community laboratories, nurse case managers, primary care physicians, and specialist physicians, improving the diagnosis and management of hypertension.³⁸ In addition, home BP monitoring by the patient and review of the progress toward goal BP by the health provider with feedback by email, mail, or telephone, improves adherence by tailoring therapy promptly without office visits. Programs incorporating telecommunications, such as MULTIFIT, have earned high levels of patient and provider satisfaction and improved outcomes.³⁹⁻⁴¹

THE GAP BETWEEN RESEARCH AND PRACTICE

It is clear from these and other studies that a combination of lifestyle and pharmacologic interventions can control hypertension and reduce associated morbidity and mortality. These interventions are significantly more effective when based on an assessment of the education and skill building needed by patients, providers, and the public. The unmet challenge in hypertension control is to extend the health benefits of these interventions to the population at large and, in particular, to groups that are more diverse, less select, and at higher risk than those studied in the clinical trials that demonstrated the efficacy of the interventions. Despite our increased knowledge and subsequent improvements in the control of hypertension, national data indicate that the majority of Americans with hypertension do not have controlled BPs and that awareness, treatment, and control rates have not increased as much as had been assumed.^{31,42} Community outreach that includes grassroots advocacy and education by voluntary health organizations, such as the American Heart Association, is necessary to eliminate the gap in the care and control of hypertension between majority and minority populations.⁴³ Evidence supports the value of community outreach activities designed with an understanding of the sociocultural context of patients' lives. Significant improvement in national hypertension control rates will require renewed commitment, a more comprehensive approach, and more clearly and strongly stated policy recommendations for effective culturally relevant community outreach.

HOW COMMUNITY OUTREACH WILL MOVE US FORWARD TO ELIMINATE HEALTH DISPARITIES

Community-Health System Partnership

Community outreach has contributed importantly to the detection and control of prevalent chronic diseases by incorporating the priorities and strategies of health professionals and those of the community.⁴⁴ This shared approach reflects a

broader definition of health and its determinants, including the social, cultural, and economic context within which health is promoted. Community-health system partnerships allow for individual and collective empowerment. These partnerships also allow the community to participate in identifying health problems and strategies for addressing those problems at interpersonal, health care organization, community, and policy levels.⁴⁵ This partnership approach is recommended by the Task Force on Community Preventive Services and The Institute of Medicine's Committee on Capitalizing on Social and Behavioral Research to Improve the Public's Health.^{46,47} Such partnership strategies are also important for addressing the Healthy People 2010 national objectives to enhance access and care management.⁴⁸

Advocacy is one such important partnership effort. Recognizing needs, identifying solutions, securing resources, and influencing policy makers have been shown to improve national and local hypertension control activities. For example, securing the availability of malls and high school tracks for people to walk and providing more low fat, low calorie, and low sodium foods in grocery stores are examples of advocacy outcomes. "Lose Weight and Win," a church-based weight loss program for BP control among African American women, is an example of a successful community-based outreach program that operated independently from health care providers, systems, and settings with the goal of modifying lifestyle to complement, enhance, and reinforce medical recommendations.⁴⁹

Academic health centers and their neighboring communities are increasingly investing in health by forming partnerships to address local environmental and social needs and maintain cohesive neighborhoods.⁵⁰ These partnerships also are one solution to the national health care issues concerning underserved minority populations.⁵¹ Opportunities abound for integrating critical care, education and research and for translating best practices while providing patient care targeted to community health priorities.⁴⁷ Such initiatives further advance both institutional and community capacity to build meaningful partnerships and collaborative community health programs.⁵²

Ecological Multidisciplinary Approach

Hypertension care and control are complex challenges. Comprehensive multifactorial and multidisciplinary approaches are needed to eliminate the gap between what has been shown to be beneficial in clinical trials and what occurs in practice and in patients' daily lives.⁴³ The five-level Ecological Model (intrapersonal, interpersonal, organizational, community, and societal) is a useful way to organize responses to these challenges.⁵³ At the societal level, for example, more people are without health insurance or are underinsured than ever before. Those who do have health insurance are finding that their benefits are covering fewer services, including preventive services such as screening and risk factor management. Community outreach programs can provide information about available affordable services to uninsured and underinsured individuals. In addition, staff in outreach programs can advocate influencing policy makers to support the provision of effective hypertension care, if the disproportionate burden of hypertension among the lower socioeconomic groups is to be addressed.

At the level of the health care organization and the individual provider with responsibility for the care of hypertensive patients, the delivery of care needs to be culturally competent as well as evidence- and guideline-based. If desired patient outcomes are to be achieved long-term, administrators and clinicians need to invest their expertise wisely. By joining with others in a multidisciplinary team and including community health workers reaching out across geographic settings, physicians can maximize use of their medical expertise. We cannot afford to ignore the evidence supporting the important contributions of nurses, nurse practitioners, physician assistants, pharmacists, nutritionists, health educators, and outreach workers.⁵⁴ The compliance challenge is multileveled, and improving outcomes requires us to address behavior not only at patient level, but also at the provider and health care organization levels.⁵⁵ The fields of medicine, nursing, and public health have unique contributions to make and together can complement one another to eliminate the gap between what we know controls hypertension and reduces its complications and what is happening daily in practice and patients' daily lives.⁴³

Use of Community Health Workers

A particularly important aspect of community-outreach and community-based team approaches is the inclusion of community health workers. Also called *health aides*, *lay advisors*, *natural helpers*, or *peer educators*, these members of the same cultural group as the patient population of interest, are receiving growing acceptance as valued members of the health care team.⁵⁶⁻⁵⁸ Often working closely with nurses, community health workers provide basic primary care services in community settings, including the home.⁵⁹⁻⁶⁴ Their role focuses on improving access to and continuity of care, educating patients and families, reinforcing adherence to treatment, and addressing needed human services, as well as promoting self-care skills and confidence. Additionally, they are advocates for the communities they serve. In research, as well as service delivery, community health workers strengthen community understanding and acceptability of medical care, and thereby the effectiveness of many outreach activities, including hypertension care programs.⁶⁵⁻⁶⁸ The members of the healthcare team are trained to (1) provide health information to improve knowledge and skills with appointments and recommended treatment; (2) assist with referrals to community resources, including assistance with financial problems; (3) monitor BP and communicate with care providers in clinical settings; and

(4) facilitate the identification and involvement of a key support person to whom the patient turns to for help with health matters. Crucial qualifications include a desire to help others and to improve the health of the community and its residents. The worker, often a member of the neighborhood, understands the community's language, culture, and socioeconomic conditions and is able to help providers and patients better understand each other's expectations. This insight and linking function facilitates the development of an individualized plan for hypertension care that the patient can adhere to within the context of his/her daily life.

In inner city Baltimore, a program of research was developed to test the effectiveness of a nurse practitioner–community health worker–physician team approach to improving hypertension care and control in young African American men. Lack of health insurance, a primary care physician, and compliance with antihypertensive treatment, as well as dependence on emergency departments for episodic care, contributed to low rates of hypertension care and control in this underserved high-risk population.^{65,69-71} Planning for the 5-year clinical trial was guided by an eclectic conceptual framework that represented an integration of models, particularly the PRECEDE-PROCEED model⁷² This approach, which is presented in Figure 40–1, integrated health education, behavioral change and health maintenance principles, culturally sensitive strategies, social action, and social learning theory. It is essential that the conceptual approaches to hypertension control incorporate economic, psychosocial, and behavioral factors (individual lifestyles, self-management practices, and long-term adherence to treatment) in elegant ways. The PRECEDE-PROCEED model incorporates predisposing, reinforcing, and enabling factors for behavioral change. Predisposing factors are those antecedents to behavior that provide the rationale or motivation for the behavior, such as knowledge, beliefs, attitudes, or values. Enabling factors are those that allow a predisposition to be translated into behavior, such as accessing health care resources or acquiring appropriate skills. Reinforcing factors, such as family, peer, or health provider/community health worker support, and supportive services are subsequent to a behavior and provide the continuing reward or incentive for the behavior as well as contribute to its maintenance. The conceptual framework used in this trial emphasized adherence with treatment recommendations in the More Intensive Intervention Group in comparison with the Less Intensive Intervention Group with the intent of improving health outcomes (Figure 40–2). A team approach to

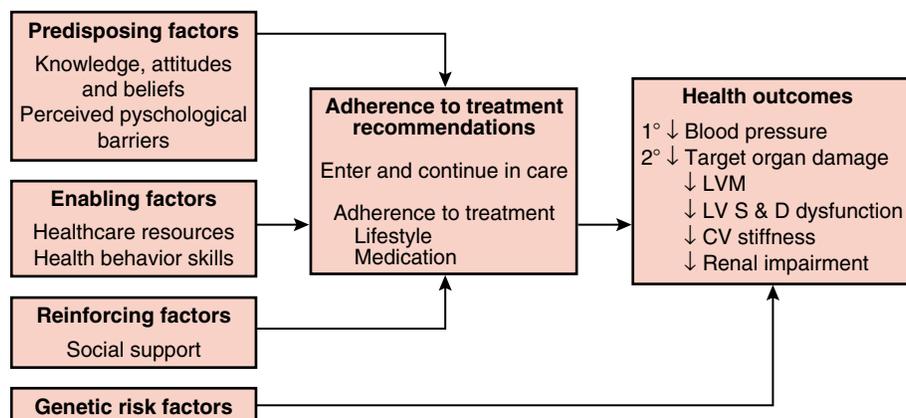

Figure 40–1 Conceptual framework. (Modified from Green LW, Kreuter MW. *Health Promotion Planning: An Educational and Environmental Approach*, 2nd ed. Mountain View, Mayfield, 1991.)

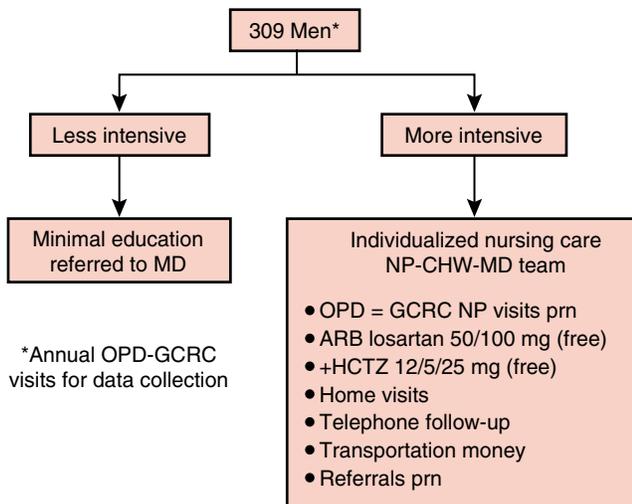

Figure 40-2 Ongoing randomized clinical trial design.

care, in which a community health worker provided outreach services led to better BP care and control compared with traditional medical care over a 5-year period.^{73,74}

An additional program in another area of inner city Baltimore focused on testing the effectiveness of nurse-supervised community health workers delivering home-based interventions.^{71,74} Trained health workers were helpful members of the investigative teams in improving hypertension care and control in these programs. These individuals contributed their community perspective and experience, which helped balance the inevitable tension between standardizing an intervention to meet protocol needs and providing individualized culturally salient patient care and service. The training and employment of residents from the community strengthened the academic-community partnerships and provided excellent career opportunities for the community members.

SUMMARY

We must redouble our efforts to improve U.S. rates of hypertension awareness, treatment and control. Community outreach offers proven strategies for complementing office- and clinic-based medical care of hypertension. Community outreach also offers strategies that increase entry into and remaining in continuous care, as well as adherence to treatment recommendations. For these reasons, one of the three major areas of focus in the NHLBI's plan to address health disparities is outreach and education. Of special importance, community-based participatory research is needed to further investigate the most cost-effective and efficient strategies in diverse populations with disproportionate burdens of hypertension and its complications.

Medication Adherence for Antihypertensive Therapy

Lars Osterberg, Peter Rudd

Hypertension remains a powerful contributor to cardiovascular diseases, which are the most common cause of death in the United States. Calculated to be the fourth largest risk factor for mortality, hypertension may predict 6% of all deaths worldwide.¹ Over the past four decades, the prevalence of hypertension has changed little (~24% of the U.S. population) despite improvements in its detection and treatment.² The importance of optimizing treatment adherence rises in proportion to the potential benefit from therapy. With successful treatment, the relative risks of fatal events fall by 40% for stroke and 26% for coronary heart disease (CHD).³

These promising results are not guaranteed. The benefits largely depend on achieving high rates of blood pressure (BP) control. National data, displayed in Figure 41–1, suggest the need for continued efforts and improvement, since less than 30% of American hypertensive patients are diagnosed, under treatment, and at goal BP. This leaves more than 30 million hypertensives in this country who remain suboptimally controlled.⁴

One of the critical factors that determines BP control is the patient's adherence to the prescribed regimen, also called *compliance*. In general, patient compliance refers to the willingness and ability of an individual patient to follow health-related advice, take medication as prescribed, attend scheduled clinic appointments, and complete recommended tests and consultations.⁵ The sizable investment in diagnosing, evaluating, and prescribing treatment for individual hypertensive patients achieves value in proportion to how well they follow the prescription: taking medications, modifying diet and activity, and making other lifestyle changes.

THERAPEUTIC PARADIGM

The path to improving BP control begins with steps taken by the clinician in evaluating, treating, and reassessing the patient's hypertension. Most clinicians titrate their patients' BP to a therapeutic goal level, which is most commonly $\leq 140/90$ mm Hg and recently revised to $\leq 135/85$ mm Hg⁶ for uncomplicated hypertensives. The clinician has multiple tasks: deciding whom to treat, when to treat, how to treat, and how to adjust treatment to optimize the benefit/risk ratio. More than two decades ago, Sackett et al.^{7–9} focused on the adjustment process. They formulated the clinician's dilemma as having to categorize the returning patient as falling into one of four mutually exclusive clusters, illustrated in Figure 41–2.

The clinician must decide whether to continue the current regimen, augment it, attenuate it, or withhold it altogether. For the busy clinician, the decision may appear deceptively

simple. If the clinician considers only two possibilities (the regimen is satisfactory *or* the regimen needs to be augmented), he is following a simplified strategy. At least two other conditions may escape detection: (1) the patient has achieved goal BP despite not having fully complied with the prescription, and (2) the patient may have failed to achieve goal BP (in part) because of imperfect adherence. To be comprehensive, the clinician must consider all four possibilities.

Very limited data exist about the relative frequency distributions of the four groupings among ambulatory hypertensive patients. The McMaster group reported data from male steelworkers assessed by pill counts and home BP assessments.^{8–10} Silas et al.¹¹ used quantitative urinary assays after calibration for the adherence measure. Their data appear together in Table 41–1.

Despite different methodologies, the two studies display remarkably similar patterns. Only a minority of studied patients achieved both goal BP and optimal adherence at the same time. Indeed, only about half of each group achieved satisfactory BP control. Perhaps most critically, more than half of those patients who failed to achieve goal BP exhibited suboptimal medication compliance. Finally, a small but definable minority achieved goal BP despite less than full adherence, perhaps because of overzealous diagnosis or prescription.

Box 41–1 enumerates some implications of these distributions. The first implication is that optimal compliance with prescribed antihypertensive medications should not be assumed, since it seems not to occur about half the time. Second, the clinician should resist automatic escalation of the drug regimen if the patient fails to achieve goal BP. About half the time, the reason for failure reflects suboptimal medication-taking behavior rather than the biology of the disease or the pharmacology of the regimen. Third, an important minority on chronic antihypertensive medication succeeds at combining full compliance without special interventions to attain goal BP levels. Finally, a small group achieves goal BP despite poor compliance but needs special assessments for detection.

There are consequences if the clinician misclassifies the patient, both in terms of risking toxic levels of drug exposure when full compliance occurs and in failing to achieve consistent BP reduction with imperfect cardiovascular risk reduction. The data indirectly support the conclusion that the impact of treatment, both positive and negative, is proportional to the amount of treatment actually received rather than to the amount prescribed.¹² Urquhart has phrased the matter succinctly: "The quality of execution of drug prescription is a patient attribute, not a drug attribute." (John Urquhart, MD, FRCP [Edin], Pharmaco-epidemiology Group, Maastricht University, Maastricht, NL, personal communication.)

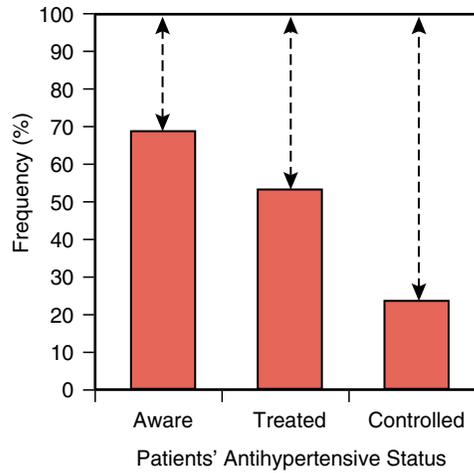

Figure 41-1 Status of antihypertensive management and opportunities for improvement: 1988-1991. Prevalence of hypertension by status of diagnosis, treatment, and BP control from the Third National Health and Nutrition Examination Survey (NHANES III; 1988-1991), based on a cross-sectional survey of the civilian, noninstitutionalized population of the United States after both an in-home interview and clinical examination for 9901 participants above age 18. The dashed arrows represent the opportunity still unrealized to optimize antihypertensive control. (From Burt VL, Whelton P, Roccella EJ, et al. Prevalence of hypertension in the US adult population. Results from the Third National Health and Nutrition Examination Survey, 1988-1991. *Hypertension* 25:305-313, 1995.)

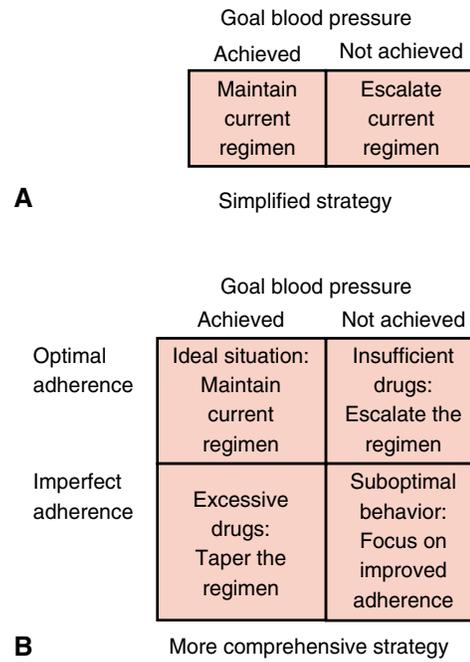

Figure 41-2 Clinicians must decide when and how to respond to returning patients prescribed antihypertensive medication. A simplified strategy, **A**, uses regimen escalation when patients fail to achieve goal blood pressure (BP). **B** illustrates a more complex strategy, acknowledging the role that both patient and clinician play in achieving therapeutic goals. (Adapted from Sackett DL, Haynes RB, Tugwell P. Compliance. *Clinical Epidemiology: A Basic Science for Clinical Medicine*. Boston, Little, Brown, 1985; pp 199-222).

Box 41-1 Implications of the Adherence Distributions

- Optimal adherence to the antihypertensive prescription should not be assumed.
 - Nonadherence occurs about half the time.
 - Overprescribing coupled with under-adhering may still produce satisfactory BP control.
- Failure to achieve goal BP despite an adequate regimen and adequate time to respond may result from biologic, pharmacologic, behavioral factors or a combination of all three components.
 - About half the time when goal BP is not achieved, suboptimal medication-taking may be present.
 - Escalating the regimen in such a context will be incorrect half the time.
- Only an important minority combines full compliance without special interventions to achieve goal BP in a consistent manner.

On the positive side, full compliance brings maximal reduction of BP and cardiovascular risk. On the negative side, full compliance also brings maximal drug-related side effects and other toxicities. All but the most naive patients quickly learn to carry out their own mini-experiments, seeking to optimize among positive and negative, short- and long-term, benefit and risk.¹³ Not surprisingly, partial or complete nonadherence is a major contributor to “refractory” hypertension.¹⁴

MEASURING COMPLIANCE

These perspectives on adherence and hypertension have evolved slowly but with increasing rapidity in the last decade with improved measures of medication-taking behavior. With better measures, clinicians have learned to broaden their focus and seize new opportunities.

For centuries, the study of medication-taking was constrained by the frailty of its measurements, as illustrated in Table 41–2.^{15–20} Allusions by Hippocrates and Plato to nonadherence underscore the long tradition but provided few metrics except for global patient self-report or clinician opinion. Both of these techniques are easy and inexpensive but prone to subjectivity and easy distortion. They are examples of indirect measures, remote in time and space from the actual consumption of prescribed medication. Other measures similar in stature and similarly subject to error are short-recall patient self-report, self-monitoring by diary, and therapeutic outcome. The latter has the hidden complexity that other factors beside adherence may determine clinical outcomes with little foundation for teasing out the separate contribution of compliance on its own.

The arrival of pill counts has been a mixed blessing. On the one side, they appear to bring a degree of precision and quantitation to measuring adherence. But, on the other hand, the parking lots of many clinical study facilities may give evidence of pill-dumping as patients try to represent themselves as adherent and cooperative.²¹ Some cynics have argued that pill counts have provided job security for a whole generation of research assistants without adding substantially to our knowledge of true compliance patterns.²²

In contrast, several groups have confirmed the relative accuracy of prescription refill rates, especially when carried out over several months compared with a home inventory.^{23,24} Important cautions, however, include discrepancies between the prescription and the medical record and using refill rates for periods less than 60 days.²⁵ Even more limiting is the need for a closed system of pharmacies for all refills and complete, computerized records. The method may also be distorted by the sharing of medications by the index patient and others taking the same drug.

Over nearly 30 years, several investigators have explored the use of medication monitors, capable of recording vial openings or discrete dispensings.^{19,22,26–42} For the first time, one could track the day-to-day dynamics of medication-taking rather than relying on an imprecise average over days, weeks, or months and also minimize the likelihood of patients misrepresenting their own report card.⁴³ Lingering problems and disappointments include relatively high cost, need for vial returns or transmissions for downloading of data, and limited discreteness of tracking individual doses with some devices. Most clinicians and investigators quickly agreed that it was

improbable that anyone would systematically dispense pills over several months as tracked by the monitor and then discard the doses without actually administering them. These indirect methods dramatically advanced our sophistication about the process of medication-taking.⁴⁴

In contrast, the available direct measures like biologic assays^{45,46} or tracer systems^{47,48} do confirm drug administration but require collection of body fluids (e.g., blood, urine, saliva) and performing discrete quantitative assays while making assumptions about hepatic and/or renal function. Such measures still do not permit retrospective review beyond several pharmacokinetic half-lives. They further suffer from relatively high cost and difficulties of administration in exchange for superior sensitivity and specificity over the short periods reflected by point estimates of drug concentrations.⁴⁹

EPIDEMIOLOGY OF MEDICATION COMPLIANCE

Patterns of Medication-Taking Behavior

Constrained by imperfect adherence measures, early studies concluded that chronic preventive treatments, such as those for hypertension, exhibit compliance rates approximating 50%.⁵⁰ More discrete measures, especially electronic medication monitors, revealed more granularity, clarity, and complexity from the data analysis. Most deviation from the prescription occurs as dose omissions rather than as dose insertions or misschedulings.^{51,52} The dose omissions occur more frequently as the dosing frequency increases, as illustrated in Figure 41–3. Medication-taking patterns commonly improve significantly in the 5 days preceding and following schedule appointments, compared with 30 days after appointments, generating a “white-coat compliance” pattern.^{35,53}

Although intuitive, the prescribing of very simple regimens (e.g., one pill once daily) does not ensure consistent adherence,⁵⁴ even among those with relatively frequent, reinforcing visits with the clinician.³⁶ There remains a core of 10% to 40% of subjects displaying imperfect dosing. The difference in compliance between once- and twice-daily dosing tends to be small in most studies, while adherence declines more dramatically as prescribed dosing frequency exceeds twice-daily.^{36,54} Electronic monitoring has confirmed that the adherence varies inversely with dosing frequency. Those on a once-daily regimen display less dosing variability than with twice-daily dosing among 198 Canadian hypertensives randomized to diltiazem twice-daily vs. amlodipine once-daily.⁵⁵ Among diabetics on oral agents, the compliance rate fell from 79% on once-daily to 38% on three-times daily dosing.⁵¹

Similar patterns appear in adherence data from diverse medical conditions, whether compliance distributions come from patients with hypertension,^{32,36,38,56} seizure disorders,^{22,35} glaucoma,^{33,40,57} or other clinical scenarios like hormone therapy and lipid-reducing agents.^{58–60} Most of the available data come from settings of chronic therapy to prevent long-term negative consequences. Figure 41–4, although a hypothetical composite, reflects the similar J-shaped distributions reported by the respective investigator groups.

Closer inspection of Figure 41–4 reveals three principal subgroups. On the positive side, 50% to 60% of the patients are *full compliers* with trivial deviations from the prescription

Table 41-2 Available Measures of Medication Adherence

COMPLIANCE MEASURE	Marginal Cost	Difficulty of Use		Approximate* Related to "Gold Standard"		Comments
		Patient	Investigator	Sensitivity	Specificity	
				Noncompliance	Compliance	
INDIRECT						
1. Self-report	+	+	+	20%-55%	80%-95%	Unspecified versus short (1-2 day) recall
2. Self-monitoring	+	++	++	40%-70%	80%-95%	Prospective logging of drug-taking
3. Clinician opinion	+		+	50%-65%	40%-80%	Point estimates of dynamic process
4. Pill/packet count	++	++	+++	60%-90%	75%-90%	Pill vial return issues: nontrivial
5. Prescription refill	++		+++	60%-90%	60%-90%	Central pharmacy or comprehensive records are critical
6. Therapeutic outcome	+		+	20%-40%	40%-80%	Implicit versus explicit criteria should be pre-defined
7. Medication monitor	+++	++	+++	85%-95%	85%-95%	Often needs supplemental pill count as well
DIRECT						
1. Direct supervision	++	+	+++	85%-95%	85%-95%	Parenteral administration versus oral drugs
2. Bioassay of drug	+++	++	+++	60%-90%	80%-95%	Bioassays not always feasible or available
3. Pharmacologic marker	+++	++	+++	60%-90%	80%-95%	Combination of marker and primary drug may need FDA approval

Arbitrary scale of degree: + = small; ++ = moderate; +++ = large

and remarkably consistent medication-taking behaviors from day to day. At the other extreme, the *noncompliers* exhibit extremely imperfect adherence, although sometimes misrepresenting their usual behavior by pill-dumping just before scheduled visits. In the middle are the *partial compliers*. Rather than a simple intermediate point, the partial compliers show a complicated mixture of nearly perfect pill-taking interspersed with periods of marked deviation from the prescription. Such a pattern suggests that they understand what they are supposed to do but have difficulty in performing the tasks in a consistent manner.⁶¹ Although not a bell-shaped distribution, the average compliance for such groups approximates 60% to 75%, consistent with other reports.⁶² Seeking more detail, Urquhart summarized the compliance distribution of a patient cohort as follows:

1. One sixth of the patients take their medications exactly as directed.
2. One sixth take nearly all the medications with some fluctuations in dose timing.
3. One sixth occasionally omit a single daily dose.
4. One sixth have a drug holiday (the sequential omission of 3 or more days' doses) 3 to 4 times per year, together with occasional omissions of 1 to 2 days' doses.
5. One sixth of the patients have a "drug holiday" monthly, together with frequent omissions of 1 to 2 days' doses.
6. One sixth take few or no doses while giving the impression of being completely compliant. (See Figure 41-5.)⁶³

All but the full compliers display important gaps in medication-taking. The consequences of such nonadherence

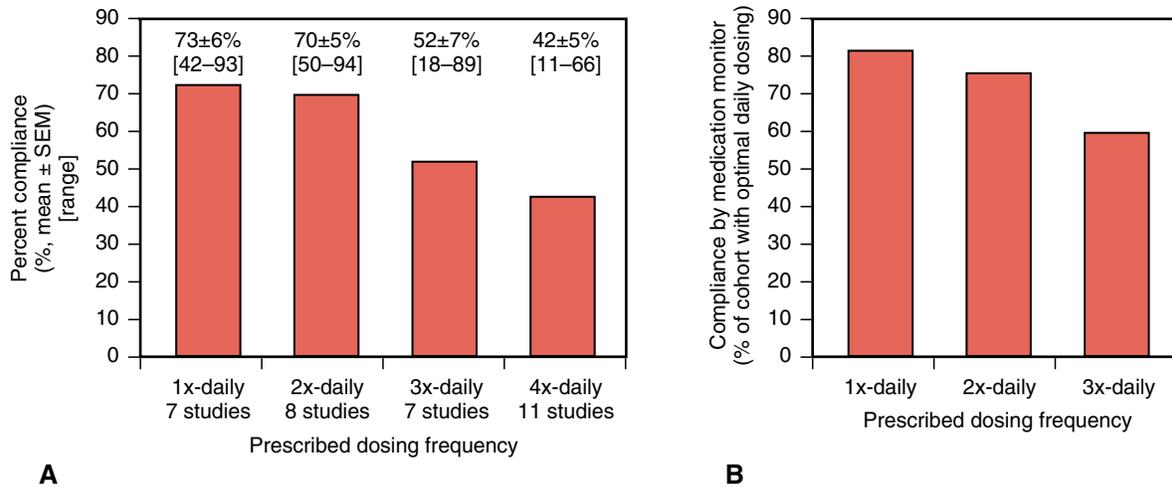

Figure 41-3 Compliance rate by dosing schedule. Compliance rates tend to fall as the frequency of daily doses increases. **(A)** Greenberg performed a literature review in 1984, reflecting adherence assessments primarily by self-report and pill count. **(B)** Eisen and coworkers employed an electronic medication monitor among hypertensive patients. Both studies support an inverse relationship between adherence and dosing frequency with more modest differences between 1x- and 2x-daily dosing than with more frequent dosing schedules. **(A)** from Greenberg RN. Overview of patient compliance with medication dosing: A literature review. *Clin Ther* 6:592-599, 1984; **B** from Eisen SA, Miller DK, Woodward RS, et al. The effect of prescribed daily dose frequency on patient medication compliance. *Arch Intern Med* 150:1881-1884, 1990.)

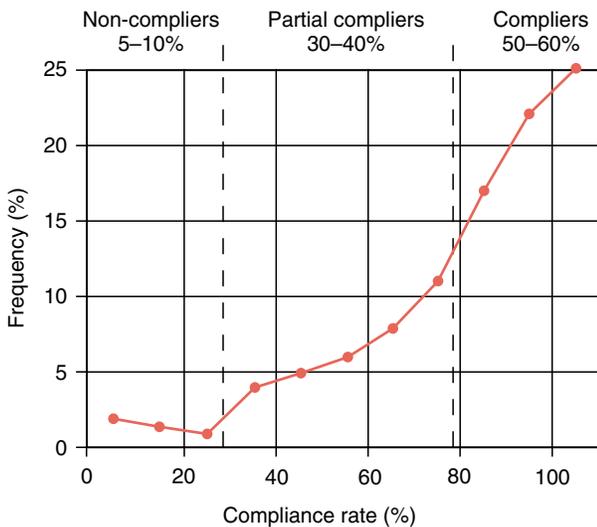

Figure 41-4 Compliance distribution composite: hypertension, seizures, glaucoma, congestive heart failure (CHF). Several investigators have reported remarkably similar patterns of compliance among ambulatory patients monitored electronically for medication-taking behavior despite dissimilar diseases like hypertension, seizures, glaucoma, and CHF (see text for references). All the conditions exhibit three clusters: (1) *full compliers* (50%-60% of total) with negligible deviations from the prescription; (2) *partial compliers* (30%-40%) with periods of excellent adherence interspersed with poor adherence or “drug holidays”; and (3) *noncompliers* (5%-10%) with low levels of compliance. (Adapted from Rudd P, Hagar RW: Hypertension: Mechanisms, diagnosis, therapy. In Topol E (ed). *Textbook of Cardiovascular Medicine*, 1st ed. New York, Lippincott-Raven, 1997; pp 109-143.)

include subtherapeutic drug concentrations; imperfect BP control; submaximal cardiovascular risk reduction; unnecessary and potentially dangerous treatment escalation; avoidable tests, procedures, and hospitalizations; and threats of withdrawal, rebound, and first-dose phenomena.⁶⁴ None of these bad outcomes should be surprising if one acknowledges that drugs act episodically in patients who dose episodically, inadequately or not at all in patients who underdose, and hazardously when dosed in intermittent patterns.⁶⁵ At a more extreme level, drugs cannot work if (1) they are never prescribed, (2) the prescription is written but never filled, (3) the drug is never taken by the patient, or (4) the drug is taken but not absorbed. Overall, the pharmacologic impact, whether beneficial or toxic, is proportional to the drug exposure and the dose received.

Predictors of Noncompliance

Given the high stakes, many groups have begun searches for predictors of noncompliance, so as to concentrate remedial resources on the groups most needy of change. Early efforts quickly concluded that no simple, nonadherent, personality profile existed. At the extremes of age, poverty, social isolation, and psychiatric dysfunction, increased noncompliance was observed. Symptom level, educational level, and objective seriousness of the medical condition provided little predictive value.⁶⁶ In contrast, Hill et al.,⁶⁷ focusing on disadvantaged, inner city populations, encountered high rates of no current antihypertensive care (49%), use of illicit drugs (45%), social isolation (47%), unemployment (40%), and lack of health insurance (51%). Low alcoholism risk and employment were identified as significant predictors of compliance with antihypertensive medication-taking behavior. Men currently using illicit drugs were 2.6 times less likely to have controlled BP compared with their counterparts who did not use illicit drugs.

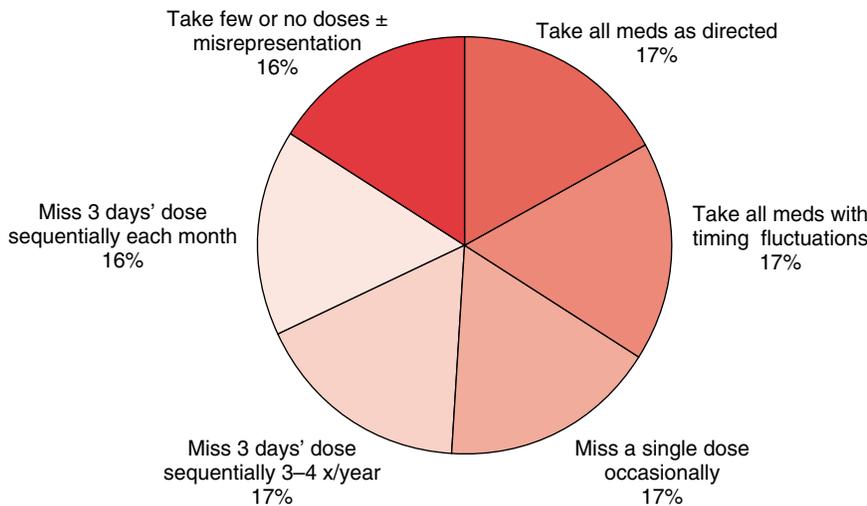

Figure 41-5 Dose-taking distribution from unpublished series of diverse patients on chronic medications by electronic monitoring of dose dispensings. (Adapted from Urquhart J. The electronic medication event monitor. *Lessons for pharmacotherapy. Clin Pharmacokinet* 32:345-356, 1997.)

Despite limited success to date in finding predictors, the obvious broad areas for future focus include characteristics of the individual patient, the disease, the prescribed treatment, the patient-provider relationship, and the clinical setting.⁶⁸ Among patient characteristics, consistent patterns of superior adherence with electronic monitoring emerged from older rather than younger patients⁶⁹⁻⁷² except for the “old-old” up to age 87.⁷¹ Among an ambulatory, hypertensive, Medicaid population, Bailey et al. reported that prescription refill compliance varied by drug class (α -blockers > ACE-inhibitors > calcium channel blockers > diuretics),⁶⁹ although others have recently reported no difference in the discontinuation rate of the various drug classes.⁷³ Independent predictors of nonadherence as measured by medication refill rates include younger age, multiple daily doses, fewer provider visits, and depressive symptoms.^{69,74} In contrast, patient gender and regimen complexity hold little predictive value.⁶⁹

Knowledge about the disease and familiarity with the regimen are necessary but not sufficient to ensure high levels of adherence.⁷⁵ Indeed, health professionals themselves are often cited to demonstrate that knowledge and education are no guarantee of compliance. Each individual, whether or not sophisticated about the medical condition and its management, must make hard choices to optimize among risks and benefits, hardships and conveniences, costs and rewards. Commonly cited barriers include simple forgetfulness, drug side effects, financial costs, confusion about the regimen, and interference with daily schedules.⁷⁶⁻⁷⁸

Some patients, especially the elderly, construct elaborate systems of locations and cues to facilitate remembering and adhering to the prescribed regimen.⁷⁶ Still others struggle with childproof vials, which functionally become person-proof.⁷⁹ Most of these coping mechanisms are highly personal and rarely emerge from routine clinical surveillance. Some advocates of patient self-management^{80,81} have argued that three issues are key to improving adherence: (1) defining the key behaviors to be mastered and implemented, (2) providing consistent guidance and reinforcement, and (3) linking the behaviors to the desired clinical outcomes.

There appears to be something beneficial associated with compliant behaviors in general, even when they consist of taking placebos in clinical trials. Three of 12 studies comparing

rates of hospitalization and mortality for chronic heart disease revealed better clinical outcomes with adherence versus nonadherence to placebo, suggesting that adherent behavior may be a marker for other behaviors with protective effects or otherwise confer an improved prognosis.⁸²

On the other side, there are some definite negative consequences for nonadherence. Interruptions in antihypertensive prescription refills among California Medicaid patients greater than 40 years old were associated with higher costs, especially for hospitalization.⁸³ Among 602 women enrolled in the Beta Blocker Heart Attack Trial, nonadherence by appointment and medications conferred a 2.4-fold (95% CI 1.1-5.6) increase in postmyocardial infarction (post-MI) death rates. Those who complied had a 2.4-fold reduction in mortality, whether or not they were randomized to receive propranolol as the active drug.⁸⁴

APPLICATION TO HYPERTENSION

Treatment of hypertension almost never occurs in isolation but arises as part of a more comprehensive strategy to reduce overall cardiovascular risk, such as from dyslipidemia, cigarette smoking, glucose intolerance, and obesity.² Unfortunately, the multiplicity of factors and resultant interventions may diminish rather than enhance some patients' motivation. The adherence burden rises when clinicians seek to have patients reduce salt, saturated fat, and alcohol intake at the same time as they have patients decrease stress and increase regular physical exercise. The sheer number of things to change may overwhelm all but the most focused, trusting, and dedicated patient.

Interactions among the treatments may create extra dilemmas and opportunities. As data emerge indicating circadian variation in cardiovascular risk, selection of specific antihypertensive agents and their optimal administration time becomes more complex.⁸⁵ The clinician must learn to choose drugs on the basis of their ability to reduce overall cardiovascular risk as well as to optimize antihypertensive efficacy, safety, quality of life, and adherence.^{86,87} Partially abandoned, the old concept of “stepped care” has been largely replaced by evolving notions of more personalized, nearly customized treatment plans.⁸⁸

Part of the rationale for more aggressive and presumably more effective treatment strategies is the growing appreciation

of lost benefits and increased risks for poor antihypertensive management. Suboptimal compliance carries increased probabilities of extra hospitalizations,⁸⁹ sudden death,⁹⁰ and other cardiovascular morbidity, even when the elevated pressures are linked to white-coat phenomena.⁹¹

Several features about treating ambulatory hypertension pose special challenges to the treating clinician. Most day-to-day responsibilities for following the regimen rest squarely on the patient's shoulders, regardless of the amount of instruction, guidance, and support provided by physician, nurse, pharmacist, or family members (see Figure 41–6). Although many factors can contribute to a patient's nonadherence to medications, the patient is still the main player in attaining full compliance.

FOCUS ON COMPLIANCE IN HYPERTENSION

The Patient

There is a diverse array of problem areas for the hypertensive patient. Some investigators classify patients according to their readiness to accept the diagnosis and undertake active participation: deniers versus acceptors versus pragmatists.⁹² Others focus on the perceived “net” barriers to full adherence, especially relevant and prevalent among younger patients and those most recently initiating treatment.⁹³ An unpublished telephone survey by the Angus Reid Group among 301 Canadian hypertensives reported that 62% of respondents admitted to not taking their prescribed antihypertensive medication as prescribed (cited in *Ontario Medicine*, June 1994, p. 19). Fully 47% of respondents acknowledged side effects from these drugs, and only 41% were aware that stroke was a major risk of hypertension. Perhaps most intriguing were the types of magical thinking among some respondents, who believed they could skip doses and remain protected, who rewarded themselves with drug holidays for good behavior, and who tended not to refill medications promptly because they were too busy.

Early studies on the effect of labeling patients as hypertensive demonstrated decreased perceived health, increased absenteeism from work, increased depressive symptoms, and a decreased quality of life, even when the “label” of hyperten-

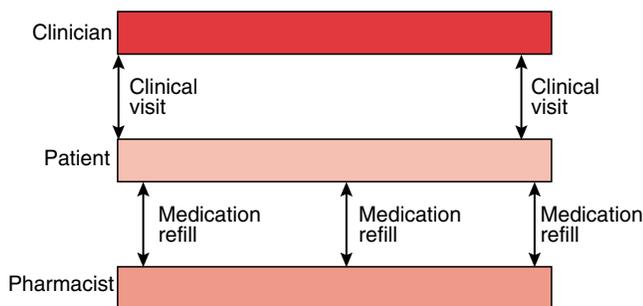

Figure 41–6 Relative contribution to adherent behaviors. The clinician, patient, and pharmacist all contribute to the frequency, consistency, and degree of adherence to the clinical prescription for ambulatory hypertensive patients. The relative contribution of the patient is the greatest, both overall and on a daily basis, despite the frequency of clinical visits and medication refills.

sion was incorrect and when no antihypertensive therapy was given.⁹⁴ The principal factors associated with increased absenteeism reflected patients' becoming aware of their condition and low medication compliance.^{94,95} Even in an academic family practice clinic, patients estimated that their recovery from an upper respiratory tract infection, urinary tract infection, or ankle sprain was about twice as long since the diagnosis of hypertension compared with those who had never had the diagnosis.⁹⁶ The adverse psychosocial impact may be tempered or even eliminated by avoiding forced screenings for the condition, providing reassurance, and offering a supportive work environment.^{97,98}

The Physician

Enlarging the focus of concern to include prescribing physicians has challenged several existing myths.⁷⁹ Many clinicians accept little if any responsibility for the complexity of the regimens they prescribe or for assisting their patients in minimizing drug-related side effects. They may overestimate their skill in detecting or preventing suboptimal adherence among their own patients and underestimate the several barriers which patients face in trying to comply.⁹⁹

Surprising to some has been the correlation of patients' adherence to recommendations of lifestyle changes and the prescribing physician's own style. Predictors of patients' adherence include the physician's job satisfaction, the number of patients seen per week, the scheduling of follow-up appointments, and the tendency to answer patients' questions.¹⁰⁰

Physicians Adherence to Clinical Guidelines

Physicians may themselves fail to adhere to evidence-based guidelines of diagnosis and treatment for hypertension. Such clinical guidelines arise from domain experts and opinion leaders and receive considerable emphasis and distribution.^{72,101,102} Although existing clinical guidelines define explicit BP targets, physicians often display misinformation about the recommended BP goals for their patients.¹⁰³ Even more problematic is the clinical inertia or “knowledge-practice gap” when clinicians know guideline recommendations but fail to initiate or intensify treatment when indicated in their patients.^{104,105} Such inertia may be particularly prevalent in treating conditions that are common and without limiting symptoms. As a consequence, prescribing clinicians may settle for BP levels above the recommendations rather than pushing themselves and their patients to attain the target range.^{104,106}

One model of physician behavior outlines five necessary and sequential steps for successful adherence to practice guidelines: awareness, agreement, self-efficacy, outcome expectancy, and presence of a cueing mechanism.^{107–109} Failures at any of these steps may lead to physician nonadherence to a guideline. By overcoming any of the barriers to achieving the five steps, physicians can attain improved guideline adherence.¹¹⁰

Effective Physician-Patient Communication

Still another physician-based opportunity arises in optimizing communication to and from patients.^{78,111,112} The components may include identifying and problem solving about barriers to full adherence, using education about risks and benefits to increase motivation, and employing active listen-

ing to patients' concerns for teasing out remaining problems of adherence. Optimizing communication among the patient and provider team provides the essential foundation for patient compliance.^{52,78,112-114}

The Healthcare System

On a larger scale, the American healthcare system introduces other problems. At least 42 million Americans remain without medical insurance.¹¹⁵ The absence of insurance alone or failure to link care with a principal provider does not in itself prevent good BP control. In fact, the multiplicity of influences obscures any simple correlation of poor access to health care to inadequate BP control.^{116,117} Improved access to medications, in contrast, has been associated with improved adherence.¹¹⁸ The growing dominance of managed care has brought pharmacy benefits management in an array of forms and formats that are sometimes helpful yet sometimes a barrier to patient compliance. The forced use of restrictive formularies, generic substitutions, and mail-away prescription-filling may exacerbate the hurdles to full adherence.^{119,120}

Opportunities for Collaboration

By defining adherence as the responsibility of several parties, new opportunities for collaboration and synergy emerge. The thoughtful clinician, concerned about optimizing a patient's BP, can bring skills, focus, and perseverance to the challenge of prescription adherence beyond proper diagnosis and evaluation. The health plan administrator, in turn, seeks to optimize outcomes for both the individual patient and the group of patients with similar characteristics and conditions. Pharmaceutical manufacturers wish to differentiate their products from competitive medications for the optimal combination of therapeutic efficacy and quality of life, while minimizing symptomatic and biochemical toxicity.¹²¹ Each constituency (patient, clinician, administrator, manufacturer) has its special priorities. Enhancing medication-taking for better outcomes will require a higher degree of sensitivity and collaboration among the principal parties than has existed in the past.¹²²

EVOLVING STRATEGIES FOR COMPLIANCE IMPROVEMENT

Guiding Principles

The field of medication compliance has shown repetitively that a one-size solution does *not* fit all. Just as there is no single cause for suboptimal compliance, so there is no single fix. The reasons underlying noncompliance are multifaceted and therefore so must be the solutions.¹²³ As the field evolves, it has come to incorporate ethnocultural and psychosocial perspectives, as well as traditional sociodemographic, clinical, pharmacologic, and medical system issues. At the core of the broadened perspective is a realization that the patient with a chronic condition, even one with few symptoms such as hypertension, has special kinds of "work" to accomplish in living with the condition. The problem solving by physicians, nurses, pharmacists, and other health professionals must go beyond the simplistic sender-message-receiver communication model used as a default. As an alterna-

tive, the patient should actively participate in the selection of therapeutic ingredients and the pace of treatment.^{124,125}

New Skills and Collaboration

The effective prescriber-clinician should ask, simplify, tailor, and reinforce. Asking the patient for input early in the process immediately sets up a different and potentially far more useful dynamic than the traditional, autocratic stance. Minimizing the total number of daily doses usually arises as a priority. Selecting the most useful cues and location for the particular patient's life and lifestyle provides an added "fit."¹²⁶

Optimization still requires a melding of patients' personal preferences with clinical and pharmacologic realities. Several recent reports emphasize the importance of effective 24-hour-a-day BP control, smooth antihypertensive effect with decreased variability in diurnal variation in BP, reduced early morning surge in BP, and minimal reflex activation of the sympathetic nervous system.¹²⁷ These characteristics assume even more prominence if medication-taking is imperfect and highly variable.

Pharmacokinetics as a Guide for Adherence

A lively debate has arisen about the value and relevance of trough-to-peak variability in BP in comparing one antihypertensive agent with another. Some have argued that the optimal drug is one with a smooth concentration-time profile and long elimination half-life to maintain stable drug concentrations and stable antihypertensive effect despite imperfect medication-taking.¹²⁸ In this context, the trough-to-peak ratio reflects the duration of drug's action relative to its dosing interval, avoiding the use of inappropriately large drug doses simply to extend the apparent duration of action. At least two different clusters of drugs have been identified. In the first group, the concentration-effect relationship is essentially linear, and the trough-to-peak ratio is almost invariably dose-independent and therefore more stable. In the second grouping, the concentration-effect relationship is sigmoid-shaped, and the trough-to-peak ratio becomes dose-dependent and highly affected by compliance.¹²⁹ The data from Meredith and Elliott, shown in Figure 41-7, illustrate some interdrug differences among several antihypertensive agents.¹³⁰

Drugs with linear relationships are more forgiving of imperfect adherence. They achieve therapeutic sufficiency with desirable and sustained reductions in BP in spite of variable pill-taking.¹³¹ Using ambulatory BP monitoring, Leenen et al. confirmed that once-daily amlodipine provided more effective and consistent antihypertensive effect than twice-daily diltiazem in the face of interrupted therapy.¹³² Some authors have used the same arguments in support of newly introduced combination products, when one of the components is especially long-lasting.^{133,134}

The New Paradigm: Challenges for the Decade

Ultimately, the clinician is the expert on the disorder and its treatment in general, but the patient remains the expert in his or her own disorder and his or her own experience with the treatment.¹³⁵ The principal challenges for the next decade will be to (1) forge strong foundations for collaboration among patient, clinician, and healthcare system; (2) reassess the

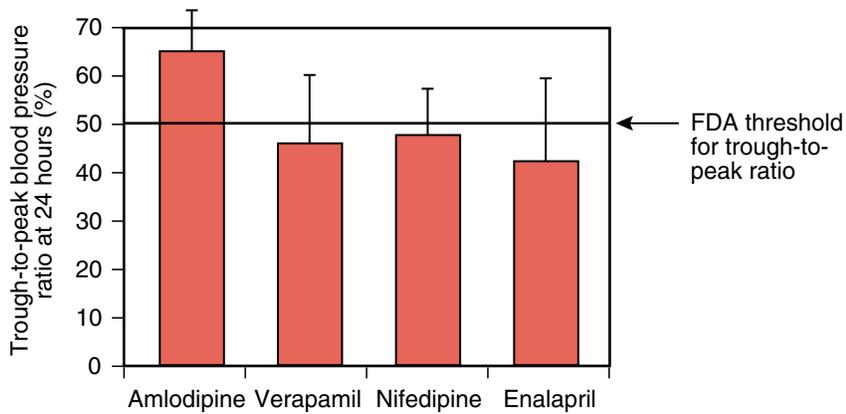

Figure 41-7 Antihypertensive response reflects plasma drug concentrations. Trough-to-peak blood pressure (BP) ratios at 24 hours provide a useful index of sustained antihypertensive effect for once-daily medications. Meredith and Elliott report the ratios for four antihypertensive agents compared with the Food and Drug Administration (FDA) benchmark of 50% at 24 hours. (From Meredith PA, Elliott HL. Amlodipine: Clinical relevance of a unique pharmacokinetic profile. *J Cardiovasc Pharmacol* 22:S6-S8, 1993.)

traditional wisdoms about predictors of nonadherence and effective interventions; and (3) establish thresholds of therapeutic sufficiency for optimizing cardiovascular benefit to hypertensive patients despite sometimes imperfect adherence.

Compliance-Enhancing Strategies for the Clinician

There are a cluster of discrete, effective, and feasible steps to detect, evaluate, and intervene among partial and noncompliant hypertensive patients, summarized in Box 41-2.⁹ The remedial steps represent challenges because few clinicians have received training in how to be educators, motivators, and coaches. For their part, many practices and medical institutions have not readily accepted responsibility for these critical efforts.¹³⁶

Box 41-2 Compliance-Enhancing Strategies for Clinicians

1. Watch for nonattenders.
2. Watch for nonresponders.
3. Inquire without confrontation about compliance barriers.
4. Encourage the development and use of a medication-taking "system."
5. Provide simple, clear instruction.
6. Simplify the regimen as much as possible.
7. Provide substitutive and sequential steps.
8. Monitor progress to goal, both in blood pressure (BP) and in compliance.
9. Reinforce desirable behaviors and outcomes whenever possible.
10. Apply useful, relevant information and help from all possible sources.
11. Make explicit the potential value of the prescribed regimen and the impact of compliance.
12. Emphasize the importance of dose timing when appropriate.
13. Seek to customize the regimen to the patient's needs and preferences.

Partially adapted from Sackett DL, Haynes RB, Tugwell P. Compliance. *Clinical Epidemiology: A Basic Science for Clinical Medicine*. Boston, Little, Brown, 1985; p 218.

1. Watch for nonattenders.

Those patients who fail initial or follow-up appointments are most at risk for dropping permanently out of care. This is especially likely to occur in the first year of treatment but may occur at any time.¹³⁷ Once detected, such patients should receive special handling to maximize the likelihood of their resuming regular visits and progress to goal.

2. Watch for nonresponders.

Most patients will respond to antihypertensive medications with a relatively prompt and sustained reduction in BP, assuming selection of a rational and suitably aggressive regimen. Initial or secondary "resistance" to treatment carries its own differential diagnosis: secondary hypertension, interfering substances, biologic factors, suboptimal regimen, and medication nonadherence.¹⁴ Retaining a low threshold for these possibilities helps promptly detect, address, and hopefully resolve any noncompliance.

3. Inquire without confrontation about compliance barriers.

When exploring for nonadherence, the art may lie in establishing collaboration rather than confrontation. Few patients will openly admit to noncompliance if the clinician asks, "You're taking all your pills, aren't you?" More useful phrasings might include the following: "Many people have difficulty taking their medications as prescribed. What kinds of problems have you had in taking the pills?" In one study of a community pharmacy, 549 submitted prescriptions were never picked up over a 9-month interval. The stated reasons included transfer to another pharmacy, forgotten prescription, patient still had medication left over, or patient no longer needed the medication.¹³⁸ In another survey of general practice patients, prescribing physicians and assisting nurses, imperfect knowledge of the medications occurred in up to 60% of patients.¹³⁹ After a suitable open-ended inquiry, the clinician may use some follow-up questions:

- (a) "Some people experience awkward or embarrassing side effects, like leaking urine or having sexual problems. These problems may be hard to discuss.¹⁴⁰ Sometimes we can reduce or eliminate these problems if we know about them. Have you had any problems like these?"
- (b) "Other people have trouble remembering the pills or find that pill-taking interferes with their normal schedule. What kind of system do you use at home or work to stay on track with your pills?"

- (c) “I once had a patient who came to see me regularly but never mentioned that he could not afford the medications I prescribed. As soon as I gave him sample drugs, his blood pressure was promptly controlled. Have you had any problems filling the prescription, opening the vials, or swallowing the pills?”
4. *Encourage the development and use of a medication-taking “system.”*
Cramer has called for compliance enhancement by asking every patient at every visit about how the prescribed medications are taken.¹²⁶ The clinician may then encourage the selection of location, time, and/or activity cues, consistent with the patient’s personal, daily routine. At each follow-up visit, the discussion may review how the selected method is working and lead to selective changes. In a survey of outpatients, Rudd and Marshall reported that the majority of patients had one or more systems of locations and cues for this purpose.⁷⁶
 5. *Provide simple, clear instructions.*
Learning theory indicates that patients will often recall the first and last things they are told but retain little of what comes in between. Uncomplicated, unambiguous directions are important, even when reinforced in writing or by review in the presence of the patient’s significant other. Reliance on the pharmacist to provide more patient instruction, reinforcement, or reassurance may not always be realistic. On occasion, the addition of a pill dispenser aid facilitates following the instructions and highlights any missed doses.
 6. *Simplify the regimen as much as possible.*
The number of dosings appears to be more of a stumbling block than the number of pills taken at any one time. In the elderly, such simplification may be particularly difficult but important when the reality is “polymedicine” for multiple, concurrent conditions rather than avoidable polypharmacy.^{141,142} One useful strategy involves selecting, whenever possible, one drug to serve more than one function, such as using an α_1 -blocker for both prostatism and hypertension or an ACE-inhibitor for both congestive heart failure (CHF) and hypertension.
 7. *Provide substitutive and sequential steps.*
Too often, the well-intentioned patient may be overwhelmed by requests to change several medications, modify diet, and increase exercise all at the same time. In most cases, urgency is unnecessary. If possible, the clinician should identify one behavior to substitute for another rather than add to the large and daunting number of requests. Well selected, the substitutive behavior takes no more work than the replaced behavior. The clinician can further assist by negotiating priorities for change in a manageable sequence rather than all at once.
 8. *Monitor progress to goal, both in BP and in compliance.*
The clinician should specify the relation between prescribed medication and the attainment of goal BP, laying the foundation for further inquiry about adherence if the goal is not achieved or is not sustained. Introducing electronic monitoring of compliance alone can enhance antihypertensive control among patients with resistant hypertension, unmasking imperfect adherence.¹⁴³
 9. *Reinforce desirable behaviors and outcomes whenever possible.*

The key behaviors to reinforce include keeping appointments, taking medications as prescribed, avoiding running out of medication, and remaining willing to work out medication-taking and other clinical problems in a collaborative way. Secret efforts to titrate down one’s medications to minimize side effects is a double loss: loss of maximal cardiovascular protection and loss of the opportunity to reduce the symptoms by adjusting the regimen. Another useful strategy is to reinforce desirable behaviors, so that they produce discomfort or dysphoria when missed, such as feeling ill at ease when going to bed without brushing one’s teeth or riding in an automobile when a seatbelt is not available. Patients may learn both the dysphoria and how to avoid it by adhering to the prescription.

10. *Apply useful, relevant information and help from all possible sources.*
Family members and significant others may provide invaluable assistance and reinforcement for pill-taking, especially for patients with handicaps or cognitive impairment. For others, visiting nurse services and home health aides offer structure and support. Sometimes, important clues to non-adherence appear from failure to request prescription refills at indicated intervals. Other potential sources of key data include symptoms, signs, or laboratory test changes linkable to the specific, prescribed medications.¹⁴⁴ On a more ambitious scale, several successful programs have used nurse-mediated services with decision support by algorithm and frequent telephone contacts to yield improved compliance and better cardiovascular control.^{145,146}
11. *Make explicit the potential value of the prescribed regimen and the impact of compliance.*
The clinician should emphasize the multiple benefits that can follow from optimal control of BP, including reduced risk of stroke, MI, heart failure, kidney failure, and peripheral vascular disease. There is a difference between an “average effect,” based on the mean level of adherence, with that achievable with maximal compliance.¹⁴⁷ Figure 41–8 illustrates the difference of lipid-lowering efficacy for cholestyramine at average and maximal levels of compliance.
12. *Emphasize the importance of dose timing when appropriate.*
Unless told and reminded, many patients will not pay much attention to the precise timing of doses. For some medications and some dosing times, electronic monitoring has confirmed the superiority of morning versus evening dosing.^{148,149}
13. *Seek to customize the regimen to the patient’s needs and preferences.*
Most patients and most clinicians appear convinced that once-daily dosing will always be superior to more frequent dosing schedules. From a theoretical perspective, Levy has argued that more frequent dosings reduce the likelihood of having drug concentrations fall to subtherapeutic levels when lapses in pill-taking occur.¹⁵⁰ Figure 41–9 illustrates the relationship for a hypothetical drug prescribed once, twice, three, or four times daily. Empirically with electronic monitoring, Kruse et al. confirmed that once-daily dosing was more likely than twice-daily dosing to result in skipped days without any treatment, especially on weekends, and that evening doses were twice as likely as morning doses to be missed.¹⁵¹ Although combination drug therapy might on one hand make a patient’s medication regimen more complicated, it might be more appropriate to use

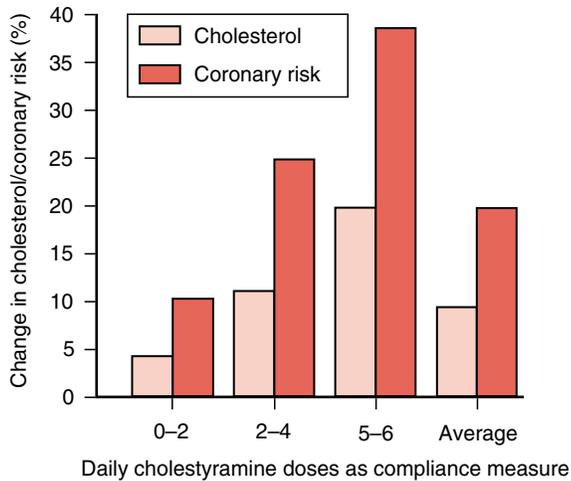

Figure 41-8 Coronary heart disease (CHD) risk reduction by cholesterol change and medication compliance. The original report of the Lipid Research Clinics Coronary Primary Prevention Trial included the now famous relation of 10% reduction in cholesterol associated with 20% reduction in coronary risk. These data reflect the “average” level of adherence with cholestyramine packets. Maximum compliance (6 packets/day) leads to nearly a 20% reduction in cholesterol and almost a 40% reduction in coronary risk. Thus benefit may co-vary with compliance.

lower doses of two drugs in some patients in order to limit the side effects that might be caused by using a higher dose of one drug.

Compliance-Enhancing Strategies for Healthcare Systems

Health care systems themselves offer new opportunities for enhancing adherence. Two converging trends should assist the process: the emergence of vertically integrated health care systems and growing accountability for outcomes. The principal opportunities consist of reminder systems, technology applications, and aligning of incentives for patients, clinicians, and administrators. Among reminder systems, there are both paper and electronic methods to highlight and alert the prescribing clinician for missed events, whether appointments, prescription refills, scheduled monitorings, or aberrant test results. The use of an electronic medical record and a closed pharmacy system greatly facilitates the tracking and reporting functions. Such reminder systems have successfully improved rates of preventive service utilization.¹⁵² Similarly, automated reminder cards for medication refills help identify poorly compliant patients and improve medication refill rates.^{153,154} Telephone reminder systems can enhance patient medication compliance as measured by electronic medication monitors.^{155,156}

Information technology may link traditional clinical practice with decision support and track progress to therapeutic goals. Decision-support software integrates disparate data sources, such as patient history, renal function, serum potassi-

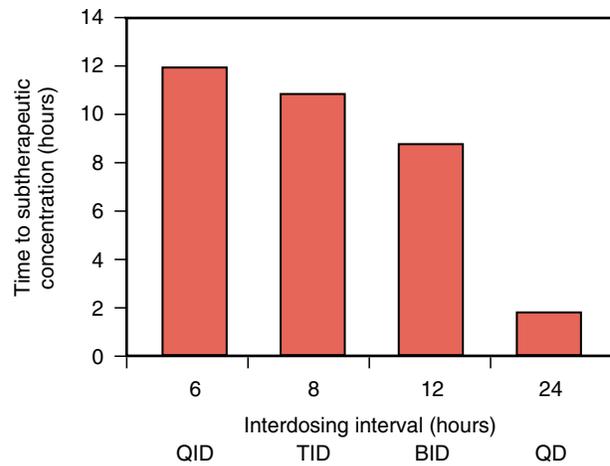

Figure 41-9 Safety margin for dosing intervals using a hypothetical drug. Levy calculated the “safety margin” associated with different dosing intervals for a hypothetical drug with a half-life of 12 hours, volume of distribution of 1 L, dose of 10 mg/kg, 100% absorption, and minimum effective concentration of 3.0 mg/L. As dosing frequency decreases, the margin for error is reduced, even though drug concentrations remain therapeutic for once-daily dosing. (From Levy G. A pharmacokinetic perspective on medication noncompliance. *Clin Pharmacol Ther* 54:242-244, 1994.)

um and most recent antihypertensive drug regimen, to guide drug and dose selections.¹⁵⁷⁻¹⁵⁹ Even with such support, the clinician can often improve clinical outcomes for patients by specifying target outcomes with regular tracking of progress. Traditional progress notes and flowsheet tables are useful but gain impact for patient and clinician alike when data are graphed against the goals over time, as illustrated in Table 41-3 and Figure 41-10.

The final opportunity arises from aligning incentives among all the interested parties: patient, significant other(s), clinician, support staff, administrator, payers, and regulators. As with all complex issues, there are multiple levels of importance and relevance, especially in managed care and prepaid settings, as illustrated in Figure 41-11.

Presumably, all participants would agree on the common goals of achieving excellent BP control for as many patients as possible and thereby minimizing cardiovascular morbidity and mortality at acceptable cost. Beyond this simple agreement, consensus becomes more difficult. For example, does the clinician remain responsible for all patients eligible to come for care or only for those who actually present for care? Does the “acceptable cost” refer to that for the insurance carrier (premiums minus expenses), the employer (tax write-offs and employee benefits), the government (tax credits), or the patient (out-of-pocket expenses)?

Under the emerging expectation of professional accountability, payers and regulators will increasingly hold health professionals responsible for the medical outcomes they produce, including the rates of BP control, complications of the condition and its treatment, and the costs associated with these

Table 41-3 Treatment to Goal

Patient: John DOE		#123-45-67		Drug #1	Drug #2	Drug #3	Serum
Date	SBP (mm Hg)	DBP (mm Hg)	Weight (lbs)	HCTZ (mg/dl)	Lisinopril (mg/dl)	Atenolol (mg/dl)	Creatinine (mg/dl)

SBP, systolic blood pressure; DBP, diastolic blood pressure.

results. The most likely consequences of high expectations and constrained resources will include larger copayments and deductibles by patients for needed medical services, as well as cost- and risk-shifting from employers to insurance carriers and from insurance carriers to medical groups and provider institutions. All parties are searching for value rather than high quality of care regardless of cost. In this context, patients' low level of adherence to appointments, monitoring, and treatments become comparable to prescribing ineffective therapy.

To date, the validation of many proposed strategies and tactics to improve adherence for antihypertensive therapy remains imperfect. Haynes et al.'s review of compliance-enhancing interventions found 33 suitable randomized

controlled trials in their computerized search of studies from 1967 through August, 2001. Half (19 of 39) of the interventions for long-term treatments were associated with improvements in adherence, and 17 interventions led to improvements in treatment outcomes. The most useful interventions for long-term care included complex combinations of more convenient care, information, counseling, reminders, self-monitoring, reinforcement, family therapy, and other forms of additional supervision or attention. Even the most effective interventions did not lead to substantial improvements in adherence.¹⁶⁰

Even if a small core of effective interventions were identified, individual clinicians and their medical groups and support staff would need orientation, training, and reinforcement, so that all components of the health care team work together in a seamless and effective manner.¹⁶¹

Several new and promising approaches warrant close review and consideration. In a population of both psychotic and nonpsychotic patients, Cramer et al. used simple, focused steps to simplify drug regimens, scheduling dosings with tailoring to individual patients' daily patterns, helping patients select reminders or cues, and offering systematic monitoring, feedback, and reinforcement. Over 6 months, mean compliance by electronic monitoring remained relatively high among 32 intervention subjects (81%→76%), significantly higher than among 28 control subjects (68%→57%; $p = .008$).¹⁶² Their intervention principles consisted of education, planning dosing regimens, clinic scheduling, and communication.¹⁶³

In a similar manner, Burnier et al. achieved mean compliance rates of 94% in refractory hypertensive patients from among a highly noncompliant subset at baseline.¹⁴³ Urquhart et al. described a spreadsheet-based method to summarize patients' drug dosing patterns, based on electronic medication monitor data.¹⁶⁴ They went on to describe a "measurement-guided medication management" approach that uses electronic medication monitors to identify noncompliant individuals and then links them to instruction by clinician, pharmacist, or trained counselor on adherence-enhancing methods.¹⁶⁵

The future path for optimizing patient, professional, and medical care system adherence for hypertension management remains largely uncharted. Its importance to ensure improved BP control becomes clearer as we examine the rate-limiting steps to bring full benefit to all hypertensive patients.

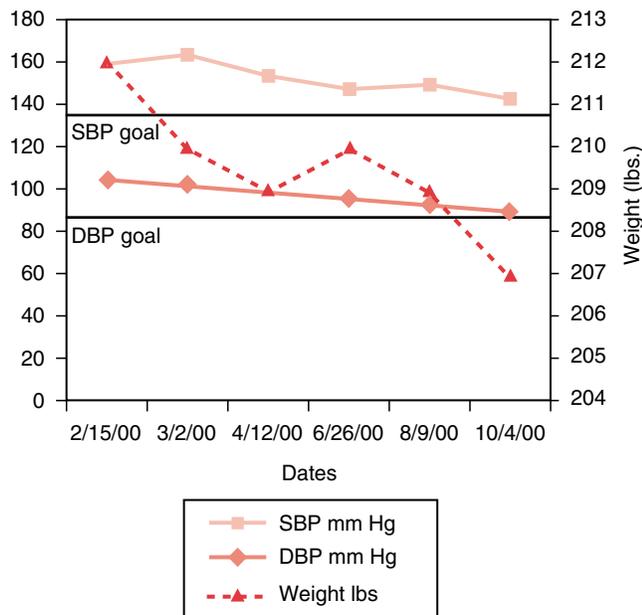

Figure 41-10 Treatment to goal. The graphic representation of data may allow more prompt and intuitive capture of rates, goals, and opportunities for improvement than tabular summaries of the same information, illustrated here with data from a hypothetical hypertensive patient. In this example, the patient's serum creatinine data were not plotted.

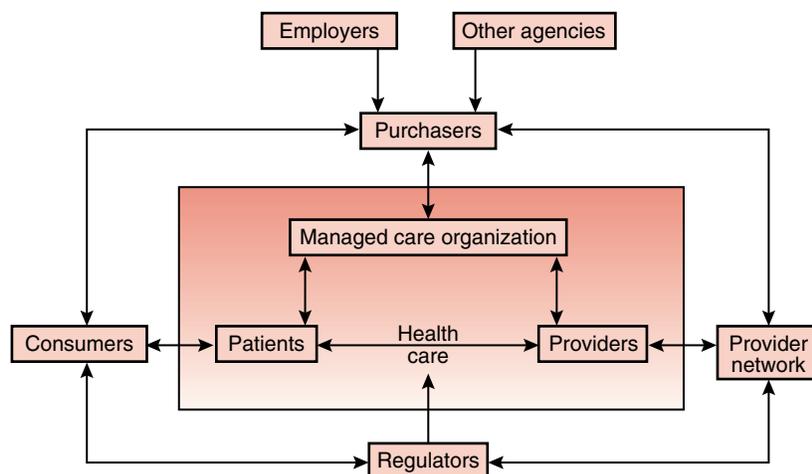

Figure 41-11 Key participants in the managed care setting. Multiple individuals and groups participate in the managed care framework: *Purchasers*, who may represent employers or other agencies, contract with *managed care organizations* to provide health and medical care to patients who are *enrollees*, who come from the larger group of potential *consumers* of the services. The *managed care organization* contracts with some physician *providers* from a larger *provider network*. The key players are all subject to guidelines issued by *regulators*, who in turn impact both consumers and provider networks with both options and constraints. (Adapted from Hopkins J, Siu S, Cawley M, Rudd P. Drug therapy: The impact of managed care. *Adv Pharmacol* 44:2, 1998.)

Diet and Nutrition

Chapter 42

Diet: Micronutrients

David A. McCarron, Molly E. Reusser

SO MANY DATA, SO LITTLE CONSENSUS

Decades of research have focused on the role of specific dietary nutrients in blood pressure regulation. Sodium, potassium, calcium, and magnesium have each been examined extensively in epidemiologic surveys, in clinical trials, and in laboratory investigations.¹ Yet the debates continue.² Despite years of investigative effort and volumes of publications, the effects on blood pressure of these individual dietary factors remain subjects of scientific controversy and public confusion.

The most obvious example is sodium chloride, which, for reasons both rational and otherwise,² has long been considered the foremost dietary cause of high blood pressure. This presumption first received “factual” support from Dahl’s classic epidemiologic study published in 1960, which included a graph with very few data points indicating an almost perfect, linear relationship between the prevalence of hypertension and salt intake among five separate populations around the world.³ Although that often-cited study has been discounted on the basis of severe design and methodologic flaws,⁴ and although the vast body of medical literature regarding the contribution of dietary salt to the worldwide prevalence of hypertension is plagued with conflicting results, the controversy surrounding the sodium–blood pressure relationship continues to engage and enrage nutrition and cardiovascular scientists.^{2,5-9}

Although not at the same magnitude and intensity as for sodium, studies of other micronutrients in association with blood pressure control are similarly equivocal. Inadequate intakes of potassium, calcium, and magnesium have all been individually implicated in increased hypertension risk in population studies and in some but not all clinical trials. Studied in isolation, each of these micronutrients has been reported to decrease blood pressure, to increase blood pressure, and to have no effect on blood pressure.^{10,11} The one similarity these studies share is that of heterogeneity; that is, modifications in nutrient intake consistently induce inconsistent responses in blood pressure.

The lack of consensus regarding the blood pressure effects of these nutrients, the discrepancies in the results of the studies, and the heterogeneity of response commonly observed in

clinical trials assessing electrolytes have a number of possible, related explanations. It is likely that the antihypertensive effects of single nutrients are small and require large-scale trials for their detection. In contrast, the results of epidemiologic surveys and of clinical trials that include modifications of more than one nutrient may reflect larger, more easily detected additive effects, as evidenced by the results of recent studies assessing overall diet patterns.¹²⁻¹⁴ Interactions among coexisting nutrients may also play a major role in the inconsistency of results in all studies in which intake levels of one or more nutrients are manipulated. Additional confounding factors in dietary studies include the degree to which baseline intake of the nutrient under study may influence individual blood pressure responses and the likely possibility that the supplemental form of nutrients used in many studies does not have an effect on blood pressure that is comparable to that seen with nutrients naturally occurring in foods.

NUTRIENT INTERACTIONS

Each of these explanations likely contributes in some part to the unresolved questions regarding the role of specific nutrients in blood pressure regulation. However, we now have available both indirect and direct evidence of the paramount role of nutrient interactions in the prevention and treatment of high blood pressure. Preliminary evidence comes from animal and human studies of sodium effects on blood pressure. Kotchen et al.¹⁵ first reported that the hypertensive effect of sodium chloride in Dahl salt-sensitive rats is preceded by the emergence of disturbances in calcium homeostasis. Kurtz et al.¹⁶ postulated that the induction of a calciuresis may indicate the mechanism(s) by which sodium chloride raises blood pressure in humans. In laboratory models of hypertensive cardiovascular disease known to be salt-sensitive, Tobian et al.^{17,18} demonstrated the protective effect of dietary potassium on blood pressure increases. Their data are supported by the clinical observation of Krishna et al.¹⁹ that short-term, severe potassium restriction induces salt sensitivity in normotensive humans and the epidemiologic data of Khaw and Barrett-Connor²⁰ indicating that adequate potassium intake protected against the potential adverse effects of sodium chloride on blood pressure regulation.

In the index report that characterized the calciuresis of essential hypertension, it was noted that this metabolic defect was more evident at greater levels of urinary sodium excretion.²¹ This report was strikingly similar to observations reported in both the Dahl salt-sensitive rat¹⁵ and the rat model of deoxycorticosterone acetate-salt hypertension²² and has also been demonstrated in humans.^{23,24} Subsequent studies have shown that reducing sodium chloride intake does not eliminate the renal defect. In the spontaneously hypertensive rat, an animal with well-characterized disturbances of calcium metabolism including a renal calcium leak,²⁵ the antihypertensive effect of increasing dietary calcium has been shown to require a normal or high-normal concurrent intake of sodium chloride.^{26,27} In humans, Hamet et al.²⁸ have reported that individuals consuming higher levels of sodium chloride could fall into the highest or lowest blood pressure group depending on whether they were consuming inadequate amounts of calcium or amounts that met recommended dietary allowances.

Similar to the relationship between sodium and other nutrients, interactions among calcium, potassium, and magnesium have also been reported. However, as emphasized by Reed et al.²⁹ in their analyses of the Honolulu Heart Study, identifying these interactions is complicated by multicollinearity that makes it inherently difficult to clearly isolate the effects of one nutrient from the effects of those consumed concurrently. From the Nurses Health Study, Witteman et al.³⁰ observed that dietary calcium and magnesium both had strong and independent inverse associations with hypertension and that adjusting for calcium and magnesium intake eliminated the observed crude inverse association of dietary potassium and fiber with hypertension risk. It was reported in the Health Professionals Follow-up Study that nutrient effects on blood pressure observed when assessed individually were obliterated when the nutrients were considered together.³¹ In the case of calcium specifically, meta-analysis of randomized controlled trials noted that the effects of food sources appear to be more effective than calcium supplements,³² likely caused in part by the presence of the other nutrients in food that track with calcium.

Thus numerous studies in recent years have examined relationships between nutrients and have identified some of the interdependencies that exist among the major electrolytes. We now recognize that nutrients function interactively both in the body and in their impact on blood pressure regulation. Considering that nutrients are not ingested in isolation but as combined constituents of a total diet, it is not surprising that manipulations of a single nutrient would produce inconsistent and often contradictory results. If one accepts the hypothesis that micronutrients express their physiologic actions through integrated pathways, it is paradoxical to expect a uniform benefit in terms of blood pressure control by altering the intake of any one of them.

DIETARY NUTRIENT PATTERNS

Whenever the consumption of a single nutrient is significantly altered, an entirely new dietary pattern is created. Nutrients occur in clusters in the typical human diet and may therefore act synergistically to alter physiologic variables such as blood pressure. In a study assessing blood pressure effects of calcium carbonate as compared with increased calcium in the diet, up to 1500 mg calcium per day, Karanja et al.³³ observed signifi-

cant simultaneous increases in consumption of magnesium, potassium, phosphorus, riboflavin, and vitamin D. In a review of the effect of sodium restriction on overall nutrient intake, Morris³⁴ found that most of the published studies did not address concomitant nutrient changes, but those that did reported significant decreases in a number of essential dietary components. Although improvements were frequently observed in energy and fat intake, these were offset by reductions in calcium, potassium, fiber, and protein intake. Interestingly, each of the first three of these dietary components has a purported role in blood pressure regulation, and all three are known to be typically consumed at less-than-adequate levels in the general population.

COMPREHENSIVE DIETARY CLINICAL TRIALS

Vanguard Studies

As a result of our increasing awareness of the impact and complexity of dietary interactions, nutrition research has expanded in recent years to include assessment of overall dietary patterns as they contribute to lower cardiovascular disease risk through the treatment or the prevention of hypertension. The Cardiovascular Risk Reduction Dietary Intervention Trial was a 4-year series of multicenter, randomized clinical studies to evaluate multiple health effects of a complete nutrition program on persons at high risk of cardiovascular disease. Free-living adults with established hypertension, dyslipidemia, and/or type 2 diabetes mellitus were provided with a prepared meal plan formulated to include levels of vitamins and minerals that meet the recommended dietary allowances (RDA) of the Food and Nutrition Board³⁵ and the levels of micronutrients and macronutrients recommended by major health organizations.³⁶⁻³⁹ The clinical effects of the total nutrition plan were compared with those of a self-selected diet based on the exchange list system.³⁹

The results of the first 14-week study in the series demonstrated significant improvements from both diet plans in blood pressure, lipid levels, glycemic control, homocysteine levels, weight, overall nutrient intake, and quality of life, with greater improvements in most of these measures observed with the prepared meal plan as compared with a self-selected diet.⁴⁰ The second Vanguard study assessed the same endpoints by using similar dietary interventions for 10 weeks but reduced the amount of contact with participants to the level more likely to occur in clinical practice when dietary therapy is recommended.⁴¹ A third trial used a 52-week intervention and reported similar results.⁴² These studies demonstrated that consumption of a nutritionally complete and balanced dietary pattern, which provides appropriate levels of multiple nutrients, can improve blood pressure as well as multiple other risk factors for cardiovascular disease, even in persons with high-normal risk profiles. Subsequent analysis of the Vanguard data identified highly predictive correlations between various electrolytes and the hormones controlling them and the observed changes in blood pressure (Figure 42-1).⁴³

DASH Trial

To specifically address the relationship between total dietary patterns and blood pressure, the National Heart, Lung, and

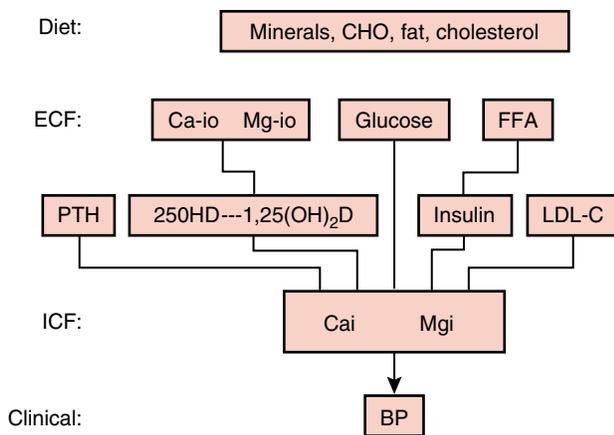

Figure 42-1 Overall scheme in which the contribution of diet to blood pressure is determined by the net effect of individual dietary components on steady-state levels of cytosolic free mineral ions such as calcium and magnesium. These effects are due both to direct ionic effects of circulating nutrient levels, such as glucose or calcium, and to ionic effects of hormones responsible for regulating the metabolism of these dietary components such as insulin, PTH, and 1,25D. ECF, extracellular fluid; ICF, intracellular fluid; CHO, carbohydrates; Ca-io, ionized calcium; Mg-io, ionized magnesium; FFA, free fatty acids; Cai, intracellular calcium; Mgi, intracellular magnesium. (From Resnick LM, Oparil S, Chait A, et al. Factors affecting blood pressure responses to diet: the Vanguard Study. *Am J Hypertens* 13:956-965, 2000.)

Blood Institute (NHLBI) initiated the multicenter, randomized, controlled Dietary Approaches to Stop Hypertension (DASH) clinical trial.¹² This carefully designed and executed study provides dramatic evidence of the effect and importance of the dietary pattern of nutrients, as they occur together in food, on blood pressure regulation. Three diets were assessed in the trial: (1) a typical American diet (control), with four daily servings of fruits and vegetables and half a serving of dairy products; (2) the fruits-and-vegetables diet, with 8.5 servings/day of these foods; and (3) the combination, or DASH, diet, which included 10 fruit and vegetable servings and 2.7 daily servings of low-fat dairy products.

Highly significant blood pressure reductions among all participants were achieved with the DASH diet; systolic pressure was reduced by 5 mm Hg more and diastolic pressure by 3.0 mm Hg more than with the control diet. Blood pressure reductions with the fruits-and-vegetables diet as compared with the control were also highly significant, but only about half (2.8 mm Hg systolic and 1.1 mm Hg diastolic) of those achieved with the combination diet. The reductions with both intervention diets were observed within the first 2 weeks of study and were sustained for the remaining 6 weeks of the intervention.

Of notable clinical significance, blood pressure reductions in hypertensive participants on the DASH combination diet were 11.4 mm Hg systolic and 5.5 mm Hg diastolic as compared with the control diet and 4.1 mm Hg systolic and 2.26 mm Hg diastolic as compared with the fruits-and-vegetables diet.¹² In a subsequent publication, the investigators reported that the DASH diet was particularly effective in older persons

with systolic hypertension,⁴⁴ such that in almost 80% of these participants, blood pressure would have been controlled by the DASH diet alone. The observed blood pressure reductions with the DASH diet in hypertensive participants were similar in magnitude to those reported in pharmacologic trials of treatment of mild hypertension.⁴⁵

The diet-related factors most commonly associated with blood pressure management—sodium, alcohol, and weight—were held constant throughout the DASH study and were similar across the three diets. Thus they were not accountable for the blood pressure changes observed in this trial and suggest a protective blood pressure effect of comprehensive nutrient intake patterns on known dietary blood pressure determinants. As we reported in *Science*,¹ the results of the DASH Trial are remarkably consistent with the epidemiologic evidence we published 20 years ago⁴⁶ that identified a close association of dietary calcium and potassium in the American diet with blood pressure control (Figure 42-2). Our 1984 article was the first to report that a diet rich in dairy foods, fruits, and vegetables was the dietary pattern associated with lower levels of blood pressure in the United States.

DASH-Sodium Trial

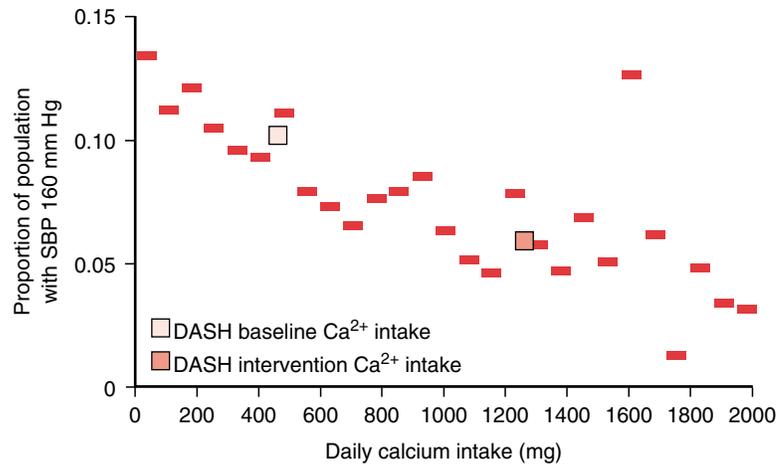

The publication of the DASH Trial¹² and the Trials of Hypertension Prevention, Phase II (TOHPS II; 47) within a few months of one another raised the question of whether the DASH diet alone was more effective than sodium restriction alone. NHLBI thus initiated a second DASH study, the DASH-Sodium Trial, in which the blood pressure effects of the DASH diet alone and in combination with sodium restriction were assessed in a study population at higher risk for salt sensitivity, that is, with overrepresentation of overweight, hypertensive adults of African American descent.¹³

The DASH-Sodium investigators concluded that the DASH diet in conjunction with sodium restriction was more effective than either of the approaches alone in reducing blood pressure in both hypertensive and normotensive persons. They stated further that their findings “provide a scientific basis for a lower goal for dietary sodium than the level currently recommended.”¹³ These interpretations of the DASH-Sodium data have been met with controversy and challenge.⁴⁸⁻⁵⁰ The actual effect of the DASH diet alone in this high-risk population was virtually identical to that observed in the first DASH Trial, supporting the reproducible, generalizable, and beneficial effect across the entire population of a diet rich in low-fat dairy foods, fruits, and vegetables.

In a subsequent publication of the subgroup analysis of the DASH-Sodium Trial, the investigators acknowledged that the effect of sodium restriction on blood pressure was significant only among hypertensive African Americans ≥ 45 years of age.⁵¹ Based on those findings and the initial concerns expressed regarding the interpretation of the DASH-Sodium Trial,⁴⁹ it is apparent that a diet that emphasizes low-fat dairy products, fruits, and vegetables has a significant effect on all adults regardless of their blood pressure status and that sodium restriction has a minimal effect isolated to older, overweight African American patients with high blood pressure.

Although there has not yet been full publication of all the data that should be made available from the DASH-Sodium Trial,⁴⁸ the data that have been shown provide critical evidence of where our priorities should be placed with regard to

Figure 42-2 National Health and Nutrition Examination Survey I data portraying the relationship between dietary calcium and systolic blood pressure⁴⁶ in relation to values (boxes) at baseline and end of the DASH combination diet intervention for dietary calcium intake and systolic blood pressure.¹² (From McCarron DA, Morris CD, Henry HJ, Stanton JL. Blood pressure and nutrient intake in the United States. *Science* 224:1392-1398, 1984.)

nutritional guidelines to prevent and to manage hypertension. The DASH-Sodium Trial confirmed that (1) the beneficial blood pressure effect of the DASH diet is generalizable to the entire population and not limited to people with hypertension, (2) the effects of the DASH diet are substantial and significantly greater than any that have been reported for sodium restriction, (3) sodium sensitivity is ablated by the DASH diet in most people who would otherwise be categorized as salt sensitive, and (4) recommendation of the DASH diet should be the first step for high blood pressure management for all individuals with hypertension.

TOWARD A NEW PARADIGM

Our efforts to understand the blood pressure effects of micronutrients, as individual components as well as interactive constituents of the human diet, have revealed several important and easily adopted answers to long-standing questions in this area. While experts in the fields of nutrition and blood pressure may continue to argue the merits of altering the intake of one nutrient or another, we have available to us today the body of appropriate and definitive data to resolve the conflicting results and to lay to rest the scientific controversies surrounding the role of dietary nutrients in preventing and managing high blood pressure. For even the most vitriolic debate, that of the sodium–blood pressure relationship,² the data now exist that could finally produce consensus on this issue.

Using established analytical standards to assess the “pool effect” of randomized controlled trials of sodium restriction, the Cochrane Collaboration⁵² recently provided a conclusive statistical evaluation of the clinical trial data addressing the role of dietary sodium in hypertension. Hooper and colleagues concluded that there was not sufficient evidence that sodium restriction was an effective therapeutic modality in the hypertensive population and that it was not appropriate as a preventive measure in the general population. They left open the possibility that future studies might demonstrate a benefit in a subset of individuals with hypertension, but no convincing data exist to support such a recommendation at this time. Furthermore, these investigators acknowledged that the available data suggest that broad application of low-sodium diets to either the general population or hypertensive individuals may actually contribute to cardiovascular events and mortality,

an issue first raised a decade ago⁵³ that still needs to be resolved conclusively with properly controlled long-term clinical trials.

The importance of first ensuring that hypertensive patients improve the overall quality of their diets was recently addressed by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).⁵⁴ In their recommendations, the National High Blood Pressure Education Program ranked the DASH diet as a primary nutritional intervention in the management of this common medical disorder. However, that transition in nutritional guidance for the patient with high blood pressure leaves several important issues to be resolved, including whether it is possible for adults at risk of hypertension and its cardiovascular consequences to incorporate the DASH diet into the multiple lifestyle adjustments these patients often have to make and whether adherence to the DASH diet will reduce cardiovascular events and lower mortality rate.

As recently reported,⁵⁵ the cumulative body of evidence from randomized controlled trials and prospective observational studies strongly suggests that, at least with regard to the dairy component of the DASH diet, the prevalence of several common cardiovascular risk factors can be reduced by regular dairy consumption with 3 to 4 servings per day, a range consistent with the DASH diet and current national dietary recommendations. The risk factors that have been shown to be improved with adequate dairy consumption include body weight, insulin-resistant syndrome, blood pressure, and serum lipids. Incorporating regular dairy food intake into the diets of at-risk young adults has been demonstrated to also lead to increased fruit and vegetable consumption⁵⁶—that is, a nutritional pattern consistent with the DASH diet.

While implementation of dietary and lifestyle changes can be a challenge for individual patients, the evidence we have today clearly indicates that improved diet quality can be the single means of managing blood pressure for many patients and that, for others, improved diets can reduce their antihypertensive medication requirements. Furthermore, it is now well recognized that positive diet and lifestyle alterations can prevent the development of hypertension. As stated in JNC 7, lifestyle modifications—including improved nutrient intake, weight loss, and increased physical activity—“are critical for the prevention of high blood pressure...decrease blood pressure, enhance antihypertensive drug efficacy, and decrease car-

diovascular risk.⁵⁴ Although some patients may require more aggressive management, for those with mild to moderate hypertension, as well as for the population at large, improving the overall quality of the diet should be the primary focus of nutritional guidance for optimal blood pressure management.

Dietary Approaches to Hypertension Management: The DASH Studies

Heather L. McGuire, William L. Fan, Laura P. Svetkey

Nonpharmacologic measures have been widely recommended for the prevention and treatment of high blood pressure (BP). Weight loss, increased physical activity, moderation of alcohol consumption, and dietary sodium reduction are discussed in Chapters 42 and 45 to 47. Several other nonpharmacologic, nutritional factors are associated with reductions in BP levels. Epidemiologic data suggest that low BP is associated with high dietary intake of potassium, magnesium, calcium, fiber, and protein and with low intake of fat. However, trials of alterations in the intake of individual nutrients or the use of nutrient supplements have led to small, inconsistent, and/or inconclusive BP effects. Combinations of nutrients or the dietary pattern itself may be more important than individual nutrients. Indeed, the Dietary Approaches to Stop Hypertension (DASH) study demonstrated that adoption of a specific dietary pattern (the “DASH dietary pattern”) lowers BP as much as single drug antihypertensive therapy.^{1,2} The DASH dietary pattern also enhances the BP-lowering effect of antihypertensive therapy.³ In individuals with prehypertension, the BP-lowering effect of the DASH dietary pattern is of a magnitude sufficient to prevent the development of hypertension. In addition, the DASH dietary pattern has beneficial effects on other cardiovascular risk factors, such as lipid profiles⁴ and homocysteine.⁵

These effects of the DASH dietary pattern were established in feeding studies and a clinical trial addressing the ability of free-living individuals to adopt the DASH dietary pattern.⁶ Similar to other nonpharmacologic interventions, there are no data directly demonstrating the ability of the DASH dietary pattern to reduce morbidity and mortality, but favorable effects of interventions on outcomes in hypertensive patients are presumed to be due to BP lowering and modulation of other cardiovascular disease (CVD) risk factors. Consequently, since 1997, national guidelines for the prevention and treatment of high BP have included the DASH dietary pattern.⁷ In this chapter we review the rationale, design, and findings of the DASH studies, consider possible mechanisms of action, and discuss strategies for implementation. Widespread implementation of the DASH dietary pattern has the potential to reduce the CVD burden attributable to BP and to reduce the rising health care costs associated with the large burden of prehypertension and hypertension in the United States and around the world.

BACKGROUND

Vegetarian Diet, Nutrients, and Blood Pressure

Observational studies have demonstrated that vegetarians have lower BP levels than comparable nonvegetarian populations.^{8,9} In addition, vegetarian diets seem to blunt the rise in BP

observed with aging.^{8,10} In a randomized controlled trial, when nonhypertensive, nonvegetarian volunteers ate a vegetarian diet, systolic BP (SBP) decreased by an average of 5 to 6 mm Hg and diastolic BP (DBP) by 2 to 3 mm Hg.⁹ Similar effects were seen when a vegetarian diet was eaten by a mildly hypertensive population.¹¹ A slight increase in SBP was found when strict vegetarians were fed isocaloric amounts of beef, but there was no change in DBP.¹² Animal products are apparently not the main culprit, however, since a BP-lowering effect is not seen when they are replaced by starch and sugar.^{13,14} Specific dietary components of a vegetarian diet (e.g., plant foods and dairy products) may be responsible for its BP-lowering effect. These dietary components include several micronutrients (namely potassium, magnesium, and calcium) that have been linked to BP regulation and that are discussed in Chapter 43. Meta-analyses suggest a relatively consistent BP-lowering effect of potassium,¹⁵ but smaller and less consistent effects of calcium and magnesium.¹⁶⁻¹⁹ Micronutrients have generally been tested individually and often in the form of supplement pills, leaving open the possibility that BP may be influenced by the micronutrient content of foods. In addition to these micronutrients, a vegetarian diet frequently has a macronutrient profile that is epidemiologically associated with lower BP, namely high fiber and low fat.

Small epidemiologic studies have found a weak inverse relationship between fiber intake and BP.²⁰ However, this relationship may be confounded by the correlation between fiber intake and intake of other nutrients. When other dietary components are held stable, fiber supplementation has no significant effect on BP.²¹ Similarly, epidemiologic data suggest that low intake of total fat and saturated fat, and a high ratio of polyunsaturated fat to saturated fatty acids, is associated with lower BP, but clinical trial evidence, generally from underpowered and/or confounded studies, does not demonstrate consistent or clinically significant BP-lowering effects of decreased fat intake by itself (i.e., without weight loss).²⁰ High protein has also been associated with lower stroke risk in certain populations.^{22,23} However, vegetarian diets tend to be low in protein,⁸ and protein supplements have no effect on BP¹³ even when the protein is from vegetable sources.¹⁴

There are several possible reasons that alterations in single micronutrients or macronutrients have not been associated with significant BP effects. First, single nutrients may individually have small effects on BP that would require a very large study to be detectable. The small effects of individual nutrients may be additive and therefore will only be detected if several nutrient changes are tested simultaneously. Second, interactions among nutrients may exist that amplify their effects when eaten in combination. Third, nutrient supplements may not affect BP in the same manner as the naturally occurring nutrients found in food, possibly because of increased bioavailability in naturally occurring

foods. Finally, the BP effects of a vegetarian diet may be due to unknown or untested nutrients that are generally found in this dietary pattern.²⁴

In summary, epidemiologic and interventional evidence suggests that elements in a vegetarian diet lead to lower BP levels, but studies that alter individual micronutrients or macronutrients have not produced consistent, significant BP effects. This apparent paradox suggests that there is a complex interaction between multiple dietary components and BP level.

Development of the DASH Dietary Pattern

The DASH dietary pattern was developed to contain the micronutrient and macronutrient profile that had been posited to be beneficial for BP—high potassium, magnesium, calcium, fiber, and polyunsaturated:saturated fatty acid ratio; and low total and saturated fat. Other goals of the diet were to contain enough animal products to make it palatable to nonvegetarians and to contain commonly available foods that were not supplemented with nutrients beyond what would normally be added as part of common food manufacturing practice.²⁵ Consequently, it emphasizes fruits, vegetables, and low-fat dairy products. It includes whole grains, poultry, fish, and nuts and is reduced in fats, red meat, sweets, and sugar-containing beverages. Its sodium content is slightly below average U.S. consumption. For a 2100 kcal diet, 18% of the energy intake comes from protein, 58% from carbohydrate, 27% from total fat, 7% from saturated fatty acids, and 10% from monounsaturated fatty acids. The DASH dietary pattern includes 31 g/day of fiber, 150 mg/day of cholesterol, 4700 mg/day of potassium, 500 mg/day of magnesium, and 1240 mg/day of calcium.

THE DASH STUDIES

The first DASH study tested the BP effects of the DASH dietary pattern compared with other dietary patterns.²⁴ By controlling for energy expenditure and keeping weight and sodium intake stable, the DASH study was able to observe the effect of dietary patterns on BP without confounding from other lifestyle modifications known to influence BP. The second DASH study tested the combined effects of the DASH dietary pattern and reduced sodium intake on BP.²⁶

The Dietary Approaches to Stop Hypertension Trial

Design

The initial DASH trial was a multicenter, randomized feeding study that tested the effects of three dietary patterns on BP: a Control diet, a diet rich in fruits and vegetables (F/V), and the DASH dietary pattern (Table 43–1). In the Control diet, micronutrient content approximated the twenty-fifth percentile of population intake, and macronutrient content was set at average American intake.²⁷ The F/V diet was rich in fruits and vegetables, but similar in macro- and micronutrient content to the Control diet. The DASH dietary pattern, as noted above, mimicked the micronutrient and macronutrient contents found to lower BP in epidemiologic studies, approximating the seventy-fifth percentile of population intake of

Table 43–1 Nutrient Composition of the Experimental Diets in the DASH Study

Nutrient	Treatment Group		
	Control	Fruits and Vegetables	DASH
Fat	37	37	27
Saturated	16	16	6
Monounsaturated	13	13	13
Polyunsaturated	8	8	8
P/S ratio	0.5	0.5	1.33
Carbohydrates (g)	48	48	55
Protein (g)	15	15	18
Potassium (mg)	1700	4700	4700
Magnesium (mg)	165	500	500
Calcium (mg)	450	450	1240
Fiber (g)	9	31	31
Cholesterol (mg)	300	300	150
Sodium (mg)	3000	3000	3000

From Appel LJ, Moore TJ, Obarzanek E, et al. A clinical trial of the effects of dietary patterns on blood pressure. DASH Collaborative Research Group. *N Engl J Med* 336(16): 1117-1124, 1997.

potassium, magnesium and calcium. To achieve this nutrient profile, the DASH dietary pattern contained 9 to 12 servings/day of fruits and vegetables; 2 to 3 servings/day of low-fat dairy products; whole grains; less than 2 servings/day of meat, fish and poultry; and minimal sweets and sugary beverages (Figure 43–1). In all three dietary patterns, sodium intake was the same and not restricted (about 3000 mg/day). Energy intake was adjusted to maintain the baseline body weight of each participant.

All meals consumed by DASH trial participants were prepared in metabolic kitchens using standardized procedures. The nutrient content of the meals was confirmed by chemical analysis.²⁸ Participants ate one meal each weekday, preferably lunch or dinner, at the clinical center, and carried out all other weekday meals, snacks, and all weekend meals. Thus all foods consumed during the study were provided. Each weekday, body weight was measured, and calorie intake was adjusted if weight increased or decreased by more than 2%.

The study population consisted of adults with high-normal BP or stage 1 hypertension who were not taking antihypertensive medication. Specifically, eligibility criteria were DBP 80 to 95 mm Hg and SBP less than 160 mm Hg, based on the average of readings obtained over three screening visits. Exclusion criteria were use of vitamin or food supplements; alcoholic beverage intake >14 drinks per week; poorly controlled diabetes mellitus; severe dyslipidemia; renal insufficiency; recent CVD event; chronic illness; and body mass index (BMI) >35 kg/m². Because of the disproportionate burden of hypertension in African Americans, the study was designed to include two-thirds minority participants, predominantly African Americans.

The DASH study consisted of two phases: run-in and intervention. After eligibility was established, participants entered a run-in phase of 3 weeks during which they were fed the Control dietary pattern. Participants were then randomly assigned to one of the three dietary interventions: Control, F/V, or DASH. The intervention phase began the day after the run-

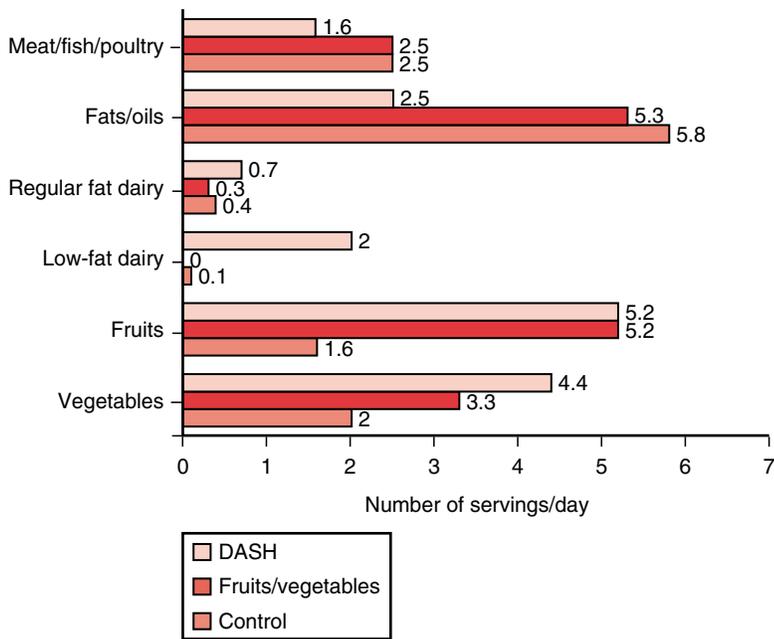

Figure 43-1 Intake of food groups in the DASH study. (From Vogt TM, Appel LJ, Obarzanek E, et al. Dietary Approaches to Stop Hypertension: Rationale, design, and methods. DASH Collaborative Research Group. J Am Diet Assoc 99[8 Suppl]:S12-S18, 1999, with permission from the American Dietetic Association.)

in feeding period ended and lasted for 8 weeks (Figure 43-2). Adherence to the study diet was assessed by observation at the on-site meal, by self-report of study participants, and by biochemical measurement. As an objective estimate of adherence, sodium, potassium, calcium, urea nitrogen, and magnesium were measured in 24-hour urine collections.

The primary outcome was the change in DBP from the end of run-in to the end of the intervention phase. Secondary end points included the change in SBP and in 24-hour ambulatory BP. Other outcomes assessed included changes in levels of serum lipids, calcium, vitamin D, and effects of baseline characteristics on BP response to intervention. All analyses were performed using the intention-to-treat principle. The study was powered to detect a difference in DBP between treatment groups of 2.0 mm Hg ($\beta = 0.15$).

Results

A total of 459 participants were randomized in the DASH trial. The mean age was 44 years; approximately 60% of participants

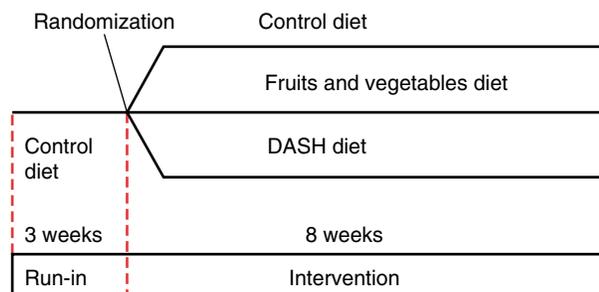

Figure 43-2 DASH study design. (From Vogt TM, Appel LJ, Obarzanek E, et al. Dietary Approaches to Stop Hypertension: Rationale, design, and methods. DASH Collaborative Research Group. J Am Diet Assoc 99[8 Suppl]:S12-S18, 1999, with permission from the American Dietetic Association.)

were African American, 50% were women, and 29% were classified as hypertensive. Baseline characteristics were similar in the three diet groups.¹ The percentages of participants who completed the intervention phase in the Control, F/V, and DASH groups were 95.5%, 97.4%, and 98.7%, respectively. Dietary adherence was excellent: more than 95% attended the required meals and ate all the meals. Urinary potassium increased in proportion to the intended increase in dietary intake of fruits and vegetables, with significant increases in both the F/V diet and the DASH diet. Urinary magnesium, phosphorus, and urea nitrogen also increased significantly in the DASH diet, reflecting the increased intake of low-fat dairy products and protein. As intended, urinary sodium excretion and body weight were unchanged from baseline.

Both intervention diets significantly lowered BP compared with the Control diet, with greater effects in the DASH diet group than in the F/V group. (Figure 43-3). The full BP effects were seen after 2 weeks and were sustained for the subsequent 6 weeks of the intervention. Compared with Control, the DASH diet reduced SBP by 5.5 mm Hg and DBP by 3.0 mm Hg ($p < .001$ for both). The F/V diet reduced SBP by 2.8 mm Hg and DBP by 1.1 mm Hg more than the Control diet ($p < .001, .07$ respectively). The DASH diet significantly reduced the SBP (2.7 mm Hg, $p = .001$) and DBP (1.9 mm Hg, $p = .002$) more than the F/V diet. Based on 24-hour ambulatory BP measurements, the BP effects of the DASH diet were also noted throughout the day and night, with retention of the diurnal pattern.²⁹

Subgroup analysis demonstrated similar improvements in BP in all groups. The DASH diet reduced BP more than the Control or F/V diet in subgroups defined by gender, race, age, hypertension status, education level, BMI, annual family income, physical activity, family history of hypertension, and alcohol intake.³⁰ The DASH dietary pattern was equally effective in men and women. It lowered BP more in participants with hypertension than in those with high-normal BP (11.6/5.3 vs. 3.5/2.2 mm Hg) (Figure 43-4). Regardless of hypertension status, African Americans had a larger BP

response to the DASH dietary pattern than did non-African Americans. The effect in hypertensive African Americans was a 13.2/6.1 mm Hg decrease in BP.

Among the 459 participants in the DASH trial, there were 72 with stage 1 isolated systolic hypertension (ISH). The DASH diet proved to be effective as first-line therapy for stage 1 ISH. Compared with the Control diet, use of the DASH diet lowered SBP by 11.2 mm Hg in these study participants ($p < .001$, 95% confidence interval (CI) -6.1 to -16.2 mm Hg). The systolic response was highly consistent, occurring in virtually every individual with ISH assigned to the DASH dietary pattern. Seventy-eight percent of these individuals achieved SBP goal (< 140 mm Hg).³¹

Conclusions

The DASH dietary pattern lowers both SBP and DBP in a broad range of individuals with high-normal BP and stage 1 hypertension. DASH is particularly effective in hypertensives and African Americans. The magnitude of effect is sufficient to potentially prevent hypertension in those with prehypertension and to serve as first-line therapy in those with stage 1 hypertension.

Given the design of the DASH trial, the effects of this complex dietary pattern on BP could be evaluated, but the specific dietary components responsible for changes in BP could not be identified. However, because of the partial efficacy of the F/V diet, it is clear that the effect of DASH was not simply attributable to the increase in either dietary potassium or calcium. It is possible that the total macronutrient and micronutrient composition of the DASH dietary pattern is necessary to achieve its full BP-lowering effect.

The Dietary Approaches to Stop Hypertension-Sodium Trial

Rationale and Design

After the publication of the DASH study results, national guidelines for lifestyle interventions for preventing and treating hypertension included the DASH dietary pattern.⁷ However, the effect of the DASH dietary pattern in combination with other recommendations was unknown. Of particular interest was the combined effect of DASH with reduced sodium intake. Additive effects of these two BP-lowering dietary strategies would be advantageous. On the other hand, previous research demonstrated that the effect of potassium on BP is greatest when sodium intake is high,^{32,33} suggesting that, to the extent that the DASH effect was due to increased potassium intake, its effects might be mitigated by simultaneously reducing sodium intake. The DASH-Sodium trial was conducted to determine the BP effect of three levels of sodium intake in combination with either the DASH or the Control dietary pattern. The three sodium levels were defined as higher (150 mM/day), intermediate (100 mM/day), and lower (50 mM/day). The higher level reflects the typical American diet, the intermediate level represents the upper limit of national recommendations, and the lower sodium level was chosen as a potentially optimal level that might produce further BP-lowering effects.

Similar to the DASH trial, the DASH-Sodium study was a multicenter, randomized feeding trial. Entry criteria and minority enrollment were also similar. The trial consisted of a

run-in period during which all individuals consumed the higher-sodium Control diet. Participants were then randomly assigned to follow either the DASH diet or the Control diet for 90 days. Within this parallel design, a crossover design provided participants each of the three sodium levels for 30 consecutive days in random order (Figure 43–5).

The primary outcome was SBP at the end of each 30-day period of dietary intervention, with DBP the secondary outcome. The study assessed sodium effects within each diet and the effects of diet at each sodium level, using an intention-to-treat analysis. The study was powered to detect a 2.1 mm Hg difference in SBP between sodium levels within each diet and 3.0 mm Hg between diets at a given sodium level ($\beta = 0.1$). Adherence was assessed by the methods described in the DASH trial above.

Results

Four hundred twelve participants were randomized. Baseline characteristics were similar in those assigned to the Control diet and those assigned to the DASH dietary pattern. The mean age was 48 years, approximately 56% were African American, and just over half were women. Forty-one percent had hypertension at baseline. A total of 95% (198 of 208) of the individuals in the DASH diet group and 94% (192 of 204) of those assigned to the Control diet group completed the study and provided BP measurements during each intervention period. Analysis of 24-hour urine collections showed that those assigned to the various levels of sodium intake nearly achieved their goals. Mean urine sodium averaged 142 mM/day during the higher-sodium period, 107 mM/day during the intermediate-sodium period, and 65 mM/day during the lower-sodium period. As expected, urinary potassium, magnesium, phosphorus, and urea nitrogen were higher in the DASH group and were stable across all three sodium levels. By design, weight remained stable throughout the intervention phase.

Both the DASH diet and reduced sodium intake led to BP lowering. BP was lower on the DASH than the Control diet at each level of sodium intake, and decreasing sodium intake reduced SBP and DBP in the context of both the DASH and the Control diets (Figure 43–6). On the Control diet, BP was reduced by 2.1/1.1 mm Hg going from the higher sodium

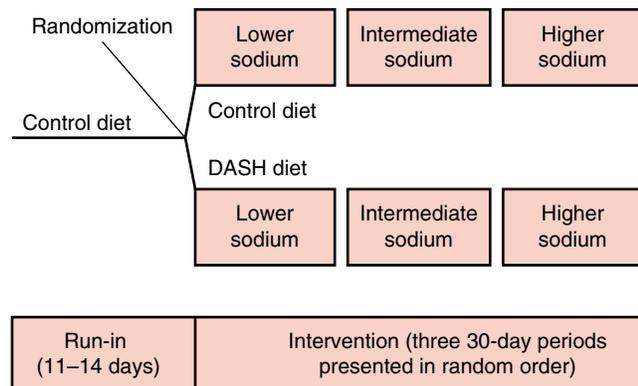

Figure 43–5 DASH-Sodium study design. (From Svetkey, LP, Sacks FM, Obarzanek E, et al. The DASH Diet, Sodium Intake and Blood Pressure Trial [DASH-sodium]: Rationale and design. DASH-Sodium Collaborative Research Group. J Am Diet Assoc 99(8 Suppl):S96-S104, 1999, with permission from the American Dietetic Association.)

intake to the intermediate sodium intake and by 4.6/2.4 mm Hg when the sodium intake was further reduced to the lower level. On the DASH diet, reducing sodium intake from the higher to the intermediate level resulted in a BP-lowering effect of 1.30/0.6 mm Hg. When these participants were fed the lower-sodium diet, BP was further reduced by 1.7/1.0 mm Hg. The effect of reducing sodium was not linear: the approximately 40-mM decrease in sodium from the intermediate to the lower-sodium diet resulted in a larger decrease in BP than the similar decrease in sodium from the higher to the intermediate level.

The largest BP effect was observed with the combination of DASH diet and lower sodium intake, although the effects were not fully additive. Participants eating the lower-sodium DASH diet had a BP reduction of 8.9/4.5 mm Hg compared with participants consuming the higher-sodium Control diet.

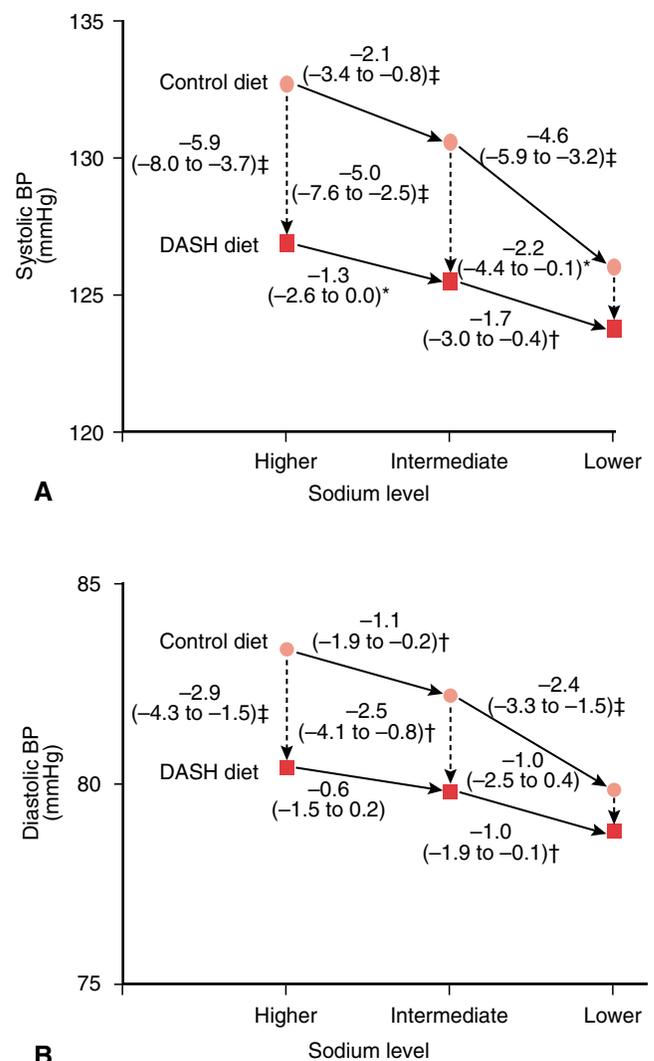

Figure 43–6 Blood pressure (BP) effects of the DASH diet and sodium intake. * $p < .05$; † $p < .01$; ‡ $p < .001$ (Significant difference between groups or dietary sodium categories.) (Reprinted with permission from Sacks FM, Svetkey LP, Vollmer WM, et al. Effects on blood pressure of reduced dietary sodium and the Dietary Approaches to Stop Hypertension [DASH] diet. DASH-Sodium Collaborative Research Group. N Engl J Med 344(1):3-10, 2001. Copyright © 2001 Massachusetts Medical Society.)

The DASH-Sodium results were consistent across subgroups defined by race, sex, age, and baseline hypertension status.² The effects of sodium were greater in participants with hypertension, in African Americans on the Control diet compared with non-African Americans on that diet, and in women on the DASH diet compared with men on that diet. In individuals with hypertension, the combination of the DASH diet and the lower sodium intake reduced SBP by 11.5 mm Hg. This effect was larger in African Americans (12.6 mm Hg vs. 9.5 mm Hg for others). The combination of the two dietary interventions had similar, but smaller, effects in individuals without hypertension (7.1 mm Hg), men (6.8 mm Hg), and women (10.5 mm Hg).² Older patients appeared to be more salt sensitive, with lower (vs. higher) sodium intake reducing BP more in older (>45 years), nonhypertensive participants fed the Control diet, compared with younger participants. However, this effect was not seen in hypertensive individuals.³⁴

Conclusions

The DASH-Sodium trial demonstrated that the DASH dietary pattern reduced BP at all levels of sodium intake compared with the Control diet, confirming and extending the findings of the DASH trial. This benefit was seen across subgroups defined by age, race, and hypertension status. In addition, sodium reduction alone decreased BP in persons eating a diet similar to the average American diet. The greatest BP-lowering effect was seen with the combination of the DASH diet and reduced sodium intake, leading to BP reductions similar to single-drug antihypertensive therapy. These findings support the use of the DASH dietary pattern and reduced sodium intake for the prevention and treatment of high BP.

OTHER EFFECTS OF DASH

Effects in Patients with More Severe Hypertension and/or Those on Antihypertensive Medication

The DASH trials reviewed previously were limited to a study population with high-normal BP (prehypertension in the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure [JNC 7]) or unmedicated stage 1 hypertension. Within that range, participants with higher BP had a greater BP reduction from the DASH diet³⁰ (Figure 43–7). The effects of DASH in persons with higher than stage 1 hypertension and/or those on BP medications is largely unknown. Conlin et al. randomly assigned participants with stage 1 or 2 hypertension to an 8-week trial of the Control or DASH diet.³ These individuals were also assigned to the angiotensin receptor blocker (ARB) losartan or placebo in an embedded double-blind crossover design. Mean baseline BP in the DASH group was 151/95 mm Hg. (compared with mean BP of 131.9/83.6 mm Hg in the DASH trial¹). During the placebo phase, the DASH dietary pattern reduced ambulatory SBP by 5.3 mm Hg ($p < .05$) compared with participants eating the Control diet, with no significant effect on DBP. Thus, the DASH diet is effective at lowering SBP in individuals with stage 1 or 2 hypertension. This study also demonstrated that the BP-lowering effect of losartan was greater in the setting of the DASH dietary pattern than when the Control diet was

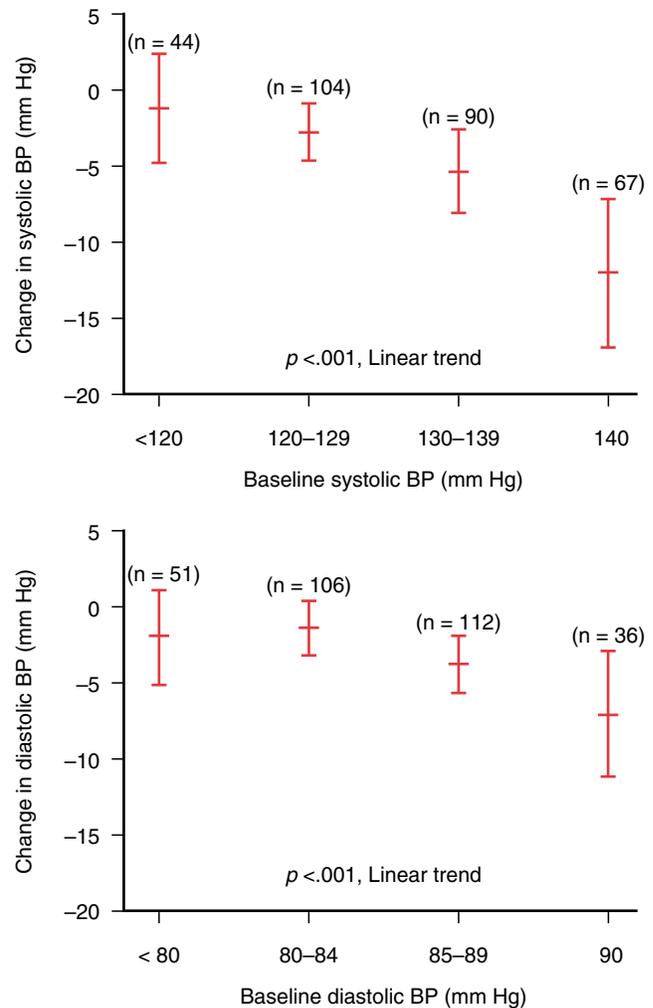

Figure 43–7 Change in blood pressure (BP) with the DASH diet as a function of baseline BP. (Bars indicate 95% confidence intervals.) (Reprinted with permission from Svetkey P, Simons-Morton D, Vollmer WM, et al. Effects of dietary patterns on blood pressure: Subgroup analysis of the Dietary Approaches to Stop Hypertension [DASH] randomized clinical trial. *Arch Intern Med* 159(3):285-293, 1999. Copyright © 1999 American Medical Association. All rights reserved.)

consumed (Figure 43–8). This trial suggests that the DASH diet enhances the BP response to antihypertensive medication that blocks the renin-angiotensin system (RAS) and raises the possibility that it also will enhance the effects of other classes of antihypertensive medication.

Effects on Other Cardiovascular Disease Risk Factors

In the DASH studies, the DASH dietary pattern, in which saturated fats are replaced by carbohydrates, monounsaturated fats, and polyunsaturated fats, reduced total and LDL-cholesterol by 13.7 mg/dl and 10.7 mg/dl, respectively⁴ (Figure 43–9). Triglycerides increased slightly. HDL-Cholesterol decreased by 3.7 mg/dl, but the total:HDL and LDL:HDL ratios were improved. These effects were observed in subgroups defined by race, sex, age, and baseline lipids. The implication of decreased HDL levels needs to be further studied, but the finding was not unexpected given the known

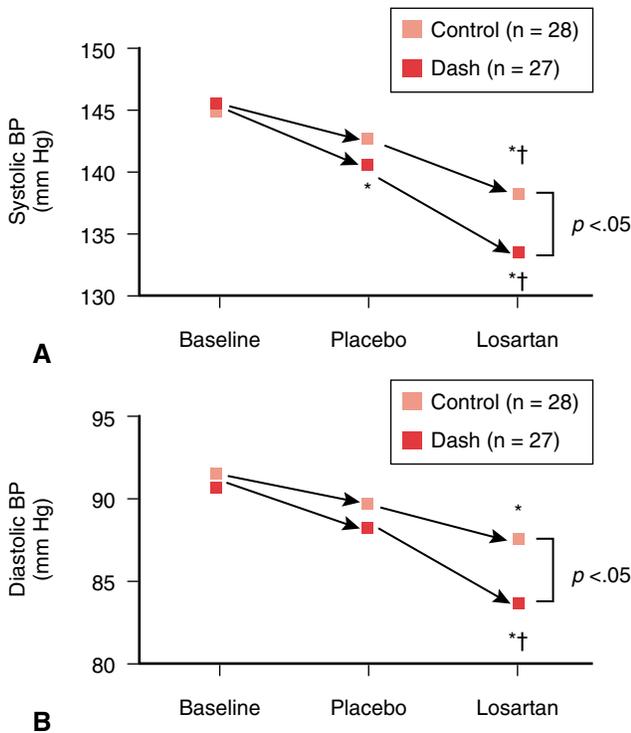

Figure 43-8 Twenty-four hour ambulatory (A) systolic and (B) diastolic blood pressures (BPs) at baseline and during placebo and losartan treatment. **p* < .05 vs. baseline; †*p* < .05 vs. placebo. (From Conlin PR, Erlinger TP, Bohannon A, et al. The DASH diet enhances the blood pressure response to losartan in hypertensive patients. *Am J Hypertens* 16(5 Pt 1):337-342, 2003, with permission from The American Journal of Hypertension, Ltd.)

decrease in HDL levels associated with low-fat diets.³⁵ There was no effect of sodium level on lipids.³⁶

The DASH diet also lowers homocysteine levels. A substantial body of observational data suggests that homocysteine is an independent risk factor for atherosclerotic cardiovascular disease (CVD). The DASH diet is rich in nutrients known to

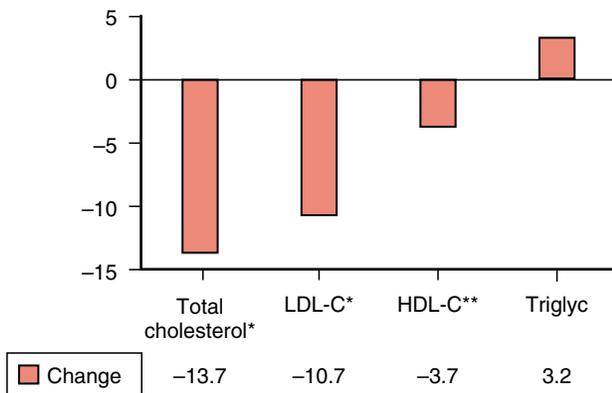

Figure 43-9 Effect of DASH dietary pattern on lipids, **p* < compared with control diet effects, **no significant change in LDL/HDL or total cholesterol/HDL ratios. (Reprinted with permission from Obarzanek E, Sacks FM, Vollmer WM, et al. Effects on blood lipids of a blood pressure-lowering diet: The Dietary Approaches to Stop Hypertension [DASH] Trial. *Am J Clin Nutr* 74(1):80-89, 2001.)

influence homocysteine metabolism, including folate, vitamin B6, and vitamin B12. In 118 patients in the DASH trial, preintervention and postintervention serum folate, pyridoxal 5' phosphate (the coenzyme form of vitamin B6), and homocysteine were measured.⁵ Compared with the Control diet, there was a 0.8- μ M/L reduction in homocysteine level in the DASH diet group (*p* = .03) (Figure 43-10).

Effects on Bone Health

Calcium intake is associated with bone health. In addition, cross-sectional studies demonstrate that a diet rich in fruits and vegetables is associated with higher bone mineral density, possibly related to promotion of a positive calcium balance from increased intake of potassium and magnesium.³⁷ In contrast, high sodium intake is associated with increases in urinary calcium excretion,^{38,39} which, in combination with inadequate calcium intake, may result in disturbances in calcium metabolism and bone loss mediated by a rise in parathyroid hormone (PTH).⁴⁰ Therefore, the DASH diet alone would be expected to improve bone health. Lin et al. studied the effect of the DASH diet and sodium intake on markers of bone turnover and calcium metabolism.⁴¹ Bone turnover was assessed using the serum marker of bone formation, osteocalcin, which is released by the osteoblast into circulation during the mineralization of newly synthesized collagen. Bone resorption was measured using the serum marker of bone resorption, C-terminal N-telopeptide (CTX), which is released from bone collagen into circulation following its degradation by osteoclasts. At all three sodium levels in the DASH-Sodium trial, the DASH diet reduced bone turnover, as indicated by decreased serum osteocalcin (8%-11%) and CTX (16%-18%). Reduction in bone turnover was significant in all subgroups regardless of hypertension status, race, gender, and age. Although there was a higher calcium intake in the DASH group, urinary calcium was similar to Control, suggesting greater calcium retention. The suppression of bone turnover observed in this study appears to be similar to or greater than that observed with calcium supplementation

Figure 43-10 Mean (95% CI) change in serum homocysteine (μ M/L) from end of run-in to end of intervention in the DASH study. (Reprinted with permission from Appel LJ, Miller ER 3rd, Jee SH, et al. Effect of dietary patterns on serum homocysteine: Results of a randomized, controlled feeding study. *Circulation* 102(8):852-857, 2000.)

alone. Thus, the DASH dietary pattern, with or without reduced sodium intake, significantly, reduces bone turnover, which if sustained, may improve bone mineral status and reduce the risk of osteoporosis.

MECHANISM OF ACTION

The BP-lowering mechanism of the DASH diet remains unknown, but there is some evidence for genetic modulation as well as effects on the RAS and sodium homeostasis.

Genetic modulation of the BP response to dietary intervention has been previously demonstrated. Both reduced sodium intake and weight loss⁴² are more effective in lowering BP in individuals with the AA genotype of the G-6A angiotensinogen (ANG) polymorphism compared with other ANG genotypes. This polymorphism is also associated with the greatest BP response to the DASH dietary pattern, with an average decrease of 6.93/3.68 mm Hg (compared with 2.80/0.20 mm Hg in those with the GG genotype).⁴³ Most of this genetic association is explained by data in whites, since African Americans have a very low prevalence of the GG genotype. The effect of the DASH diet in relationship to other BP-modulating genes is under investigation.

In the losartan study by Conlin noted above, the larger BP response to losartan experienced by non-African Americans compared with African Americans was substantially neutralized when the African American participants were eating the DASH diet.³ The fact that BP reduction is comparable in African Americans and whites on losartan when it is taken in the context of the DASH dietary pattern is reminiscent of the racial parity in BP effects of angiotensin-converting enzyme (ACE) inhibitor or ARBs when combined with diuretics.^{44,45} Indeed, there is evidence that the DASH diet may have diuretic effects. Akita et al.⁴⁶ demonstrated that the DASH diet increases the slope of the pressure natriuresis curve, a measure of the relationship between arterial pressure and urinary sodium excretion, without shifting the curve along the BP axis. These findings are consistent with a natriuretic action.

The DASH diet is high in potassium and calcium. Previous studies suggest that these micronutrients play a role in the function of the renin-angiotensin-aldosterone system (RAAS). Hollenberg et al.⁴⁷ showed that a low potassium intake (40 mmol/day) reduced renal blood flow and blunted the vascular response to angiotensin II, consistent with an increase in RAAS function. Potassium supplementation lowers BP and increases plasma renin activity (PRA).¹⁵ A relationship between calcium supplementation, calcium regulating hormones, and the RAAS also exists.⁴⁸ Administration of oral calcium significantly increases PRA and suppresses calcium-regulating hormones. These findings suggest that there is an interaction between the DASH diet and the RAAS in BP control. The other micronutrients and macronutrients involved in BP control could not be identified because of the study design. Further studies are required in order to understand the precise mechanisms and the specific dietary components that contribute to the BP-lowering effect of the DASH diet.

IMPLEMENTATION

The DASH and DASH-Sodium trials were relatively short-term feeding studies. They were not designed to assess either

adherence to the diet among people selecting their own food or the long-term effects of the DASH dietary pattern. The PREMIER trial attempted to address the feasibility of implementing the DASH diet along with other established recommendations for lowering BP in free-living persons.⁶ PREMIER was a multicenter randomized trial that included 810 adults with above-optimal BP or stage 1 hypertension who were not taking antihypertensive medications. The participants were randomly assigned to one of three intervention groups: (1) the “Established” intervention, a behavioral intervention that implemented long-standing recommendations (weight loss, sodium reduction, increased physical activity, and limited alcohol intake); (2) the “Established Plus DASH” intervention, which also implemented the DASH diet; and (3) an “Advice Only” comparison group. The main outcome was BP measurement and hypertension status at 6 months, with continued intervention and follow-up for a total of 18 months postrandomization. Results demonstrated gradients in BP and hypertension status across the groups. The mean net reduction in SBP was 3.7 mm Hg ($p < .001$ compared with Advice Only) in the Established group and 4.3 mm Hg ($p < .001$ compared with Advice Only) in the Established Plus DASH group. The prevalence of hypertension was decreased from the baseline of 37% to 26% in the Advice Only group, 17% in the Established group, and 12% in the Established Plus DASH group (Figure 43–11). In addition, the percent of individuals with optimal BP, defined as

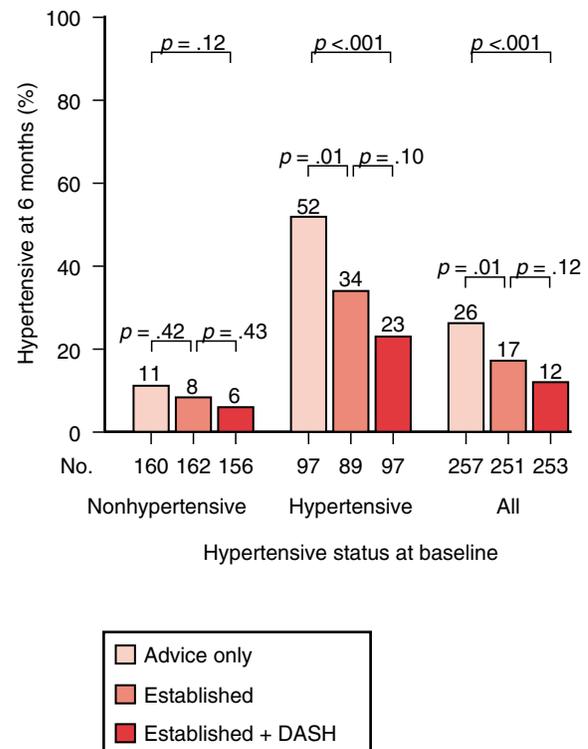

Figure 43–11 Percentage of participants in the PREMIER study with hypertension at 6 months by randomized group, by hypertension status at baseline. (Reprinted with permission from Appel LJ, Champagne CM, Harsha DW, et al. Effects of comprehensive lifestyle modification on blood pressure control: Main results of the PREMIER clinical trial. *JAMA* 289(16):2083-2093, 2003. Copyright © 2003 American Medical Association. All rights reserved.)

less than 120/80 mm Hg,⁷ went from 0% to 19% in Advice Only, 30% in Established, and 35% in Established Plus DASH (Figure 43–12). The trial demonstrated that free-living adults can adopt multiple lifestyle changes with improvement in BP control. Lifestyle modifications were effective in preventing the development of hypertension and increasing the number of individuals with optimal BPs.

A potential limitation of the PREMIER study was the unexpected reduction in BP in the Advice Only group, making it difficult to estimate the true effects of the active interventions (Established and Established Plus DASH). Participants randomized to the Advice Only “control” group made lifestyle changes similar to (but to a lesser extent than) the active intervention groups, suggesting that the advice that was provided conferred a less intense but still active behavioral intervention. A smaller, randomized controlled feeding trial, the Diet, Exercise, and Weight Loss Intervention Trial (DEW-IT), found that multiple lifestyle modifications including the DASH dietary pattern are effective in reducing BP compared with control (no intervention).⁴⁹ After a 9-week intervention of a hypocaloric DASH diet, moderate-intensity exercise program, and 100 mM/day sodium intake, participants assigned to the intervention arm had a reduction in mean ambulatory BP of 9.5/5.3 mm Hg ($p < .001$, $p < .002$ respectively) compared with the controls. This feeding trial confirmed the efficacy of multiple lifestyle interventions but did not address effectiveness. DEW-IT does provide evidence that the DASH dietary pattern in combination with other lifestyle modification reduces BP compared with a true control. Taken together, the PREMIER and DEW-IT trials show that the currently recommended lifestyle modifications, including the DASH dietary pattern, are feasible and improve BP control.

Implementation outside of the research context requires that the study results be broadly applicable and that the interventions be feasible. The DASH dietary pattern was tested in a population that was demographically heterogeneous, consisting of approximately 50% women, and 37% with household incomes less than \$30,000. African Americans were overrepresented in order to ensure that the interventions were effective in this population at increased risk of BP-related morbidity and mortality. With the exception of minority composition, the participants were similar to the U.S. adult population.³⁰ The range of baseline BP in the study populations represents at least 40% of U.S. adults.⁵⁰ The feeding trials used commonly available foods. However, the DASH dietary pattern, for daily energy consumption of 2000 kcal, includes 8 to 10 servings of fruits and vegetables a day, twice the current average amount consumed by U.S. adults⁵¹ and higher than the U.S. Department of Agriculture’s *Dietary Guidelines for Americans*⁵² recommended 5 to 7 servings. DASH includes 2 to 3 servings of low-fat dairy products, consistent with current recommendations, but again approximately twice the current intake.⁵³ Further, to be feasible, the recommended dietary pattern must be reasonably priced. Based on U.S. Department of Agriculture estimates of food bills for a typical American family of four in January 1997, the estimated cost of a week of food for the DASH dietary pattern falls between “low cost” and “moderate.”³⁰ Adoption of the DASH dietary pattern may be facilitated by descriptions based on a recommended number of food group servings per day rather than on goals for consumption of targeted nutrients. Meal plans and DASH recipes are readily available on the Internet (<http://www.nhlbi.nih.gov/health/public/heart/hbp/dash/>) and in a book written for the general public.⁵⁴

IMPLICATIONS

The DASH dietary pattern is an effective nonpharmacologic treatment for high BP. In the participants with hypertension, the reduction in BP with the DASH diet is similar in magnitude to that observed in trials of drug monotherapy for stage 1 hypertension.⁵⁵ Further, the DASH dietary pattern improves the BP response to the antihypertensive medication losartan, especially in the African American population. It seems reasonable to predict that the DASH dietary pattern would have similar interactions with other medications that affect the RAAS. Adoption of the DASH dietary pattern by patients with hypertension could decrease medication costs by reducing the amount of medication required to control BP and limiting the side effects of hypertension treatment due to numerous drugs.

Individuals with prehypertension⁵⁶ and high-normal BP⁷ also achieve reductions in BP with the DASH dietary pattern. Despite nonhypertensive BP, these individuals have excess BP-related cardiovascular risk.⁵⁷ In addition, because BP increases with age, it is the population with prehypertension now that is most likely to develop hypertension in the future.⁵⁸ Despite the expected benefits of lowering BP in the population with prehypertension or high-normal BP, pharmacologic interventions in this very large segment of the population have not been tested and may not be cost-effective. Widespread adoption of the DASH dietary pattern could prevent the development of hypertension in this group and subsequently lower CVD risk.

The DASH studies and PREMIER demonstrated a significant BP-lowering effect of the DASH dietary pattern. However, these relatively short studies did not directly assess the expected consequences of the observed BP changes (i.e., reduced cardiovascular outcomes). If applied population-wide, the DASH dietary pattern could lead to a small decrease in the population distribution of BP that would result in a large decrease in the number of cardiovascular events. It is estimated that a population-wide reduction in SBP or DBP of the magnitude observed with the DASH diet would reduce incident coronary heart disease (CHD) by approximately 15% and stroke by approximately 27%.⁵⁹

Erlinger et al. used the Framingham risk equation and data from the Third National Health and Nutrition Survey (NHANES III) to estimate the number of CHD events that would be prevented in the United States by a population-wide adoption of the DASH diet.⁶⁰ Applying an overall uniform SBP reduction of 5.5 mm Hg (the mean reduction in DASH), there was a predicted reduction of 668,426 CHD events over 10 years. After accounting for differential BP effects by race and baseline SBP, there was a predicted reduction of 416,514 CHD events (94,828 in African Americans and 321,080 in whites). This represents a decrease in CHD events of 9% in African Americans and 3% in whites. The greatest risk reduction occurred in African Americans with hypertension. These data imply that adoption of a healthy dietary pattern could have a substantial impact on the incidence of CHD in the United States, especially among African Americans.

The DASH dietary pattern may also have health benefits beyond its role in BP reduction. Several observational studies suggest that a prudent diet similar to DASH may reduce CHD events and total mortality. The Nurses' Health Study identified two dietary patterns: "prudent" and "Western."⁶¹ The prudent diet was similar to the DASH diet, while the Western diet was similar to the Control diet. After 8 years of follow-up, the prudent diet was associated with a relative risk of 0.64 for cardiovascular events (95% CI 0.44-0.92) comparing those at the extremes of either diet. A similar study in men without known CVD at baseline found a similar decrease in the risk of CVD events in those eating the DASH-like diet.⁶² Further, observational data suggest that a healthy dietary pattern similar to DASH is associated with a 20% to 30% reduction in total mortality.⁶³ Based on these observational studies, there may be additional benefits of the DASH dietary pattern beyond its favorable effects on BP, cholesterol, and homocysteine levels.

Obesity and Hypertension: Impact on Cardiovascular and Renal Systems

John E. Hall, Daniel W. Jones, Jay J. Kuo, Alexandre A. da Silva, Jiankang Liu, Lakshmi Tallam

Obesity and physical inactivity are estimated to cause more than 300,000 premature deaths each year in the United States, especially from cardiovascular disease.¹ Excess weight gain increases the risk for cardiovascular disease through multiple mechanisms, including hypertension, diabetes, dyslipidemia, atherosclerosis, and chronic renal dysfunction, many of which are interdependent.²⁻⁴ This cluster of disorders is often referred to as the “metabolic syndrome,” although excess weight gain is the primary cause in most patients.

Although kidney disease has not, in the past, been widely recognized as a major consequence of the metabolic syndrome or obesity per se, there is little doubt that excess weight gain is a major cause of hypertension and type 2 diabetes, which together account for approximately 70% of end-stage renal disease (ESRD). Accumulating evidence also suggests that even in nondiabetic obese patients, there is some degree of renal dysfunction that can lead to more serious renal injury as metabolic and hemodynamic disturbances worsen with prolonged obesity.⁵

The overall impact of obesity on hypertension and kidney disease is likely to become even more important in the future, as the prevalence of obesity continues to increase, especially in children and adolescents. Currently, more than 64% of adults in the United States are overweight, with a body mass index (BMI) greater than 25, and almost one third of the population is obese, with a BMI greater than 30.⁶ Similar trends have been reported in most industrialized countries and there appears to be no abatement of this worldwide “epidemic.” In children and adolescents the prevalence of obesity is rising even more rapidly, suggesting that obesity-associated medical problems are likely to worsen in the future unless these trends can be slowed or reversed.^{7,8}

OVERWEIGHT AND OBESITY—PRIMARY CAUSES OF ESSENTIAL HYPERTENSION

Population studies have shown that excess weight gain (as estimated by BMI, waist:hip ratio, abdominal diameter, and other indices of adiposity) is one of the best predictors for development of hypertension.⁹⁻¹¹ The relationships between BMI and systolic blood pressure (SBP) and diastolic blood pressure (DBP) are almost linear and have been observed in diverse populations throughout the world.⁹⁻¹² Moreover, the association between BMI and arterial pressure occurs not only for obese hypertensive subjects, but also for nonobese normotensive subjects.⁹⁻¹⁰ In general, the relationship between BMI and arterial pressure appears to be continuous, extending from the range of very lean to very obese.¹⁰ The strength of the association between BMI and blood pressure (BP), however,

may vary in different ethnic groups, possibly because of differences in body fat distribution or other factors that influence the susceptibility of BP to increased adiposity.

The full impact of obesity on hypertension has been difficult to estimate from cross-sectional population studies because its effects on BP are likely to worsen as obesity is sustained for many years and as injury to various target organs develops. Also, nonlinear, synergistic relationships may exist among the multiple effects of obesity (e.g., hyperlipidemia, glucose intolerance, and hypertension) in increasing the risk for cardiovascular and renal disease. Although these complex, time-dependent effects of obesity are difficult to assess in population studies, risk estimates from the Framingham Heart Study suggest that approximately 78% of hypertension in men and 65% in women can be attributed to obesity.¹¹

Clinical studies also suggest that obesity is an important cause of increased BP in many patients with essential hypertension, and the therapeutic value of weight loss in reducing BP has been demonstrated in normotensive as well as hypertensive obese subjects.^{9,13-15} (For a comprehensive discussion of the management of obesity, see Chapter 46.) Even modest weight loss of 5% to 10% of baseline weight may lower BP and reduce the need for antihypertensive medication.¹⁴ Clinical trials have also demonstrated the effectiveness of weight loss in primary prevention of hypertension.¹⁵ Weight loss does not always completely normalize BP in obese hypertensive patients, however. This is perhaps not surprising in view of the many pathologic changes that occur as excess adiposity is maintained for long periods of time. For example, prolonged obesity may lead to glomerular injury, loss of functional nephrons, and resetting of renal-pressure natriuresis to higher BPs.^{4,5}

Although some overweight or obese persons may not have BPs greater than 140/90 mm Hg and are therefore not considered to be “hypertensive” by the usual standards, weight loss usually lowers their BP. Excess weight gain shifts the frequency distribution of BP toward higher levels, increasing the probability of a person’s BP falling into the hypertensive range. This suggests that in these “normotensive” obese persons, BP is higher than it would be at a lower body weight, and that many are likely to be “prehypertensive,” a term introduced by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).¹⁶ It is increasingly recognized that, in prehypertensive persons, reducing BP may provide protection against future development of cardiovascular disease,¹⁶ especially when additional risk factors are present, as is the case for most obese subjects.

Studies in experimental animals have provided mechanistic insights into the cardiovascular and renal changes associated with excess weight gain. In dogs and rabbits a reproducible rise in BP is observed with weight gain induced by a high-fat

diet.¹⁷⁻¹⁹ Moreover, the metabolic, endocrine, cardiovascular, and renal changes caused by diet-induced obesity in experimental animals closely mimic the changes observed in obese humans^{3,20} (Table 44-1). Some of these changes are time dependent, occurring rapidly after weight gain and later becoming obscured by pathologic changes associated with prolonged obesity. For example, the glomerular hyperfiltration, characteristic of the early phases of obesity, may eventually subside as renal injury and nephron loss occur in association with obesity-induced hypertension.

HEMODYNAMIC, CARDIAC, AND VASCULAR CHANGES IN OBESITY

Increased Heart Rate and Cardiac Output

In experimental animals and humans, obesity induces a rise in resting heart rate due primarily to withdrawal of parasympathetic tone rather than increased sympathetic activity or increased intrinsic heart rate.^{21,22} Obesity also causes extracellular volume expansion and higher blood flows to many tissues.^{3,17,18} These elevated tissue blood flows summate to raise venous return and cardiac output.

Part of the increased cardiac output observed with weight gain is due to additional blood flow required for the excess adipose tissue. However, obesity also increases blood flow in nonadipose tissue, including the heart, kidneys, gastrointestinal tract, and skeletal muscles.^{17,18,23} The mechanisms responsible for increased regional blood flows have not been fully elucidated but are probably due, in part, to higher oxygen consumption and metabolic rate, accumulation of local vasodilator metabolites, and growth of the organs and tissues in response to increased metabolic demands associated with obesity.

Cardiac Hypertrophy and Impaired Systolic and Diastolic Function

Obesity is associated with eccentric and concentric cardiac hypertrophy.^{24,25} Moreover, cardiac hypertrophy is more severe in obese than in lean subjects with comparable hypertension.²⁶ Because blood volume and venous return are increased, there is increased preload, cardiac dilation, and development of eccentric left ventricular hypertrophy (LVH) in obese subjects.

The rise in BP also increases cardiac afterload, leading to increased left ventricular wall thickness. Thus, when obesity is combined with increased BP, cardiac workload is greatly amplified, leading to marked LVH. High sodium chloride intake, which often occurs concurrently with high caloric intake, exacerbates obesity-induced cardiac hypertrophy, even when the high-salt diet does not raise arterial pressure.²⁷

Functional changes in the heart also occur rapidly after excess weight gain. In animals fed a high-fat diet for 12 weeks, cardiac filling pressures were increased, and diastolic dysfunction, associated with decreased left ventricular compliance, was evident even at this early stage of obesity.²⁸ With more prolonged obesity, impaired systolic function may also occur. The mechanisms responsible for cardiac diastolic and systolic dysfunction in obesity are not well understood, but they probably involve structural changes in the heart, such as fibrosis, as well as functional changes, such as impaired β -adrenergic receptor signaling.²⁹ There may also be increases in intramyocellular lipids that lead to increased formation of reactive oxygen species, apoptosis, and deposition of collagen.³⁰ All of these structural and functional changes in the heart combine to greatly increase the risk for congestive heart failure (CHF) in obese persons.³¹

ENDOTHELIAL DYSFUNCTION AND ARTERIAL STIFFNESS IN OBESE SUBJECTS

Obesity is associated with impaired endothelial-mediated vasodilation,³² and weight reduction improves flow-mediated vasodilation in obese individuals.³³ Accelerated arterial stiffening also occurs in elderly, middle-aged, and even young adults (20-40 years of age) who have excess adiposity, as estimated by increased BMI, abdominal visceral fat, larger waist circumference, and increased waist:hip ratio.³⁴ Moreover, higher aortic pulse-wave velocity, a measure of aortic stiffness, strongly correlates with increases in BMI, waist circumference, and waist:hip ratio independent of SBP, race, and sex.³⁴ Important effects of excess weight gain that impair vascular function may be apparent even in children.³⁵

The mechanisms responsible for the deleterious effects of obesity on the vasculature are likely to be due to interactions of multiple disorders, including increased BP, inflammation, "lipotoxicity" caused by excessive non- β -oxidative

Table 44-1 Hemodynamic, Neurohumoral, and Renal Changes in Experimental Obesity Caused by a High-Fat Diet and in Human Obesity

Model	Arterial Pressure	Heart Rate	Cardiac Output	Renal Sympathetic Activity	Renal Renin Activity	Na ⁺ Balance	Renal Tubular Reabsorption	GFR*
Obese rabbits (high-fat diet)	↑	↑	↑	↑	↑	↑	↑	↑
Obese dogs (high-fat diet)	↑	↑	↑	↑	↑	↑	↑	↑
Obese humans	↑	↑	↑	↑	↑	↑	↑	↑

*The GFR changes refer to the early phases of obesity before major loss of nephron function has occurred. GFR, glomerular filtration rate.

metabolism of fatty acids, oxidative stress, and activation of multiple neurohumoral systems. There is increasing evidence that adipose tissue itself is an important source of cytokines and other factors that create a vascular milieu of inflammation and oxidative stress and may contribute to endothelial dysfunction, vascular stiffening, and eventually atherosclerosis.³⁶

MECHANISMS OF OBESITY HYPERTENSION—IMPAIRED RENAL-PRESSURE NATRIURESIS

Excess renal sodium reabsorption appears to play a major role in initiating the rise in BP associated with weight gain, and obese subjects require higher-than-normal arterial pressure to maintain sodium balance, indicating impaired renal-pressure natriuresis.^{4,37} With chronic obesity, increases in arterial pressure, glomerular hyperfiltration, neurohumoral activation, and metabolic changes may cause renal injury, further impairment of pressure natriuresis, and greater increases in BP.

Three mechanisms appear to be especially important in mediating increased sodium reabsorption, impaired renal-pressure natriuresis, and hypertension associated with weight gain (Figure 44–1): (1) increased sympathetic nervous system (SNS) activity, (2) activation of the renin-angiotensin-aldosterone system (RAAS), and (3) compression of the kidneys by fat accumulation within the kidneys and around the renal capsule and by increased abdominal pressure. As obesity is sustained and as metabolic disturbances (e.g., hyperlipi-

demia, glucose intolerance) worsen, renal injury may occur, resulting in progressive impairment of renal-pressure natriuresis and further increases in arterial pressure.

Sodium Retention Caused by Obesity-Induced Sympathetic Nervous System Activation

Several observations suggest that increased SNS activity contributes to obesity hypertension^{3,4,38,39}: (1) Obese persons have elevated SNS activity, as assessed by microneurography, tissue catecholamine spillover, or other methods; (2) pharmacologic blockade of adrenergic activity reduces BP to a greater extent in obese than in lean subjects; and (3) renal denervation markedly attenuates sodium retention and the development of obesity hypertension associated with a high-fat diet in experimental animals.

Obesity-Induced Sympathetic Nervous System Activation May Be Differentiated

Cardiac sympathetic activity does not appear to be substantially elevated in obese humans,^{40,41} and the high heart rate observed in obese persons appears to be related mainly to decreased parasympathetic activity.^{21,22} In contrast, SNS activity is usually increased in skeletal muscle and kidneys of obese rather than lean subjects.^{40–42}

SNS responses to weight gain may vary depending on ethnicity and factors such as fat distribution. In Pima Indians, who have a high prevalence of obesity but a relatively low prevalence of hypertension, muscle SNS activity is lower than in whites and does not track well with adiposity.⁴³ In African American men, however, the prevalence of increased SNS activity and hypertension is higher than in white men despite comparable levels of obesity.⁴⁴ In young, overweight African American women, adiposity is associated with high SNS activity.⁴⁴

The mechanisms for ethnic differences in SNS responses to obesity are unclear but may be related to factors such as differences in fat mass distribution. For reasons that are still unclear, abdominal obesity may elicit greater SNS activation than lower body obesity.⁴⁵ Almost all human studies have measured muscle SNS activity rather than renal SNS activity, the primary pathway by which the SNS causes chronic hypertension.⁴ Because there is considerable heterogeneity in the control of autonomic outflow to different organs, measurements of muscle SNS activity may not necessarily reflect renal SNS activity. No comprehensive analysis of the multiple factors that influence the relationships among obesity, SNS activity, and hypertension in diverse populations has been conducted.

Adrenergic Blockade or Renal Denervation Attenuates Obesity Hypertension

Studies in experimental animals fed a high-fat diet indicate that combined α - and β -adrenergic blockade markedly attenuates the rise in BP during the development of obesity.⁴⁶ Clonidine, a drug that stimulates central α_2 receptors and reduces sympathetic activity, also prevents most of the rise in BP in dogs fed a high-fat diet.⁴⁷ In obese hypertensive patients, combined α - and β -adrenergic blockade for 1 month reduced ambulatory BP significantly more than in lean essential hypertensive patients.⁴⁸

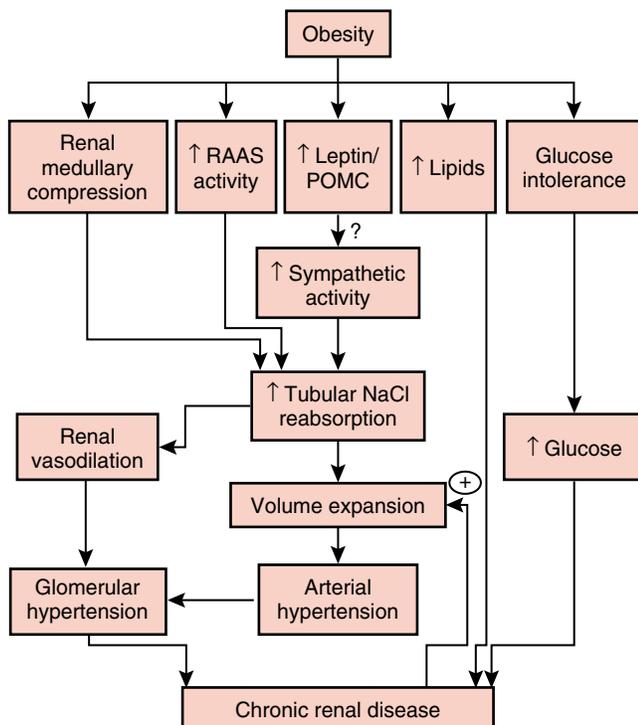

Figure 44–1 Summary of mechanisms by which obesity causes hypertension and renal injury by activating the sympathetic nervous system, the renin-angiotensin-aldosterone system (RAAS), by physical compression of the kidneys, and by metabolic abnormalities. POMC, proopiomelanocortin pathway; NaCl, sodium chloride.

These findings suggest that increased adrenergic activity contributes to the development and maintenance of obesity hypertension in experimental animals and in humans.

The renal sympathetic efferent nerves mediate much of chronic effects of SNS activation on BP in obesity. In obese dogs fed a high-fat diet, bilateral renal denervation greatly attenuated sodium retention and hypertension.⁴⁹ Thus, obesity increases renal tubular sodium reabsorption, impairs pressure natriuresis, and causes hypertension, in part, by increasing renal SNS activity.

Mechanisms of Sympathetic Nervous System Activation in Obesity

Although the mechanisms that increase renal SNS activity in obesity have not been fully elucidated, several potential mediators have been suggested, including (1) hyperinsulinemia, (2) fatty acids, (3) angiotensin II (Ang II), (4) hyperleptinemia, (5) impaired baroreceptor reflexes, and (6) activation of chemoreceptor-mediated reflexes associated with sleep apnea. Some of these mechanisms have been reviewed previously.⁵⁰⁻⁵³

Evidence supporting direct cause-and-effect relationships for most of these mechanisms in obesity-induced SNS activation is scanty. For example, multiple studies in experimental animals and humans have shown that hyperinsulinemia, although closely correlated with hypertension, cannot account for increased arterial pressure in obese subjects.⁵¹ In fact, chronic hyperinsulinemia caused by insulin infusion or insulinoma in dogs and humans is often associated with reduced, rather than increased, BP.⁵¹ Likewise, studies from our laboratory do not support a major role for increased levels of fatty acids in causing chronic SNS activation associated with obesity.⁵⁴ Studies in experimental animals and in humans suggest that obesity is associated with impaired ability of baroreceptor reflexes to suppress SNS activity during acute increases in BP induced by pharmacologic agents.⁵⁰ However, whether these acute measures of baroreflex sensitivity reflect the long-term influence of arterial baroreceptors on SNS activity in obesity hypertension is unclear.

Possible Role of Leptin and Hypothalamic Melanocortins in Sympathetic Nervous System Activation

Leptin may be an important link between obesity and SNS activation⁵⁵ (Figure 44-2). Leptin is secreted by adipocytes in proportion to the degree of adiposity and crosses the blood-brain barrier via a saturable receptor-mediated transport system. Leptin binds to its receptor in various regions of the hypothalamus and activates signaling pathways, especially in the arcuate nucleus, that regulate body weight by decreasing appetite and increasing energy expenditure.⁵⁶ Evidence that leptin acts as a powerful controller of body weight comes from genetic studies of mice and humans demonstrating that missense mutations of the leptin gene cause extreme, early-onset obesity.⁵⁶ Mutations of the leptin gene, however, are very rare in humans, and the importance of abnormalities of leptin production or sensitivity of leptin receptors in contributing to obesity is still unclear.

There is substantial evidence in rodents that high levels of leptin can activate SNS activity and increase arterial pressure.^{3,55,57,58} The rise in BP with hyperleptinemia is slow in

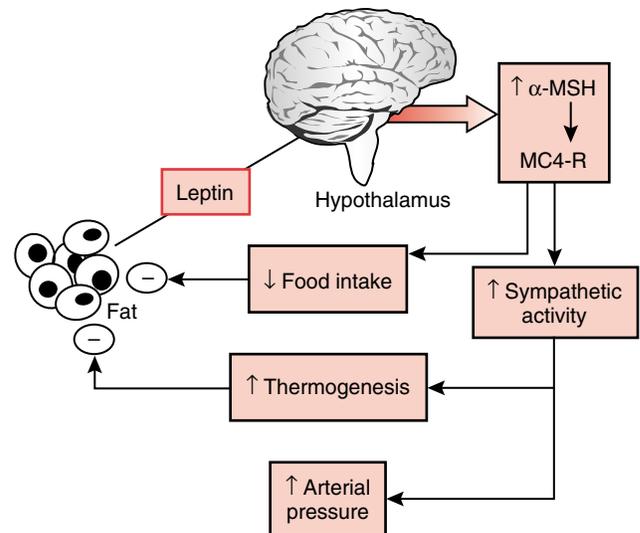

Figure 44-2 Possible links between leptin and its effects on the hypothalamus, sympathetic activation, and hypertension. Leptin may mediate much of its effects on appetite and sympathetic activity by stimulating other neurochemical pathways, including α -melanocyte stimulating hormone (α -MSH), which activates melanocortin 4-receptors (MC4-R).

onset and occurs over a period of several days despite decreased food intake, which would otherwise tend to lower BP.⁵⁸ Moreover, the hypertensive effects of leptin are enhanced when nitric oxide synthesis is inhibited,⁵⁹ as often occurs in obese subjects with endothelial dysfunction. The chronic effects of leptin to raise arterial pressure are completely abolished by α - and β -adrenergic blockade, indicating that they are mediated by adrenergic activation.⁶⁰

An observation that points toward leptin as a potential link between obesity and hypertension is the finding that mice with leptin deficiency and rats with mutations of the leptin receptor usually have little or no increase in arterial pressure despite severe obesity when compared with their lean controls.^{3,61} There have been few studies in which BP has been measured in obese children with leptin gene mutations. In one study by Ozata et al.,⁶² four young patients with homozygous missense mutations of the leptin gene were found to have early-onset, morbid obesity but no indication of hypertension. Each of these children also had impaired sympathetic activity, postural hypotension, and attenuated RAAS responses to upright posture.⁶² Moreover, hypertension was absent in spite of severe insulin resistance and hyperinsulinemia. These observations are consistent with those in leptin-deficient mice and suggest that hyperleptinemia may be an important factor in linking obesity with SNS activation and hypertension in humans as well as in rodents. However, these studies do not rule out the possibility that prolonged obesity may also activate other mechanisms that raise BP, such as renal injury.⁴

The stimulatory effect of leptin on SNS activity may be mediated, in part, by interaction with other hypothalamic factors, especially the proopiomelanocortin (POMC) pathway. Antagonism of the melanocortin 3/4 receptor (MC3/4-R) completely abolished the acute effects of leptin on renal SNS activity.⁶³ In addition, chronic blockade of the MC3/4-R in rats caused rapid weight gain but little or no increase in arterial pressure and a decrease in heart rate.⁶⁴ As weight gain

usually raises BP and heart rate, these findings are consistent with the possibility that a functional MC3/4-R is important in linking excess weight gain with increased SNS activity and hypertension. However, the importance of the POMC pathway and MC3/4-R in controlling SNS activity and raising BP in obese humans has not, to our knowledge, been investigated.

Renin-Angiotensin-Aldosterone System Activation in Obesity

Even though excess weight gain is associated with sodium retention and expansion of extracellular fluid volume, obese subjects often have small increases in plasma renin activity (PRA), angiotensinogen, angiotensin-converting enzyme (ACE) activity, Ang II, and aldosterone levels.^{3,65} Possible mechanisms for increased renin secretion and activation of the RAAS include (1) increased loop of Henle sodium chloride reabsorption and reduced sodium chloride delivery to the macula densa and (2) activation of the renal sympathetic nerves. Increased angiotensinogen formation by adipose tissue has also been suggested to contribute to elevated Ang II levels in obesity.⁶⁵ Although the quantitative importance of these different pathways for forming Ang II in obesity is uncertain, activation of the RAAS appears to contribute to elevated BP and target organ damage in obese persons.

Role of Ang II in Obesity Hypertension and Renal Injury

A significant role for Ang II in stimulating sodium reabsorption, impairing renal-pressure natriuresis, and causing hypertension in obesity is supported by the finding that treatment of obese dogs with an Ang II antagonist or an ACE inhibitor blunted sodium retention, volume expansion, and increased arterial pressure.^{66,67} Also, ACE inhibitors are effective in reducing BP in obese humans, particularly in young patients.⁶⁸ Whether the effects of Ang II to raise BP in obesity are due primarily to direct actions on the kidneys or to SNS activation is unclear. The direct renal sodium-retaining effects of Ang II are well known, as are the direct effects of Ang II on SNS activity.⁶⁹

Activation of the RAAS may also contribute to the glomerular injury and nephron loss associated with obesity. Increased Ang II formation, by constricting efferent arterioles, exacerbates the rise in glomerular hydrostatic pressure caused by systemic arterial hypertension.⁶⁹ Studies in type 2 diabetic patients, who are usually obese, clearly indicate that ACE inhibitors or Ang II antagonists slow the progression of renal disease.⁷⁰⁻⁷³ However, further studies are needed in nondiabetic, obese subjects to determine the efficacy of RAAS blockers compared with other antihypertensive agents in reducing the risk of renal injury.

Role of Aldosterone in Obesity Hypertension and Renal Injury

Studies in experimental animals and in humans have provided evidence that antagonism of aldosterone may provide an important therapeutic tool not only for lowering BP, but also for attenuating target organ injury in hypertension.⁷⁴ However, few studies have examined the role of aldosterone in contributing to sodium retention, hypertension, or renal

injury in obesity. We have shown in obese dogs fed a high-fat diet that antagonism of aldosterone markedly attenuated sodium retention, hypertension, and glomerular hyperfiltration (Figure 44-3).⁷⁵ Moreover, this protection against

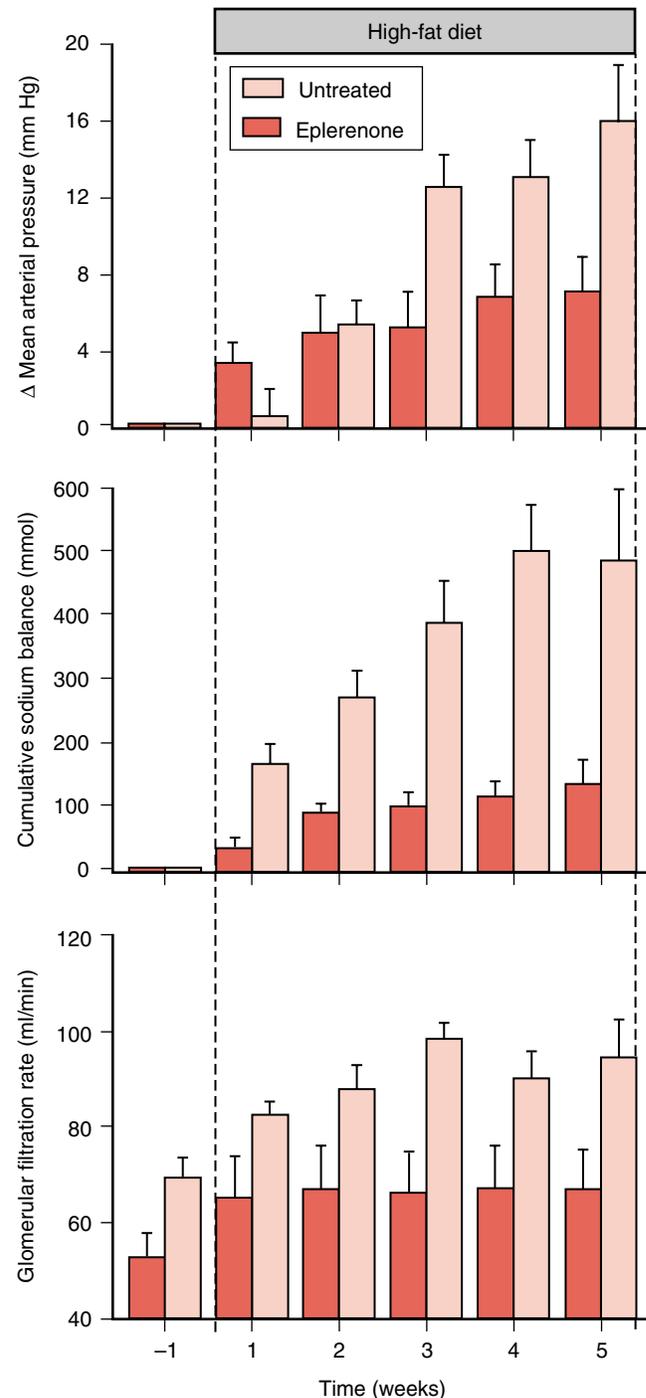

Figure 44-3 Changes (Δ) in mean arterial pressure (mm Hg), cumulative sodium balance (mmol), and glomerular filtration rate (ml/min) in control, untreated, and eplerenone-treated (10 mg/kg, twice daily) dogs that were fed a high-fat diet for 5 weeks to develop obesity. (Redrawn from data in de Paula RB, da Silva AA, Hall JE. Aldosterone antagonism attenuates obesity-induced hypertension and glomerular hyperfiltration. *Hypertension* 43:41-47, 2004.)

sodium retention and hypertension occurred despite marked increases in PRA, suggesting that combined blockade of aldosterone and Ang II might be even more effective in preventing obesity-induced sodium retention and hypertension.

The fact that aldosterone antagonism markedly attenuated glomerular hyperfiltration associated with obesity may have important implications for renal protection. Although there are no studies, to our knowledge, that have tested this concept directly in obese subjects, previous studies in various experimental models of hypertension have provided evidence that aldosterone antagonism attenuates renal injury.⁷⁴

Renal Compression Caused by Visceral Obesity

Visceral obesity initiates several changes that lead to compression of the kidneys and increased intrarenal pressures.^{3,5} For example, intraabdominal pressure rises in proportion to sagittal abdominal diameter, reaching levels as high as 35 to 40 mm Hg in some subjects.⁷⁶ In addition, retroperitoneal adipose tissue often encapsulates the kidneys and penetrates the renal hilum into the renal medullary sinuses, causing additional compression and increased intrarenal pressures.^{3,5} Obesity also causes increased formation of a renal medullary extracellular matrix that could exacerbate intrarenal compression and sodium retention.^{3,5} Although these physical changes in the kidneys cannot account for the initial increase in arterial pressure that occurs with rapid weight gain, they may help to explain why abdominal obesity is much more closely associated with hypertension than lower body obesity.

OBESITY AND CHRONIC RENAL DISEASE

Although obesity is not widely recognized as a major cause of renal disease, its impact becomes obvious if we consider that the two most important causes of ESRD are diabetes and hypertension, both of which are closely associated with excess weight gain. Moreover, the rapid rise in the prevalence of ESRD in the past two decades has been paralleled by increasing obesity and diabetes.⁷⁷ In fact, most of the increasing prevalence of ESRD has been attributed to increasing type 2 diabetes.

Obesity Exacerbates Development of Nondiabetic Renal Diseases

In addition to causing renal injury through diabetes and hypertension, obesity also exacerbates the effects of other primary renal insults, even those that are often considered to be relatively benign, such as unilateral nephrectomy.⁷⁸ In patients who underwent unilateral nephrectomy an average of 13.6 ± 8.6 years before, 92% of those with a BMI >30 developed proteinuria or renal insufficiency, whereas only 12% with a BMI <30 developed these disorders⁷⁸ (Figure 44–4).

In patients with immunoglobulin A (IgA) nephropathy, those with a BMI >25 at the time of renal biopsy had more severe renal lesions and increased proteinuria, as well as a much faster decline of renal function and progression to chronic renal failure compared with patients with a BMI <25 .⁷⁹ Moreover, moderate weight loss in overweight patients with chronic nondiabetic proteinuric nephropathies markedly reduced proteinuria, whereas in overweight subjects who

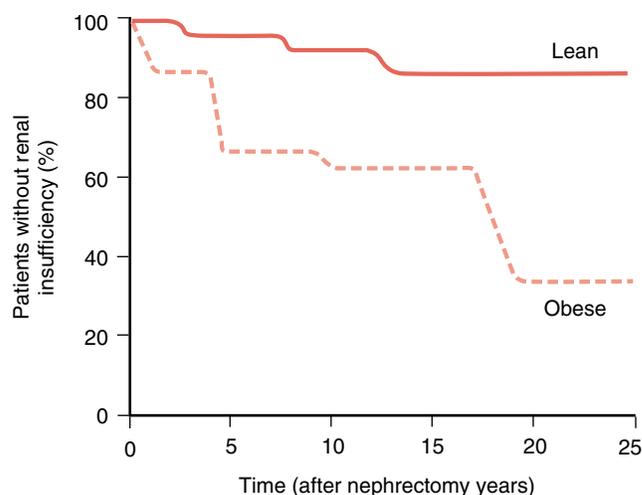

Figure 44–4 Percentage of patients who did not develop renal insufficiency after unilateral nephrectomy and who were lean (BMI <25 , solid line) or obese (BMI >30 , dashed line) at the time of unilateral nephrectomy. (Redrawn from data in Praga M, Hernandez E, Herrero JC, et al. Influence of obesity on the appearance of proteinuria and renal insufficiency after unilateral nephrectomy. *Kidney Int* 58:2111-2118, 2000.)

did not lose weight, renal function worsened with time.⁸⁰ These observations indicate that obesity greatly exacerbates loss of renal function in patients with preexisting glomerulopathies, and that weight loss may lessen the impact of renal injury from other causes.

Early Structural and Functional Renal Changes in Obese Subjects

Even in the absence of preexisting renal disease, excess weight gain causes early structural and functional changes in the kidneys that may eventually lead to more serious renal disorders. Significant structural changes in the kidneys were observed in dogs placed on a high-fat diet for only 7 to 9 weeks.⁸¹ These changes included enlargement of Bowman's space, increased glomerular cell proliferation, increased mesangial matrix, thicker basement membranes, and increased expression glomerular transforming growth factor β .⁸¹ Moreover, these early changes occurred with only modest hypertension, no evidence of diabetes, and only mild metabolic abnormalities.

Obese humans often develop proteinuria, frequently in the nephrotic range, that may be followed by progressive loss of kidney function even in the absence of diabetes or severe hypertension.⁸⁰ The most common types of lesions observed in renal biopsies of obese subjects are focal and segmental glomerulosclerosis and glomerulomegaly.⁸² A review of 6818 biopsies indicated that the incidence of obesity-related glomerulopathy, defined as combined focal glomerulosclerosis and glomerulomegaly, rose tenfold from 1990 to 2000, coincident with the rapid increase in the prevalence of obesity during this period.⁸²

The mechanisms of obesity-induced renal injury likely involve a combination of hemodynamic and metabolic abnormalities. Obesity causes marked glomerular hyperfiltration and preglomerular vasodilation that permits greater

transmission of the increased arterial pressure to the glomerular capillaries.⁸³ These renal hemodynamic changes, along with the metabolic abnormalities, such as hyperglycemia and hyperlipidemia, likely exacerbate the effects of increases in arterial pressure to cause renal injury.

A synergistic relationship may exist between the metabolic abnormalities and increased glomerular pressure in causing chronic renal vascular disease and nephron loss. Results of the Prospective Cardiovascular Munster (PROCAM) study suggest that this is the case for coronary artery disease.⁸⁴ For example, the risk for myocardial infarction (MI) was increased about twofold by hypertension and twofold by diabetes. However, when hypertension and diabetes occurred together the risk was increased more than eightfold. When hypertension, diabetes, and hyperlipidemia were all present, as occurs in most obese patients, the risk for MI increased almost 20-fold. Similar synergistic relationships between glomerular pressure and metabolic abnormalities may also exist for renal vascular disease, although there are no large-scale studies that have addressed this issue.

Do Caloric Restriction and Weight Loss Prevent or Attenuate Renal Disease?

There is compelling evidence in experimental animals that excess caloric intake causes progressive nephron loss and that caloric restriction protects against glomerular injury. Modest food restriction (8%-18% below the usual ad lib amounts) in the obese Zucker rat, for instance, reduces renal injury and increases life span by approximately 30%.⁸⁵ Similar beneficial effects of food restriction have been observed in other models of obese and nonobese rodents, indicating that food restriction can largely prevent chronic renal disease in rats.

In nondiabetic obese humans, short-term weight loss also produces marked reductions in proteinuria. An antiproteinuric effect of weight loss is also evident in overweight persons with nephropathies caused by factors other than obesity.⁸⁰ The renal benefits of weight loss appear to occur whether they are induced by diet and exercise or by surgical methods (e.g., gastroplasty), although there have been no large studies directly comparing the effectiveness of different methods of weight loss on progression of renal dysfunction. Also, most studies have lasted only a few weeks or months. Studies lasting for at least a year, however, have shown remarkable reductions in proteinuria (>80%) with a weight loss of about 12%.⁸⁶ Although the long-term consequences of weight loss in protecting against renal disease have not been rigorously tested in humans, there is little doubt that weight loss reduces hypertension and prevents or reverses the development of type 2 diabetes, the two main risk factors for development of ESRD.

TREATMENT OF OBESITY HYPERTENSION AND RENAL DISEASE

Weight Loss and Lifestyle Modification

The numbers of people affected and the severity of the consequences are rapidly making obesity the most important and most prevalent health care problem of the modern world. Few effective treatments are available to prevent or treat obesity (see Chapter 46). For morbidly obese patients (BMI >40) or

for patients with a BMI >35 and comorbid conditions, various surgical procedures, especially gastric bypass surgery, are becoming increasingly popular and usually produce significant weight loss. However, the long-term consequences of these procedures in reversing cardiovascular and renal disease and on overall mortality are still uncertain.

Only two drugs, sibutramine (a sympathomimetic that induces satiety and increases thermogenesis) and orlistat (a gastrointestinal lipase inhibitor), are currently approved by the U.S. Food and Drug Administration (FDA) to promote weight loss. Both of these drugs have significant side effects that limit their use in many patients, and their long-term effects on morbidity and mortality are unknown.

Until more effective and safer pharmacologic treatments are available, voluntary weight loss associated with lifestyle modifications, including increased physical activity, is still the best option for most overweight patients.⁸⁷ Several studies have demonstrated that weight loss lowers BPs in normotensive or hypertensive obese subjects^{88,89} and may prevent the development of hypertension in persons with "high normal" BPs.⁸⁸ Even modest weight reductions of 5% to 10% can improve control of BP and reduce the amount of medication necessary to achieve goal BPs.^{14,90,91} Weight loss also is effective in reducing other risk factors for cardiovascular and renal disease (e.g., blood glucose and lipids) in many hypertensive patients.

Current guidelines for achieving weight loss usually recommend as a first step the development of an individualized plan to reduce caloric intake and increase energy expenditure by behavioral modification.⁸⁷ A major obstacle, however, in successful prevention and treatment of obesity has apparently been the lack of adequate involvement of health care professionals. Fewer than half of obese adults report that their physicians advised them to lose weight.⁹² Patients whose physicians advised them to lose weight, however, were three times more likely to attempt weight loss as those who were not so advised.⁹³ The successful management of obesity will require the same attention and planning for effective treatment as other important medical conditions, such as hypertension.

Drug Therapy of Hypertension in Obese Patients

Until effective strategies for preventing and treating obesity are developed, physicians will be left with the responsibility of managing the cardiovascular, metabolic, and renal consequences of obesity. Selection of specific drugs for antihypertensive therapy in obese subjects is often empiric or based on clinical experience and knowledge of the physiology of obesity hypertension.^{83,94} No large clinical trials have tested the effectiveness of different drugs in reducing BP and preventing cardiovascular and renal disease in obese compared with lean subjects. The Antihypertensive Therapy and Lipid-Lowering Heart Attack Trial (ALLHAT), however, included many overweight subjects and may provide some useful information about the relative effectiveness of the four main classes of antihypertensive drugs tested: diuretics, α -adrenergic blockers, ACE inhibitors, and calcium antagonists.⁹⁵ Also, some inferences may be drawn from other randomized, controlled clinical trials of drug therapy in essential hypertension, because most of these trials have included many participants who were overweight or obese.

The potential advantages and disadvantages of different antihypertensive drugs in obese patients have been previously discussed.^{94,96} However, it is important to point out that adequate BP control in obese patients may not be the usual <140/90 mm Hg. For many, lower levels of BP should be the goal because of the coexistence of other risk factors, such as hyperlipidemia, glucose intolerance or diabetes, and atherosclerosis. Another important consideration for obese persons is that hypertension may often be difficult to control with one drug. Therefore, combination therapy is often required for the effective management of obese hypertensive patients.

Diuretics

Because of their ability to reduce renal sodium and water reabsorption and decrease extracellular fluid volume, diuretics may be useful in lowering BP in many obese hypertensive patients.⁹⁷ Some clinicians prefer diuretics in obese patients because of the strong evidence from randomized controlled clinical trials indicating that reducing BP with diuretics lowers cardiovascular morbidity and mortality.¹⁶ Because obese patients often have glucose intolerance and dyslipidemia, some clinicians avoid diuretics to prevent worsening these metabolic abnormalities.⁹⁸ Although studies using high doses of diuretics have demonstrated significant adverse metabolic effects, such as increases in insulin resistance and plasma lipids, low-dose diuretics are less frequently associated with these effects, and, when used in combination with other agents, can be very useful in treating obesity hypertension.¹⁶

β -Adrenergic Blockers

There is strong outcome evidence for treatment of essential hypertension with β -blockers.¹⁶ In obese patients, β -blockers may be useful in countering some effects of obesity-induced sympathetic activation, such as stimulation of renin secretion. β -blockers are also especially beneficial in patients after MI, and studies have demonstrated that these drugs decrease morbidity and mortality in diabetic patients, most of whom are overweight or obese.⁹⁹ However, β -blockers may make it more difficult for the obese patient to lose weight and, in some studies, are associated with worsening glucose control, higher lipid levels, and increased body weight.⁹⁴ Thus, although β -blockers may be indicated in obese hypertensive patients with ischemic heart disease and/or arrhythmias, other drugs may be preferable for initial therapy in obese patients who have no evidence of heart disease.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors offer some theoretical advantages in treating obesity-related hypertension. As discussed previously, the RAAS is activated in obesity, suggesting that blockers of this system should be effective in lowering BP. The ability of ACE inhibitors to attenuate glomerular hyperfiltration and urinary protein excretion provide an advantage in managing BP in obese patients who are particularly prone to renal disease. The improved insulin sensitivity associated with ACE inhibitors is also a positive feature. One of the few randomized, controlled trials in obese hypertensive patients included an ACE inhibitor. The Treatment of Obese Patients with Hypertension (TROPHY) study compared the BP responses to the ACE

inhibitor lisinopril and the diuretic hydrochlorothiazide in obese hypertensives.⁶⁸ Both agents effectively lowered SBP and DBP after 12 weeks of therapy. African Americans and older participants were more likely to respond favorably to the diuretic, while the white and younger participants were more likely to respond to the ACE inhibitor.

Studies in patients with hypertension and/or CHF have demonstrated that the response to ACE inhibitors depends on sodium intake and volume status. These drugs can be used in combination with diuretics in the obese hypertensive patient for optimal BP responses, even in patients who do not have elevated PRA.¹⁶

Angiotensin II Receptor Antagonists

Ang II receptor antagonists have not been studied extensively in obese hypertensive patients. Studies in patients with essential hypertension suggest that they have BP-lowering effects similar to ACE inhibitors.¹⁶ Some differences between these two classes (e.g., the effect of ACE inhibitors to increase kinin levels) may be responsible for subtle differences in the incidence of complications such as angioedema and cough. It is likely that obese patients have similar BP responses to ACE inhibitors and Ang II antagonists. Extensive trials have been completed in hypertensive patients, including those with diabetes, to examine the effects of Ang II antagonists on cardiovascular morbidity and mortality and on progression of renal disease. Two different Ang II antagonists were shown to prevent or decrease proteinuria in hypertensive patients with type 2 diabetes mellitus.⁷¹⁻⁷³

α_1 -Adrenergic Blocking Agents

Results of ALLHAT suggest that α_1 -adrenergic blockers are not as effective as diuretics in preventing heart failure and cardiovascular disease.¹⁰⁰ Therefore, these drugs will likely be used less as monotherapy for patients with essential hypertension, including those who are obese. Because they lower plasma lipids, they may continue to play a role in combination therapy for managing obese hypertensive patients with dyslipidemia.¹⁰¹ They may also be useful as part of a combination of medications in many patients with resistant hypertension, which is common among obese persons.¹⁰²

Calcium Channel Blockers

These drugs are frequently used to treat obese hypertensive patients. Their effectiveness does not seem to be very dependent on the status of blood volume, the RAAS, or SNS activity. Because calcium channel blockers are effective in a broad range of hypertensive patients, including obese patients, they have gained popularity.¹⁶ However, some studies suggest that calcium channel blockers are less effective in obese than in lean hypertensive patients.^{94,103} The dihydropyridine calcium antagonists have the potential disadvantage of further increasing heart rate in obese patients. The nondihydropyridine calcium antagonists, in contrast, lower heart rate.¹⁶

It is clear that a randomized controlled outcome trial is needed to guide drug selection for obese hypertensive patients. In the meantime, clinicians should continue to use their best judgment, based on their understanding of the pathophysiology of obesity hypertension and the characteris-

tics of the individual patient, in selecting a regimen of pharmacologic therapy appropriate to control BP, attenuate the development of cardiovascular and renal disease, and avoid worsening of other metabolic disorders associated with obesity.

SUMMARY

There has been an alarming increase in the prevalence of overweight and obesity in most industrialized countries, resulting in increasing diabetes mellitus, hypertension, and renal disease. Excess weight gain is the key risk factor for increased BP in most patients with essential hypertension and also appears to be a major cause of chronic kidney disease. Obesity initially raises BP by increasing renal tubular reabsorption, impairing pressure natriuresis, and causing volume expansion. These changes are due to activation of the SNS and RAAS and to physical compression of the kidneys when visceral obesity is present. Blockade of the SNS and RAAS is therefore effective in reducing BP in obese subjects. With prolonged obesity, there may be progressive renal dysfunction that worsens the hypertension. In some obese individuals, renal injury may progress to ESRD, especially if other preexisting glomerulopathies are present. Weight reduction is an essential first step in the management of obesity-associated hypertension and renal disease. There are, however, few drugs available to produce significant long-term weight loss and few guidelines for treating obesity-associated hypertension, other than the recommendation of reducing weight. Special considerations for the obese patient, in addition to controlling the BP, include correcting the metabolic abnormalities and protecting the kidneys from further injury. More emphasis should be placed on prevention of obesity and on lifestyle modifications that help patients to maintain a healthier weight.

Alcohol and Hypertension

Ian B. Puddey, Lawrence J. Beilin

The relationship between regular alcohol consumption and hypertension that was first described by Lian¹ in 1915 in young French ex-servicemen was largely ignored until the latter half of the twentieth century, when interest in the phenomenon reemerged with case series of higher blood pressures (BPs) in problem drinkers.^{2,3} In one such study, heavy drinkers who abstained were noted to have a higher prevalence of persisting hypertension following alcohol withdrawal than those who resumed drinking.⁴ Subsequent reports from hypertension clinics in Scotland^{5,6} and Sweden⁷ noted an increase in the prevalence of abnormal liver function tests among hypertensives, which the authors attributed to heavy alcohol consumption. In the Swedish study, patients with hypertension who were resistant to antihypertensive drug therapy were noted to include a high proportion of heavy drinkers in whom compliance with treatment was thought to be a major issue.⁷ In 1976 Matthews⁸ noted a positive association between death rates from stroke and cirrhosis and an inverse relation with coronary heart deaths in England and Wales and speculated that alcohol consumption might be the key to these relationships. However, it was not until Klatsky et al.⁹ published the Kaiser Permanente Insurance data relating current alcohol consumption to the prevalence of hypertension in over 80,000 contributors to a health insurance plan that the issue really claimed the attention of the medical scientific community.

CROSS-SECTIONAL STUDIES

The Kaiser Permanente data showed a J-shaped relationship between alcohol and BP in both men and women in the three ethnic groups studied, whites, African Americans, and those of Asian origin (Figure 45–1). The effect was also seen in both smokers and nonsmokers and in obese and nonobese participants and with all types of alcoholic beverage commonly drunk in the United States. Those drinking on average 3 or more standard drinks a day had twice the prevalence of hypertension (>160/90 mm Hg) compared with current nondrinkers. Ex-drinkers seemed to have similar BP to abstainers. Approximately 100 cross-sectional population studies from around the world have now confirmed a relationship between alcohol and increased BP.

Many of the population studies have not had alcohol as a primary focus, and there have been concerns about underreporting of consumption, particularly in heavier or problem drinkers and in women, because of the perceived social stigma. Arkwright et al.¹⁰ evaluated the relative importance of the effects of alcohol on BP in relation to other lifestyle factors in a younger population of working men. In 491 men aged 20 to 44 years, alcohol consumption, assessed by 7-day retrospective diaries, was found to be linearly related to BP and the prevalence of mild hypertension (Figure 45–2). The effect was

independent of all other lifestyle factors studied, including smoking, physical activity, and tea and coffee consumption. The effects were additive to those of body mass index (BMI) and were seen equally in smokers and nonsmokers. Ex-heavy drinkers had similar BPs to lifelong abstainers, suggesting that the effects of alcohol on BP were reversible. Fifty percent of the men who averaged 3 or more standard drinks (1 standard drink estimated at 10 g ethanol equivalent) a day, principally as beer, had three to four times the prevalence of systolic hypertension (140 mm Hg or more) compared with current nondrinkers. In multivariate analysis, alcohol consumption equated with BMI in the magnitude of its contribution to population variation in BP levels, presumably reflecting the relatively high levels of alcohol drinking in this young male Australian population.

The relation between alcohol and BP is by no means restricted to heavier-drinking populations and has been demonstrated in studies from nations in all five continents. Although most of these reports come from acculturated societies, alcohol use has also been an important factor in relation to elevated BP in unacculturated populations with low mean BP. For example, in a community sample of urban and rural Chinese, it was estimated that 33% of hypertension could be attributed to alcohol in the Yi farmers compared with 9.5% in the urban-living Han.¹¹

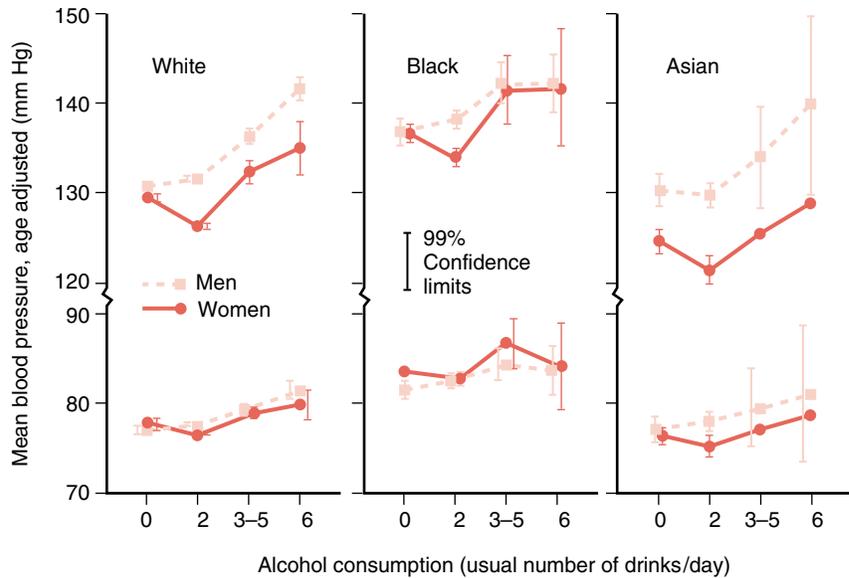

A number of issues have arisen out of the earlier population studies. These include the linearity of the dose-response relationship between alcohol and BP; possible gender differences in the responses; interactions between the effects of alcohol, smoking, and age on BP; whether the association in cross-sectional studies really represents cause and effect; mechanisms of any alcohol-related pressor effect; and possible effects of different patterns of drinking and of types of alcoholic beverage on both BP and clinical manifestations of cardiovascular disease.

The pressor effects of alcohol appeared to increase with age at least up to the 1960s¹² but have been demonstrated in adolescent men and women as young as 18 years who reported drinking patterns outside Australian National guidelines for safe drinking.¹³ Despite the fact that clinic BPs tend to be lower in smokers, some studies suggest a greater pressor effect of regular alcohol with smoking.^{14,15}

The shape of the dose-response relationship between alcohol and BP has been questioned, as some of the population studies have shown a J-shaped relationship (e.g., the original Kaiser Permanente study),⁹ with a threshold of around 2 drinks a day in men, while others, such as that by Arkwright et al.¹⁰ and others,^{16–18} have shown a linear relationship.

Ambulatory BP measurements have provided further insights into the effects of alcohol on BP. The Harvest study¹⁹ in 1100 Italians is the largest population study that has used ambulatory BP to examine factors influencing the daily variation of BP. Participants aged 18 to 45 years with clinical

Figure 45-1 Mean systolic blood pressures (upper bar graph) and mean diastolic blood pressures (lower bar graph) of white, African American, and Asian men and women with known drinking habits. Small circles represent data based on fewer than 30 persons. (Reproduced with permission from Klatsky A, Friedman G, Siegelau A, et al. Alcohol consumption and blood pressure: Kaiser-Permanente Multiphasic Health Examination Data. *N Engl J Med* 296:1194-2000, 1977; copyright © 1977 Massachusetts Medical Society.)

diastolic blood pressures (DBP) of 90 to 99 mm Hg or isolated systolic hypertension (ISH) were enrolled. Alcohol intake was linearly related to daytime BP and heavier drinkers showed greater BP variability. Alcohol intake, as well as family history of hypertension, obesity, smoking, coffee consumption, physical activity, oral contraceptive use, and environmental temperature, influenced ambulatory BPs to a greater extent than office pressures.

TYPES OF ALCOHOLIC BEVERAGE

The Kaiser Permanente study reported similar effects on BP in North Americans drinking beer, wine, or spirits,⁹ and studies from countries drinking predominantly sake,²⁰ wine^{21,22} or beer^{10,23,24} have shown similar relationships. However, wine drinking has been associated with smaller effects on BP. For example, in the Lipid Clinics Prevalence Study²⁵ in the United States, regression data from participants who reported drinking only one type of alcoholic beverage showed significant positive regression coefficients for wine and spirits and BP but no significant relationships for wine drinkers. The PRIME study also found a weaker association for wine and BP compared with beer.²⁶ Such studies should be regarded with a high degree of circumspection given the potentially confounding effects of differences in diet and other behaviors between groups drinking predominantly wine, beer, or spirits.²⁷ Although both of the aforementioned studies adjusted for obvious confounders such as age and BMI, neither adjusted for diet, and this and other lifestyle differences may have accounted for the findings. Moreover, in a recent 4 × 4-week crossover trial in Perth comparing effects of wine, dealcoholized red wine, beer, and water on 24-hour ambulatory BP in 26 men, similar increases in BP were observed with the two alcohol-containing beverages (Zilkens et al., personal communication). The effect of red wine and beer was predominantly on awake systolic blood pressure (SBP) with significant increases of 2.9 mm Hg for red wine and 1.9 mm Hg for beer compared with water.

PROSPECTIVE POPULATION STUDIES

Prospective studies such as Framingham and others from North America have shown a strong association between levels of alcohol consumption and the subsequent risk of developing hypertension in men or women with initially normal BP. In 1999 a meta-analysis of three prospective studies reported a 40% increase in the relative risk of developing hypertension in those drinking more than 25 g alcohol per day and a more than fourfold increase in risk in those drinking more than 100 g/day.²⁸ Subsequently, large-scale prospective studies from Japan²⁹⁻³¹ and the United States, have reported up to a twofold risk of hypertension with intakes of 30 to 50 g/day or more. In the ARIC study it was estimated that in participants drinking 30 g/day or more, one in five cases of hypertension could be attributed to alcohol consumption.³² In young middle-aged Swedish males, alcohol intake emerged as an important determinant of the development of hypertension over a period of 6 years.³³ Increases in BP have also been reported in those who initiate drinking^{34,35} and decreases in those who decrease intake or stop consuming alcohol.^{31,36}

GENDER EFFECTS

The nature of the alcohol-BP relationship is less certain in women. As in men, heavier drinking has been associated with an increased prevalence of hypertension, and some Australian³⁷ and South American studies³⁸ indicate that this relationship is linear. The pressor effect of alcohol also seemed additive to that of oral contraceptives in the Lipid Research Clinic Prevalence Study³⁹ conducted in the United States when higher dose estrogens were in vogue. However, other reports describe a depressor effect of lower levels of alcohol consumption in women, with a greater curvilinearity of the alcohol-BP relationship compared with men.^{9,40} Moreover, a meta-analysis of 11 population studies up to 1993⁴¹ suggested that BPs and the risk of hypertension were decreased in women drinking low levels of alcohol compared with non-

Figure 45-2 Percentage of each drinking category with systolic or diastolic hypertension. Numbers in columns refer to total in the population subgroup. The χ_0^2 trend for systolic hypertension and alcohol consumption = 8.09, $p < .005$; for diastolic hypertension, χ_0^2 trend = 5.84, $p < .025$. (Reproduced with permission from Arkwright PD, Beilin LJ, Rouse I, et al. Effects of alcohol use and other aspects of lifestyle on blood pressure (BP) levels and prevalence of hypertension in a working population. *Circulation* 66: 60-66, 1982.)

drinkers. However, women have generally been underrepresented in population studies of the effects of alcohol, especially in heavier drinking categories. A cross-sectional survey of 19,000 persons in the United States found that women reporting a prior diagnosis of hypertension also reported drinking less alcohol than those not reporting hypertension,⁴² whereas the opposite was true of hypertensive men. In a United Kingdom-based study of 14,000 female employees of the firm Marks and Spencer,⁴³ the prevalence of hypertension was decreased with consumption of up to 14 drinks a week. These findings could largely be explained by confounding effects of age, BMI, physical activity, and family history of premature coronary artery disease. The NHANES III study,⁴⁴ which included more than 9000 women, found that associations between alcohol intake and BP and pulse pressure were

weaker in women than men, whereas a smaller Brazilian study³⁸ showed the opposite. Greater sensitivity about admitting heavy drinking in different cultures may account for this variability, but the issue remains to be resolved.

Prospective population studies also leave uncertainty as to gender differences in the alcohol-BP relationship. A Canadian report⁴⁵ that compared the effects of drinking 8 or more drinks in one sitting with a nonbinge drinking pattern found that only the binge-drinking men showed an increased risk of hypertension after 8 years of follow-up. However, in the ARIC study³² the relative risks for those drinking more than 210 g alcohol per week were increased similarly for men and women. The largest prospective study, the Nurses Health Study,⁴⁶ reported a biphasic effect of alcohol in female nurses aged 25 to 42 at baseline. There was a 14% decrease in the risk of developing hypertension in those consuming 2 to 3.5 drinks per week compared with nondrinkers and a 20% increased risk in those drinking more than 14 drinks a week.

Randomized controlled trials demonstrating the effects on BP of changing alcohol consumption in regular drinkers have so far either been confined to men or included too few women for assessment of a gender effect of alcohol on the direction or magnitude of BP change.

RANDOMIZED CONTROLLED TRIALS

Randomized controlled trials in drinkers have shown unequivocally that regular alcohol consumption can raise BP in men. The first of these trials, conducted by Puddey et al.⁴⁷ in Western Australia, used a crossover design in normotensive drinkers who reduced their alcohol intake for a period of 6 weeks by consuming low-alcohol (0.9% ethanol) beer as a control for the normal-alcohol (5% ethanol) beer from which it was distilled. This enabled the volunteers to reduce their alcohol consumption by at least 80% while retaining their usual intake of fluid, electrolytes, and other nutrients and micronutrients. The study demonstrated a pressor effect of alcohol, which was at least partially reversible, with the major fall in BP evident within 1 to 2 weeks of reducing alcohol intake and continuing over 4 to 6 weeks. The time course of the changes indicated that any BP-raising effect of alcohol could not be solely attributed to acute alcohol withdrawal. A pressor effect of regular drinking of similar magnitude was subsequently shown to occur in both untreated⁴⁸ and treated⁴⁹ hypertensives in further crossover intervention trials. Based on clinic BP measurements, the trials suggest that the magnitude of this pressor effect equates to around 0.6 to 1.0 mm Hg systolic for each standard drink per day in those with normal BP or mild hypertension.

This pressor effect was confirmed in a recent meta-analysis of 15 randomized controlled trials of effects of changing alcohol consumption on BP⁵⁰ (Figure 45-3). Seven of the trials came from the Perth group, including the first to assess effects of patterns of alcohol consumption on ambulatory BP.⁵¹ Men were the sole participants in 12 of these studies and predominated in the remaining three. Seven of the trials studied hypertensives; six studied only normotensives; two studied both normotensive and hypertensives; and six trials studied hypertensives who were taking antihypertensive medication. The duration of most of these studies ranged from 4 to 18 weeks with a median duration of 8 weeks and a

Figure 45-3 Average net change in systolic BP (left) and diastolic BP (right) and corresponding 95% CIs related to alcohol reduction intervention in 15 randomized controlled trials. Net change was calculated as the difference of the baseline minus follow-up levels of BP for the intervention and control groups (parallel trials) or the difference in BP levels at the end of the intervention and control treatment periods (crossover trials). The overall effect represents a pooled estimate obtained by summing the average net change for each trial, weighted by the inverse of its variance. (Reprinted with permission from Xin X, He J, Frontini MG, et al. Effects of alcohol reduction on blood pressure: a meta-analysis of randomized controlled trials. *Hypertension* 38:1112-1117, 2001.)

median 76% reduction in alcohol intake from a baseline of 3 to 6 standard drinks a day. The meta-analysis indicated that this reduction resulted in a mean fall in BP of 3.3/2.0 mm Hg, with similar reductions seen in normotensive and hypertensive (treated and untreated) participants. There was a significant positive relationship between the mean percentage reduction in alcohol intake and the corresponding net reductions in SBP and DBP, consistent with a dose-response effect. The mean fall in BP corresponded well with estimates predicted from large cross-sectional population studies such as Intersalt,⁵² where BPs in nondrinkers were 2.7/1.6 mm Hg lower than in those drinking 2.8 to 4.8 drinks a day.

In contrast, the largest long-term randomized controlled intervention study, the Prevention and Treatment of Hypertension Study,⁵³ carried out in 641 moderate- to heavy-drinking men with baseline DBPs 80 to 99 mm Hg, showed small and nonsignificant (0.9/0.6 mm Hg) reduction in SBP and DBP in the intervention compared with the control group. This negative result was attributed to the fact that both groups reduced alcohol consumption so that the intervention group averaged only 1.3 drinks a day less than controls. However, in a work-site program in France in which 129 hypertensives considered to be excessive drinkers were randomized to intervention or control groups for counseling, there was a 7 mm Hg greater fall in SBP in the active group at the end of the 8-week intervention and 6 mm Hg systolic difference at 2 years of follow-up.⁵⁴ This was despite

a difference of only 1.2 units/day in the reduction in alcohol consumption between the two groups. Advice on moderation of alcohol intake has also been shown to be effective in a hypertension clinic setting in Britain, resulting in a halving of reported alcohol consumption over 18 months in association with significantly greater reductions in DBP and liver enzymes in the treatment group than in controls.⁵⁵

A number of potential interactions between the effects of alcohol reduction and other lifestyle changes have been studied in randomized controlled trials in Perth. A factorial study of alcohol moderation and 5 kg weight reduction by calorie restriction in overweight drinkers who averaged 5 to 6 standard drinks a day at baseline found independent and additive effects on BP reduction.⁵⁶ At the end of 5 months, BPs had fallen by 5 mm Hg systolic with alcohol or weight loss alone and by 9 to 14 mm Hg systolic in the group that reduced both weight and alcohol (Figure 45-4). The latter group also showed the greatest improvement in blood lipids and in left ventricular diastolic function as assessed by echocardiography. The study demonstrated the potential power of lifestyle changes to produce sustained reductions in BP in overweight persons who consume large amounts of alcohol, many of whom have high normal BP or mild hypertension. In contrast, a factorial study of the effects of sodium restriction and alcohol moderation only showed an effect of reducing alcohol consumption in treated hypertensives, suggesting that dietary salt played no part in the BP elevation of these moderately

Effects of alcohol and caloric restrictions on blood pressure and serum lipids in overweight men. *Hypertension* 20:533-541, 1992.)

heavy drinkers.⁵⁷ Similarly, a factorial study of exercise training and alcohol moderation showed only an effect of alcohol reduction on BP.⁵⁸ However, in a large cross-sectional population study, the pressor effect of alcohol was partly ameliorated by increased physical fitness.⁵⁹

Several studies from Japan demonstrated a biphasic effect of drinking on BP in hypertensives, with acute BP falls lasting for up to 8 hours following evening drinking, followed by a sustained pressor effect.⁶⁰ Kawano et al.⁶¹ used home BP recording in 52 essential hypertensives in a randomized crossover trial to show that when alcohol was reduced from a mean daily intake of 66.5 to 10.2 ml, morning BPs rose by 4.4/2.9 mm Hg while evening pressures fell by 7.4/5.7 mm Hg.

MECHANISTIC STUDIES IN ANIMALS

The cause of alcohol-related hypertension remains elusive, and animal (predominantly rat) models have been utilized to gain further insights. Findings of animal studies have proved controversial because of inconsistencies in BP outcomes

between studies. One of the first such studies demonstrated no significant effects on BP of chronic ethanol feeding in either normotensive Wistar-Kyoto (WKY) rats or spontaneously hypertensive rats (SHR).⁶² Chan et al.⁶³⁻⁶⁵ on the other hand, have consistently identified a pressor response in Wistar rats following 12 weeks of alcohol feeding. They have described a slight increase in calcium pump activity together with decreased membrane cholesterol content in association with the increase in BP.⁶⁴ Such changes were interpreted as compensatory to the known acute fluidizing effects of alcohol on cell membranes, with altered lipid composition ultimately resulting in increased Ca^{2+} , Mg^{2+} -ATPase activity. Similarly, our group has reported changes in red cell membrane lipid composition with alterations in the polyunsaturated to saturated fatty acid ratio in red cells, which were directly related to alcohol-induced increases in BP.⁶⁶ These findings suggest altered membrane function or diminished availability of arachidonic acid precursors as potential mechanisms for alcohol-induced hypertension.

Increases in vascular smooth muscle calcium uptake and BP have been seen in WKY rats chronically fed even lower doses of alcohol.⁶⁷ Renal arteriolar vascular smooth muscle hyperplasia occurred in the alcohol-fed rats and could be reversed by coadministration of the calcium entry blocker verapamil.⁶⁸ The increases in BP and intracellular calcium and the renal vascular changes in this model could be reversed by coadministration of n-acetyl cysteine,⁶⁹ suggesting an important role for the metabolism of alcohol to acetaldehyde in alcohol-induced hypertension. In another report, a pressor response to alcohol in WKY rats was identified with as little as 1% alcohol v/v in the drinking water ad libitum over a period of 14 weeks.⁷⁰ Coadministration of dietary vitamin B6 (which augments methionine metabolism to cysteine) decreased tissue acetaldehyde conjugates, prevented an increase in intracellular calcium levels, and counteracted both the increase in BP and renal arteriolar changes. Hsieh et al.⁷¹ have reported that magnesium supplementation can also prevent the development of hypertension in Wistar rats chronically fed alcohol. They postulated that the magnesium counteracted an alcohol-induced increase in intracellular calcium and suppressed sodium pump activity. In the same rat model, more severe hypertension has been induced by the combination of chronic alcohol feeding with chronic heat stress, suggesting that this synergistic increase in BP is mediated by chronic activation of the sympathetic nervous system.⁷²

Chronic alcohol administration to male Sprague Dawley rats had no effect on basal BP but impaired arterial baroreceptor responses,⁷³ likely providing a pathophysiologic basis for subsequent BP elevation. After 12 weeks of alcohol administration, this mechanism was clearly identified in Wistar rats but less evident in Sprague Dawley rats,⁷⁴ although in both strains chronic alcohol feeding led to modest increases in BP.

In contrast to findings in the Wistar rat and those of Vasdev et al.⁶⁷⁻⁷⁰ in WKY rats with low doses of alcohol, high-dose alcohol has usually produced hypotensive effects in SHR, stroke-prone SHR, and WKY rats.⁷⁵⁻⁷⁷ Sanderson et al.⁷⁵ found reductions in BP after feeding SHR 20% alcohol solutions for 16 weeks, while Howe et al.^{76,77} reported a retardation of the rise in BP normally seen with aging in both SHR and stroke-prone SHR. Reductions in BP after alcohol feeding occur in these strains despite heightened heart rate responses to stress⁷⁸ and enhanced vascular contractility,⁷⁹ possibly due

to a myocardial depressant effect of alcohol, a phenomenon known to be augmented in the setting of hypertension in these strains.^{80,81} The alcohol-induced BP reductions may also have resulted from the lower weight gain characteristically observed when rats are fed alcohol ad libitum.⁷⁸ In this regard, the previously discussed increases in BP after chronic alcohol feeding in Wistar rats have not been confirmed when animals were pair fed with control animals to maintain identical calorie and fluid intakes.⁷⁹

Some of the differences between rat models may relate to the dose of alcohol and its means of administration as well as the timing of BP measurement in relation to the last intake of alcohol. Howe et al.⁷⁶ reported an increase in BP lasting several days after sudden withdrawal of alcohol in SHR; in Sprague Dawley rats, a hypertensive response has also been reported 24 hours after cessation of alcohol feeding.⁸² An acute increase in BP is also characteristic of the alcohol withdrawal syndrome in humans.

Gender may have been a further confounding factor in animal studies. Despite achieving identical blood alcohol concentrations, the acute administration of ethanol intragastrically resulted in hypotensive responses in female but not male Sprague Dawley rats, together with evidence of myocardial depression.⁸³ These differences are clearly estrogen dependent,⁸⁴ but their mechanisms have yet to be fully elucidated.

MECHANISTIC STUDIES IN HUMANS

The phenomenon of alcohol-related hypertension is something of a paradox in view of the acute vasodilator and BP-lowering responses that occur within minutes of ingesting alcohol and last several hours. Acute alcohol withdrawal in heavy drinkers is often associated with a rise in BP along with increases in circulating catecholamines, renin, and vasopressin. This observation has led to suggestions that the effects observed in population studies might be due to transient effects of acute alcohol withdrawal under survey circumstances where participants abstain after previous consumption.^{85,86} There is some support for this interpretation in heavy drinkers from the British Heart Survey,⁸⁷ in whom hypertension was more likely to be diagnosed on a Monday than at the end of the week (the assumption being that on Monday the drinkers were exhibiting withdrawal pressor effects following heavy weekend drinking). Different alcohol drinking and weekday BP relationships were observed between men in France and Northern Ireland.⁸⁸ In the Irishmen, many of whom binge drank on weekends, BPs were highest on Monday, whereas no such weekday effect was seen in the French, whose alcohol consumption was assumed to be more homogeneous through the week. However, as reviewed elsewhere,⁸⁹ other authors have reported that the overall consumption of alcohol averaged over a week or more is more important than the pattern of intake with regard to BP elevation.^{90,91}

To help resolve this controversy, we conducted a randomized controlled crossover trial in 55 men, 14 of whom drank more than 60% of their alcohol on weekends and the remainder of whom were daily drinkers.⁵¹ Baseline 24 hour BPs were higher on Mondays than Thursdays in weekend but not daily drinkers, an effect that was lost after switching to low-alcohol beer (Figure 45-5). Both groups showed a fall in 24 hour ambulatory BP when changing from normal to low alcohol

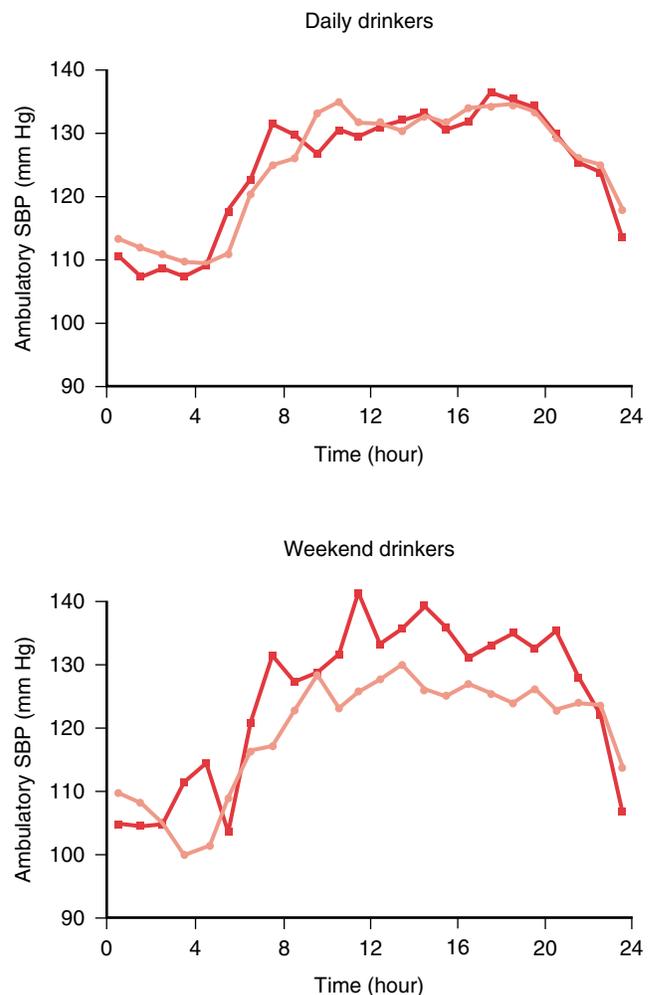

Figure 45-5 The 24-hour ambulatory systolic blood pressure (SBP) profile by day of assessment for daily drinkers compared with weekend drinkers. ■, Monday SBP; ●, Thursday SBP. (Reproduced with permission from Rakic V, Puddey IB, Burke V, et al. Influence of pattern of alcohol intake on blood pressure in regular drinkers: A controlled trial. *J Hypertens* 16:165-174, 1998.)

beer, an effect that was evident after 1 week in the weekend drinkers but not until the fourth week in daily drinkers. This study indicated there are elements of both acute withdrawal hypertension and more sustained BP elevation in weekend drinkers, whereas those who drink throughout the week show a more sustained pressor response.

Studies indicate that sustained alcohol ingestion likely induces hypertension in humans through effects on the autonomic nervous system. In case control studies, measurements of circulating catecholamines, renin activity, angiotensin II, and cortisol have shown no differences between regular drinkers and age-matched controls,⁹² but direct sympathetic nerve recordings in muscle show increased activity during drinking compared with nondrinking periods.⁹³ In controlled trials, reductions in alcohol consumption are associated with reductions in heart rate.^{47,49} Drinkers also show increased BP variability,^{19,94} and studies in humans suggest that acute ethanol ingestion leads to impaired baroreceptor function, which may contribute to hypertension.⁹⁵

Pseudo-Cushing's syndrome has been reported in heavy drinkers,⁹⁶ raising a question as to whether increased ACTH and cortisol could contribute to alcohol-induced hypertension. However, studies comparing regular drinkers and abstainers⁹⁷ suggest that normally there is no increase in cortisol production in age- and obesity-matched participants. Cases of pseudo-Cushing's syndrome in heavy drinkers appear to be the exception rather than the rule.

Alcohol causes acute vasodilation, but more prolonged use may result in direct vasoconstrictor effects. However, most studies of effects of alcohol on vascular function in humans have involved acute alcohol administration.^{98,99} A study of the effects of 4 days of alcohol ingestion on forearm vascular function demonstrated decreased responsiveness to noradrenaline, which the authors interpreted as being mediated through α -adrenoreceptors.¹⁰⁰ More recently attention has focused on possible effects of alcohol on endothelial vasodilator function.¹⁰¹ A case control study in chronic alcohol abusers showed decreased flow-mediated dilation (FMD) in the brachial artery after 3 months of abstinence compared with nondrinking controls.¹⁰² In contrast, a study in 108 Japanese men with coronary artery disease, 54 of whom consumed alcohol on at least 1 day per week, revealed better endothelial function of the brachial artery in the drinkers despite a worse coronary risk factor profile.¹⁰³ Further, a randomized controlled crossover trial of reducing alcohol consumption from beer from 72.4 to 7.9 g/day in 16 healthy Perth-based male drinkers showed no changes in either FMD of the brachial artery or biomarkers of endothelial function.¹⁰⁴ These noninvasive studies do not exclude vasoconstrictor or endothelial effects of alcohol on selective vascular beds, as has been suggested from some animal studies.¹⁰⁵

Effects of drinking on large artery stiffness have been implied from changes in augmentation index assessed by radial artery applanation tonometry. Acute and chronic alcohol consumption had differential effects on arterial stiffness, the augmentation index being higher in 67 men drinking more than 21 units of alcohol a week than in 156 lesser drinkers or abstainers.¹⁰⁶ In contrast, in a small substudy of 8 participants drinking red wine (alcohol 0.8 g/kg), augmentation index fell acutely along with BP and pulse wave velocity.¹⁰⁶ There was no effect of dealcoholized wine.¹⁰⁶

In summary, although the mechanism of BP elevation with regular alcohol consumption is unclear, a central nervous system effect leading to impaired baroreceptor function, increased sympathetic outflow, and greater BP and heart rate responses to environmental stress seems most compatible with the data. A balance between these effects and the peripheral vasodilator actions of alcohol may account for some of the individual variability in BP responses, while in heavy drinkers myocardial depressant effects may further influence the final levels of BP attained.

γ -GLUTAMYLTRANSEPTIDASE

γ -Glutamyltranspeptidase (γ GT) has long been utilized as a biomarker for alcohol intake. Its serum level has been consistently associated with level of BP in cross-sectional¹⁰⁷ and longitudinal population studies,¹⁰⁸ as well as poor BP control in treated hypertensive drinkers.⁷ However, the association of γ GT with BP in several studies persisted even after adjustment for alcohol intake, leading to the hypothesis that an increase in

γ GT may reflect individual susceptibility to the pressor effect of regular alcohol consumption. One cross-sectional study in Japanese male workers in a metal products factory¹⁰⁹ and a second large prospective study in Korean steel workers¹¹⁰ support this concept. In both studies, when drinking and nondrinking participants were categorized on the basis of high or low levels of γ GT, only drinkers with a high γ GT demonstrated increasing levels of BP and increased risk of hypertension with increasing alcohol intake. Moreover, in both normotensive and hypertensive Japanese drinkers, following a 4-week period of moderation of alcohol intake, BP levels decreased more markedly in those who initially had the highest γ GT levels.¹¹¹

Why γ GT should be an independent predictor for alcohol-related hypertension, hypertriglyceridemia and other elements of the metabolic syndrome,^{112,113} type 2 diabetes mellitus,¹¹⁴ coronary artery disease,¹¹⁵ and stroke^{116,117} is unknown. It is clearly more than just a reflection of underlying hepatic damage or induction of the enzyme by alcohol (the commonly accepted explanations). γ GT is a membrane-bound ectopeptidase that cleaves the glutamyl group from glutathione, the first step in the uptake of extracellular glutathione. Nitric oxide also increases intracellular glutathione levels in aortic endothelial cells through a pathway that is γ GT dependent, and both nitric oxide and the glutathione cycle appear to be coordinately regulated.¹¹⁸ Maintenance of intracellular glutathione levels is integral to redox homeostasis and an increase in γ GT with chronic alcohol ingestion may be a marker for those participants who develop increased oxidative stress and/or nitric oxide depletion with alcohol. Such oxidative stress may be an important pathogenic mechanism for the subsequent development of hypertension¹¹⁹ and atherosclerosis.^{120,121} γ GT has also been shown, at least in T lymphocytes,¹²² to control the rate of nitric oxide production from the naturally occurring nitrosothiol, S-nitrosoglutathione, a mechanism that may markedly affect the physiologic response to this compound. This suggests an additional mechanism of the pathogenesis of alcohol-related hypertension.

GENE-ENVIRONMENT INTERACTIONS

Particularly in Japanese subjects, a point mutation with a G to A substitution at -357 of the promoter region of the gene coding for the aldehyde dehydrogenase isozyme, ALDH2, leads to a deficiency in metabolism of the major metabolite of ethanol, acetaldehyde. This ALDH*2/2 genotype results in high levels of acetaldehyde after drinking, leading to acute increases in the pulse rate, facial flushing, and decreases in BP.¹²³ A role for this polymorphism in the pathogenesis of alcohol-induced hypertension has been investigated in several Japanese studies.¹²⁴⁻¹²⁷ The first examined a large cohort of 4000 male participants, and found that those with the ALDH*2/2 genotype consumed less alcohol and as a result were significantly less likely to have hypertension.¹²⁴ A similar conclusion was drawn in 2 smaller studies in middle-aged men where influences of the mutant gene on drinking behavior also confounded the results.^{125,126} A recent study that included only participants who consumed >300 g per week¹²⁷ has suggested a significantly higher odds ratio for higher SBP in those with the ALDH*2/2 genotype, even after adjustment for alcohol consumption, as well as for other potential demographic and lifestyle confounders.

In high alcohol consumers, metabolism of ethanol via the mitochondrial cytochrome P450 oxidase is an important metabolic pathway. Investigation of a polymorphism of CYP2E1, the c2 allele, has suggested that this mutation predisposes to higher BP, possibly as a consequence of higher acetaldehyde levels.¹²⁶ Polymorphisms of another important alcohol-metabolizing enzyme, alcohol dehydrogenase, have not yet been widely evaluated in relation to the alcohol–BP relationship. An alcohol dehydrogenase type 2 polymorphism did not predict risk of alcohol-related hypertension in a Japanese study.¹²⁶ Among men in the Physicians' Health Study,¹²⁸ slow metabolism of alcohol due to presence of an alcohol dehydrogenase type 3 polymorphism was associated with decreased risk of myocardial infarction (MI), probably because of higher HDL-cholesterol levels, but the implications of this polymorphism for alcohol-related hypertension were not reported. Apolipoprotein E polymorphisms have also been investigated as determinants of alcohol-related hypertension.¹²⁹ The E2/E3 and E3/E3 genotypes were identified with stronger alcohol—BP relationships than E4/E3 genotypes in Finnish participants. However, in an intervention study, we found no relationship between the apolipoprotein E genotype and the magnitude of the reductions in BP with alcohol restriction.¹³⁰

ALCOHOL AND HYPERTENSIVE TARGET-ORGAN DISEASE

In contrast to its tendency to increase BP, regular consumption of alcohol is associated with a decreased risk for coronary artery disease, as shown in a recent meta-analysis.¹³¹ A J-shaped curve was observed with its nadir at 20 g ethanol per day, where the mean decrease in relative risk was approximately 20%. This protective effect was lost at the level of 72 g/day, and at intakes greater than 89 g/day there was a mean 5% increase in relative coronary risk. A putative antiatherosclerotic effect of alcohol has been supported by the observation that light regular alcohol consumption decreases the incidence of atherosclerotic peripheral vascular^{132,133} and renal vascular disease.¹³⁴ These protective effects may be related to alcohol-induced increases in high-density lipoprotein cholesterol (HDL-C) and its major apolipoproteins A-I and A-II,¹³⁵ decreases in fibrinogen levels,¹³⁶ and reductions in platelet adhesiveness.¹³⁷ Loss of these protective effects and the increase in cardiovascular risk with heavy alcohol consumption may reflect the influence of alcohol-related hypertension, as well as increases in triglyceride and plasma homocysteine levels and increased risk of cardiac arrhythmias and sudden cardiovascular death. When data from the Honolulu Heart Program¹³⁸ were subjected to statistical modeling, estimates indicated that while 50% of the decrease in coronary risk with alcohol could be attributed to the increase in HDL-C, there was a corresponding 17% increase in risk due to higher SBP.

A comprehensive systematic review of the association between alcohol and stroke included 41 studies where careful categorization of the type of stroke and amount of alcohol consumed had been performed.¹³⁹ For ischemic stroke, the authors observed a J-shaped relationship similar to that reported for coronary heart disease events. The evidence linking light to moderate alcohol consumption with a reduction in risk was thought to be inconsistent, while that linking increased consumption, especially recent consumption and binge drinking,¹⁴⁰ to increased risk of both ischemic and hemorrhagic

stroke was considered strong. Alcohol-induced hypertension may be in the causal pathway for this increase in stroke risk, although in some reports the increase in risk has persisted after adjustment for BP.¹⁴¹ In a Japanese study,¹⁴² heavy drinking acted synergistically with hypertension to increase the risk of cerebral hemorrhage and infarction twofold and threefold, respectively. In contrast, in the Department of Health Hypertension Care Computing Project, including over 10,000 British patients attending a hypertension clinic,¹⁴³ there was a 40% decrease in relative risk of stroke in drinkers, with the lowest risk of stroke mortality at intakes of 1 to 10 units (8 to 80 g alcohol) per week. This population included few heavy drinkers and the beneficial effects of alcohol were offset at intakes >21 units/wk by an increasing incidence of noncirculatory causes of death.

Alcohol consumption has been associated with increased echocardiographically determined left ventricular mass^{144,145} and electrocardiographic evidence of left ventricular hypertrophy.¹⁴⁶ These associations have persisted after controlling for BP, suggesting that direct trophic effects of ethanol on the myocardium may be a more important determinant than alcohol-related hypertension. Such hypertrophic changes are a feature of the alcoholic cardiomyopathy characteristic of prolonged heavy alcohol abuse. In contrast, recent large population-based studies have emphasized the protective effects of light to moderate consumption of alcohol against heart failure. In the Framingham Heart Study¹⁴⁷ there was an approximate halving of the hazard ratio for congestive heart failure among men who consumed 8 to 14 drinks/wk and women who consumed 3 to 7 drinks/wk compared with those who consumed less than 1 drink/wk. A prospective cohort study of elderly participants showed a similar halving of the relative risk for heart failure among moderate drinkers,¹⁴⁸ while in the Studies of Left Ventricular Dysfunction (SOLVD), among patients with established ischemic left ventricular dysfunction, light-to-moderate alcohol consumption was independently associated with a reduced risk of all-cause mortality, particularly for death from MI.

Effects of alcohol on the kidney have not been well characterized. Several reports suggest that heavy alcohol use can increase the risk of microalbuminuria,^{145,149} an effect that in at least one of these studies appeared to be mediated by alcohol-related hypertension.¹⁴⁵ In a case control study in Maryland,¹⁵⁰ the finding of an increased risk of end-stage renal disease with increasing alcohol intake was independent of any effects of alcohol on hypertension. Results from postmortem studies in the Honolulu Heart Program¹³⁴ indicate that alcohol intake is negatively associated with the degree of renal arteriolar hyalinization, suggesting that effects of alcohol to reduce the risk of intrarenal atherosclerotic vascular disease may counteract any potential for hypertensive nephrosclerosis due to alcohol-related hypertension.

PUBLIC HEALTH IMPLICATIONS AND RECOMMENDATIONS

The importance of the relation between alcohol consumption and hypertension has been recognized in national and international guidelines on the prevention and management of hypertension.¹⁵¹⁻¹⁵³ However, from the point of view of cardiovascular disease, alcohol is a two-edged sword. Despite predisposing to

BP elevation, regular mild-to-moderate drinking appears to protect against coronary events, and possibly ischemic stroke, while higher-level consumption increases the risk of hemorrhagic and ischemic stroke, cardiac arrhythmias, and sudden cardiovascular death.¹⁵⁴ The “benefits” in this equation are less in populations with a low risk of atherosclerosis. Heavier drinking is also a significant factor in resistance to antihypertensive drug therapy and alcohol-related cardiomyopathy. From the point of view of cardiovascular risk, an intake averaging 1 to 2 standard drinks a day in men and up to 1 a day in women seems optimal for those who can control drinking habits. Binge drinking appears to carry a particular risk for several cardiovascular outcomes. Outstanding issues include possible mechanisms for alcohol-related hypertension, gender differences, effects on endothelial function, and the relation between moderate alcohol consumption, diabetes, and congestive cardiac failure. Because alcohol may contribute to hypertension in up to 30% of heavier drinkers and because heavy and binge drinking increase the risk of stroke in particular, the potential for prevention by moderation of consumption should be a major medical and public health priority.

Obesity in Hypertension: Role of Diet and Drugs

Panagiotis Kokkoris, Xavier Pi-Sunyer

Obesity is very common in the United States. The prevalence of obesity and overweight has increased during the last decade. It is estimated that more than 100 million Americans are obese or overweight.¹ The Third National Health and Nutrition Examination Survey (NHANES III) reported that 59.4% of men and 50.7% of women are obese or overweight.²

It is known that obesity may lead to many serious disorders, including myocardial infarction, dyslipidemia, diabetes mellitus, gallbladder disease, osteoarthritis, sleep apnea, heart failure, stroke, end stage renal disease, and hypertension.³⁻⁵ Hypertension is especially common among obese people. In addition, hypertensive patients have a higher incidence of obesity compared with normotensive people.⁶ The Framingham Heart Study showed that obese individuals have a twofold increase in the prevalence of hypertension compared with normal weight individuals and that for every 10% increase in relative body weight there is an increase in systolic blood pressure (SBP) of 6.5 mm Hg.⁷

The pathogenesis of obesity-related hypertension is not completely understood. Hyperinsulinemia and insulin resistance, very common findings in obese patients, may be reasons for the rise in the blood pressure (BP). Hyperinsulinemia may cause hypertension through different mechanisms, such as increased sympathetic nervous system activity, increased renal sodium reabsorption, proliferation of the vascular smooth cells, and alterations in the renin-angiotensin-aldosterone (RAAS) system.⁸⁻¹¹

Measurement of BP can be difficult in obese persons, so special care should be taken in this group of patients. A common error is use of a cuff that is too small, which gives a falsely high BP. The cuff must be wide enough to cover 80% of the circumference and 75% of the length of the upper arm. The patient should rest for about 5 minutes before the measurement and the final BP measurement should be the average of two or more readings in both the lateral and the contralateral arm.

It is important to know the total fat burden and the fat distribution of a patient for the management of BP elevation. A simple and relatively accurate way to estimate total fat burden is to calculate the body mass index (BMI), which is (weight in kg)/(height in m²) (Box 46-1). The BMI correlates fairly well with the degree of obesity except in very muscular individuals.¹² According to the World Health Organization, BMI of 18.5 to 24.9 kg/m² is defined as normal, 25 to 29.9 kg/m² as overweight, and more than 30 kg/m² as obese, with 30-34.5 kg/m² class I obesity, 35-39.9 kg/m² class II obesity, and more than 40 kg/m² class III or extreme obesity¹³ (Table 46-1). Central fat distribution is also correlated with high BP. Central obesity can be evaluated by measuring the waist circumference or the waist:hip ratio (WHR). Waist circumference should be measured at the uppermost lateral border of the iliac crest. A waist circumference greater than 102 cm (40

inches) in men and 88 cm (35 inches) in women is considered abnormal and indicates increased risk for type 2 diabetes, hypertension, and cardiovascular disease (CVD). Waist circumference is especially useful in estimating the CVD risk in patients with a BMI between 25 and 34.9 kg/m², since patients with a BMI greater than 35 kg/m² are already at an increased risk.¹ A WHR greater than 1.0 in men and greater than 0.85 in women is considered abnormally high.

Weight loss has been associated with a decrease in BP in many studies. It is estimated that for every kg of weight loss there is a reduction of 0.45 mm Hg in both SBP and diastolic blood pressure (DBP).¹⁴ Weight loss can be achieved with lifestyle interventions such as diet and exercise, with pharmacotherapy, and with surgery. The initial target of weight loss therapy should be the reduction of body weight by 10% to 15%. This weight loss goal, which can reasonably be achieved with a combination of lifestyle modification and drug therapy, is associated with significant improvement in BP. With weight loss, hypertensive patients may be able to discontinue antihypertensive medications.¹⁵⁻¹⁷

OVERVIEW OF WEIGHT LOSS THERAPY

Before starting a weight loss program, a careful preliminary assessment has to be made. This should include the patient's usual diet, food preferences, and eating habits. Also, a history of previous weight loss attempts and the reason why they failed has to be taken. Losing weight is a difficult and time-consuming process, so the patient has to be appropriately motivated. Behavior modification is focused mainly on changing eating habits, increasing physical activity, altering attitude, and developing support systems.

Patient motivation is a prerequisite for achieving the target of weight loss. Motivation can be increased by describing to the patient the health risks of obesity. Some things that have to be considered before starting the weight loss procedure include the following:

1. How serious and determined to lose weight is the patient?
2. How well does the patient understand the dangers of being obese?
3. Can the patient's family and friends help him or her in the attempt to lose weight?
4. Is the patient prepared to start exercise along with diet therapy?
5. Does the patient have adequate time to spend in the attempt to lose weight?

It is very important for the patient to trust the physician or other health care provider involved in the weight loss process and for the physician to show respect and concern for the

Box 46–1 Calculation of Body Mass Index (BMI)**You Can Calculate BMI as Follows:**

$$\text{BMI} = \frac{\text{weight (kg)}}{\text{height squared (m}^2\text{)}}$$

If pounds and inches are used:

$$\text{BMI} = \frac{\text{weight (pounds)} \times 703}{\text{height squared (inches}^2\text{)}}$$

Calculation Directions and Sample

Here is a shortcut method for calculating BMI.

(Example: A person who is 5 feet 5 inches tall weighing 180 lbs.)

1. Multiply weight (in pounds) by 703
 $180 \times 703 = 126,540$
2. Multiply height (in inches) by height (in inches)
 $65 \times 65 = 4225$
3. Divide the answer in step 1 by the answer in step 2 to get the BMI
 $126,540/4225 = 29.9$
BMI = 29.9

patient. This patient–physician partnership is basic for the success of the weight loss program.

First, the physician and the patient must set an achievable goal. Some patients set unrealistic goals (for example, to lose half of their weight). They must be counseled to set goals that are easier to achieve (to lose 10% of their initial weight in a certain period of time). If they achieve this goal and maintain it for a year, they can then set another goal to lose more weight.

The behavior of an obese patient has to be changed gradually, following reasonable steps. This program has to be individualized for each case. The first step is to determine what exactly has to be modified. Usually this requires the patient to self-monitor to allow him or her to understand his or her eating and activity patterns. For example, keeping records of food choices, food quantity, and times of meals helps both the patient and the physician to identify and correct what can be changed. The mood of the patient and its relation to the type and the amount of food can also be recorded in the same diary. Everyday physical activity and weight change should also be included in the diary.

The second step is to control stimuli that affect eating behavior. The patient learns how to identify situations that are

associated with unnecessary eating, for example, periods of increased stress and anxiety. The specific stimulus has to be identified and the patient has to learn to stay away from it. For example, when a patient finds that he or she eats a lot of unnecessary food while watching television, he or she has to make an effort to stop eating in front of the television.¹⁸

The third step is to find ways to control eating. This might include the places where the patient eats, the speed of eating, or the frequency of meals. All these things can be identified and modified. In finding ways to control eating, it is sometimes helpful to reward a patient. For example, if the patient achieves a specific goal, then he or she receives a small reward (for example, a small amount of money). These rewards help the patient to gradually achieve small goals and increase or maintain motivation.

Another step is stress management. Stress management with different techniques (for example, meditation or relaxation) can help keep the patient from overeating. Finally, social support from family members, friends, and/or colleagues can be very helpful to the obese individual in losing weight.

Once some weight has been lost, the most difficult thing for an individual is to maintain the weight loss. Most patients regain a part or all of the weight they have lost.¹⁹ Furthermore, after a 6-month weight loss period, the rate of weight loss usually declines. It is important to prevent weight regain particularly at this point. A weight maintenance program is considered successful when weight regain is not more than 3 kg in 2 years.¹ This can be done with the same tools the patients used to lose weight, that is, diet, physical activity, and behavior therapy. Successful weight loss and weight maintenance both require long-term effort by the patient. Especially in the weight maintenance period, the importance of physical activity has to be stressed.

DIET

The most important aspect of a weight reduction program is the diet. A hypocaloric diet combined with increased physical activity can result in significant weight loss and a decrease in BP in obese hypertensive individuals. The typical American diet consists of approximately 15% protein, 35% fat, and 50% carbohydrates.²⁰ Fat should be reduced and portion sizes should also be decreased. Heavy intake of sugar should be discouraged, while fiber consumption should be increased. Alcohol consumption should also be eliminated or drastically reduced, because alcohol not only provides excess calories but also elevates BP. The target is a 500 to 1000 kcal deficit for the weight loss phase. In specific individuals it may be helpful to use a low-calorie liquid formula diet for a limited time (usually 12 to 16 weeks).

The basic target of a weight loss program is the reduction of fat mass, rather than lean tissue. However, during a weight loss period there is always a reduction in lean body mass. In order to minimize lean body mass reduction, the protein that is consumed must be of high biologic value (e.g., egg whites, fish, poultry, lean meat, low-fat dairy products). The remaining calories should come from carbohydrates and fat. It is very important that an individual on a weight-loss diet take adequate amounts of vitamins and micronutrients. Fat is a high-energy food, containing 9 calories per gram, while

Table 46–1 Classification of Obesity and Overweight by Body Mass Index (BMI)

Classifications	BMI
Underweight	<18.5 kg/m ²
Normal weight	18.5-24.9 kg/m ²
Overweight	25-29.9 kg/m ²
Obesity (Class I)	30-34.9 kg/m ²
Obesity (Class II)	35-39.9 kg/m ²
Extreme obesity (Class III)	≥40 kg/m ²

carbohydrate and protein have only 4 calories per gram. Thus, reducing high-fat foods in the diet provides a significant caloric decrease.

Total fat should not exceed 30% of total daily caloric intake, with saturated fatty acids not more than 8% to 10% of total calories. Monounsaturated and polyunsaturated fatty acids should be up to 15% and 10% of total calories, respectively. Protein should be approximately 15% of total calories. Either plant protein or lean animal protein should be used. Carbohydrates should be approximately 55% of total calories. The daily carbohydrate intake should include 20 to 30 grams of fiber from fruits, vegetables, whole grains, and legumes. Fiber helps in weight loss by increasing satiety at lower levels of calorie intake.²¹

A low-calorie diet (LCD) includes 800 to 1500 calories per day and is the cornerstone of a dietary treatment program. A caloric deficit of 500 to 1000 calories per day can result in a weight loss of 70 to 140 grams per day, or 0.5 to 1 kg per week (about 1-2 pounds per week).²¹ A diet of 1200 to 1500 calories per day for men and 1000 to 1200 calories per day for women seems reasonable, but this should be individualized according to the differing needs of each person. It is important for a diet to contain the necessary amounts of vitamins and micronutrients. LCDs usually contain the daily vitamin and mineral requirements. LCDs can achieve the target of a 10% reduction in body weight over a 6-month period. Studies have shown that this weight loss is approximately 75% fat and 25% lean tissue.²²

A very low-calorie diet (VLCD) is a diet with fewer than 800 calories per day (300 to 800 calories per day). VLCDs are usually given in the form of liquid formulas with a known caloric content. VLCDs should never be used without medical supervision. Their duration is usually 12 to 16 weeks. During that time the obese individuals have 4 to 5 portions per day. After that time, regular food can be added and substituted in the daily schedule. VLCDs may produce a rapid weight loss. However, this weight loss is generally not permanent and the obese individuals tend to regain a part of the weight they have lost. Studies have shown that VLCDs are not more effective than LCDs in long-term weight loss.²³ Also, VLCDs usually do not contain all the necessary vitamins and micronutrients, so supplementation with these components is necessary. Side effects of the VLCD are gallstones, gout, and cardiac arrhythmias.

EFFECT OF DIET ON BLOOD PRESSURE

The Dietary Approaches to Stop Hypertension (DASH) trial was a multicenter, randomized, controlled-feeding trial that was designed to test the effect of specific dietary patterns on BP. In this trial, 459 adults with untreated SBP less than 160 mm Hg and DBP between 80 and 95 mm Hg were randomized into three different diet groups, after an initial 3-week period when they all had the same “control” diet low in fruits, vegetables, and dairy products, with a fat content typical of the average American diet. After this introductory period the first group continued the same diet; the second group received a diet rich in fruits and vegetables, and the third group received a combination diet including fruits, vegetables, low-fat dairy products, whole grains, poultry, fish, and nuts. Sodium intake and body weight were maintained at the same

levels. After 8 weeks of following these diets, there was no weight loss, but the combination diet reduced SBP and DBP by 5.5 and 3.0 mm Hg respectively compared with the control group, while the “fruits and vegetables” diet reduced SBP by 2.8 mm Hg and DBP by 1.1 mm Hg compared with the control diet (Figure 46–1).^{24–28} Thus, dietary modifications can reduce BP, even without weight loss or dietary sodium reduction.

Another study looked at the effects of reducing dietary sodium in conjunction with the DASH diet.²⁹ A total of 412 individuals were randomized into two groups following either a control diet or the DASH diet. In each group there were three subgroups with high, intermediate, and low sodium consumption. The weight of the participants was maintained during the 30-day study. At the end of the study the group on the DASH–low sodium diet had 7.1 mm Hg lower SBP and 3.7 mm Hg lower DBP for normotensive participants and 11.5 mm Hg lower SBP and 5.7 mm Hg lower DBP for hypertensive participants, compared with the control diet group.

The Diet, Exercise, and Weight Loss Intervention Trial (DEW-IT) examined the effects of combined dietary and physical activity interventions on BP in 44 overweight, hypertensive adults on a single antihypertensive medication.³⁰ Lifestyle changes consisted of a moderately intense exercise program three times per week and a hypocaloric DASH diet with restriction of sodium intake. At the end of the 9-week study, there was a reduction in body weight of 4.9 kg in the

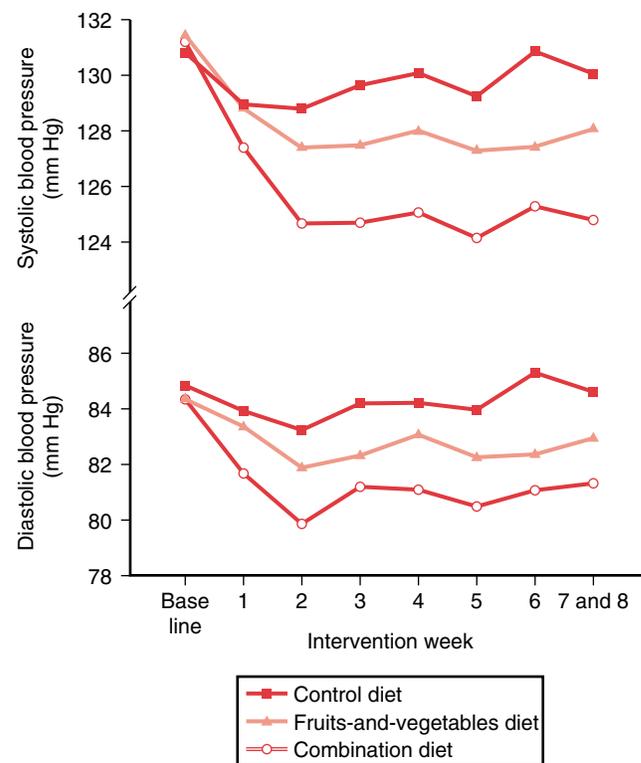

Figure 46–1 Changes in systolic and diastolic blood pressures during the intervention period in the DASH Study. (From Appel LJ, Moore TJ, Obarzanek E, et al. A clinical trial of the effects of the dietary patterns on blood pressure. DASH Collaborative Research Group. *N Engl J Med* 336: 1117-1124, 1997; copyright © 1977 Massachusetts Medical Society.)

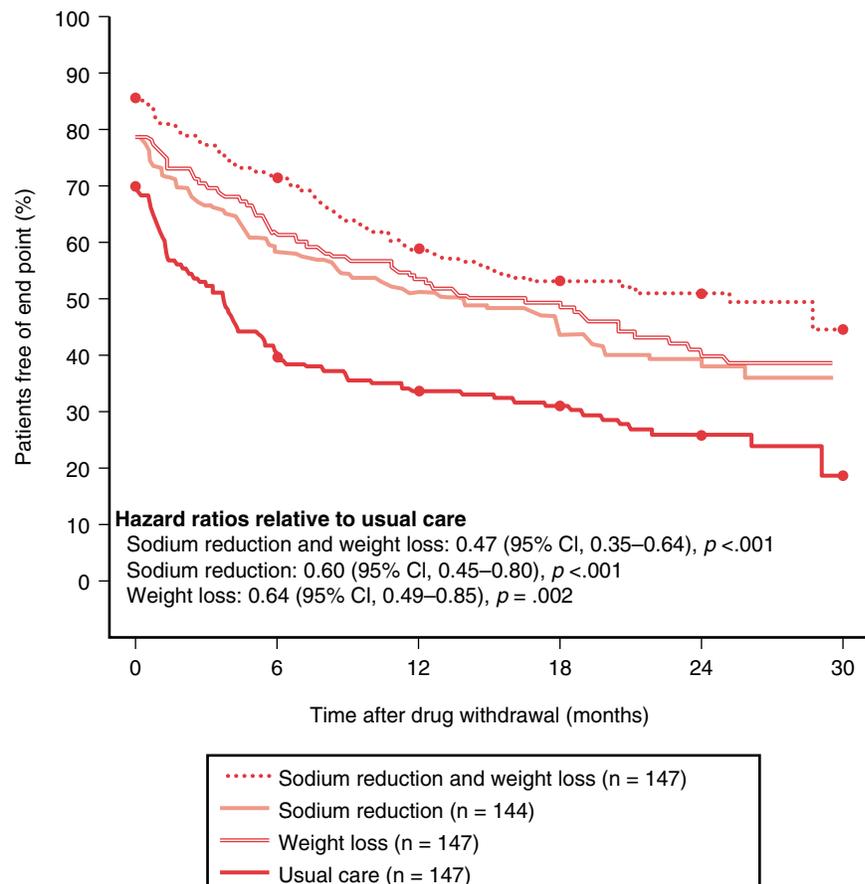

lifestyle group compared with the control group and a reduction in SBP and DBP of 12.1 mm Hg and 6.6 mm Hg, respectively compared with the control group.

Similar results were found in another study that examined the impact of nonpharmacologic interventions on the treatment of hypertension in older individuals.³¹ The 975 hypertensive persons aged 60 to 80 years old who participated received a single antihypertensive medication and had a BP of less than 145 mm Hg (systolic) and less than 85 mm Hg (diastolic). Of these, 585 were obese, and they were randomized into four groups. The first had a diet low in sodium; the second was assigned to a weight loss program with diet and physical exercise; the third had both salt restriction and diet for weight loss; and the fourth was the control group (Figure 46–2). The 390 nonobese participants were assigned either to the reduced sodium group or to the usual care group. After a period of time, a medication withdrawal was attempted. Before the medication withdrawal, the mean SBPs and DBPs were significantly lower in all intervention groups compared with the usual care group. There was a mean decrease of 3.4 mm Hg in SBP and 1.9 in DBP compared with the baseline in the sodium reduction group, and a decrease of 4.0 mm Hg in SBP and 1.1 in DBP in the weight loss group, and a decrease of 5.3 mm Hg in SBP and 3.4 in DBP in the combined intervention group, but only a slight decrease of 0.8 mm Hg in both SBP and DBP in the usual care group. The average weight loss at 9 months of the study was 3.8 kg for the patients assigned to weight loss versus an average of 0.9 kg for the patients not assigned to weight loss groups.

The Trial of Hypertension Prevention (TOHP-Phase I and II) investigated the effect of weight loss in the prevention of hypertension. The aim of TOHP-Phase I was to determine the efficacy of nonpharmacologic interventions in reducing or preventing an increase in the DBP. Participants in this study were overweight or obese individuals (body weight was 15% to 65% above the desirable for their height), with DBP 80 to 89 mm Hg. They were randomly assigned to either an 18-month weight loss intervention program (with caloric reduction and increase in physical activity) or a control condition. The average weight loss for the intervention group at 6, 12, and 18 months was 6.5, 5.6, and 4.7 kg for men and 3.7, 2.7, and 1.6 kg for women, respectively. The mean change in the DBP and SBP for the intervention group was -2.8 mm Hg and -3.1 mm Hg for the men and -1.1 mm Hg and -2.0 mm Hg for the women, respectively, compared with the control group. BP reduction was greater among those individuals who lost more weight.³²

TOHP Phase II investigated the long-term effects of weight loss on BP. In this phase, 595 individuals were assigned to a weight loss group, and another 596 individuals were assigned to the control group. The participants' baseline BMI was 31 kg/m² for both men and women in the weight loss group and 31 kg/m² for the men and 30.8 kg/m² for the women in the control group. The average SBP and DBP were 127.6 mm Hg and 86.0 mm Hg, respectively, for the intervention group, and 127.3 mm Hg and 85.8 mm Hg for the control group. The mean weight loss from baseline in the intervention group was 4.4 kg, 2.0 kg, and 0.2 kg at 6, 18, and 36 months respectively,

Figure 46–2 Percentages of obese participants in the TONE study who remained free of cardiovascular events and hypertension and did not have an antihypertensive drug prescribed during follow-up. (From Whelton PK, Appel LJ, Espeland MA, et al. Sodium reduction and weight loss in the treatment of hypertension in older persons: A randomized controlled trial of nonpharmacologic interventions in the elderly (TONE). TONE Collaborative Research Group. *JAMA* 279:839-846, 1998.)

while in the control group at the same time points there was an increase in body weight of 0.1, 0.7, and 1.8 kg. BP was significantly lower in the intervention group compared with the control group at all time points (Figure 46–3). Participants who lost at least 4.5 kg at 6 months and maintained this weight for the next 30 months had the best results in their BP. The final result of this trial is that even modest weight reduction may lead to a significant decrease in BP.³³

The Trial of Antihypertensive Interventions and Management (TAIM) and the Treatment of Mild Hypertension Study (TOMHS) investigated the effects of combining lifestyle intervention and pharmacologic treatment on BP control in hyper-

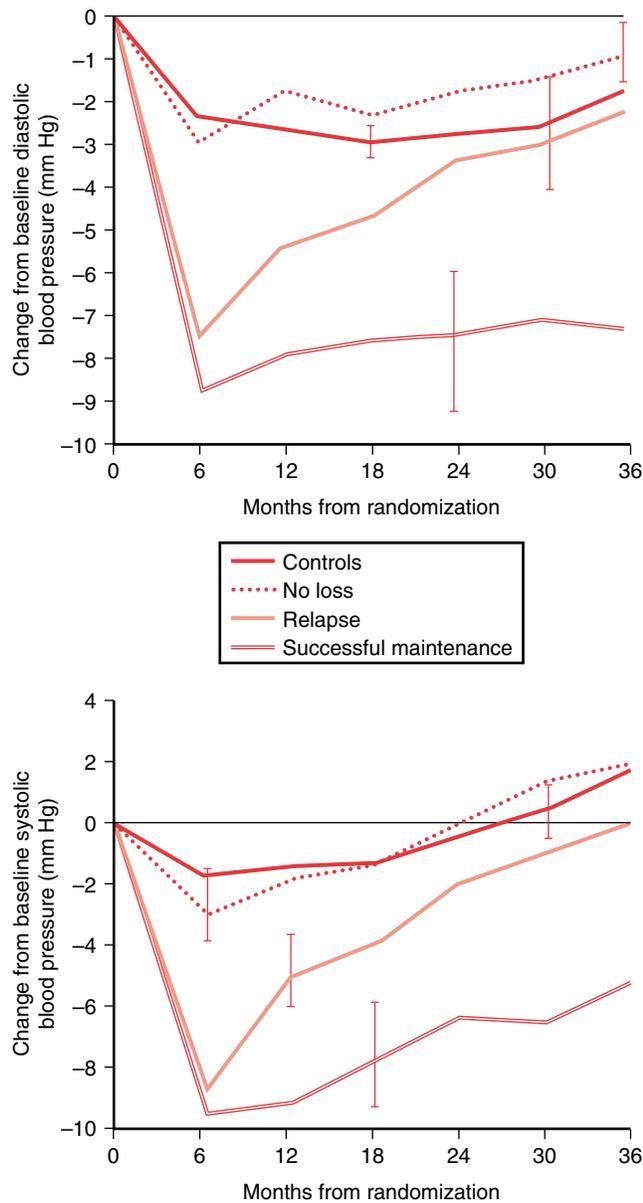

Figure 46–3 Mean change in diastolic and systolic blood pressures during the intervention period in the TOHP II study. (From Stevens VJ, Obarzanek E, Cook NR, et al. Long-term weight loss and changes in blood pressure: Results of the Trials of Hypertension Prevention, phase II. *Ann Intern Med* 134:1-11, 2001.)

tensive individuals, either obese or nonobese. In the TAIM study, 692 obese or overweight individuals with DBP between 90 mm Hg and 100 mm Hg were randomized into nine different groups according to diet (usual, low sodium, weight loss) and antihypertensive medication (placebo, chlorthalidone, atenolol). Six months later there was a significant decrease in both SBP and DBP in the diet intervention groups, especially in the weight loss group.³⁴

TOMHS compared the effectiveness of five different antihypertensive medications in combination with lifestyle changes in lowering BP. All 902 participants were advised to lose weight and decrease sodium and alcohol consumption and increase physical activity. Then they were randomized into one of the six groups according to antihypertensive medication (placebo, chlorthalidone, acebutolol, doxazosin, amlodipine, and enalapril). At the end of the study there was a reduction in BP in all six groups, although less in the placebo group, indicating that weight loss and other lifestyle interventions play an important role in BP control.³⁵

The Hypertension Control Program was a 4-year study that investigated whether patients with modestly elevated BPs could discontinue antihypertensive drug therapy with the help of dietary modification. One hundred eighty-four patients were randomized to three groups. Patients in the first group discontinued antihypertensive drugs and modified their diet, reducing salt and alcohol and losing weight, while patients in the second group discontinued drug treatment without dietary modification. Patients in the third group continued their usual antihypertensive therapy. At the end of the study, 39% of the patients in the first group remained off hypertensive medication, while only 5% of the second group remained normotensive without medication.³⁶

Similar results were found in the Dietary Intervention Study in Hypertension (DISH). In this study 496 patients who were normotensive while receiving antihypertensive drugs were randomized into seven groups. The overweight patients were randomized into four groups (antihypertensive drugs, no drugs or diet, no drugs but sodium restriction, and no drugs but weight reduction) and the normal weight patients were randomized into three groups (drugs, no drugs or diet, and no drugs but sodium restriction). At 56 weeks, the weight reduction group had the highest percentage (59.5%) of patients off medication. The average weight loss in this group was -4 ± 5 kg.³⁷

In a trial of 421 participants with hypertension on the Optifast program, a commercial weight loss program using a hypocaloric formula diet, 54% had a decrease in their BP. More than half of those who achieved a weight loss of more than 20% of the initial body weight achieved normal BP at the end of the study, but resolution of the hypertension required weight loss of more than 10% of initial body weight.³⁸

A summary of some of the studies that examined the effect of weight loss on BP is shown in Table 46–2.

PHYSICAL ACTIVITY

Physical activity is very important for the maintenance of weight loss over time. In the absence of a contraindication such as a cardiac, orthopedic, or metabolic reason, exercise should be encouraged. The role of physical activity in BP control is discussed in Chapter 47.

Table 46-2 Summary of the Studies of the Effects of Weight Loss on Blood Pressure

Study Name	Participants' Characteristics	Study Duration	Treatment Groups	Weight Change (kg)	Systolic/Diastolic BP Change
DASH ²⁴	459 adults with untreated hypertension	8 weeks after a 3-week introductory period	Usual diet Fruits/vegetables Fruits/vegetables and low fat	-0.1 -0.3 -0.4	-2.8/-1.1 mm Hg* -5.5/-3.0 mm Hg*

DRUG TREATMENT FOR WEIGHT LOSS

Currently, the only medications available in the United States for the treatment of obesity are orlistat and sibutramine.

Orlistat

Orlistat is an inhibitor of pancreatic intestinal lipase.³⁹ The result of this inhibition is that about 30% percent of the daily ingested fat intake is not absorbed. This would lead to a 200-calorie deficit per day in an individual who consumed a diet of 2000 calories per day with 30% of calories as fat. The most common side effects of orlistat are gastrointestinal, such as fatty or oily stools, more frequent defecation, and fecal incontinence. Another side effect is a slight reduction in fat-soluble vitamins, generally not outside of the normal range.

Several studies have confirmed the efficacy of orlistat in losing weight. The European Multicenter Orlistat Group carried out a double-blind study in which 688 obese individuals (average BMI 36 kg/m²) were assigned to orlistat or placebo for 1 year, in combination with a hypocaloric diet (minimum energy intake 1000-1200 kcal/day). At the end of the first year they were reassigned randomly to either orlistat or placebo for another year. At the end of the first year of the study the mean weight loss was 10.2% for the orlistat group and 6.1% for the placebo group. During the second year of the study, the participants who were switched to placebo gained twice as much weight as those who continued on orlistat. Participants who were switched from placebo to orlistat lost 0.9 kg more than in the first year of the trial.⁴⁰

Similar results were found in another U.S. study.⁴¹ In this trial, 892 obese individuals (BMI 30-43 kg/m²) who were previously on a 4-week controlled-energy diet plus placebo were randomized into either continuing placebo or starting orlistat 120 mg three times in a day (tid). After 52 weeks, the participants started a weight maintenance diet, and those in the orlistat group were rerandomized to continuing orlistat (60 mg or 120 mg tid) or placebo for another 52 weeks. Participants who were already on placebo continued taking placebo. At the end of the first year the participants on orlistat had lost more weight than those on placebo (8.76 ± 0.37 kg vs. 5.81 ± 0.67 kg). At the end of the second year participants on orlistat 120 mg tid regained less weight than those on orlistat 60 mg tid or placebo (3.2 ± 0.45 kg, 4.26 ± 0.57 kg, and 5.63 ± 0.42, respectively).

These studies showed that there is a significant weight loss with the use of orlistat in combination with diet during the first year, and that the tendency for weight regain that occurs during the second year is less with the use of orlistat.

Weight loss with orlistat also helps in the treatment of comorbidities, including high BP. A U.S. trial investigated the effect of orlistat on BP.⁴² The participants were randomized to either orlistat plus diet or placebo plus diet. After 1 year of treatment, participants in the orlistat group had greater reductions in BMI and DBP than the placebo group (-1.9 kg/m² vs. 0.9 kg/m², and -11.4 mm Hg vs. -8.4 mm Hg, respectively).

Another multicenter trial investigated the effect of orlistat on obese hypertensive patients.⁴³ Participants in this study (n = 628) were randomly assigned to orlistat plus diet or placebo plus diet. At the end of the study the decreases in SBP and DBP were 9.4/7.7 mm Hg for the orlistat group and 4.6/5.6 mm Hg for the placebo group.

Sibutramine

The other drug that can be used for the treatment of obesity is sibutramine. Sibutramine is a serotonin and norepinephrine reuptake inhibitor that decreases body weight by reducing food intake (by decreasing appetite).

The effect of sibutramine on weight loss was investigated in a multicenter dose-ranging study.⁴⁴ Participants (n = 1047) were randomly assigned to either sibutramine (1-30 mg) or placebo. After 6 months a dose-dependent weight loss was observed (1.2% weight loss with placebo compared with 2.7% with sibutramine 1 mg, 3.9% with 5 mg, 6.1% with 10 mg, 7.4% with 15 mg, 8.8% with 20 mg, and 9.4% with 30 mg).

Another study investigated the effect of sibutramine on weight loss, using VLCD and sibutramine, compared with the same diet and placebo.⁴⁵ In the sibutramine group, 86% of the participants lost at least 5% of their initial body weight compared with 55% of the placebo group 6 months after the study entry. At month 12, 75% of the sibutramine group maintained at least 100% of their weight loss, compared with 42% of the placebo group.

The Sibutramine Trial in Obesity Reduction and Maintenance (STORM) investigated the effect of sibutramine in maintaining weight that was lost on a hypocaloric formula diet.⁴⁶ In this trial, 605 obese patients, after losing weight, received 10 mg sibutramine daily for 6 months. After this period, participants who achieved at least 5% reduction in their body weight were randomly assigned either to continue with sibutramine for 18 more months or to receive placebo. Of the participants who completed the study, 43% of the sibutramine group maintained more than 80% of their original weight loss, while in the placebo group only 16% maintained this level of weight loss.

Sibutramine's side effects include dry mouth, headache, insomnia, and constipation, but, most important, it can increase heart rate by 4 to 6 beats per minute and elevate DBP by 2 to 3 mm Hg. Sibutramine should not be used in patients with a history of coronary heart disease, arrhythmias, or heart failure. Although some studies support sibutramine use in obese hypertensive patients,⁴⁷⁻⁴⁸ it must be used with great caution or not at all in patients with uncontrolled hypertension. Patients taking sibutramine should regularly be monitored for their heart rate and BP.

Antihypertensive Drugs

Although weight loss may reduce BP, there are many obese hypertensive patients who either cannot lose weight or having lost weight still have elevated BP. These individuals need treatment with antihypertensive drugs.

Thiazides have been used for many years for the treatment of hypertension. BP lowering with the use of these medications has been shown in obese hypertensive patients, but usually higher doses (up to 50 mg/day hydrochlorothiazide) are required to achieve this effect. One of the side effects of the thiazides is causing or worsening of insulin resistance. Since many obese patients are insulin resistant, thiazide diuretics should be used with caution in these patients, or in combination with other antihypertensive drugs, such as ACE inhibitors. β -Blockers may be effective in decreasing BP in obese hypertensive patients. However, β -blockers may decrease insulin sensitivity and increase glucose intolerance,

so they are not the first-choice treatment for these patients. β -blockers may decrease the early insulin response and increase insulin sensitivity, so they might be a good choice for obese hypertensive patients. However, they do not protect against heart failure, which occurs commonly in obese hypertensive individuals, so they have limited use as monotherapy or initial therapy for controlling hypertension in these patients. Used in combination with other antihypertensive drugs, α -blockers are helpful in the management of hypertension in obese patients.

Calcium antagonists lower BP by reducing peripheral vascular resistance. Unlike diuretics and β -blockers, they have no effect on insulin sensitivity, glucose uptake, or lipid profile. However, they frequently cause lower extremity edema, which may be especially troublesome to obese people.

ACE inhibitors reduce peripheral resistance, increase insulin sensitivity, decrease left ventricular mass, and protect the kidney, so they have theoretical advantages over other classes of antihypertensive agents for treating obese people with high BP. Angiotensin II receptor blockers (ARBs) have similar advantages with respect to intermediate endpoints. However, no particular advantage or disadvantage of any class of antihypertensive drug for treatment of obese patients has been demonstrated in outcome trials.

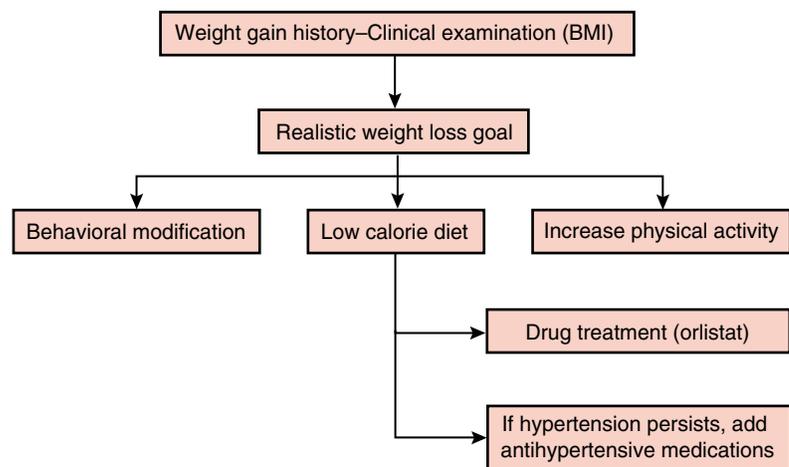

SUMMARY

Obese patients who are hypertensive should undergo a program of behavior modification to decrease caloric intake and increase physical activity. Numerous studies have documented that this will lower BP. The weight loss drugs orlistat and sibutramine may be used to enhance and maintain the weight loss process, but sibutramine must be used with extreme caution in hypertensive patients. If hypertension is not controlled with weight loss, antihypertensive therapy should be initiated. An algorithm for the treatment of obese hypertensive patients is shown in Figure 46–4.

Exercise and Hypertension

Garry L. R. Jennings

Regular exercise is an increasingly rare component of modern living. With the advent of electronic communication and transportation, large amounts of physical movement no longer underpin everyday life. Recreational activities and many forms of work can now be undertaken from the comfort of the home or office. This societal trend toward sedentary lifestyles is affecting many spheres of health, including osteoporosis and its complications, metabolic syndromes such as diabetes, coronary heart disease (CHD), and other consequences of atherosclerosis. It is also significantly influencing the prevalence and management of hypertension.

As seen in a wide range of communities throughout the world, individuals with hypertension are more likely to have sedentary lifestyles than their normotensive counterparts. While hypertension is much more than an exercise deficiency condition, the link between the two is evident. Researchers have found that hypertensive children undertake less physical activity when playing games than normotensive children. In animal models, this link also exists. Genetically hypertensive strains of rats voluntarily undertake less physical activity than normotensive strains when a treadmill is introduced into their cage. Resting blood pressure (BP) is inversely related to objective indices of physical fitness. It is likely that these benefits to BP are contributing to the observed lower cardiovascular mortality in the more active members of the general population.

Nevertheless, it was not very long ago that doctors recommended that hypertensive patients avoid strenuous physical activity. The basis of this was probably the observation every clinician has made that BP falls as soon as patients are admitted to hospital and rest in bed. This view may have also reflected the fact that BP increases acutely during isometric exercise and to a lesser extent during isotonic exercise. There are also frequently publicized, although rare, instances of sudden cardiac death among athletes. These events are more likely to occur during competition than between. The purpose of this chapter is to review some of the bases for the complete aboutface that has occurred in professional attitudes toward regular physical activity among hypertensives.

Strong recommendations have ensued among hypertension guidelines such as the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)¹ and the World Health Organization/International Society of Hypertension (WHO/ISH)² Committee and authoritative national reports, including the U.S. Surgeon General's Report on Physical Activity,³ to encourage regular physical activity for the entire community, including those with hypertension.

In considering this issue several paradoxes are apparent. The change in BP with acute exercise is largely dependent on the type of activity undertaken. In some forms, such as power lifting, the increase in systolic blood pressure (SBP) is profound. With others it is minimal depending on where and how the BP is measured (see discussion in sections that follow).

After acute exercise, BP generally falls for some hours. With repeated bouts of exercise there is increased physical fitness and also lower BP than before training, even when BP is measured at a considerable time after the last bout of exercise.

It is important to emphasize that even if regular aerobic exercise had no effect on BP whatsoever, there would be strong grounds for recommending it in the hypertensive population. Regular exercise is broadly efficacious in providing cardioprotection, acting not just through BP regulation but also through metabolic systems affecting cardiovascular risk, including insulin resistance and lipids, a powerful sympatholytic activity and effects on other neurohormonal systems.

Hypertensives are a high-risk population susceptible to multiple adverse cardiovascular risk factors. They are therefore most likely to benefit from regular exercise. On a population basis the association between exercise and BP may be particularly important to public health. The greatest threat associated with the slight decrease in prevalence of hypertension in developed communities is the rapidly increasing prevalence of obesity and its associated metabolic and other consequences. There is a strong argument that diminishing physical activity in the community is a major contributor to obesity and that increasing body weight is not just a consequence of excessive energy intake, but also of diminished energy expenditure through occupational and leisure time physical activity.

ISOTONIC AND ISOMETRIC EXERCISE

Many forms of exercise in normal daily life are a mixture of isotonic and isometric forms. Isotonic exercise involves shortening and lengthening of various muscle groups. Typical forms include running, cycling, and swimming. When performed for more than a few minutes these involve an increase in maximum oxygen uptake by the body. The body matches the increase in oxygen consumption mainly by exercising skeletal muscle. Isometric exercise, by definition, is skeletal muscle contraction without shortening. Resistance exercises such as power lifting involve a high degree of isometric and a limited isotonic component. The effects of acute isotonic and acute isometric exercise on BP are reviewed in the next sections.

ACUTE ISOTONIC EXERCISE

Blood Pressure during Exercise

To the clinician performing exercise stress testing, the BP response to acute isotonic exercise may seem straightforward. SBP measured indirectly at the brachial artery with a sphygmomanometer increases linearly in relation to workload. This is seen universally in healthy participants and in most patients with cardiovascular disease. However, in a few patients with

poor left ventricular function and/or major coronary artery disease, SBP does not increase, and in some cases it may even fall. The latter carries grave prognostic implications unless successful therapeutic intervention occurs. There is some variation in the extent to which BP increases with workload in the healthy population, leading to suggestions that an exaggerated rise in SBP with exercise may be a portent of hypertension later in life.

Factors affecting brachial systolic pressure determined sphygmomanometrically include cardiac output, which increases linearly with workload, and the properties of large arteries. A stiffer proximal vasculature will be associated with higher SBP. Pulse wave reflection from the periphery also contributes to SBP, having different effects at different levels of the arterial system. It is responsible for considerable amplification of the arterial pulse wave from the aortic valve to the brachial artery and beyond. In fact, much of the increase in brachial systolic pressure during exercise is due to increased effects of pulse wave velocity on the brachial systolic pressure as exercise progresses. When central BP is measured directly and invasively at the aortic root, there is very little change in aortic systolic pressure across the range of 25% to 100% of maximal oxygen uptake, even though brachial or radial artery systolic pressure increases considerably. Mean arterial pressure changes very little during progressive aerobic exercise^{4,5} (Figure 47-1).

Diastolic blood pressure (DBP) is not measurable by any of the conventional noninvasive means during exercise. Even invasively measured DBPs may be unreliable unless great care and attention is given to the frequency response and other characteristics of the apparatus used. DBP tends to slightly fall during progressive aerobic exercise (see Figure 47-1). As a consequence of this, high SBPs seen by clinicians using a sphygmomanometer in patients with hypertension during acute exercise do not translate into the expected increases in afterload. The heart experiences a vastly increased preload due to increased blood flow to and from the heart related to profound vasodilation in working skeletal muscle. Increased load

on the heart is also brought about by the tachycardia of exercise, which results from a combination of vagal withdrawal and cardiac sympathetic stimulation. The latter also increases cardiac contractility.

Although increased brachial systolic pressure during exercise is in a sense artifactual (it does not reflect increased central arterial pressures), there have been many proponents for the notion that exercise BP is a useful predictor of both hypertension and cardiovascular morbidity and mortality. The evidence for this is reviewed in the next sections.

Systemic Hemodynamic Changes during Exercise

BP is regulated closely during exercise, as can be understood by looking at the overall systemic hemodynamic changes. As stated previously, a primary hemodynamic driver during aerobic exercise is vasodilation in working skeletal muscle. This serves to meet the increased oxygen and nutrient demands at the local level. Increased oxygen is also extracted by exercising muscles. It is likely that the maximum vasodilatory capacity of skeletal muscle is never reached in normal healthy participants during aerobic exercise, because flows of 240 mm Hg per minute to the exercising quadriceps muscle alone have been measured during leg exercise.^{4,6}

If vasodilation in working skeletal muscle were the only hemodynamic change during exercise, BP would fall considerably. The fact is that active vasoconstrictor tone is maintained in both exercising and resting skeletal muscle, as well as in splanchnic and other beds during exercise. The net result is the redistribution of blood flow to exercising skeletal muscle away from other organs, some more than others. With persisting exercise, other factors become important, including demand for blood flow to the respiratory muscles, which may account for as much as 10% of total oxygen uptake at near maximal exercise. In the cutaneous circulation, there is dilation, which assists in the dissipation of heat generated by exercise.

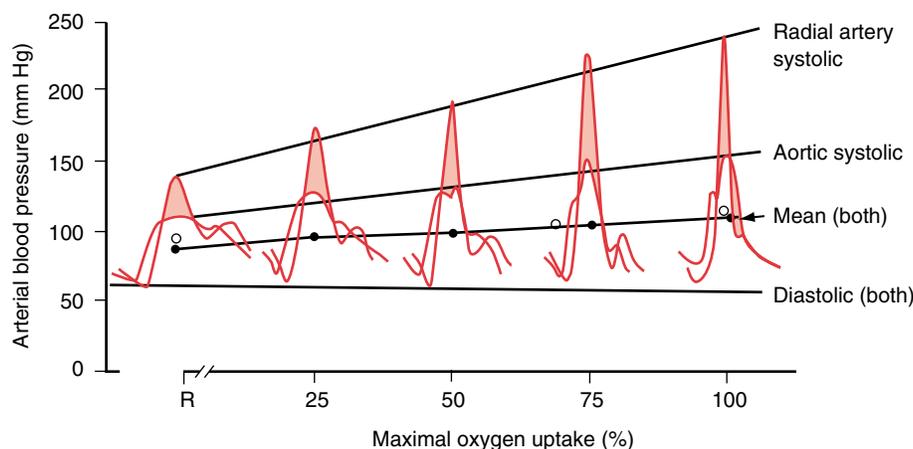

Figure 47-1 Simultaneously measured radial arterial and aortic pressures during rest (R) and upright exercise. Note the similarities in mean aortic pressures at a given percentage of VO_2 max from two studies on participants whose absolute values of VO_2 max varied widely. Peripheral wave amplification caused large increases in radial arterial pulse pressure. Pressure waveforms were traced from direct simultaneous recordings from a representative subject. (Redrawn from Rowell LB. Human Cardiovascular Control. New York, Oxford University Press, 1993; p 183. Used by permission of Oxford University Press, Inc.)

The heart responds to the increase in venous return with an increase in diastolic volume that tends to increase stroke volume by the Frank Starling mechanism.⁷ Cardiac output increases linearly with exercise workload, but the mechanism is different at lower and higher exercise levels. At lower levels, stroke volume increases. At higher levels, exercise tachycardia is more important, and both end-diastolic and end-systolic volume decrease despite increases in filling pressure.⁸⁻¹⁰

There has been a considerable amount of experimental work on the role of the arterial baroreflex in BP responses to acute aerobic exercise. Early workers considered that the reflex must be inhibited during such exercise. An apparent simultaneous increase in heart rate and arterial BP seemed to indicate that the arterial baroreflex was ineffective under these conditions. However, more recent data suggest that the arterial baroreflex remains active, albeit working at different operating points, so that vascular conductance and cardiac output are matched over the entire range from rest to maximum exercise.^{4,11}

Blood Pressure after Exercise

BP generally falls after an acute bout of exercise. This occurs within a few minutes and may last several hours. The mechanism probably involves reduction in peripheral resistance below preexercise levels, in part related to sympathetic inhibition.

In the longer term, engaging in a regular exercise program will reduce both resting BP and exercise-related BP increases (Figure 47-2). These effects can be seen after 2 weeks, with a further reduction in resting BP noted after 4 weeks of training.

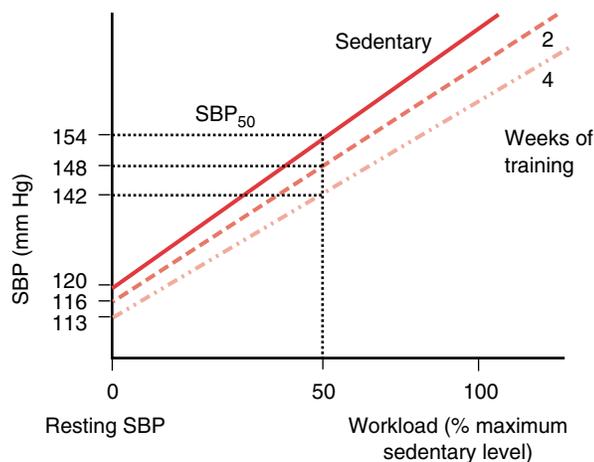

Figure 47-2 Exercise lowers resting systolic blood pressure (SBP) and SBP during acute exercise, both at any given absolute workload or at workloads expressed as percent of maximum work (e.g., SBP_{50} = SBP at 50% of maximum workload achieved during a graded exercise test). Lower blood pressure at any given level of exercise reflects both carryover of the effects at rest and a reduction in the slope of the relationship between workload and SBP. [Data [fitted to linear regression equations] from Jennings G, Nelson L, Nestel P, et al. The effects of changes in physical activity on major cardiovascular risk factors, hemodynamics, sympathetic function, and glucose utilisation in man: A controlled study of four levels of activity. *Circulation* 73:30-40, 1986.]

Other Changes with Acute Exercise

Metabolic

In addition to its effects on BP, exercise is associated with a number of other changes, chiefly metabolic, that contribute to reduced cardiovascular risk. These changes occur with different intensities and durations of exercise. A reduction in BP can be seen with a relatively low threshold of around 50% of maximum oxygen expenditure. At these levels, insulin resistance measurements show a biphasic response, with a very transient impairment followed by many hours of improved insulin sensitivity. Lipid measurements also change acutely with exercise. A fall in triglycerides and increase in high-density lipoprotein (HDL) cholesterol is consistently observed. These changes appear to be dependent on the intensity and duration of exercise. Transient efflux of HDL cholesterol can be measured from exercising skeletal muscle, probably reflecting a reduction in intracellular triglyceride levels due to metabolism. Prolonged exercise seems to be necessary for an acute effect of exercise on low-density lipoprotein (LDL) cholesterol levels.

There is, of course, a nexus between the acute and chronic effects of exercise. For example, some of the long-term effects of chronic exercise may be due to repeated acute effects. Moreover, exercise training increases exercise capacity, permitting more intense and prolonged exercise sessions, which may compound the acute effects.¹²

Implications of Hypertension on the Blood Pressure Responses to Acute Exercise

Hypertension is associated with left ventricular hypertrophy (LVH), which involves both cardiomyocytes and the cardiac interstitium. With early LVH in young participants, the effects of the cardiomyocyte hypertrophy may be the main determinant of the hemodynamic performance. There is evidence that at given levels of preload and afterload, cardiac contractility is higher with LVH than without. Thus, younger patients with mild LVH may have increased cardiac output during exercise and consequently higher SBP both centrally and in the periphery. More profound LVH in older participants is associated with stiffening of the ventricle, left ventricular diastolic dysfunction, and, if progressive, diminished left ventricular function and even cardiac dilation and failure. These changes would tend to lessen the BP responses to aerobic exercise.

Hypertension is also associated with impairment of the buffering effects of the arterial baroreflex. As mentioned previously, recent data indicate that the baroreceptor–heart rate reflex remains intact and operative, contributing to BP regulation during acute bouts of exercise, albeit operating at different set points as exercise progresses. However, reflex buffering of BP is impaired in the setting of ageing and hypertension, likely altering BP responses during and after exercise in this population.

ACUTE ISOMETRIC EXERCISE

The cardiovascular response, particularly the change in BP during isometric exercise, is quite different from that seen during isotonic aerobic exercise. In the contracting skeletal muscle bed there is a large increase in vascular resistance,

mainly due to extravascular constriction of the vessels. This elicits a powerful reflex, resulting in an increase in BP that is largely sympathetically mediated. Systolic, diastolic, and mean BP, as well as cardiac output, increase.

Observers suggested that this major increase in BP during acute isometric exercise might account for a small but significant increase in the likelihood of stroke due to intracerebral hemorrhage in susceptible individuals. This is the main reason why many authorities in the past have suggested that patients with hypertension and other cardiovascular disease should avoid heavy straining. However, there are also likely health benefits that arise from regular and repeated episodes of resistance exercise.

EXERCISE, BLOOD PRESSURE, AND CARDIOVASCULAR DISEASE MORTALITY

There has been considerable interest over many years in the extent to which differences in BP during acute exercise reflect prognosis. As outlined previously, the primary physiologic mediators of exercise BP include cardiac performance, which may be influenced by the prevailing levels of sympathetic activity, by cardiac hypertrophy, and by the presence of underlying cardiac disease. The second important mediator of exercise BP is the characteristics of the major arteries, including arterial compliance and the influences of wave reflection. Peripheral mechanisms that play a role include total peripheral resistance, which affects mean BP and DBP specifically, and cardiac preload, which is affected by the properties of the venous circulation. Other determinants of exercise BP are listed in Box 47-1.

A large number of studies have looked at the long-term outcome in relation to various indices of exercise BP at an initial exercise test. The results of some of these studies¹³⁻¹⁶ are shown in Figure 47-3.

Overall, the studies show an inconsistent relationship between exercise BP and subsequent mortality, although some of the better designed and controlled studies show a significantly positive relationship with a hazard ratio of around 2 for patients with high exercise BP compared with those without. Whether this is a useful finding applicable to clinical practice and whether any relationship between exercise BP and cardiovascular disease or mortality is causal or an indirect measure of other more important predictors is uncertain.

One consideration is the very strong interdependence of BP variables. In any population of hypertensive or normotensive participants, there are generally strong relationships between various BP variables, including SBP, DBP and/or mean BP,

resting BP, and submaximal or maximal exercise BPs. The linearity of the SBP response measured at the brachial artery at different workloads determines that the relationship can be described by an intercept (resting BP) and slope of the BP workload relationship. At any given slope of this relationship, a higher intercept (resting BP) will result in higher absolute BPs at each level of absolute work, including maximum work capacity. Thus, one explanation of the relationship between exercise BP and cardiovascular disease or mortality is that it indirectly reflects the known relationship between resting BP and outcome.

However, mortality has been shown to be independent of resting BP in several recent studies. At present the utility of the putative prognostic information arising from measurement of exercise BP is limited, not only because of the lack of a clear conceptual framework but also due to the lack of agreed measurement techniques and established normal values in local populations.

Long-Term Effects of Regular Aerobic Exercise on Blood Pressure

To some extent the question of whether exercise per se has a long-term antihypertensive benefit becomes less important in the light of strong epidemiologic, experimental, and clinical evidence that, irrespective of the effects on BP, regular exercise reduces mortality from CHD. It is not our purpose to review in detail the studies relating to regular exercise and CHD outcome, as these have been reviewed elsewhere.¹⁷⁻²⁰ However, studies using a range of measures of physical activity or fitness have consistently shown benefits, particularly those conducted since the late 1980s, in which greater attention has been paid to methodologic rigor. Classic studies contributing to this knowledge base have included those of Harvard alumni,²¹⁻²² Framingham,²³ UK civil servants,²⁴ and major trial patients,²⁵ as well as health screening programs in Texas.²⁶

The relationship between physical activity and morbidity or mortality in hypertensive or normotensive subgroups has been compared in a number of epidemiologic studies. In Harvard alumni,²¹ sedentary hypertensives had about twice the risk of death compared with those who were normotensive over the follow-up period of 12 to 16 years. The age-adjusted death rate per 10,000 man-years of observation was 173 in hypertensives and as low as 79 in normotensives. The relative risk of hypertension in sedentary participants throughout the follow-up period was 2.18, considerably higher than the figure of 1.58 observed in the most active alumni participants. Designation to the most active groups in this study required an estimated additional 2000 kcal/wk in work or leisure time exercise. This is a fairly substantial increment over sedentary levels, and more recent studies have examined milder increases in weekly exercise. These data suggest that hypertensives may benefit more from increased physical activity than those in the community who have normal BP.

By analogy with drug therapy, any benefit of regular exercise on BP should be reflected in reduced stroke rates. Wannamethee and Shaper²⁷ followed 7735 men for 9.5 years and observed an inverse relationship between physical activity and stroke risk. This persisted after statistically controlling for age, coronary risk factors, alcohol intake, and known vascular disease. The relative risk of stroke (assessed by questionnaire) was 0.6 for moderate activity compared with inactivity

Box 47-1 Determinants of Exercise Blood Pressure

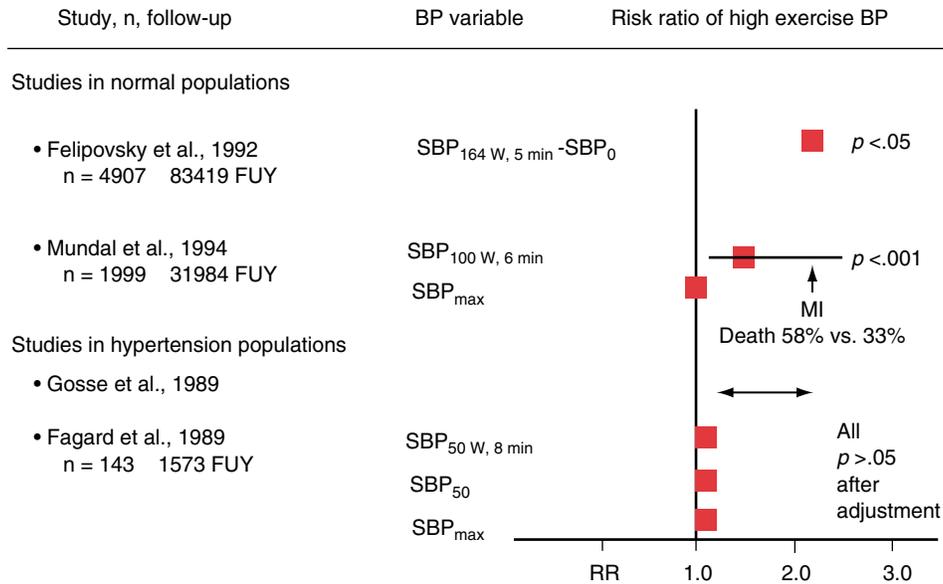

Figure 47-3 Exercise blood pressure (BP) and cardiovascular mortality. FUY, years of patient follow-up; n, number of subjects; W, workload in watts; SBP_n, systolic BP at n% of maximum workload; SBP_{nw}, systolic BP at an absolute workload of n watts.

and 0.3 for vigorous activity. However, the vigorous exercise group had a somewhat higher risk of myocardial infarction (MI). The lowest combined risk of stroke and MI was seen in the group with a moderate level of physical activity.

Epidemiologic data also support the benefit of regular exercise in primary prevention of hypertension. Blair et al.²⁶ determined physical activity indirectly by measuring physical fitness by treadmill testing. They followed more than 7000 men and women for a median of 4 years (range 1-12 years). Those with low levels of physical fitness at the outset of the study had a risk of 1.52 of developing hypertension relative to physically fit individuals even after adjustment for sex, age, duration of follow-up, baseline BP, and body mass index (BMI).

Epidemiologic approaches have also been used to determine whether a dose-response relationship exists between physical activity and cardiovascular mortality. However, interpretation of cross-sectional studies can be difficult, because there is a need to account for possible confounding effects of differences in body weight, diet, and other lifestyle habits in those who voluntarily and habitually adopt a lifestyle involving regular exercise. Although a general consensus is emerging from the epidemiologic data that moderate levels of physical activity are most protective, individual studies can be found in the literature to support the views that a very low,²⁸⁻³² a medium, or a high level²¹ of exercise is optimal. This question is better assessed in longitudinal studies using either crossover or parallel group designs where BP can be measured in exercising participants compared with appropriate controls.

Clinical Studies

If regular aerobic exercise were an antihypertensive drug, widespread recommendation of its use would require knowl-

edge of a full therapeutic profile, including indications, contraindications, side effects, precautions, interactions, adverse reactions, optimal dosage, and form of administration. Many clinical trials have been performed using exercise training as an intervention and many conclusions can be drawn. However, there are so many ways in which the level of physical activity can be altered in the course of normal daily life that it is not possible to provide a complete picture from clinical studies. Nor have major clinical outcome trials of the kind performed with antihypertensive drugs been feasible for studying the effects of regular exercise on BP and cardiovascular outcomes. The design and measurement challenges of such a study are formidable. Under these circumstances it is likely that the most complete picture will be obtained from carefully designed and conducted clinical studies using intermediate endpoints, particularly BP itself, and other measures of cardiovascular risk supported by coherent data from epidemiologic, experimental, and observational studies.

Major Design and Measurement Considerations

Many studies have investigated the effect of regular exercise on BP. Variability in the results of efficacy studies can largely be attributed to study design. Major design factors include the following:

1. Controls

The effect of regular exercise as an intervention cannot be measured in a double-blind, placebo-controlled trial. Nevertheless, to have no control intervention³³ is unacceptable. The general perception of exercise as a healthy activity ensures that there is likely to be a significant placebo contribution to any result where exercise has been involved. Some studies have used normal sedentary activity

as the control intervention³⁴⁻³⁶; others have used specific sedentary activities such as reading³⁷ or light exercises that were thought to be below the threshold for any possible active benefit of exercise.³⁸⁻⁴⁰ In an early meta-analysis, an average fall of BP in control groups in exercise studies was calculated at 2/2 mm Hg.⁴¹

2. Selection and randomization

Many members of the community regularly engage in physical activity during their work or recreation. There is a known tendency for health-conscious groups to volunteer for clinical trials. In order to diminish the contrast between active and inactive groups or trial phases, it is important that only sedentary participants be enrolled in controlled trials. Nevertheless, many previous studies have used athletes, who have been a convenient sample, but this has reduced the contrast between baseline, or control, and active groups or phases of the study.

3. Blood pressure measurement

It is clearly good clinical trial practice to measure BP using a method that is free of observer bias. There are several ways in which this can occur. Ambulatory BP measurements are now being used fairly routinely in clinical trials of antihypertensives. In the case of exercise studies, ambulatory BP recording avoids common biases from clinic measurements and has a limited placebo effect. However, it is important to recognize and account for the effect of physical activity performed during the day, as this is the major determinant of variance in ambulatory BP in a given individual. Even if BP recordings are not disrupted during the day of measurement by the acute BP effects during an exercise bout, variations in daily physical activity are important determinants of the variation in ambulatory BP. It has been observed that the level of physical activity that free-living individuals perform in the community depends to some extent on their physical fitness, so the group that has been engaged in the exercise intervention may be more active on rest days than the group that has not.

The timing of BP measurements is clearly important in relation to the most recent bout of acute exercise. Some studies have avoided the postacute exercise phase of up to 24 to 48 hours after the last bout of exercise.

4. Method of training

It is mandatory for good trial design that training be both quantitated and supervised. In many studies the level of exercise prescribed during the training phase has been expressed as a percentage of maximum work capacity or maximum oxygen uptake. However, as participants progress through the exercise program and their fitness improves, this translates to a higher absolute workload if work is adjusted according to the change in maximum capacity, or a diminishing fraction of maximum capacity if it is not. Therefore, whatever is done, the exercise-training stimulus will be different at the end of a period of regular exercise training from at the beginning.

It is particularly difficult to quantitate the amount of exercise performed in mixed programs involving different forms of exercise. However, these have been commonly used in longitudinal studies assessing the benefits of exercise on BP with the justification that they are more realistic and acceptable to the participants than laboratory-based studies.

5. Confounding factors

Regular exercise is always part of a general lifestyle package. The trial analysis and design must be able to account for major confounding influences such as changes in body weight, alcohol consumption, and sodium intake that might occur as the imposition of the exercise program impacts other aspects of daily life.

Summary and Meta-Analyses of Longitudinal Studies of Exercise Training on Blood Pressure

In the absence of a major outcome study, the best clinical trial evidence comes from meta-analyses that selectively include the studies with the design characteristics outlined previously. The earliest exercise studies were conducted from the early to middle 1970s, particularly in Japan,⁴² but most were flawed by inadequate or absent controls, nonrandom allocation of participants, or inadequate blinding of BP measurements. There have now been a number of systematic reviews of these data dating back to 1990.^{41,43-49}

Reports from more highly controlled studies now exist, including both males and females over a wide age range from teenagers to those older than 70 years. The exercise periods have varied from 1 to 8 or more months, and typical training frequency has been three times a week with a session time of 30 to 120 minutes. More frequent and less frequent exercise bouts have also been studied. Studies now exist on the effects of isotonic training, including bicycling, walking, jogging, running, calisthenics, and various combinations. The training intensity has usually been 40% to 80% of maximum oxygen consumption, and most have been in the 50% to 60% range.

Normotensive, borderline, and established hypertensive patient populations have all been studied. The presence of hypertension may be an important factor in determining the magnitude of BP change, although this remains somewhat controversial. Fagard⁴¹ reported that in early studies in normotensive participants, the average reduction in BP with exercise training was 4/4 mm Hg. In those with higher BPs (>140 mm Hg systolic), the average reduction was 11/6 mm Hg when corrected for reductions in the control groups. Several studies have shown that the BP reduction with exercise training is independent of changes in body weight or sodium consumption.^{50,51}

Most studies have been of longitudinal design. Crossover studies are more challenging, particularly if a larger number of participants are to have exercise intervention. However, they do avoid influences due to genetic and other confounding environmental factors acting on BP. In crossover studies, a standard exercise intervention of three 40-minute periods of cycling on a bicycle ergometer at 60% to 70% of maximum work capacity for 4 weeks reduced the BP in participants with mild hypertension by 11/9 mm Hg. The same protocol reduced the BP of normotensives by slightly less (10/7 mm Hg).^{50,51} These changes are at the upper limit of what has been observed in most well-controlled studies investigating the effects of exercise training on BP. This may have reflected population characteristics such as an extremely sedentary prestudy lifestyle and/or the improved contrast allowed by a crossover and a balanced Latin square design.

Whelton et al.⁴⁷ published a meta-analysis using English-language articles published before September 2001 as the data source. Using predetermined selection criteria, the authors

identified 104 original reports, including 121 trials. Of these, 54 trials from 38 reports met the requirements for the systematic analysis. These requirements included provision of adequate controls, limited ability for confounding factors to influence results, enrollment of participants older than 18 years old, and follow-up for more than 2 weeks. The median number of participants in each trial was 28 and the largest study included 247 people. In total, 2419 participants contributed data; 12 trials included predominantly men and 17 included predominantly women. Although most of the participants were white, six trials were conducted in Asian populations and four in African American. About half of the studies were performed in normotensive participants. The median duration of the trials was 12 weeks, ranging from 3 weeks to 2 years. The trial designs varied, and five had some kind of active intervention in the control group.

Baseline SBP varied from 101 to 168 mm Hg, with a median of 126.5 mm Hg. Corresponding diastolic values were 61 to 104 mm Hg, with a median of 77 mm Hg.

Overall the pooled effect of aerobic exercise on SBP was -3.84 mm Hg. The 95% confidence limits were between -4.97 and -2.72 , $p < .001$. The pooled effect on DBP was a reduction of 2.58 mm Hg (95% confidence intervals -3.35 to -1.81 ; $p < .001$). It is interesting that when only studies where the exercise intervention was supervised were included, the net change in BP increased, on average, to -4.13 mm Hg over -2.68 mm Hg. The mean change also increased when studies in which antihypertensive medications were allowed were excluded.

It is difficult to draw conclusions from subgroup analyses with such a relatively small number of trials and study participants. However, there appeared to be a greater reduction in BP in studies of shorter duration (<10 weeks).⁴⁷ In trials of longer duration, participants were allowed to exercise without supervision. It is likely that failure to adhere to the prescribed exercise intervention therapy contributed to this result.

MECHANISMS OF BLOOD PRESSURE REDUCTION BY REGULAR EXERCISE

The mechanisms contributing to the antihypertensive effects of exercise have proven difficult to elucidate. There has been some debate over whether the fall in BP is due to a reduction in cardiac output⁵²⁻⁵⁵ or total peripheral resistance.^{37,50,51} Methodologic and population differences may be responsible, and these have been reviewed previously.⁴⁶ Possible mechanisms include changes in neural regulation of the circulation, various hormonal systems, including the renin-angiotensin-aldosterone system (RAAS), and altered regulation by ion channels, growth, or endothelial factors. It has been proposed that exercise-elevated prostaglandin E levels⁵⁶ or increased intrinsic depressor systems, including atrial natriuretic peptide (ANP),⁵⁷ play a role. However, other studies have failed to show any change in cardiac secretion or renal extraction of ANP with 4 weeks of moderate training.⁵⁸ Other work has shown increased serum taurine in conjunction with training,⁵⁸ with consequent natriuretic⁵⁹ and sympatholytic⁶⁰ changes.

The most consistent response to regular exercise is reduction in resting heart rate. This is brought about by both reduced sympathetic activity^{61,62} and enhanced parasympathetic activity.^{63,64} It is highly likely that sympathetic modulation plays a role in other longer-term hemodynamic effects of

regular exercise. As mentioned previously, there is a reduction in sympathetic nerve activity after a single acute bout of exercise.⁶⁵ Many studies have shown that venous plasma norepinephrine concentration is reduced after training.^{34,37,50,51} More detailed catecholamine kinetic studies at the Baker Heart Research Institute have confirmed that there is substantial reduction in sympathetic efferent activity with regular exercise. Regional norepinephrine spillover studies⁶⁶ have shown that norepinephrine spillover into the circulation is substantially reduced after training compared with control periods. The majority of this effect is seen in the renal bed, which contributes two thirds to the fall in norepinephrine spillover.

Although these and many other changes associated with exercise training may contribute to the antihypertensive effect, it is difficult to determine which are causal and which are consequential. Meredith et al.³⁷ determined the time course of changes in BP in norepinephrine spillover and cardiac structure in healthy participants in a crossover study of training and sedentary periods. Interestingly, the reduction in BP was a relatively early phenomenon, being evident and statistically significant after only a little more than a week from commencement of a 4-week period of moderate exercise, three times per week. On the other hand, reduction in norepinephrine spillover took longer, being evident after approximately 3 weeks of training, at the same time as increased cardiac dimensions were noted using echocardiography. This suggests that other factors are responsible for the initiation of BP reduction after exercise training, although sympathetic inhibition may contribute over the longer term, perhaps as a consequence of altered cardiac afferent activity when the heart dilates. Inhibition of renin secretion with regular exercise may follow the sympathetic responses as reduction in renal norepinephrine spillover accounts for the major proportion of the total change in spillover.⁶⁶

Of several mechanisms proposed for the early reduction of BP by regular exercise, change in vascular function is supported. Systemic arterial compliance falls after a single bout of exercise and is seen to be below pretraining levels in the first week of a training program (three times per week). This has reflex effects on the circulation, particularly the baroreceptor heart rate reflex, probably by altering afferent input from the carotid baroreceptors. Exercise training has been consistently shown to reduce the maximum tachycardia response to BP reduction.⁶⁷⁻⁶⁹ This may be a factor in the orthostatic intolerance reported occasionally by athletes.⁷⁰ The reflex effects of training are slightly different when autonomic function is impaired, as in hypertension. In hypertension reduction there is a deficit in the parasympathetic component of the baroreceptor heart rate reflex.⁷¹⁻⁷³ In the context of hypertension and heart failure, baroreflex failure has been reported to be a marker of high risk of sudden cardiac death.⁷⁴ Regular exercise tends to improve reflex function. Interestingly, regular exercise, particularly when combined with a weight loss program, has been demonstrated to reduce BP under both resting and stress (laboratory mental stress) conditions.⁷⁵

There has been considerable interest in the possibility that the vascular effects of regular exercise involve alterations in nitric oxide (NO) action on large and small arteries. Short-term diet and exercise intervention in healthy participants was associated with reductions in BP, measures of oxidative stress, and NO availability, as well as alterations in the metabolic profile, including fasting insulin and improvement in the HDL cholesterol

ratio.⁷⁶ Kingwell et al. reviewed the influence of regular exercise on endothelially mediated vasodilation⁷⁷ and found consistent evidence that exercise training enhances endothelial NO release. However, there is a difference between short- and longer-term exercise in the balance of effects on basal NO release and that stimulated by agonists such as acetylcholine.⁷⁷

A likely sequence of events, at least with a moderate exercise training program three times a week at an intensity of about 60% of maximum work capacity, is an early fall in BP due to reduced compliance of large arteries and NO-mediated vasodilation of peripheral resistance vessels. As a result, increased vascular perfusion, particularly in skeletal muscle during acute exercise, increases venous return with a consequent increase in central blood volume. Over a period of about 3 weeks this is associated with left and right ventricular dilation and increased cardiac output. Altered cardiopulmonary afferent input to the brain as a result of this cardiac remodeling reduces brain stem sympathetic efferent activity, particularly to the renal circulation, causing a reduction in renin production and natriuresis (Figure 47–4).

After 4 weeks, a three-times-weekly exercise program on a bicycle ergometer in normal and hypercholesterolemic participants⁷⁸ is associated with higher basal NO release than in sedentary controls, but stimulated release is similar. Constrictor responses to the endothelium-dependent agonist acetylcholine are seen in cross-sectional studies in athletes compared with sedentary participants. It is possible that there is progressive adaptation in the NO system during long-term training. In the study referred to previously,⁵² a single bout of

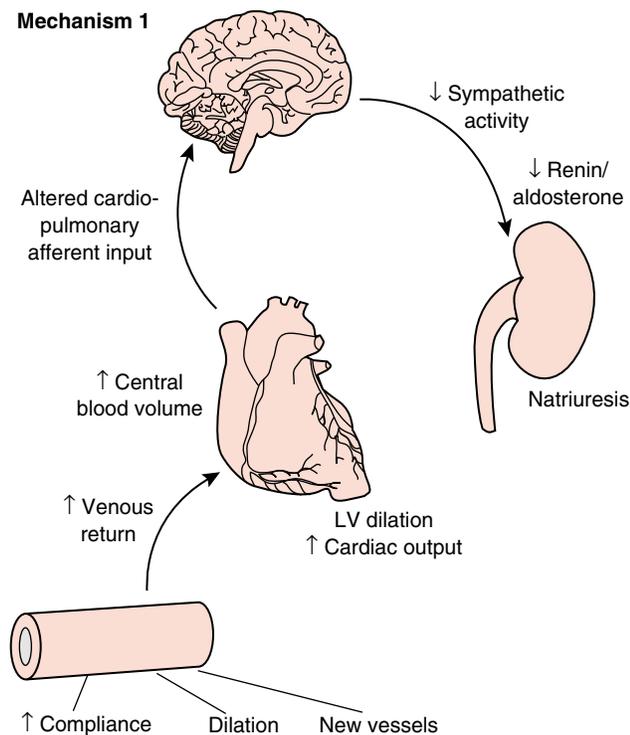

leg exercise increased forearm shear stress, a pertinent factor in the up-regulation of endothelial NO synthase. This may be responsible for the early demonstration of increased NO production and vasodilation between exercise bouts over the first few weeks. Over months, adaptations to meet increased metabolic demands during exercise may develop, involving changes in metabolic enzymes and perhaps vascular structural modification along the lines of that referred to previously for the heart. Another factor in free-living individuals is that over the long term, there are likely to be changes in the lipid profile, which will have beneficial effects on endothelial function. Endothelial function may be an important initiating factor and prognostic marker in vascular disease, and changes induced by regular exercise could be an important component of its protective effect.

Over the longer term a program of regular aerobic exercise can reduce LVH in hypertensive participants.^{79,80} It is not clear whether this reflects long-term BP lowering and is afterload dependent or whether there are specific effects of regular exercise on myocardial hypertrophy and/or the cardiac interstitium.

Effects of Resistance Exercise on Blood Pressure

Historically there has been concern over persons with hypertension performing more than moderate levels of resistance exercise because of the acute rise in BP, which exceeds that occurring with isotonic aerobic exercise. On the other hand, there are a number of likely benefits of resistance exercise that should apply to hypertensive patients as well as to the general population. These include maintenance of muscle bulk in later years, particularly in the upper limbs, which may be important in maintaining quality of life. There are also metabolic benefits in relation to, for example, glucose utilization that may differ from those seen with regular isotonic exercise.

Few data address whether progressive resistance exercise has effects on BP in the long term. Kelley and Kelley have reviewed studies that were indexed between January 1966 and December 1998 and required resistance exercise as the only intervention for at least 4 weeks.⁸¹ Only 12 studies met the criteria, and one of these was excluded from the final analysis because of missing BP data. Six of these studies were published in journals and five as part of doctoral theses. The 11 studies analyzed had a total of 320 participants, 182 of whom received the exercise intervention. The average number of participants in each group ranged from 6 to 31 in the exercises. Both males and females were included, and some studies had patients on antihypertensive medications. Training programs were variable. The overall pooled effects using fixed effects modeling in this study showed a decrease of approximately 2% and 4% for SBP and DBP, respectively. Both of these reductions were statistically significant. The authors concluded that progressive resistance exercise is efficacious for reducing resting SBP and DBP “in adults” but noted the need for additional data in hypertensive persons.

Mechanism 2

THE SAFETY OF EXERCISE

Hypertensives are a high-risk group for underlying CHD and other manifestations of atherosclerosis, particularly in later

life. In patients with CHD, whether it is overt or latent, sudden cardiac death may occur at any time. That it sometimes occurs during physical exercise is not surprising. The risks are lower with moderate exercise programs, beginning slowly and gradually progressing the workload level.

Supervised maximal exercise testing may be warranted before patients at high risk (i.e., severe hypertension [BP >180/110 mm Hg] or mild to moderate hypertension with additional risk factors) engage in an exercise program of moderate intensity (40%-60% of maximum work capacity). For patients who have CHD, heart failure, or stroke, exercise is best initiated under direct medical supervision.

By far the most common complications of an exercise program are associated with the musculoskeletal system, involving sprains, muscle tears, and soft tissue injury. Again these can be minimized by relatively simple measures, particularly by gradual and progressive increase in the intensity of exercise, and by not doing too much too soon.

SUMMARY OF CURRENT RECOMMENDATIONS

It is no longer considered beneficial for hypertensives to avoid physical activity. The available evidence³ supports the widespread adoption of regular aerobic exercise in the general population, including those with hypertension. Regular exercise lowers resting BP and has a positive impact on cardiovascular health. The existing trend toward sedentary lifestyles may be reversed through a concerted effort to increase the uptake of regular exercise in the community. Likely consequences include a reduction in the prevalence of hypertension, as well as lower mortality from CHD. An optimal exercise program in hypertensives may be on the order of 30 to 45 minutes of aerobic exercise about three times a week at a level of 50% to 70% of maximum work capacity. It is not clear whether all forms of regular exercise are similarly effective. These recommendations certainly apply to walking, running, cycling, and mixed programs. There are conflicting data on swimming, as some studies show BP lowering and others do not. Nevertheless, swimming has considerable overall health benefits and specific advantages, since the lack of weight bearing may be the only form of exercise available to some participants with musculoskeletal disorders.

It should be emphasized that the studies reviewed in this chapter involved participants who were generally adherent to the programs. This will clearly not apply in the general community. Strategies for improving adherence to nonpharmacologic measures for cardiovascular risk reduction have been reviewed.⁸² The issue is complex, and there are relatively few solutions. One important issue that emerges from the literature is the key role of clinicians in providing their imprimatur on the adoption of nonpharmacologic measures, including exercise, by their patients. Data suggest that if the doctor does not mention the benefits of exercise, weight loss, stopping smoking, or other hygienic measures during a consultation, many patients assume that it is not necessary for them to change. In the light of the present data, clinicians should consider and articulate their exercise and lifestyle prescriptions as clearly and carefully as they do a drug prescription for their patients.

Pharmacologic Treatment

Chapter 48

Initial Choices in the Treatment of Hypertension

Myron H. Weinberger

A plethora of important studies conducted during the 1990s have provided an incredible database of new information concerning the benefits of antihypertensive therapy, the comparative effects of various classes of antihypertensive agents, and even information concerning optimal blood pressure (BP) levels in both uncomplicated and complex hypertensive patient groups. This information is slowly being analyzed, evaluated, published, reevaluated, compared, and considered by the medical community ranging from researchers and specialists, to primary care physicians, and even by the lay public. In many cases the results have formed the basis of recommendations for optimal levels of BP and for specific forms of therapy for some individuals, promulgated by a variety of national and international medical organizations, ranging from specialty groups to national and international health and policy-making bodies. As a result of the ever-increasing size, complexity, and costs of these studies, media publicity aimed at the consumer has often followed and, in some cases, even preceded the presentation of the results to the scientific community. This barrage of information has led to much confusion on the part of the practitioners as well as the general public. This chapter attempts to survey the most important and largest of these endeavors to assist physicians in making a rational and beneficial choice for initial antihypertensive therapy. Other chapters are devoted to specific classes of antihypertensive agents and particular subgroups of patients and provide much more detailed and comprehensive information.

WHEN AND WHOM TO TREAT

Evidence regarding the impact of BP on morbidity and mortality has undergone drastic reevaluation on the basis of several important studies that have provided new insight into the importance of this major risk factor for cardiovascular disease. For example, observational data from more than 1 million individuals participating in a variety of studies has indicated that the risk of cardiovascular morbidity and mortality begins to increase at BP levels of 115/75 mm Hg and doubles at each increment of 20/10 mm Hg above that level.¹

When considering the traditional criteria of 140/90 mm Hg for the definition of hypertension, it is important to recognize that the Framingham Heart Study has demonstrated that individuals with a BP between 130 and 139 mm Hg systolic and 80 to 89 mm Hg diastolic are at twice the risk for the development of future hypertension as those with “normal” BP.² Thus we have two compelling prospective observations documenting the increased risk of cardiovascular events in persons with BPs below 140/90 mm Hg. Moreover, individuals with normal BP at the age of 55 years have a 90% chance of developing hypertension in their lifetime.³ Thus those fortunate enough to reach the age of 55 without becoming hypertensive have an overwhelming likelihood of doing so as they age. These convincing and compelling findings led the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) to draw attention to lower BP levels than had previously been of concern, by defining BP levels between 120/80 mm Hg and 139/89 mm Hg as “prehypertensive” and by recommending nonpharmacologic therapy as a means of reducing those levels.⁴ These nondrug approaches will be discussed subsequently.

The guidelines of 120-139/80-89 mm Hg for nonpharmacologic intervention and drug treatment for those above 140/90 mm Hg, the traditional point for initiation of drug treatment for those not adequately controlled with nondrug approaches, apply to uncomplicated individuals. However, there are several subgroups with evidence of, or at high risk for, vascular disease or other conditions such as diabetes mellitus or renal disease, for whom BP levels even lower than the traditional 140/90 mm Hg are desirable. These persons should require antihypertensive drug therapy to achieve more aggressive BP goals. The most recent guidelines suggest that the goal for diabetics should be a BP consistently below 130/80 mm Hg and for those with renal disease of any form, below 125/75 mm Hg. Individuals with congestive heart failure (CHF) comprise another group for whom BP levels lower than the traditional 140/90 mm Hg have been advocated, but specific levels have not been precisely defined.

NONPHARMACOLOGIC THERAPY FOR THOSE WITH “PREHYPERTENSION”

The nonpharmacologic approaches that have been shown to lower BP, and which have been advocated as initial therapy for the stage 1 hypertensive, do not have universal efficacy in all individuals. For example, weight loss for the obese person is usually associated with a reduction in BP. Curiously, BP tends to fall early in the weight loss program, if it falls at all. Thus massive weight loss, even for the grossly obese individual, is not always required for a beneficial reduction in BP. As with all interventions, maintaining the weight loss is more difficult than initially achieving it.⁵ The benefit of aerobic exercise on BP is less consistent. Some of the earlier studies of exercise failed to control for the effect of weight loss on BP, and thus the effects of uncontrolled weight loss accompanying the exercise regimens may have confounded the results. Nonetheless, a regular exercise program aids in maintaining weight loss and improves cardiovascular fitness and is thus to be recommended as a nondrug approach whenever possible. In general, weight loss has been associated with greater decreases in BP than those reported with exercise alone.⁶ Another lifestyle alteration that has been shown to reduce BP is a decrease in alcohol consumption for those who drink more than 2 ounces of alcohol daily.⁷ Monitoring adherence to this recommendation is often difficult in view of the central nervous system effects of alcohol and the need to precisely limit the quantity consumed.

The greatest reductions in BP among the nondrug approaches have been seen in salt-sensitive individuals who reduce their sodium intake to levels at or below 100 mM/dl (2.3 g/day). Salt sensitivity is essentially a research definition but its prevalence has been observed to be greater among older individuals (older than 60 years of age), African Americans, diabetics, and those with a family history of hypertension in a first-degree relative.⁸ In many individuals who are salt sensitive, a deficient intake of potassium has been noted, and thus potassium supplementation has been shown to lower BP. In fact, a recent study that incorporated both sodium restriction and potassium supplementation by dietary means (the Dietary Approaches to Stop Hypertension [DASH] diet) was effective in reducing BP in those with “high-normal” and stage 1 BP elevation.⁹ This study demonstrated that the BP lowering effect of the original DASH diet was enhanced by reduction of sodium intake from 100 mM/dl to 65 mM/dl (1.5 g/day).

The decision of when and how to treat BP is sometimes influenced by factors other than the office or clinic BP measurements. Patients have been identified who manifest higher BP readings in the office or clinic than outside the medical environment, the so-called white-coat hypertension syndrome. This phenomenon may not be as innocuous as many believe, since it may be associated with early evidence of target organ disease and with the progression to established hypertension with the passage of time. Given the new prehypertension category, such individuals certainly will require closer scrutiny and earlier treatment. The decision of whether to embark on nonpharmacologic or drug therapy may require 24-hour ambulatory BP monitoring, which should include careful attention to the presence or absence of the typical nocturnal decline in BP. Individuals in whom this nocturnal “dip” is not present are exposed to a greater pressure load over the 24-hour period and thus are more apt to demonstrate early

target organ changes.¹⁰ The diagnosis of hypertension is made when the average awake ambulatory BP exceeds 135/85 mm Hg and the nocturnal average is more than 120/75 mm Hg.

Another consideration that may influence the decision to begin antihypertensive drug therapy is the presence of other risk factors for cardiovascular disease. Diabetes mellitus and renal disease have already been mentioned as conditions in which lower BP levels have been clearly shown to be beneficial. Elevated BP or even prehypertension represents only one of many risk factors requiring attention in many other patient types. As examples, the patient with a history of cigarette smoking who can not be induced to quit, the dyslipidemic patient, the individual with the metabolic syndrome (“X”), and the obese patient all represent individuals for whom even a mild increase in BP above the “normal” level of 120/80 mm Hg represents increased risk for cardiovascular events and for whom drug therapy may be considered appropriate. Moreover, the impact antihypertensive drugs on these other risk factors requires particular consideration as will be outlined in the next section. A drug that lowers BP but has an adverse effect on glucose tolerance or lipids will be less beneficial in reducing the risk of cardiovascular events than a drug that reduces BP to the same degree without an undesirable effect on the other risk factors.¹¹⁻¹³

FACTORS TO CONSIDER IN CHOOSING INITIAL DRUG THERAPY

When the decision has been made to begin antihypertensive therapy, several considerations are appropriate in selecting the agent. The BP level provides an initial clue regarding whether a single agent is likely to produce adequate BP lowering to achieve the desired goal. Individuals with BPs above 160 mm Hg systolic and/or 100 diastolic mm Hg will generally require more than a single drug to reach goal levels. A detailed discussion of such combination therapies will follow consideration of monotherapy, which is generally more appropriate for those with elevations of BP less than 160/100 mm Hg. Because factors such as age, ethnicity, cigarette smoking, and concomitant risk factors and disorders influence the response to, and benefit of, specific drug therapy, such factors need to be identified and considered.

In persons younger than age 50 and in those with evidence of increased sympathetic drive as manifest by a hyperdynamic chest wall and/or a resting tachycardia, β -adrenergic blocking drugs are a good initial choice. Such agents are also effective in patients with a history of angina or migraine, and those with familial tremor. The more lipid-soluble agents such as propranolol and nadolol seem to be the most effective in the latter two situations, while virtually all β -blockers have been reported to be effective in reducing angina. A history of asthma represents a contraindication to the administration of β -blockers. In patients with symptomatic peripheral vascular disease, agents that act by inducing peripheral vasodilation are preferable to β -adrenergic blocking drugs, which may worsen the symptoms of peripheral vascular insufficiency.

In salt-sensitive subjects,⁸ BP is most responsive to agents that have a diuretic and/or natriuretic effect. Diuretics fall into this category but for reasons suggested in the previous section and discussed in more detail subsequently, they may not always be an ideal initial choice for antihypertensive monotherapy. An

alternative consideration for the salt-sensitive hypertensive is the administration of a calcium channel blocker, because such agents have been shown to have a diuretic and natriuretic effect¹⁴⁻¹⁶ in addition to their vasodilator action, reducing peripheral resistance. Comparative studies have demonstrated equivalent efficacy for diuretics such as hydrochlorothiazide and chlorthalidone and calcium channel blockers such as amlodipine in reducing BP in older hypertensives and those with the characteristics of salt sensitivity.¹⁷ The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was composed of a highly salt-sensitive hypertensive cohort that included mild hypertensives, 36% Black, and 36% diabetic and with an average age of 67 years. The ALLHAT trial demonstrated equivalent BP reduction in the groups randomized to chlorthalidone and amlodipine, which is significantly greater than the reduction achieved by the group assigned to initial therapy with lisinopril. At the end of this 5-year study, however, only one third of the participants were receiving monotherapy, while the remaining majority required multiple drugs to reach the BP goal of 140/90 mm Hg or less.

In contrast to the findings of the ALLHAT trial, observations from a study in almost exclusively white hypertensives in Australia showed greater benefit from initial treatment with an angiotensin-converting enzyme (ACE) inhibitor than a diuretic.¹⁸ This would seem to confirm earlier observations suggesting that diuretics and calcium channel blockers are preferred *initial* therapeutic choices for the older hypertensive, the Black hypertensive, and the diabetic hypertensive, about whom more detail will be provided shortly. In contrast, β -adrenergic blockers, ACE inhibitors, and angiotensin II receptor blockers (ARBs) are more effective in younger persons, particularly in white hypertensives as *initial* therapy. For example, the Veterans Administration Cooperative Study Group showed that in an older, male population with the typical characteristics of individuals obtaining their care at such facilities, diuretics and calcium channel blockers were more effective than β -adrenergic blocking drugs and ARBs.¹⁹ Not surprisingly, these observations are consistent with the findings of the ALLHAT trial, because many of the ALLHAT sites were Veterans Administration Hospital clinics.

Most studies examining the effect of gender have failed to reveal a significant difference in the responses of men and women to specific antihypertensive monotherapy when other factors such as age, ethnicity, and diabetes are considered. These important studies then permit a broad, general summary of the likely BP efficacy of the major antihypertensive drug classes. However, the treatment of hypertension involves much more than lowering BP. Thus the major antihypertensive drug trials emphasize cardiovascular and other outcomes.

What have we learned from the large, long, and expensive antihypertensive drug trials conducted since the original Veterans Administrative Cooperative Study,²⁰ which first documented the beneficial effects of lowering BP in severe hypertensives compared with placebo more than 40 years ago? First and foremost, we have learned that lowering BP reduces cardiovascular events, including stroke, heart attacks, and CHF, as well as renal impairment and failure. All of these events have not consistently been shown to be reduced in the earlier trials, some of which may not have been conducted for a sufficiently long period of time to document benefit in reducing events other than stroke, for which BP reduction has consistently been shown to be beneficial. The ALLHAT trial con-

firmed the benefit of BP reduction in preventing stroke by demonstrating that stroke was significantly (40%; $p < .001$) more common among Black hypertensives assigned to lisinopril as initial therapy compared with those whose first drug was chlorthalidone.¹⁷ An important contributor to this dramatic finding is higher BP (4 mm Hg systolic and 2 mm Hg diastolic) in the Black subgroup randomized to lisinopril compared with the groups assigned to chlorthalidone. Although it is difficult to believe that such small differences in BP could account for such a large relative increase in stroke, the very large size and tremendous statistical power of the ALLHAT trial provide confidence in the relevance of the finding. Thus it would appear that no antihypertensive regimen will provide cardioprotective benefit unless it lowers BP to a degree comparable with other agents.

Beyond BP reduction, there are other benefits of antihypertensive therapy. Although stroke incidence decreases almost immediately after effective BP reduction in hypertensive subjects, a reduction in coronary artery disease events has not always been observed. There is considerable debate about the reasons for this. Some have suggested that BP is less important in the prevention of coronary disease than in stroke. Others have proposed that while the benefit of antihypertensive drug treatment in decreasing stroke incidence is primarily due to pressure reduction per se, coronary disease results from a much more complex array of factors and is more insidious in its development. Thus the relatively short duration of most antihypertensive trials may not have been sufficient to disclose beneficial effects on this endpoint. Exclusion of persons at high risk for vascular events from many studies may have also influenced the impact on heart disease events.

It has also been suggested that the potential adverse metabolic effects of some antihypertensive drugs on insulin sensitivity and lipids, both well-recognized risk factors for coronary artery disease, may have counterbalanced the benefit of BP reduction on coronary events. Thus it has been more difficult to demonstrate a reduction in heart disease than stroke by BP lowering. Evidence from several large trials that were conducted for sufficient time to examine these issues in detail has revealed some support for the latter hypothesis. For example, in the ALLHAT trial, which had an average 5-year follow-up period, the chlorthalidone-assigned group had a 40% greater incidence of new-onset diabetes ($p < .001$) at the end of the study compared with the group assigned to lisinopril, which had an incidence not significantly different from the amlodipine group.¹⁷ Although this increase in diabetes was not reflected in more coronary events during the course of the trial, the longer-term implications of the development of de novo diabetes must be a consideration in choosing initial antihypertensive therapy. Two other trials that compared a β -adrenergic blocking regimen with either an ARB (the Losartan Intervention for Endpoint Reduction in Hypertension Study [LIFE])²¹ or a calcium channel blocker (the International Verapamil-Trandolapril Study [INVEST])²² regimen also demonstrated a significantly ($p < .01$) greater incidence of new onset diabetes in the group randomized to β -adrenergic blocking drug.

Dyslipidemia is another important risk factor for cardiovascular disease, particularly coronary artery disease. Antihypertensive drugs have been shown to have variable effects on the lipid profile, which may impact on these risks.¹¹⁻¹³ Some have argued that the effects of diuretics on the lipid profile

are only transient. However, the observation of significantly ($p < .01$) higher total cholesterol levels at the end of 5 years of follow-up for those participants in the ALLHAT trial assigned to a chlorthalidone compared with the lisinopril and amlodipine groups indicates that these changes, although small, are certainly persistent and clinically relevant. Similarly, β -adrenergic blocking agents can also reduce high-density lipoproteins, increase triglycerides, and thus raise the risk for cardiovascular events.^{11,13}

Another surprising finding from the ALLHAT trial relates to the effects of the assigned drug regimens on renal function in this cohort without renal dysfunction at baseline (serum creatinine in the normal range was one of the entry criteria for the study). At the end of the 5 years of the study, the chlorthalidone and lisinopril groups evidenced a significantly ($p < .05$) greater decrease in glomerular filtration rate (GFR) than the amlodipine group.¹⁷ This was surprising in view of the evidence of a beneficial effect of ACE inhibitors and more consistently, ARBs, in the stabilization of renal function in those with chronic kidney disease.²³⁻²⁶

IS THERE A BEST SINGLE DRUG?

It should be clear from the experience of these large trials, supported by a tremendous older literature, that no single drug class will provide an optimal choice for all patients. The overriding message from these studies is that the majority of even mild and uncomplicated hypertensive patients will require multiple drug therapy to reach the new recommendations for BP goals as stated by JNC 7.⁴ In fact, JNC 7 recommends beginning with two drugs when the BP is above 160 mm Hg systolic and/or 100 mm Hg diastolic. Even among the 10% of ALLHAT participants who were untreated at entry to the study and who had an average baseline BP of 157/90 mm Hg, more than 60% required three drugs to reach treatment goals.¹⁷ Thus arguments concerning which agent is best for the initiation of therapy are often moot because multiple drug therapy will usually be required. Moreover, because reducing the dose of diuretics decreases both their dose-dependent adverse effects and their BP-lowering efficacy, it seems appropriate to consider combination therapy as a means of achieving BP goals and minimizing adverse effects.

What then are the two-drug combinations that have proven to be effective? Are there any particular benefits to specific combinations? The literature on these issues is too extensive for a detailed discussion in this chapter and thus their implications will simply be summarized. One of the major limitations of the large and important ALLHAT trial resided in the treatment algorithm. Because the primary aim of the study was to determine whether any of the three newer classes of antihypertensive drugs assignments was better than a thiazide-type diuretic in reducing fatal and nonfatal heart attack, the design attempted to minimize “crossover” of the test drugs (amlodipine, chlorthalidone, doxazosin, and lisinopril).¹⁷ For this reason, participants who did not reach the goal BP of <140/90 mm Hg (almost two thirds of the study population) could be given an open-label or third-step agent at the discretion of the investigator. For the second-step, drugs working by interfering with the sympathetic nervous system (reserpine, clonidine, or atenolol) were recommended. Such agents are not generally effective in reducing BP in salt-sensitive hypertensives, who

comprised the majority of the ALLHAT cohort. Therefore participants assigned to lisinopril who did not achieve the BP goal on monotherapy would not be expected to achieve that goal with one of the second step agents. Thus the third-step drug, hydralazine, a short-acting direct vasodilator would be recommended. However, this agent causes salt and water retention and volume expansion and would also not likely be effective in salt-sensitive subjects. In other words, the treatment algorithm employed in this study was flawed from the standpoint of physiologic factors and pharmacologic efficacy. In general, low-dose diuretic therapy increases the efficacy of drugs from the sympatholytic and vasodilator classes. Although the combination of diuretic and β -adrenergic blocking agent has greater BP-lowering efficacy than either monotherapy, the adverse effects of both agents on insulin sensitivity, glucose, and lipids make this a less-than-ideal choice for most uncomplicated hypertensives.

Combining ACE inhibitors or ARBs with low-dose diuretic therapy is a very effective antihypertensive approach that has an added benefit of blocking many of the adverse metabolic effects of diuretic therapy, which are largely mediated by activations of the renin-angiotensin-aldosterone system.²⁷ The combination of calcium channel blockers with diuretics has questionable additive efficacy on the basis of relatively few studies with small numbers of subjects.²⁸ This is not surprising when it is recognized that both agents have diuretic and natriuretic effects, while calcium channel blockers have an additional vasodilator effect, accounting for greater efficacy. In contrast, the combination of calcium channel blockers with ACE inhibitors or ARBs has a powerful additive efficacy. Moreover, such combinations are devoid of adverse metabolic actions and each of the components has been shown to have beneficial effects on cardiovascular disease outcomes.

α -Adrenergic blocking drugs have fallen into disfavor because of a lack of benefit on cardiovascular disease outcomes reported in the ALLHAT trial.²⁹ However, that may be a short-sighted conclusion in view of the fact that most patients require the addition of a low-dose diuretic for antihypertensive efficacy with this class of drugs. α -Adrenergic blockers are very useful in the treatment of the symptoms of benign prostatic hyperplasia, a disorder frequently found in older hypertensive men.³⁰ In addition to the combination of α -adrenergic blocker and diuretic, the combination of α - and β -adrenergic blocker has been shown to be effective for many individuals. Aldosterone antagonists, represented by the older agent, spironolactone, and the new generation drug, eplerenone, which has side effects, have recently been shown to be effective antihypertensive agents.³¹

COMPELLING INDICATIONS FOR SPECIFIC DRUG THERAPY

There are several subgroups of hypertensive patients for whom specific antihypertensive drugs should be prescribed. Examples include diuretics, β -adrenergic blocking agents, ACE inhibitors, ARBs, and aldosterone antagonists for the patient with heart failure; β -adrenergic blocking agents, ACE inhibitors, and aldosterone antagonists for postmyocardial infarction; diuretics, ACE inhibitors, ARBs, and calcium channel blockers for diabetics; ACE inhibitors and ARBs for chronic kidney disease; diuretics, calcium channel blockers, and ACE inhibitors for stroke prevention (primary or recurrent); and

diuretics, β -adrenergic blocking agents, ACE inhibitors, and calcium channel blockers for those at high risk for coronary artery disease.⁴ It should be recognized that not *all* of these recommended agents need to be given in combination to every patient with the problems indicated, but rather that treatment with these agents requires special and individualized consideration. Moreover, many of these drugs will not be efficacious in lowering BP unless combined with other agents, such as those suggested previously.

Pharmacokinetics of Antihypertensive Drugs

Alexander M. M. Shepherd

INTRODUCTION

The previous edition of this book did not contain a chapter dedicated to the disposition of the drugs used in the treatment of hypertension. I considered whether clinicians need to know much about the kinetics of this group of drugs. After all, we can readily measure the response to them and alter the administered dose to achieve the desired antihypertensive response.

On reflection, however, I created a fairly long list of reasons why knowledge of drug disposition and mode of action was essential to a clinician using drug therapy to treat hypertension. This list includes the following:

1. Knowledge of the route and manner of elimination from the body would permit dose alteration in disease states; for example, accumulation of a drug in hepatic failure or of its active metabolites in renal failure could increase toxicity or efficacy.
2. This knowledge would also be of use in predicting drug interactions; for example, knowing that verapamil is broken down in the liver by the Phase 1 microsomal isoenzyme cytochrome P450 3A4 would predict the possibility of an interaction with some of the “statins” used to treat the hypercholesterolemia that commonly accompanies the hypertension. This interaction could increase the blood level of the statin and make toxicity more likely.
3. Knowledge of the plasma half-life of a drug can aid in determining the dosing schedule, for example, furosemide should be used twice daily because its duration of action is relatively short and blood pressure control may be lost if the drug is given once a day. Caution must be exercised in predicting duration of effect from plasma half-life. We tend to dose many drugs once every half-life because we can easily tolerate swings in blood levels of around 50%. With antihypertensive drugs, the effect tends to last longer than would be predicted—sometimes much longer. Examples include the hydralazine plasma half-life of around 90 minutes, which does not easily translate into the twice-daily regimen effective in many patients. Also, propranolol has a plasma half-life of less than 5 hours but can be given twice daily.
4. Knowledge of whether a drug is lipid or water soluble may help in determining whether it will cause central nervous system side effects, whether it will be well absorbed when given by mouth, and whether it will be rapidly metabolized in the liver. An example of this is the β -adrenergic blocker group, of which some (e.g., propranolol and metoprolol) are lipid soluble and therefore more likely to be rapidly eliminated from the body, requiring twice-daily dosing, and also may be more likely to cause insomnia and nightmares.
5. Knowledge of whether the drug has first- or zero-order elimination may aid in deciding on dose escalations. Doubling the dose of a drug with first-order (a fixed proportion of the drug is eliminated per unit time) elimination will approxi-

mately double the antihypertensive effect, whereas the same escalation in a drug with zero-order (a fixed amount of the drug is eliminated per unit time) elimination could produce much greater effect and side effects than expected.

6. Knowledge of the mode of action of the drug is also important, because this permits the appropriate drug to be given to match the pathophysiology of the hypertension in a particular patient. For example, use of a β -blocker may benefit a young patient with systolic hypertension but may actually elevate the blood pressure in an old patient with systolic hypertension. The first patient is more likely to have elevated cardiac output (reduced by the drug) and the second to have reduced compliance in the large arteries (worsened by the drug). Also, beneficial drug combinations can be predicted from knowledge of the mode of action. For example, addition of a diuretic to therapy with an angiotensin-converting enzyme inhibitor (ACEI) is predicted to—and does—enhance efficacy by plasma volume reduction, thus increasing the reliance of the blood pressure on the renin angiotensin system. Finally, nothing damages the confidence of a patient in his physician more than to have the physician prescribe a first drug that does not cause blood pressure reduction but that does cause symptomatic side effects. This can often be prevented by knowing both the mode of action and the pathophysiology of the disease. After all, about half of the patients can be controlled with one drug and about half of the remainder with the addition of a second drug. The physician must start with the correct drug.

This chapter addresses the clinically important aspects of the pharmacokinetics of the different drug classes used for the treatment of hypertension.

These classes are as follows:

1. Diuretics (thiazides, loop diuretics, and potassium-sparing diuretics)
2. β -Adrenergic blockers
3. α_1 -Adrenergic blockers
4. Central α_2 agonists
5. ACEIs
6. Angiotensin receptor blockers
7. Direct-acting vasodilators
8. Calcium channel blockers (CCBs)
9. Selective aldosterone receptor antagonists
10. Drug classes under development

DIURETICS

Thiazides

There are many drugs in this class. Some are described in Table 49–1.

Table 49-1 Thiazides

Drug	Plasma $t_{1/2}$ (hours)	Dose Frequency (time/day)	Usual Dose (mg/day)	Maximum Dose (mg/day)
Chlorothiazide	1-2	2	125-500	1000
Chlorthalidone	40-60	1	12.5-25	50
Hydrochlorothiazide	10-12	1	6.25-25	50
Indapamide	14-15	1	1.25-2.5	5
Methyclothiazide	?	1	2.5-5.0	10
Metolazone	8-14	1	0.5-1.0	1
Polythiazide	25	1	1-2	4
Trichlormethiazide	2-3	1	1-2	4

$t_{1/2}$, half-life.

It can readily be seen from the table that there is little correlation between plasma half-life and effect half-life. All can be given once daily, except chlorothiazide, which should usually be given twice daily. The side effect profiles are similar between the drugs, and most clinicians will choose based on price rather than on drug disposition, side effects, or effectiveness.¹

The drugs as a group have good (60%-80%) absorption after oral administration, independent of dose, apart from chlorothiazide, which has poor, saturable absorption that therefore decreases further with dose increases. Giving two 250-mg tablets produces about the same blood levels as one 250-mg tablet.

These drugs have distribution volumes of 3 to 25 L/kg of body weight, indicating that most of the drug is present in the tissues rather than in the circulating compartment. This makes it unlikely that hemodialysis will remove much of the drug.

This class is defined as the “low ceiling” class of diuretics because most of the blood pressure lowering effect occurs at lower doses. Increasing the dose above this level will produce little or no additional lowering of blood pressure. On the other hand, adverse effects continue to increase in a dose-related manner. For example, hypokalemia will become more pronounced as the dose increases above 25 mg/day of hydrochlorothiazide, whereas most of the hypotensive effect occurs at 25 mg/day or less. It makes sense, therefore, to use these drugs at lower doses and to add a second drug if adequate effect is not obtained.

Blood potassium levels will stabilize about 2 weeks after a dose change, so continued measurement of blood potassium levels is usually not necessary after that time. Prevention of significant fall in blood potassium level will prevent a portion of the increased insulin resistance that is sometimes seen with the thiazide diuretics. This can most easily be done by measuring blood potassium before and 1 month after starting or changing the dose of the drug.

In the past it was thought that thiazides induced an increase in total and low-density lipoprotein (LDL) cholesterol and in triglycerides in the blood. This is true in the short term, but after 1 year of therapy, the thiazides have the same effect on lipid levels as ACEIs and CCBs.

Several troublesome but relatively rare adverse effects must also be mentioned. All the thiazides contain -SH groups and

cause reactions in patients who are sensitive. The alternative is ethacrynic acid, which does not have such a group.

Many of the thiazides can cause photoallergies, resulting in itchy skin rashes in the sun-exposed areas of the body. Stopping the drug does not always result in regression of the rash.

Loop Diuretics

Loop diuretics are shown in Table 49-2.

This group of drugs is used in the treatment of hypertension, but thiazides are preferable in all but a few clinical situations (e.g., concomitant heart failure or renal failure, or when minoxidil is also being used), as the thiazides have longer duration of action, more gradual blood pressure reduction, and fewer adverse effects.

Absorption of furosemide is incomplete and erratic, with large intersubject variation. Absorption is lower in heart failure and in renal failure, making parenteral administration (usually intravenous) a more certain way to achieve a clinical response in the short term. Absorption of the other drugs in the group does not appear to be significantly affected by these conditions.²

These drugs have high protein binding and small distribution volumes. They reach their site of action in the ascending limb of the loop of Henle by first being filtered in the glomerulus and passing from the luminal side of the tubule into the cells. This means that when renal function is reduced, there will be resistance to its diuretic effects because the drug cannot get to the site of action. Increased doses are used in this clinical situation to achieve the desired effect. Because the drug is now distributed systemically in the body but not in the urine, there is increased risk of adverse effects, particularly hearing loss with furosemide. This must be monitored when the drug is used for long periods of time at high doses.

Potassium-Sparing Diuretics

Potassium-sparing diuretics are described in Table 49-3.

Amiloride is chemically unrelated to other diuretics but has structural similarities to triamterene. The mechanism of action of amiloride, and of triamterene, is interference with the potassium-sodium exchange mechanism in the distal convoluted tubule.³ Spironolactone has a different mode of action. It is a synthetic steroid aldosterone antagonist and

Table 49-2 Loop Diuretics

Drug	F (%)	Vd (L/kg)	Protein Binding (%)	Plasma $t_{1/2}$ (hours)	Dose Frequency (times/day)	Usual Dose (mg/day)	Maximum Dose (mg/day)
Bumetanide	90	0.2	95	1.5	1	0.5-1.0	2
Ethacrynic acid	100*	?	90	1-4	2	50-100	600
Furosemide	65	0.2	95	0.5-2	2	40	160†
Torsemide	85	0.2	99	3	1	5	10

F, systemic availability after oral administration; Vd, distribution volume; $T_{1/2}$, terminal phase plasma half-life.

*A small study has measured absolute oral bioavailability and found it to be much lower (21%) when it is compared with the levels seen after intravenous administration.

†Doses up to 640 mg/day have been used, but a better approach would be to add alternative drugs to the antihypertensive regimen.

Table 49-3 Potassium-Sparing Diuretics

Drug	F (%)	Vd (L/kg)	Protein Binding (%)	Plasma $t_{1/2}$ (hours)	Dose Frequency (times/day)	Usual Dose (mg/day)	Maximum Dose (mg/day)
Amiloride	60	5	Low	7	1	10	20
Spironolactone	75	?	90	1.3	1-2	25	50
Triamterene	50	1.5	60	2	2	100	300

inhibits aldosterone effect by competing with aldosterone for mineralocorticoid receptors.

All of these drugs are well absorbed after oral administration and can be given on a once- or twice-a-day basis despite short plasma half-lives. Because of their actions, they will tend to increase plasma potassium levels and to conserve potassium. In hypertension, they are usually given with a loop or a thiazide diuretic to prevent or remedy a fall in plasma potassium levels. This is especially important in patients with concomitant heart failure, in whom circulating aldosterone levels will be high. Given alone, they are not very effective in causing reduction in blood pressure.

β -ADRENERGIC BLOCKERS

The β -blockers that are used in the emergent, or maintenance, treatment of hypertension are shown in Table 49-4.

Their antihypertensive action is probably related to their β_1 -adrenergic blocking action on the heart and on the juxtaglomerular apparatus in the kidney. The effect on the heart will reduce cardiac output and the renal effect will reduce renin secretion.

All except esmolol (given parenterally) have reasonable oral bioavailability, ranging from 30% of the administered dose of carvedilol up to about 100% for penbutolol. Complete absorption would be more desirable, as there would be less inter- and intra-subject variability in plasma levels. Some, such as propranolol, have high first-pass uptake in the liver as they pass from the gut to the systemic circulation, particularly after the first dose. This results in very high inter-subject variability in plasma levels.⁴

The degree of lipid solubility varies from low to high in this group of drugs. A low degree of lipid solubility is preferable, because there may be less likelihood of the central nervous system adverse effects of insomnia and nightmares. Nadolol and atenolol, both of which have low lipid solubility, are renally excreted and have fairly long half-lives. All of the others require hepatic metabolism for all or a major portion of their excretion. Despite a wide range of plasma half-lives, all except pindolol can be dosed on a once- or twice-a-day basis.

Many have active metabolites formed in the liver that will tend to prolong the activity of the drug, especially when given on a chronic basis. *Cardioselectivity* is a term used to describe the presence of more β_1 - than β_2 -adrenergic blocking activity. About half of this group is classified as cardioselective, but this selectivity tends to disappear as dose is increased. A cardioselective drug should have fewer adverse effects because there will be less blockade of β_2 receptors in the lungs, resulting in less bronchoconstriction, and in the peripheral blood vessels, resulting in vasoconstriction, both potentially undesirable effects.

Only two, carvedilol and labetalol, have significant α -adrenergic blocking activity to go along with the β -blocking effect. This is potentially useful because it means that there will be less likelihood of a reflex vasoconstriction to oppose the acute reduction of cardiac output. This permits these two drugs to be used in the acute reduction of blood pressure. However, it must be remembered that the β -to- α -blocking effect is at least three to one for labetalol and more than that for carvedilol, so that the afterload reducing effect is much less than the negative chronotropic and inotropic effect on the heart in patients with congestive heart failure.

Several β -blockers, including carvedilol and propranolol, stabilize membranes. This provides a theoretical advantage in

Table 49-4 β -Blockers Used in the Emergent, or Maintenance, Treatment of Hypertension

Drug	F (%)	Lipid Solubility	Protein Binding (%)	Vd (L/kg)	$t_{1/2}$ (hours)	Dosing (times/day)	Main Route of Elimination	Active Metabolites?	Cardio-Selective?	α -Adrenergic Block?	MSA?	ISA?

MSA, membrane stabilizing ability; ISA, intrinsic sympathomimetic activity; NA, drug always given parenterally, usually as a one-time dose. Main route of elimination: H, hepatic; R, renal; O, metabolized by esterases in the cytosol of red blood cells.

potentially reducing the likelihood of cardiac arrhythmias. These benefits have not been seen in clinical practice, however.

Another difference within this group is whether they are partial agonists at the β_1 receptor. The term *partial agonist* means that when the drug attaches to the receptor, it stimulates the receptor to a lesser degree than if a full agonist were to attach to it. Pindolol is the most potent partial agonist, and when the patient is resting, it results in less reduction in heart rate than other β -blockers. When the patient is undergoing even moderate exercise, this difference disappears. A second potential advantage of partial agonist activity is that it may cause less increase in triglycerides and less decrease in HDL levels. Whether this is of clinical significance is not clear. It may be of use in hypertensive patients who need a β -blocker but experience an excessive bradycardic response to other β -blockers.

Esmolol differs from the other β -blockers in having a very short plasma half-life. It is broken down in the cytoplasm of the circulating red blood cells even before it gets to the liver. This means that it has to be given by the intravenous route, which limits its use in hypertension to the emergent and operative situations. It is useful in limiting the hypertensive response to laryngoscopy and to endotracheal intubation.

α_1 -ADRENERGIC ANTAGONISTS

α_1 -Adrenergic antagonists used in the treatment of hypertension are described in Table 49–5.

Each has good and reliable absorption after oral administration. Protein binding to albumin in the blood is high, resulting in much of the drug being localized in the central compartment. Plasma half-life of the prototype drug prazosin is short, resulting in the need for administration three times a day. For an asymptomatic disorder such as hypertension, few patients can reliably take a drug long term on such a frequent schedule. Subsequent drugs doxazosin and terazosin, with the same mechanism of action, have longer residence in the blood, permitting a much easier dosing schedule to be followed. All are extensively metabolized in the liver with subsequent excretion in the urine and feces as a combination of parent drug and metabolites.⁵

The mechanism of action is competitive antagonism at postsynaptic α_1 -adrenergic receptors on the vasculature. This can result in orthostasis by preventing reflex vasoconstriction, especially in the elderly and in diabetic patients who have peripheral autonomic dysfunction. The selective blockade of postsynaptic α_1 -adrenergic receptors permits continued activation of the α_2 receptors. This results in less catecholamine release and less cardiac stimulation, which tends to reduce the compensatory increase in cardiac output.

This group of drugs has potentially beneficial biochemical effects: improvement in the lipid profile and reduction in insulin resistance. Whether these effects translate into improved morbidity and mortality has not been shown. The only outcome trial to test this hypothesis, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Disease (ALLHAT) trial, showed no benefit in heart attack prevention and harm in terms of increased heart failure and stroke with doxazosin as compared with the diuretic chlorthalidone (see Chapter 30). An infrequent but distressing adverse effect is the occurrence of priapism, which must

be treated rapidly by surgical intervention if erectile function is to be preserved.

These drugs must be started in low doses and titrated in small steps to prevent the occurrence of the “first dose phenomenon,” which results in a much greater fall in blood pressure after the first dose than is seen with subsequent doses of the same size. The effect is seen in the first hour or two after dosing and can last for up to 8 hours. Optimally, the first dose is given at bedtime to prevent exacerbation of this effect by standing upright.

CENTRAL α_2 -ADRENERGIC AGONISTS

Central α_2 -adrenergic agonists used in hypertension are described in Table 49–6.

This group of drugs has good oral bioavailability and a wide range of distribution volumes, plasma protein binding, and plasma half-lives, as shown in Table 49–6. The two older drugs can each be given on a twice- or three-times-a-day basis⁶; the newer drugs, guanfacine and guanabenz, can be given on a once- or twice-a-day basis. Potency ranges from low for methyl dopa to high for clonidine, and the daily dose requirements reflect this range. All have sedation and dry mouth as common side effects, and this seems to be inseparable from the therapeutic α_2 -agonist effect in the central nervous system. This high incidence of adverse effects limits the use of this class of agents.

Clonidine may be given as a transdermal patch that minimizes the peak plasma drug concentrations and reduces the incidence of the adverse effects. It may also be given by the intravenous route, but this can cause transient hypertensive effects as the drug acts peripherally before it penetrates into the central nervous system.

α -Methyl dopa forms the false neurotransmitter α -methyl norepinephrine in the central nervous system, and this substance stimulates inhibitory central α_2 -adrenergic receptors and reduces central sympathetic outflow. In addition, it may have a peripheral ganglionic blocking effect, which would explain its tendency to cause orthostatic falls in blood pressure. A Coombs’ positive hemolytic anemia is seen uncommonly, and rebound hypertension may be seen when higher doses of both α -methyl dopa and clonidine (more than 0.8 mg daily) are withdrawn suddenly. The same rebound may be seen when more than 32 mg/day of guanabenz is withdrawn suddenly, although the likelihood may be less than that for clonidine.

ANGIOTENSIN RECEPTOR ANTAGONISTS

Angiotensin receptor antagonists are shown in Table 49–7.

Losartan is the first of this class of nonpeptide angiotensin receptor blockers. It was introduced to overcome the disadvantages of the earlier peptide (and therefore, not orally active) drugs that antagonized both angiotensin II type 1 (AT_1) and angiotensin II type 2 (AT_2) receptors.⁷ This class of drugs has poor to moderate oral bioavailability and high plasma protein binding that, for those without avid tissue binding, means that the volume of distribution is small. The dosing frequency is once a day, even for those with a short plasma

Table 49-5 α_1 -Adrenergic Antagonists Used in the Treatment of Hypertension

Drug	F (%)	Vd (L/kg)	Protein Binding (%)	Plasma $t_{1/2}$ (hours)	Dose Frequency (times/day)	Usual Dose (mg/day)	Maximum Dose (mg/day)

*Dose-dependent half-life, 7-16 hours; active metabolite half-life, 7.5 hours.

[†]Active metabolite half-life, 10 hours.

[‡]Active metabolite half-life, 7 hours.

half-life, partly because candesartan, irbesartan, and losartan, which have short half-lives, have active metabolites that prolong their action. Also, because they are competitive antagonists, the duration of effect will depend more on residence time on the receptors than on the time in the plasma.

The mode of action is to competitively inhibit the binding of angiotensin II to its AT₁ receptors, which are found throughout the cardiovascular and renal systems.

Displacement of angiotensin II from AT₁ receptors opposes its biologic effects including smooth muscle contraction, aldosterone and catecholamine release, arginine vasopressin release, stimulation of thirst, and hypertrophy of smooth muscle in the vascular tree. The effects of the drugs depend on the activity of the renin-angiotensin system in maintaining cardiovascular homeostasis. Antihypertensive efficacy will therefore be expected to be more pronounced in younger rather than older patients.

Because this class of drugs (unlike the ACEIs) does not prevent bradykinin breakdown, there is lower likelihood of them

causing cough and angioedema. At present, many clinicians regard their place in therapy as being in patients who need an ACEI but do not tolerate them. Because they act through the renin angiotensin system, they cause greater reductions in blood pressure in patients who are volume depleted and whose blood pressure depends more on the renin angiotensin system. This has the disadvantage of introducing uncertainty about the magnitude of antihypertensive response on initial dosing but the advantage of permitting greater efficacy when they are combined with a diuretic.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACEIs are shown in Table 49-8. Most of the ACEIs are given by mouth as the prodrug to ensure adequate absorption into the systemic circulation. Captopril and lisinopril are the exceptions. Enalaprilat, the active metabolite of enalapril, is

Table 49-8 Angiotensin-Converting Enzyme Inhibitors

Drug	F (%)	Vd (L/kg)	Protein Binding (%)	Plasma $t_{1/2}$ (hours)	Dose Frequency (times/day)	Usual Dose (mg/day)	Maximum Dose (mg/day)

†Drug given intravenously for severe hypertension.

‡Data for active metabolite.

§After administration of enalapril.

given by the intravenous route as emergent treatment of severe hypertension or when oral drugs cannot be given. Limitations of enalaprilat in this clinical situation include variability in response (depending on whether the patient is volume depleted or not), a rather modest magnitude of antihypertensive effect, and a relatively slow attainment of peak antihypertensive effect.

As is usual with any class of drugs, the first one (captopril) has the same efficacy as the latter members of the class but has less-convenient pharmacokinetics. Captopril has the shortest efficacy half-life and requires three-times-a-day administration in hypertension. This has the disadvantage of reducing compliance with therapy but the advantage of a shorter duration of action. The latter effect is of use when starting therapy, because the response may be unpredictable and the short duration of effect will limit the duration of hypotension if it occurs, particularly in patients with heart failure or reduced intravascular volume. Most ACEIs have relatively small distribution volumes, indicating that much of the drug and the metabolite are concentrated in the central compartment. Captopril is the only ACEI that contains a sulphhydryl group. This has been blamed for the higher likelihood of neutropenia and proteinuria seen with large doses of captopril. Adverse effects common to the class include a dry, irritating, principally nocturnal cough in about 10% of patients. If it occurs, trial with another member of the class may not produce the same adverse effect. Angioedema of the upper respiratory tract may also be seen in about 0.1% of patients, and very rarely angioedema of the pancreatic duct may occur, causing pancreatic pseudocysts if the drug is not rapidly discontinued.

DIRECT-ACTING VASODILATORS

Direct-acting vasodilators are described in Table 49-9.

Both of these drugs are very effective when given by the oral route. They dilate the arteries but not the veins. Because they cause the anticipated homeostatic effects of reflex tachycardia and fluid retention, they are now given in combination with a diuretic and a sympathetic antagonist. Because of the particularly severe fluid retention with minoxidil, most patients will require a loop diuretic when started on this drug.⁸

Despite its short plasma half-life, hydralazine may be given on a twice-daily basis, or sometimes three times a day when higher doses are given. This is probably because the drug binds covalently to its site of action on vascular smooth muscle.⁹

The anticipated adverse effects of both drugs are headache, palpitations, and edema that may be prevented by using these drugs in combination with a diuretic and β -blocker, as indicated above. In addition, hydralazine is metabolized partly by *N*-acetylation, and that portion of the drug that is not acetylated will interact with cell constituents, eventually resulting in a lupus-like syndrome. This syndrome is more likely in patients with the slow acetylator phenotype and less likely in patients of African descent. It is less likely than systemic lupus erythematosus to involve the kidneys. Patients taking hydralazine should have an antinuclear antibody test performed annually.

Minoxidil is likely to cause hirsutism. This is a major problem for younger women, particularly those with dark hair and pale skin. Silently accumulating pericardial effusions have been seen in patients with end-stage renal disease who are treated with minoxidil.

Table 49-9 Direct-Acting Vasodilators

Drug	F (%)	Vd (L/kg)	Protein Binding (%)	Plasma $t_{1/2}$ (hours)	Dose Frequency (times/day)	Usual Dose (mg/day)	Maximum Dose (mg/day)
Hydralazine	20-50*	0.5	90	1.5	2	50	300
Minoxidil	95	2.5	Low	42	1	10	80

*Bioavailability is lower in fast acetylators and higher in slow acetylators because of differences in first-pass uptake in the liver.

CALCIUM CHANNEL BLOCKERS

CCBs are described in Table 49-10.

From a functional point of view, there are two groups of CCBs: those that block the action of the sinoatrial and the atrioventricular nodes in the heart—diltiazem and verapamil—and those that do not—the dihydropyridine group. The CCBs block voltage-dependent calcium entry of the vascular smooth muscle cells and to a lesser extent, cardiac myocytes and smooth muscle cells in the gastrointestinal tract. The latter effects are responsible for some adverse effects, namely negative inotropic effects on the heart and constipation. All CCBs will cause negative inotropic effects, which are only significant in patients with impaired ventricular function. Amlodipine and felodipine are less likely to do this than are other CCBs, possibly because of less distribution into cardiac tissue. Blood pressure lowering occurs because of reduced calcium entry into vascular smooth muscle, which relaxes the arterioles, reducing peripheral resistance.¹⁰

All CCBs are fairly well absorbed from the gut, but because of extensive first-pass uptake by the liver, systemic availability tends to be low. Amlodipine is the best absorbed CCB and has the lowest first-pass uptake. There is a significant drug interaction between grapefruit juice taken within several hours of ingesting several CCBs. Flavonoids in grapefruit juice inhibit the metabolism of the three dihydropyridine CCBs—nisoldipine,

felodipine, and nifedipine. This inhibition occurs in the cytochrome P450 enzymes in the gut wall, so that there is greater systemic availability of the drugs. Verapamil inhibits cytochrome P450 3A4 and will therefore cause higher blood levels of other drugs metabolized by this route, such as many of the hydroxymethylglutaryl coenzyme A inhibitors (statins?).

All CCBs in clinical use have high plasma protein binding, but displacement from protein by other drugs is not a significant source of interactions. The CCBs also cause ankle edema in a significant number of patients. This edema is not associated with weight gain and is not effectively treated by diuretics. CCB-induced edema has been attributed to precapillary dilation, thus raising the intravascular pressure in the capillaries and inducing extravasation of fluid.

The first three CCBs in clinical use—verapamil, nifedipine and diltiazem—had short plasma and therapeutic half-lives and had to be taken three times a day. This reduced patient compliance with therapy. For this reason, and because of questions about the safety of short-acting dihydropyridine CCBs, these drugs are used as controlled release preparations and may all be given once a day. Because absorption occurs only when the drug is in the small intestine, changes in gastrointestinal motility could significantly alter systemic availability of these controlled-release drugs. In contrast, felodipine and amlodipine have sufficiently long plasma half-lives to permit once-a-day dosing.

Table 49-10 Calcium Channel Blockers

Drug	F (%)	Vd (L/kg)	Protein Binding (%)	Plasma $t_{1/2}$ (hours)	Dose Frequency (times/day)	Usual Dose (mg/day)	Maximum Dose (mg/day)
Amlodipine	65	21	95	45	1	5	10
Diltiazem	42	5.3	85	3.9	1 *	240	540
Felodipine	15	10	99	13	1	10	10
Isradipine	19	1.6	97	8	2	10	20
Nicardipine	35 [†]	0.6	96	8.6	2*	90	120
Nifedipine	50	1	95	2.5 [‡]	1*	60	120

Verapamil	30	3.8	91	8	1*	240	480

*Controlled release preparation.

[†]Also used as intravenous preparation.

[‡]Apparent plasma half-life is up to 28 hours from controlled release preparation because of continued absorption from the gut.

SELECTIVE ALDOSTERONE RECEPTOR ANTAGONISTS

Spironolactone, a nonselective aldosterone receptor antagonist, has been used for almost 20 years in treating high blood pressure. However, it is a nonselective antagonist and binds to other steroid receptors. This results in significant side effects such as gynecomastia. Eplerenone is the first of a new class of selective competitive antagonists of the aldosterone receptor. It is administered by mouth, and its oral bioavailability is approximately 98%. The distribution volume is 1 L/kg and is approximately 60% bound to plasma proteins. It is broken down in the liver to inactive metabolites, primarily cytochrome P450 3A4. This results in the potential for significant interactions with other drugs broken down by the same pathway. The plasma half-life is 5 hours. The usual daily dose is 50 to 100 mg, administered twice daily. Adverse effects are similar to those with placebo, but there is, as would be expected, a tendency for hyperkalemia.

DRUG GROUPS UNDER DEVELOPMENT

Classes under development include potassium channel openers, dopamine agonists, serotonin-related agents, renin inhibitors, imidazolines, endothelin antagonists, and neutral endopeptidase inhibitors. Perhaps the most interesting are the neutral endopeptidase inhibitors. These drugs, which include omapatrilat and sampatrilat, are dual inhibitors of both angiotensin-converting enzyme and neutral endopeptidase. These drugs have good efficacy in lowering blood pressure and cause very few adverse effects. They have desirable pharmacokinetic profiles. However, there may be a predisposition to cause angioedema, and this has resulted in delay in obtaining FDA approval.

DRUGS USED IN THE EMERGENT TREATMENT OF HYPERTENSION

Oral drugs, such as clonidine and labetalol, are described previously. Other drugs, apart from phenoxybenzamine, are given parenterally and are described in Table 49–11. (For a complete discussion of the management of hypertensive emergencies and urgencies, see Chapter 78.)

As may be seen from the table, much of the pharmacokinetic information is missing. These are old drugs that are not used extensively now and have not been subjected to the detailed investigation that is now routine with newer drugs.

Fenoldopam mesilate is a benzazepine derivative with selective postsynaptic dopamine-1 (DA-1) receptor agonist properties and minimal adrenergic effects. Blood pressure is lowered by peripheral vasodilation and with renal artery dilation. Because of the renal artery dilation, this drug is of use in patients with severe hypertension and impaired renal function. The short plasma and therapeutic half-life require that the drug be given as an intravenous infusion, at a dose of 40 µg/ml in dextrose or saline solution. Fenoldopam is metabolized extensively in the liver, principally to inactive metabolites, by conjugation rather than by cytochrome P450 mechanisms.

Diazoxide is a direct-acting vasodilator that was formerly given orally for the treatment of severe hypertension. It caused sufficient hyperglycemia that physicians would start an oral hypoglycemic agent contemporaneously with the diazoxide. It is now used only in the emergent treatment of hypertension as an intravenous preparation. Its half-life is long and its time to peak hypotensive effect is short, so it is given as a series of small bolus injections, with measures of blood pressure prior to each bolus. As with other direct-acting arterial vasodilators, a common adverse effect is hirsutism, with vellus hair growth affecting all normally hairy areas of the body except the pubic and axillary regions.

Sodium nitroprusside is a direct acting vasodilator that acts on the arterial and venous sides of the circulation by releasing NO into the vascular smooth muscle cells. It is light sensitive, and both the infusion bag and the tubing must be shielded from light. It should be diluted in dextrose solution and, because of its very short half-life, administered with an infusion pump with the blood pressure measured by an intraarterial probe. Metabolism in the vessel walls releases cyanide, which is rapidly detoxified by endogenous thiosulphate to thiocyanate. The body can detoxify the cyanide at a rate equivalent to infusion at a rate of about 2 µg/kg/min. Faster infusion rates of nitroprusside can be safely used if exogenous thiosulphate is administered. Thiocyanate has its own toxicity, because it blocks iodine uptake by the thyroid gland and causes hypothyroidism if long-term infusions of nitroprusside are used. Blood levels of thiocyanate should be measured if nitroprusside is given for more than 48 hours and, because of the renal excretion of thiocyanate, if there is renal dysfunction.

Table 49–11 Drugs Used in the Emergent Treatment of Hypertension

Drug	Vd (L/kg)	Protein Binding (%)	Plasma t _{1/2}	Initial Dose	Maximum Dose
Fenoldopam	0.6	?	5 minutes	0.1 µg/kg/min	1.6 µg/kg/min
Diazoxide	0.2	90	28 hours	100 mg	Repeat every 10 minutes until DBP less than 100 mm Hg
Nitroprusside	?	?	4 minutes	0.3 µg/kg/min	10 µg/kg/min
Phentolamine	?	70	19 minutes	5 mg	5 mg every 2 hours to total of 20 mg
Phenoxybenzamine	?	?	24 hours*	10 mg po bid	40 mg po tid

*After intravenous administration; not known after oral administration. po, orally; bid, two times per day; tid, three times per day.

Toxicity is associated with circulating thiocyanate levels of more than 10 mg/dl.

Phentolamine is a nonselective reversible α -adrenergic antagonist that is used to treat patients with pheochromocytoma, particularly during surgery to remove the tumor. It may also be of use in clonidine withdrawal rebound hypertension. It has a short duration of action and is extensively metabolized in the liver. Because the α -adrenergic block is nonselective, presynaptic α -adrenergic receptor blockade will remove the negative feedback inhibition of catecholamine release, and cardiac output will rise to oppose the fall in blood pressure. This limits the utility of phentolamine in essential hypertension. The mode of action of both phentolamine and phenoxybenzamine means that most of the antihypertensive effect is orthostatic, and the patient may remain hypotensive when in the supine position but be hypertensive when standing or sitting. Both drugs cause severe nasal stuffiness in some patients.

Phenoxybenzamine has similar actions to phentolamine but binds covalently and therefore irreversibly to the α -receptors. Its onset of action is slow and its effect lasts for more than 24 hours. The duration of action is a function of the rate of synthesis of new α -adrenergic receptors rather than of the concentration and persistence of the drug in the plasma. Oral bioavailability is 25%, and it may be used by either the oral or the intravenous route. It is used to treat pheochromocytoma on a chronic basis.

SUMMARY

There are now many effective and safe antihypertensive agents. For most, the duration of antihypertensive effect is much longer than would be predicted from the plasma half-life of the drug.

Fixed Combination Antihypertensive Therapy

Joel M. Neutel

The aggressive use of fixed-dose combination therapy early in the management of hypertension may be the most important change clinicians can make in their attempt to achieve adequate blood pressure control in hypertensive patients. Hypertension has been identified as the most powerful modifiable risk factor for the development of cardiovascular disease,¹ and its control has been shown to significantly decrease cardiovascular morbidity and mortality.²⁻⁴ Despite this knowledge, only one third of the hypertensive patients in the United States achieve the conservative goals of 140/90 mm Hg.⁵ Because inadequate blood pressure control remains an important risk factor for coronary artery disease, it is not surprising that the reductions in coronary artery disease among hypertensive patients have been disappointing. Achieving optimal blood pressure control is the most important issue in the management of hypertension, and in the majority of hypertensive patients, it is difficult or impossible to control blood pressure with one drug.⁶⁻⁹ The use of combination therapy as first-line treatment, or early in the management of hypertension, will substantially enhance blood pressure control rates⁵ and ultimately have a significant impact on coronary artery disease among hypertensive patients.

THE IDEAL ANTIHYPERTENSIVE AGENT

The ideal antihypertensive agent would have the following qualities:

1. Highly efficacious—providing the ability to achieve adequate blood pressure control with a single agent in the majority of hypertensives
2. Provide 24-hour efficacy with once-a-day dosing
3. A high response rate—works in all groups of hypertensive patients: young, elderly, African Americans, and diabetics
4. Minimal symptomatic adverse effects
5. Minimal metabolic adverse effects
6. Affordable
7. Supported by outcomes data

No such drug exists for the management of hypertension. If it did, physicians would be using only one or two agents to manage this condition. There are in excess of 81 approved drugs for the management of hypertension,⁵ testament to the fact that the ideal antihypertensive agent does not exist. Although several new drugs and drug classes are being developed for hypertension—including renin inhibitors, aldosterone antagonists, endothelin antagonists, and vasopeptidase inhibitors—early clinical data suggest that none of these newer agents will be more effective (as monotherapy) than the drugs already available (see Chapters 11, and 69-72). Thus we must face the fact that, in terms of efficacy, we currently have what we are going to have for the next 10 years for treating hypertension.

With this in mind, the concept of combination therapy is, Can we create, from the drugs we have, the ideal antihypertensive agent? Is it possible to combine complementary agents to provide maximal efficacy and at the same time minimize side effects?

RATIONALE FOR THE USE OF COMBINATION THERAPY

The two qualities most important to physicians in their selection of antihypertensive agents are efficacy and safety. Use of combination therapy potentially optimizes these qualities.

Efficacy

The most important reason for use of combination therapy in clinical practice is that combining two complementary antihypertensive agents produces significantly greater efficacy than either of the components as monotherapy.¹⁰⁻¹² This is not surprising because the cause of hypertension is multifactorial, and many pathophysiologic factors contribute to high blood pressure. In most patients, blocking one system will activate counter-regulatory mechanisms and result in persistence of elevated blood pressure. However, when two physiologic systems are interrupted, counter-regulatory mechanisms are frequently neutralized, enabling greater reductions in blood pressure.

For example, diuretics, which stimulate the renin-angiotensin system, are ideally combined with angiotensin-converting-enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). Alternatively, diuretics may be combined with β -blockers, which inhibit the release of renin. Dihydropyridine calcium channel blockers (CCBs) increase circulating catecholamines, which also tend to activate the renin-angiotensin system. Thus, dihydropyridine CCBs may be logically combined with ACE inhibitors. On the other hand, nondihydropyridine CCBs decrease circulating catecholamines, so combination with β -blockers is not logical. Similarly, ACE inhibitors and β -blockers both seem to interrupt the renin-angiotensin system and so are not a logical combination.

The combination of two complementary antihypertensive agents often results in blood pressure reductions that are additive, and in some cases, such as low-dose bisoprolol added to low-dose hydrochlorothiazide, may be synergistic.¹³ All of the currently available fixed-dose combination products are significantly more effective than each of their components. Indeed, this is a major requirement of the U.S. Food and Drug Administration (FDA) for approval of a combination agent.

Safety

Safety and efficacy tend to move in opposite directions as we increase the dose of antihypertensive agents (Figure 50-1).

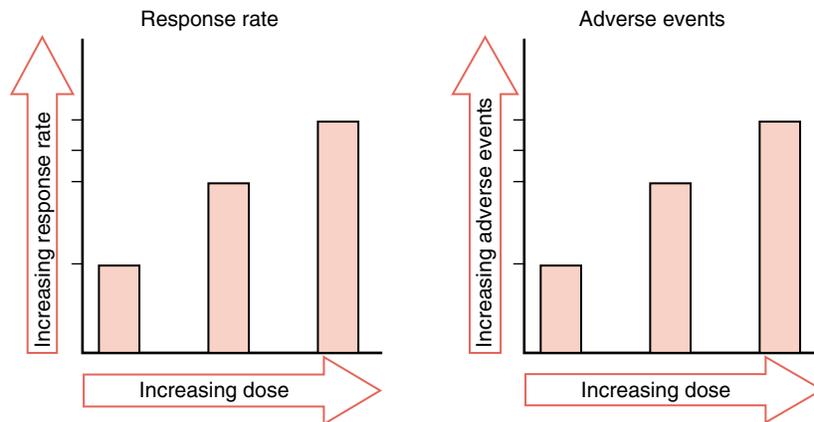

Figure 50-1 Increasing doses of antihypertensive agents result in increasing efficacy because of the dose response curve of antihypertensive agents, but it also results in increasing dose-dependant adverse events.

This frequently results in physicians accepting less-effective blood pressure control to minimize adverse effects. Most of the adverse effects of antihypertensive drugs are dose dependent, with the exception of ACE inhibitor-induced cough and angioedema. Thus, combinations that use smaller drug doses in hypertensive patients will cause fewer adverse effects. Combination therapy provides adequate blood pressure control with smaller doses of each of the components, thereby reducing dose-dependent adverse effects. For example, use of a low-dose combination of a β -blocker and a diuretic results in less fatigue, impotence, and bradycardia than higher doses of each of the components.¹³

In the management of hypertension it is better to reduce blood pressure in a physiologic manner, thus reducing adverse events. For example, dihydropyridine CCBs are powerful arterial vasodilators. Although useful in the management of hypertension, these drugs reduce blood pressure by affecting only the arterial side of the circulation, leading to frequent adverse events—for example, peripheral edema and increased proteinuria in diabetic patients with renal disease. Adding an ACE inhibitor to a dihydropyridine CCB now provides venous dilation, and the combination produces a more physiologic reduction in blood pressure involving the entire vascular tree. This combination reduces not only CCB-induced edema¹² but also proteinuria in diabetic patients with renal disease, often to a greater extent than an ACE inhibitor given as monotherapy.¹⁴ In some instances combination therapy results in fewer adverse effects than the same dose of the components given as monotherapy despite significantly greater reductions in blood pressure.^{12,15}

ADVERSE METABOLIC SIDE EFFECTS

Adverse metabolic effects of antihypertensive agents are generally dose dependent. For example, the effects of diuretics on potassium are dose dependent, as are their effects on lipids and insulin.¹⁶ Use of combination therapy facilitates blood pressure control with lower doses of diuretics, thus minimizing their metabolic effects. For example, while high doses of thiazides frequently require potassium supplementation to prevent hypokalemia, combining a thiazide diuretic with an ACE inhibitor provides adequate blood pressure control with

lower doses of hydrochlorothiazide (12.5 mg in many of the available combinations),^{17,18} thus preventing decreases in potassium. In addition, ACE inhibitors are potassium sparing, further reducing the risk of potassium loss and the need for potassium supplementation.

TWENTY-FOUR-HOUR EFFICACY WITH COMBINATION THERAPY

Use of once-a-day medication in the management of hypertension is critical to obtain patient compliance. Once-a-day agents must provide true 24-hour blood pressure control, including the last 4 to 6 hours of the dosing interval. The same principle applies to combination therapy. Most of the commercially available fixed-dose combinations have been carefully selected to include drugs that have 24-hour efficacy as monotherapy. The duration of action of the combination must be at least similar to that of the components. In some instances¹⁹ the combination of two agents results in a lengthening of the duration of action as compared with the individual components. For example, captopril as monotherapy is a short-acting ACE inhibitor, which should be dosed two or three times per day, but combining it with hydrochlorothiazide significantly lengthens its duration of action. Ambulatory blood pressure monitoring data should be used to determine the duration of action of combination antihypertensive agents.

RESPONSE RATES

Use of combination therapy results in greater efficacy across all subgroups of hypertensive patients and may have additional cardiovascular benefits. For example, ACE inhibitors and ARBs are generally less effective in African American patients, who tend to have lower plasma renin activity than Caucasian patients. Addition of a diuretic or CCB to an ACE inhibitor or ARB will stimulate the renin-angiotensin system and enhance the efficacy of the renin-angiotensin system blocker in African Americans. The blood pressure reductions seen with the combination are then similar in African American and Caucasian patients.²⁰

ACE inhibitor/ARB-diuretic combinations in African American patients also have cardiovascular benefits independent of blood pressure reduction. African Americans have often been denied renin-angiotensin system blockers because of a perceived lack of antihypertensive efficacy. This is an important misconception, particularly in light of the African American Study of Kidney Disease and Hypertension.²¹ African Americans should be treated with an ACE inhibitor or ARB to achieve the vascular protective benefits of these agents, which are independent of blood pressure. Adding a diuretic can achieve both antihypertensive efficacy and cardiovascular protection. (See Chapter 56 for a more complete discussion of the management of hypertension in African Americans.)

CONVENIENCE

There is a clear inverse relationship between the complexity of the dosing regimen and patient compliance. Clinicians recognize that polypharmacy is not well tolerated by patients and try hard to avoid it in the management of hypertension, frequently at the expense of adequate blood pressure control.

Thus, in the selection of antihypertensive drugs, two properties need to be considered to enhance convenience and compliance:

1. *Once-daily dosing.* Adherence to antihypertensive agents that are dosed once daily is greater than drugs that are dosed twice daily.²² There is little reason to prescribe antihypertensive drugs that must be taken three times a day. Many antihypertensive drugs can be safely and effectively given once daily. It is important for clinicians to select drugs that provide adequate blood pressure control over the entire 24-hour dosing interval. Some agents marketed as once-a-day preparations tend to lose efficacy during the final few hours of the dosing interval.²³ Because most antihypertensive drugs are dosed in the morning, loss of blood pressure control tends to coincide with the rapid increase in blood pressure during arousal from sleep, at the time at which the peak incidence of stroke and myocardial infarction occurs.^{24,25} It is believed, although not proven, that optimal blood pressure control during this early morning period is needed to prevent ischemic events.

Duration of action can be assessed clinically by instructing patients to omit dosing on the morning of their clinic visit. If blood pressure remains controlled 24 to 26 hours after dosing, this is good evidence of once-a-day efficacy. As discussed, most of the available fixed-dose combination drugs include agents that provide 24-hour blood pressure control as monotherapy, and the added blood pressure reduction of the combination product is sustained for 24 hours. In some cases, combining agents may even prolong the hemodynamic effect of the components.¹⁹

2. *Polypharmacy.* There is an inverse relationship between the number of drugs that patients have to take and their adherence to a regimen. This decrease in compliance is related to the following:

- a. *Convenience*—It is easier to forget to take multiple drugs.
- b. *Confusion*—Patients often become confused by multiple drugs with difficult dosing regimens and frequently dose incorrectly.

- c. *Cost*—There is higher cost with multiple drugs.

For these reasons, many physicians believe that monotherapy is more convenient and will improve compliance in the management of hypertension. However, the availability of increasing numbers of fixed-dose combination agents provides dosing that is no less convenient than monotherapy. In fact, it is more convenient to use combination therapy than monotherapy in that it is possible to decrease polypharmacy, which simplifies the dosing regimen and in many instances may reduce medication costs.²⁶

Many clinicians believe that as long as the dosing of antihypertensive medication is once daily, the number of drugs given does not influence compliance. This has been shown to be incorrect in a recent study performed in more than 6000 patients.²⁷ When patients were given amlodipine and benazepril as a single tablet, the compliance rate was significantly greater than if they were given the same drugs as two separate pills dosed once daily. Not surprisingly, the control rate was greater in the patients taking the combination product.³⁹

COST

In most instances combination therapy is no more expensive than monotherapy. Use of combination agents requires only one copayment and one dispensing fee, which may be less costly than multiple drug therapy. In addition, low-dose combination agents are usually marketed as a “package deal” in that they are more expensive than each of the components individually but less expensive than both components administered separately. High-dose monotherapy may be more expensive than combination agents. Furthermore, many patients are limited to a certain number of drugs by their medical plans (e.g., Medicaid). If they exceed this number, they are responsible for paying for their drugs. A combination agent represents only one drug and its use allows another drug to be covered by the plan, resulting in decreased cost for the patient.

Higher blood pressure is associated with higher management costs. To the extent that blood pressure can be controlled more quickly with combination therapy, the cost of treating hypertension is reduced.

OUTCOMES DATA

More outcomes data are available for combination therapy than for monotherapy. Virtually all recent outcomes studies in hypertension have utilized combination therapy, although the second, third, and fourth drugs in the regimens were usually “add ons” to an initial agent to which patients were randomized.^{3,4,6-9} One of the requirements of outcomes studies is to provide their participants adequate blood pressure control. To achieve accepted blood pressure goals, the majority of patients enrolled in outcome studies require two or more drugs.⁵⁻⁹ Importantly, studies such as the United Kingdom Prospective Diabetes Study and Hypertension Optimal Treatment²⁹ have shown a significant reduction in cardiovascular disease outcomes in patients with tight control compared with those with less tight control.

The Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial (FACET) was one of the few outcomes

studies that compared combination therapy to monotherapy.³⁰ Patients with type 2 diabetes and hypertension were randomized to fosinopril or amlodipine. If their blood pressure was not adequately controlled, the alternative drug could be added. Patients were followed for 36 months to assess the development of cardiovascular disease. At the end of the study, patients treated with the ACE inhibitor had less cardiovascular disease than those treated with the CCB, but patients treated with the combination of the two drugs had the greatest reduction of cardiovascular disease incidence, probably related to the greater blood pressure reduction achieved with two agents.

In the ALERT study (A Lotrel Evaluation of Hypertensive Patients with Arterial Stiffness and Left Ventricular Hypertrophy),³¹ patients were treated with a low-dose combination of amlodipine plus benazepril (5/20 mg) or with high-dose amlodipine (10 mg) or high-dose benazepril (40 mg) as monotherapy. Blood pressure reductions were similar in patients treated with the combination agents or the high-dose amlodipine but slightly less in those treated with high-dose benazepril. However, patients treated with the combination therapy had greater improvement in arterial compliance and greater regression of left ventricular hypertrophy (LVH) than those treated with either high-dose monotherapy. This study demonstrates that the combination of two complementary drugs results in greater cardiovascular benefits than high-dose monotherapy. Importantly, although blood pressure reduction in patients treated with the combination therapy was not different from that in patients treated with high-dose amlodipine, the ACE inhibitor in the combination treatment resulted in greater improvement in arterial compliance and greater regression of LVH. This clearly demonstrates the benefit of an ACE inhibitor, beyond blood pressure control, on cardiovascular protection. Furthermore, the combination of amlodipine and benazepril resulted in greater improvement in arterial compliance and greater regression of LVH than high-dose benazepril, demonstrating that the higher dose of the ACE inhibitor could not offset the benefit afforded by the greater reduction in blood pressure achieved with the combination in terms of vascular protection.

These findings suggest that an ACE inhibitor, even at smaller doses, in a combination product that provides larger blood pressure reductions has a greater cardiovascular protective effect than a high-dose ACE inhibitor with smaller reductions in blood pressure. Thus, greater cardiovascular protection is achieved by adding a second drug to a patient inadequately controlled on an ACE inhibitor than by uptitrating the ACE inhibitor. Additional benefit may also be associated with more complete blockade of the renin-angiotensin system, achieved by including high doses of an ACE inhibitor in combination treatment. Findings of the ALERT study illustrate the principle that both blood pressure control and vascular protective effects of an antihypertensive regimen are critical in the attempt to achieve target organ protection.

ACHIEVING RAPID BLOOD PRESSURE CONTROL

The common teaching is that there is no great urgency to achieve blood pressure control and that this process can take 3 to 6 months. It is believed that there may be fewer side

effects with a slower, smooth reduction in blood pressure over several months. However, there is now convincing evidence that “the longer you take to achieve blood pressure control, the less likely you are to get to goal blood pressure”³² and, more importantly, the more likely your patient is to suffer a cardiovascular event related to uncontrolled blood pressure.⁹ Many obstacles to the management of hypertension entice physicians to accept inadequate blood pressure control (Figure 50-2). It has been clearly shown that there is a negative association between the number of changes that a physician makes in antihypertensive treatment and patient compliance at 1 year.

Achieving rapid control has several benefits:

1. Patients tend to have more confidence in their physicians.
2. Patients believe that their drugs are working effectively if they get to the goal blood pressure outlined by their physicians more rapidly, and so they tend to be more compliant. On the other hand, if a patient is started on a low dose of a drug, which has minimal effects on his or her blood pressure, but has a potential for adverse events (as outlined in a package insert), the patient is likely to be disheartened and discontinue the drug in favor of nonpharmacologic treatment, which is perceived to be just as effective.
3. Reluctance of doctors to titrate. Many physicians prefer the flexibility of being able to titrate monotherapies and feel that this is limited by the use of fixed combination therapy. However, in actual practice, most physicians do not uptitrate doses of antihypertensive and lipid-lowering drugs for patients whose blood pressures and/or lipid levels are uncontrolled. Physicians often avoid titration over concerns of cost, adverse events, polypharmacy, metabolic side effects, patient perception (higher doses mean they are sicker), or because they may have improved (but not controlled) blood pressure and so refocus on another disease entity.³³ Undertreatment results in inadequate blood pressure control and its associated cardiovascular risks. Early use of combination therapy often avoids these problems.
4. Cardiovascular protection. Earlier blood pressure control affords cardiovascular protection by reducing the stress of elevated blood pressure on the vasculature, thus lowering the risk of an acute event. Data from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) and Valsartan Antihypertensive Long-term Use Evaluation (VALUE) provide convincing evidence that protection from cardiovascular disease outcomes is greatest in patients who achieve blood pressure control most rapidly.^{7,9} This is particularly true in patients who are at high risk because of coexistent cardiovascular disease or multiple risk factors.

The concern over achieving rapid blood pressure control is whether it is associated with a greater number of adverse events caused by precipitous reductions in blood pressure. Several factorial studies have compared low-dose combination agents with each of their components given first line in achieving blood pressure control. These multifactorial studies are required by the FDA to gain approval for a combination product. As is shown in Tables 50-1 and 50-2, despite significantly greater reductions in blood pressure achieved with the combination agent, there were no significant differences in adverse effects. Thus, blood pressure reduction over days to weeks (as occurs with combination therapy) is well tolerated and has benefits as compared with blood pressure reduction that requires months. This should be distinguished from

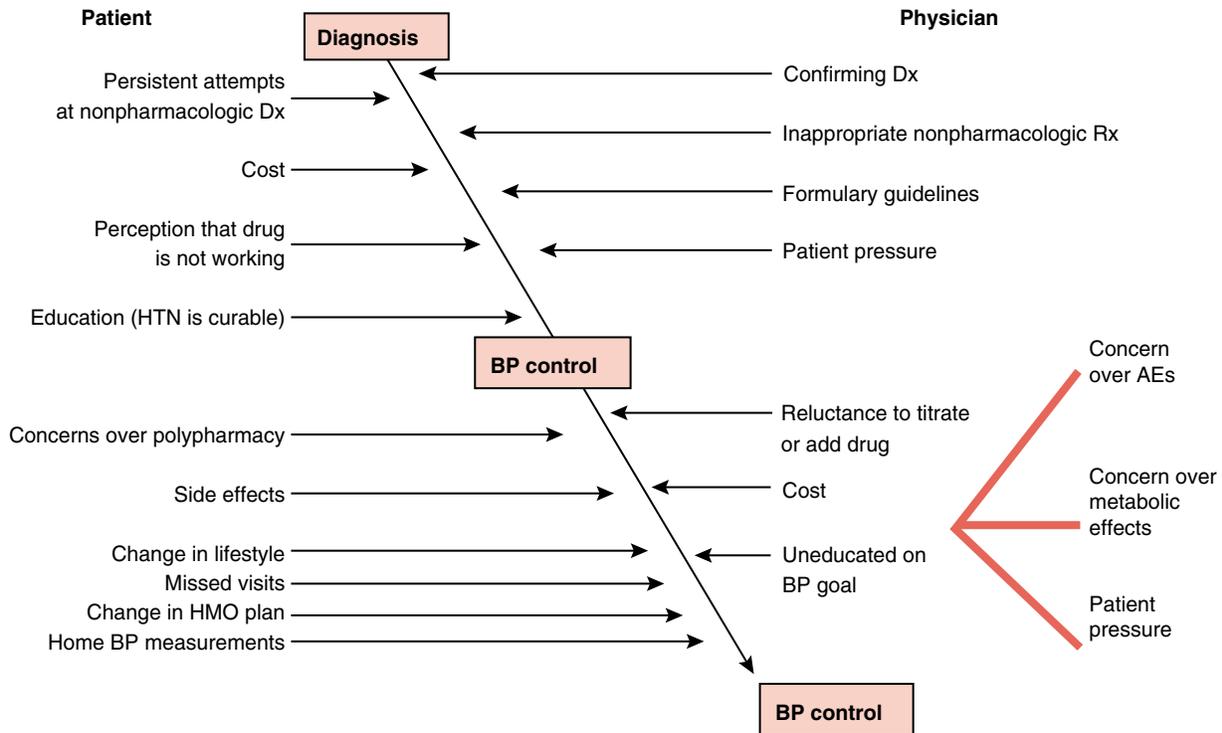

Figure 50-2 The clinical path from the diagnosis of hypertension to BP control is fraught with many potential obstacles, which may result in the acceptance of inadequate BP control. To the extent that BP is controlled earlier (*hatched box*), several of the obstacles are potentially eliminated, increasing the chance of achieving adequate BP control.

Table 50-1 BP Reductions and AEs with First-Line Use of Amlodipine, Benazepril, or the Combination

Placebo (77)	Amlodipine 5 mg (77)	Benazepril 20 mg (77)	Benazepril 5/20 mg (77)

blood pressure reduction that occurs in minutes to hours, as with sublingual nifedipine. Extremely rapid blood pressure reduction with this agent has been shown to cause adverse effects and serious cardiovascular outcomes, including acute myocardial infarction.

Caution should be exercised with first-line use of combination therapy in the elderly. Despite frequently requiring multiple drugs to control their blood pressures, these patients are prone to postural hypotension and may take longer to reset their baroreceptors. A slower, more cautious approach to blood pressure reduction may be prudent in these patients. It is important to mention that although the recommended goal in the elderly is a systolic blood pressure of <140 mm Hg, in many cases older people cannot tolerate this blood pressure. This is the one instance in which we should back off to a point where patients have no adverse effects and accept inadequate blood pressure control, with the knowledge that for every 20-mm Hg reduction in systolic blood pressure, the rate of cardiovascular disease is halved.⁴

IMPROVING WORLD-WIDE BLOOD PRESSURE CONTROL

One of the most important issues facing us in clinical medicine is the fact that fewer than one third of hypertensive patients have adequately controlled blood pressure when using a blood pressure of 140/90 mm Hg as goal, which many would argue is too high. This is troubling, considering that hypertension is the most important modifiable cardiovascular risk factor and that coronary artery disease is the most common cause of death in the industrialized world. Inadequately controlled blood pressure seen in patients on antihypertensive medication remains an important risk factor for coronary artery disease.

Complementary antihypertensive agents—for example, an ARB plus hydrochlorothiazide, an ACE inhibitor plus a dihydropyridine CCB, or a β -blocker plus hydrochlorothiazide—achieve rates greater than 70%. Thus, use of complementary combination agents has the potential to sharply increase control rates by 30% to 40%. This would have a dramatic impact on the incidence of cardiovascular disease worldwide. Earlier and more aggressive use of combination therapy for hypertension may be one of the most important changes that we can make in our approach to antihypertensive management.

Outcomes studies have shown that diastolic blood pressure goals can be achieved in >90% of patients and systolic goals in >60% of patients.^{7-9,35} This clearly demonstrates that we have the tools to control hypertension in most patients. These studies have also shown that in more than 75% of patients, two or more drugs are required to achieve blood pressure goals.

AVAILABLE COMBINATION AGENTS

Multiple fixed-dose combination agents are available for use in the management of hypertension (Table 50-3). All combi-

nation agents contain drugs that are complementary in action and provide an additive or even synergistic reduction in blood pressure, as well as side effect profiles that are better than or not different from their components. Over the next few years, many more antihypertensive combination agents will be added to the market, including three-drug combinations, and even combinations of agents for different disease processes—for example, hypertension and dyslipidemia. To provide physicians maximum flexibility in dosing, new combination agents are being developed by using all the recommended doses of each of the components.

The realization that cardiovascular risk factors seldom occur in isolation and that the presence of two or more cardiovascular risk factors are synergistic in their ability to cause cardiovascular disease has resulted in development of combination agents, which include drugs for the treatment of different disease processes. This represents a whole new era in combination therapy. For example, it is estimated that there are 27 million hypertensive patients in the United States³⁶ who also have dyslipidemia and require treatment of both conditions. However, frequently only the hypertension is treated pharmacologically and the dyslipidemia is treated nonpharmacologically in an effort to reduce polypharmacy. A novel new single-pill combination of atorvastatin plus amlodipine has become available in the United States.³⁷ This will enable clinicians to treat both conditions with a convenient single-drug preparation and will almost certainly decrease cardiovascular risk in these patients and improve patient compliance for these two important cardiovascular risk factors. Other similar combination agents are currently being developed, and it is likely that combination agents that include drugs for the treatment of other cardiovascular risk factors will be developed in the future. These advances in available therapeutic agents will facilitate achieving goals in patients with the metabolic syndrome.

SUMMARY

Combination therapy provides a modality of treatment that is much closer to the “ideal antihypertensive” agent than anything we have currently or will have in the foreseeable future for the treatment of hypertension. The success rate in achieving blood pressure goals and decreasing cardiovascular events in hypertensive patients is greater with combination therapy than with monotherapy.

Hypertension is a multifactorial disorder that is difficult to control with monotherapy in many patients. Blocking two or more blood pressure regulatory systems provides a more effective and more physiologic reduction in blood pressure that is more likely to get patients to goal. This is critical in the prevention of cardiovascular disease. Use of combination therapy as first-line treatment, or early in the management of hypertension, is perhaps the most important change that can be made in attacking the major public health problem of poorly treated hypertension.

Table 50-3 Antihypertensives Available as a Fixed-Dose Combination Product

Class	Combination	Trade Name
β-Adrenergic Blockers and Diuretics	Atenolol 50-100 mg/clorthalidone 25 mg	Tenoretic
	Bisoprolol 2.5-10 mg/HCTZ 6.25 mg	Ziac*
	Metoprolol 50-100 mg/HCTZ 25-50 mg	Lopressor HCT
	Nadolol 40-80 mg/bendroflumethiazide 5 mg	Corzide
	Propranolol 40-80 mg/HCTZ 25 mg	Inderide
	Propranolol ER 80-160 mg/HCTZ 50 mg Timolol 10 mg/HCTZ 25 mg	Inderide LA Timolide
ACE Inhibitors and Diuretics	Benazepril 5-20 mg/HCTZ 6.25-25 mg	Lotensin HCT
	Captopril 25-50 mg/HCTZ 15-25 mg	Capozide*
	Enalapril 5-10 mg/HCTZ 12.5-25 mg	Vaseretic
	Lisinopril 10-20 mg/HCTZ 12.5-25 mg	Zestoretic; Prinzide
Angiotensin II Receptor Blockers and Diuretics	Losartan 50 mg/HCTZ 12.5-25 mg	Hyzaar
	Valsartan 80-160 mg/HCTZ 12.5-25 mg	Diovan HCT
	Irbesartan 150-300 mg/HCTZ 12.5 mg	Irbesartan HCT
	Telmisartan 40-80 mg/HCTZ 12.5 mg	Telmisartan HCT
	Olmesartan 20-40 mg/HCTZ 12.5-25 mg	Olmesartan HCT
	Candesartan 16-32 mg/HCTZ 12.5 mg	Candesartan HCT
Calcium Antagonists and ACE Inhibitors	Amlodipine 2.5-10 mg/benazepril 10-20 mg	Lotrel
	Diltiazem 180 mg/enalapril 5 mg	Tezzem
	Felodipine 5 mg/enalapril 5 mg	Lexxel
	Verapamil 180-240 mg/trandolapril 1-4 mg	Tarka
Other Combinations	Clonidine HCl 0.1-0.3 mg/chlorthalidone 15 mg	Combipres
	Deserpidine 0.25-0.5 mg/methyclothiazide 5 mg	Enduronyl (Forte)
	Guanethidine 10 mg/HCTZ 25 mg	Esimil
	Hydralazine 25-100 mg/HCTZ 25-50 mg	Apresazide
	Hydralazine 25 mg/reserpine 0.1 mg/HCTZ 15 mg	Ser-Ap-Es; Unipres; Tri-Hydroserpine
	Methyldopa 250 mg/chlorothiazide 150-250 mg	Aldoclor
	Methyldopa 250-500 mg/HCTZ 30-50 mg	Aldoril
	Prazosin 1-5 mg/polythiazide 0.5 mg	Minizide
	Rauwolfia 50 mg/bendroflumethiazide 4 mg	Rauzide
	Reserpine 0.125 mg/Chlorthalidone 25 mg	Demi-Regroton
	Reserpine 0.125 mg/chlorothiazide 250-500 mg	Diupres
	Reserpine 0.125 mg/HCTZ 25-50 mg	Hydropres; Hydroserpin
	Reserpine 0.125 mg/hydroflumethiazide 50 mg	Salutensin (-Demi)
	Reserpine 0.25 mg/polythiazide 2 mg	Renese-R
	Reserpine 0.1 mg/trichlormethiazide 2-4 mg	Metatensin

ACE, angiotensin-converting enzyme; HCTZ, hydrochlorothiazide.

Chronotherapeutics in the Treatment of Hypertension

Michael H. Smolensky, Ramon C. Hermida, Francesco Portaluppi, Erhard Haus, Alain Reinberg

Chronotherapeutics is the purposeful timing of medications, with or without the utilization of special drug-release technology, to proportion serum and tissue concentrations in synchrony with known circadian rhythms in disease processes and symptoms as a means of enhancing beneficial outcomes and/or attenuating or averting adverse effects.¹ The concept of chronotherapeutics, although relatively new to hypertension and cardiovascular medicine, was first introduced and proven worthy in clinical medicine in the 1960s; the morning alternate-day corticosteroid tablet dosing schedule was introduced as a convenient means of minimizing the adverse effects of such antiinflammatory medications as prednisone and methylprednisolone.^{2,3} The chronotherapy of hypertension takes into account the clinically relevant features of the 24-hour pattern of blood pressure (BP) (i.e., the accelerated morning rise at the commencement of diurnal activity and the extent of decline during nighttime sleep) plus potential administration-time (circadian rhythm) determinants of the pharmacokinetics and dynamics of individual antihypertensive medications. Herein, we focus on the chronotherapy of hypertension; however, as necessary background we first present the major concepts and mechanisms of biologic timekeeping.

BIOLOGIC RHYTHMS AND BIOLOGIC TIME STRUCTURE

Biologic processes and functions are organized in time as rhythms of discrete periods. Ultradian rhythms, exemplified by neural and neuroendocrine activities, exhibit periods in the range of seconds, minutes, or hours. Infradian rhythms, characteristic of many biologic processes and functions, exhibit periods much longer than 24 hours, in the range of days (~week), weeks (~month, e.g., menstrual cycle), and months (~year). Circadian (*circa* = about; *dies* = day) rhythms, characteristic of nearly every life process, exhibit 24-hour or near-24-hour variation and are important to clinical medicine. They play a role in the pathophysiology of many chronic disease states, and they may influence the response to diagnostic tests, as well as the therapeutic efficiency and side-effect profile of prescribed treatments.^{1,4}

The body's circadian rhythms are controlled by an endogenous master clock network composed of the paired suprachiasmatic nuclei (SCN), located within the hypothalamus, and the pineal gland through its 24-hour cycle of melatonin synthesis and secretion.^{5,6} The activities of specific genes (e.g., *per*¹, *per*², *per*³, *bmal*, *clock*, and *CRY*) and their gene products along with the cyclic (nocturnal) circulation of melatonin constitute the mechanism of circadian timekeeping.^{6,7} This

master clock network orchestrates the period and staging of the multitude of subservient peripheral circadian clocks located in cells, tissues, and organ systems. The end effect is an ordered temporal organization of the biology during each 24-hour period in support of peak functioning during diurnal activity and of rest and repair during nocturnal sleep.

Circadian rhythms are generated and coordinated by the genetically inherited brain clock network. Interestingly, the inherited period of circadian clocks, for as yet unknown reasons, is not precisely 24 hours.⁸ The inherited period of the master clock of most persons is slightly greater than 24 hours (e.g., 24.2 hours), while in some it is slightly less than 24 hours. The master and subservient peripheral circadian clocks are synchronized to an exact 24-hour ambient and social cycle by specific external time cues, the most important being the environmental light-dark cycle.^{9,10} The features of the natural light and dark cycle vary predictably both over the 24 hours and year. The central clock network relies on the 24-hour environmental light-dark cycle to titrate its period to exactly 24 hours. It also relies on information derived from sensing the duration of the daily environmental photoperiod to adjust the biology seasonally as circannual (~1-year) rhythms. Ambient light-dark time cues sensed by specialized noncone, nonrod photoreceptor cells of the retina are conveyed to the SCN and pineal gland via the retinohypothalamic neural tract.¹⁰ Serum melatonin concentration displays a prominent circadian rhythm, with its synthesis and secretion occurring almost exclusively during nighttime sleep. Exposure to light at an atypical time—during the middle of the night, which is the case when working nights or when rapidly traveling across time zones—induces compensatory adjustment of the SCN-pineal gland clock network during the several days thereafter and in turn the staging of the circadian time structure.^{11,12} Daytime light exposure exerts no effect on the SCN-melatonin clock network, while light exposure very late at night or during the initial hours of sleep delays the body clock and melatonin rhythm and ultimately the staging of all the other circadian rhythms. In contrast, light exposure in the early morning hours, close to the end of the sleep span, advances the melatonin and other circadian rhythms.

The integrity of the circadian time structure is central to efficient biological and cognitive functioning. This is amply illustrated by the acute feelings and complaints—the symptoms of jet lag—that result from the abrupt alteration of the habitual sleep-wake cycle and ensuing transient disruption of the circadian time structure following the rapid transmeridian displacement of travelers by jet aircraft.¹³ Recurrent and chronic disturbance of the circadian time structure, common in career shift and night workers, is associated with elevated risk of sleep disorders, peptic ulcer, coronary heart disease

(CHD), cancer, and other medical problems.¹⁴⁻¹⁶ Some of these health problems may result, at least in part, from the inhibition of melatonin production due to light exposure during night work.^{15,16} Substantiation of the health risks of career shift workers implies that therapeutic interventions should preserve the circadian timekeeping network and the body's temporal organization. Indeed, the integrity and strength of the circadian time structure of cancer patients has been shown to be a sensitive predictor of the response to and outcome of chemotherapy.¹⁷

CIRCADIAN BLOOD PRESSURE RHYTHM IN HYPERTENSION

Twenty-four hour intraarterial and ambulatory BP monitoring (ABPM) studies clearly reveal the circadian pattern and features of systolic blood pressure (SBP) and diastolic blood pressure (DBP) (Figure 51-1, A). In diurnally active normotensive persons the pattern is characterized by a decline during nighttime sleep of 10% to 20% from the daytime mean, sharp morning rise coincident with the commencement of daily activity, elevated level during the daytime and descending level in the evening. This day-night BP cycle results both from endogenous factors (circadian rhythms in autonomic nervous system and endocrine function) and exogenous factors (predictable-in-time differences in posture, stress, and activity).^{18,19} The 24-hour BP pattern is much the same in the majority of uncomplicated essential (primary) hypertension patients except that either the temporal oscillation occurs around an abnormally elevated 24-hour mean or the amplitude of change is exaggerated resulting in an abnormally high level of pressure during a significant portion of the day. The BP pattern in secondary hypertension is often different. The extent of the nocturnal decline, relative to the daytime mean, may be blunted (less than 10%) or even reversed, with the sleep-time BP being higher than the daytime BP.²⁰

Hypertension is a well-known risk factor for cerebrovascular and cardiovascular accidents. During the past two decades specific features of the 24-hour BP pattern have been assessed as potential sources of injury to target tissues and as triggers of cardiac and cerebrovascular events in hypertensive patients. Indeed, the prominent 24-hour variation in the occurrence of a variety of acute cardiovascular events, such as myocardial infarction (MI), angina, cardiac arrest, sudden cardiac death, and pulmonary embolism, has been shown to be closely related to the circadian BP pattern of hypertensive persons.²¹ For example, the rate of rise of BP coincident with the commencement of diurnal activity has been identified as an independent predictor of one's risk of morning stroke and acute coronary syndrome, and is also hypothesized to be a trigger for MI at this time of day.²²⁻²⁷ Interestingly, recent studies reveal that the 24-hour pattern and the characteristic morning peak in the occurrence of both ischemic²⁸ and hemorrhagic²⁹ stroke is the same in normotensive and hypertensive persons. Moreover, other cardiovascular events, such as acute aortic dissection, display prominent 24-hour variation, with a significant morning peak both in hypertensive and normotensive persons.³⁰ Taken together, all of these observations strengthen the suggestion that the morning surge in BP (whether in the presence or absence of hypertension) is a crucial determinant of the rupture of a vulnerable and critically weakened arterial wall.³¹

A growing number of studies also indicates that the extent of the nocturnal BP decline is deterministic of cardiovascular injury and risk. Absence of the normal 10% to 20% sleep-time BP decline is associated with elevated risk of target organ injury, particularly to the heart (left ventricular hypertrophy [LVH] and MI), brain (stroke), and kidney (albuminuria, progression to end-stage renal disease [ESRD]).^{20,32-35} On the other hand, too great a decline in the sleep-time BP by more than 20% of the daytime mean (i.e., superdipping) may result in nocturnal hypotension, with heightened risk of nighttime stroke, ischemic ocular disorder, and perhaps falls with resultant fractures due to syncope with sudden change in posture (e.g., on bathroom use).³⁶⁻³⁹ The chronotherapy of hypertension takes into account the epidemiology of the various features of the day-night BP pattern. The specific goals of chronotherapy are discussed in the next section

CHRONOTHERAPY OF BLOOD PRESSURE-LOWERING MEDICATIONS

The pharmacotherapy of hypertension has been strongly influenced by the concept and assumptions of homeostasis. Until the last 10 years or so, the vast majority of the medical community believed SBP and DBP to be relatively constant throughout the 24 hours.⁴⁰ Consequently, it was deduced that a major goal of antihypertensive pharmacotherapy ought to be constancy of medication level throughout the 24-hour dosing interval. The application of intraarterial and ABPM methods during the past 10 to 15 years has clearly documented the prominence of the 24-hour variation in both SBP and DBP. In essential hypertension, as schematically represented in Figure 51-1, B, the relatively constant medication level achieved by conventional (homeostatically styled) antihypertensive therapies may be lower than required in the morning when SBP and DBP surge to peak or near-peak levels, whereas it may be higher than required during nighttime sleep when SBP and DBP decline to their lowest level.

The goals of the chronotherapy of essential hypertension are significant moderation of the morning accelerated rise in BP and reduction of abnormally elevated daytime, nighttime, and 24-hour BP means, without overcorrection (induction of superdipping) of sleep-time SBP and DBP. One way to achieve these goals is to utilize special drug-delivery technologies. The chronotherapeutic perspective of 24-hour BP control entails the purposeful tailoring of medication level over the 24 hours in close synchrony with the known (and expected) day-night pattern in SBP and DBP to optimize effect. A key premise of the chronotherapy of essential hypertension is that some 15% to 20% of each dose of once-a-day conventional medications is wasted by maintaining greater than required drug concentration during nocturnal sleep when BP is lowest, and not uncommonly normal in mild hypertension (Figure 51-1, B). Chronotherapeutic formulations rely on unique technology to redistribute this proportion of the daily dose to the time of day when BP rises to peak or near-peak levels and when the greatest concentration of antihypertensive is required for BP control. Unique drug-delivery technology, or in some instances bedtime dosing times of certain conventional medications, is thus utilized to ensure that peak and trough concentrations of antihypertensive medications are circulated in synchrony with predicted greatest and lowest SBP and DBP,

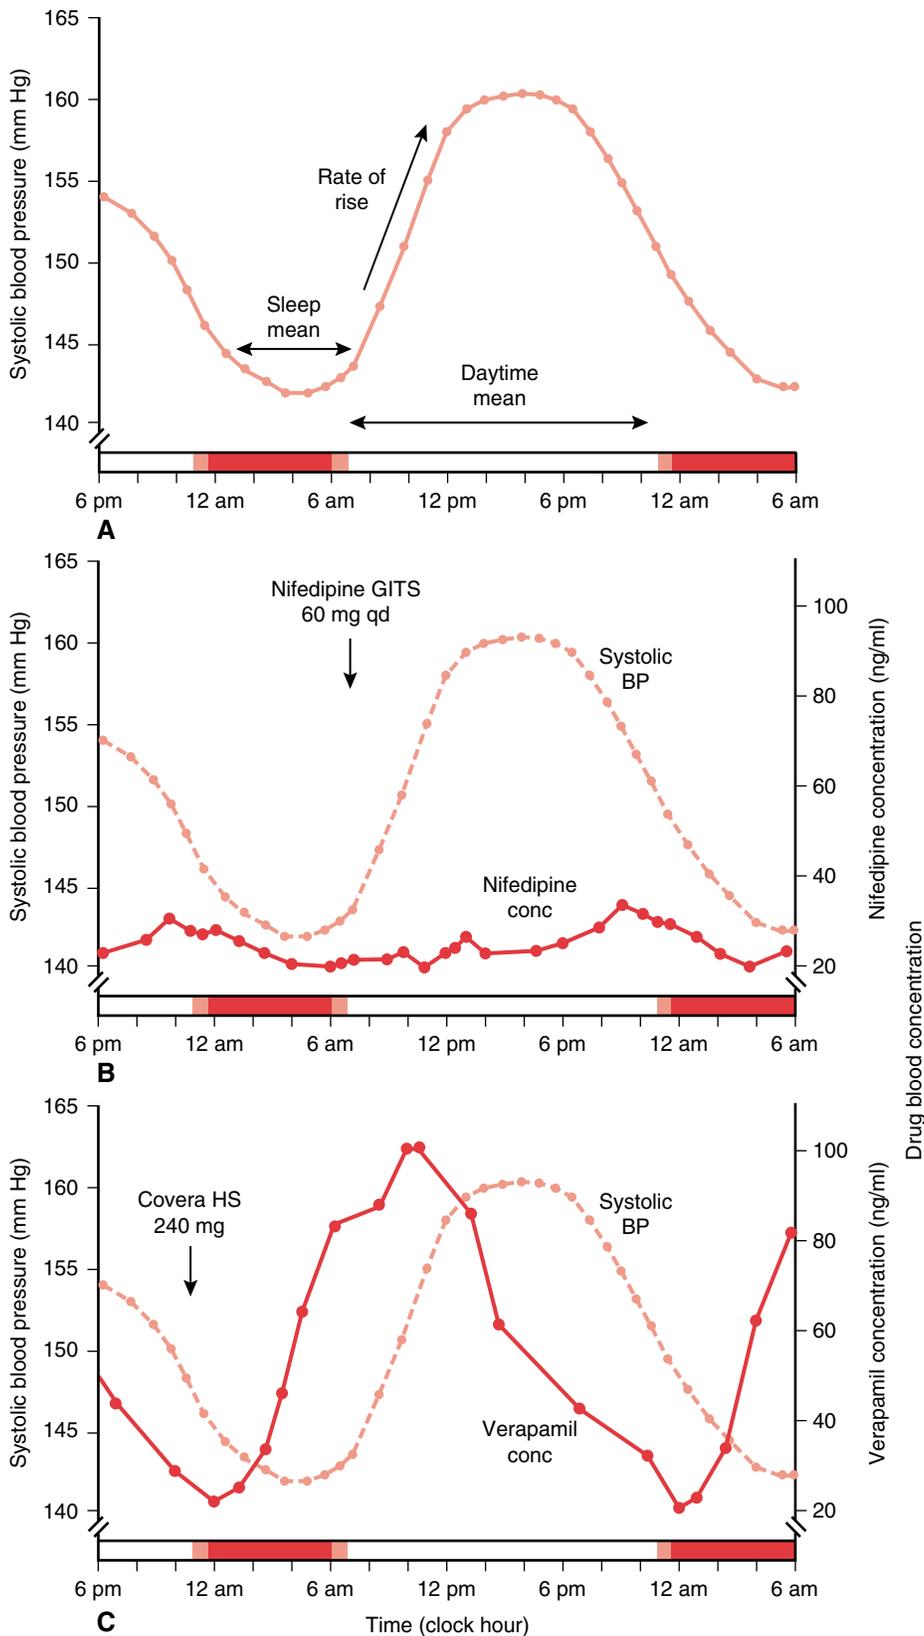

Figure 51-1 **A**, Clinically important features of the circadian rhythm of blood pressure (BP) in essential hypertension (EH): rate of rise and level of BP in the morning, sleep-time, diurnal, and 24-hour BP means and dipping status (mean daytime BP – mean sleep-time BP/mean daytime BP \times 100%). **B**, BP circadian rhythm in EH relative to the steady-state nearly constant nifedipine concentration produce by morning ingestion of 60 mg of the (homeostatically styled) conventional nifedipine GITS formulation. The nearly constant blood drug concentration is likely to be too low in the morning to adequately control peak or near-peak values of SBP and DBP in EH that occur at this time of day, and it is likely to be greater than needed to control SBP and DBP during nighttime sleep when they decline to lowest levels of the 24 hours. **C**, The circadian BP rhythm in EH is depicted in relation to the 24-hour temporally modulated verapamil concentration following ingestion of 240 mg of COER-verapamil chronotherapy at bedtime. Note that the 24-hour pattern in verapamil concentration varies purposefully during the 24 hours in close synchrony with the expected circadian BP variation in EH to enhance control of the elevated morning and afternoon SBP and DBP and to avoid their excessive reduction during sleep when they are lowest during the 24 hours. Dark and light regions of the horizontal time axis indicate, respectively, the spans of nighttime sleep and daytime activity.

respectively, during the day and night. In the following section, we review those specific formulations that are now marketed—at least in the United States—as chronotherapies of hypertension.

MARKETED CHRONOTHERAPIES OF HYPERTENSION

Calcium Channel Blockers

The calcium channel blocker (CCB), controlled-onset, extended-release (COER)–verapamil was the first special drug-delivery tablet used for chronotherapy of hypertension (and stable angina pectoris^{41,42}). COER–verapamil (United States: Covera HS; other markets: Chronovera) was approved in the United States by the Food and Drug Administration (FDA) in 1996 for marketing by the Searle Pharmaceutical Company. The drug-delivery technology of this tablet medication delays the release of verapamil for approximately 4 to 5 hours following bedtime ingestion as recommended. Medication is released thereafter so the highest blood concentration is achieved in the morning around the time of awakening, generally between 6 and 10 A.M., with an elevated level sustained throughout diurnal activity (Figure 51–2, A). The half-life kinetics of verapamil results in a progressive decline of drug level in the evening and over night, so the reduced (trough) concentration occurs during nighttime sleep when BP in essential hypertension is lowest.⁴³

Multicenter clinical trials⁴⁴ of this verapamil chronotherapy utilizing 24-hour ABPM methods document the enhanced control of the morning BP rate of rise and level (Figure 51–3, A). Moreover, a statistically significant dose (placebo and 120, 180, 360, 540 mg)-dependent reduction of SBP and DBP was verified, both at the peak (between 6 and 10 A.M.) and trough (between 6 and 10 P.M.) drug concentration times. COER–verapamil has been shown to be therapeutic for both dipper and nondipper hypertensive patients; in nondippers, it effectively reduces abnormally elevated morning as well as nocturnal BP, particularly SBP, in a dose-dependent manner.⁴⁵ Furthermore, it is as effective in African Americans as in Caucasians.⁴⁶ COER–verapamil compared with the CCB nifedipine GITS formulation, which utilizes a special drug-delivery system to achieve near-constancy in drug concentration throughout the 24 hours, achieves significantly better BP control during the morning when BP typically rises to highest or near-highest levels.⁴⁷ Clinical trials show that COER–verapamil is safe. No significant differences were detected in reported side effects between COER–verapamil and placebo, apart from dose-related constipation and second-/third-degree atrioventricular block with the highest (540 mg) dose.⁴⁴

Chronotherapeutic oral drug absorption system (CODAS)–verapamil is a second special drug-delivery–based CCB chronotherapy of hypertension. CODAS–verapamil (Verelan PM, Schwarz Pharma) was approved by the FDA in 1999. Release of verapamil from the polymer-coated beads of this capsule medication following recommended bedtime ingestion is delayed for approximately 4 hours (Figure 51–2, B). Medication is then dispersed in increasing amount so that peak blood concentration is achieved in the morning, between 6 and 10 A.M., when SBP and DBP are expected to rise to peak or near-peak levels.⁴⁸

Two placebo-controlled, parallel-design, double-blind 24-hour ABPM trials involving stages 1 and 2 essential hypertensive patients document the exaggerated reduction of BP during the initial hours of diurnal activity (see Figure 51–3, B). Furthermore, they substantiate the dose (placebo and 100, 200, 300, 400 mg)-dependent reduction of SBP and DBP both at the peak, between 6 and 10 A.M. when BP is typically greatest, and at the trough, between 6 and 10 P.M. when BP declines to near low levels, drug concentration times.^{49,50} The results of a large community-based trial (CHRONO⁵¹) involving almost 2400 previously treated and nontreated essential hypertensive patients further confirm the efficacy and safety of the CODAS–verapamil chronotherapy. Study participants received a starting dose of 200-mg; if the target clinic BP of <140/90 mm Hg was not achieved after 4 weeks of treatment, the dose was up-titrated to 300-mg for another 4 weeks. Patients who failed to attain goal BP with this dose were again up-titrated to 400-mg for an additional 4 weeks. In total, 62.6% of the participants achieved the target BP goal with this monotherapy; 36.7% achieved it with the 200-mg dose; 18.9% with the 300-mg dose, and 6.9% with the 400-mg dose. CODAS–verapamil chronotherapy was effective in both previously untreated and treated patients no matter their age, gender, or race, and it was well tolerated; the most frequent adverse events being gastrointestinal (8.2% of patients), primarily constipation.

Graded-release long-acting diltiazem (Cardizem LA, Biovail Pharmaceuticals) was approved by the FDA in 2003 for once-daily dosing either in the morning or evening. Multiple-dose studies⁵² show that ingestion of the 360-mg dose of this special diltiazem medication at 10 P.M. results in the desired kinetic profile for the chronotherapy of essential hypertension. Trough blood diltiazem concentration occurs during nighttime sleep (~2 A.M.) and peak concentration during the morning (between ~10 A.M. and noon), with maintenance of an elevated drug level during the afternoon and early evening (Figure 51–2, C). In contrast, multiple-dose studies show the ingestion of 360 mg of this medication in the morning at 8 A.M., as opposed to at bedtime, results in trough drug level in the morning between 8 and 10 A.M. (when SBP and DBP in essential hypertension reach highest or near highest levels) and peak drug level in the evening between 6 and 8 P.M. (when SBP and DBP are declining) (Figure 51–2, C). The discordance between the timing of the peak and trough diltiazem blood concentrations relative to the circadian pattern of BP in essential hypertension, as exemplified by the ingestion of diltiazem at the improper time of the day, emphasizes the critical importance of patient and physician compliance to the recommended bedtime dosing of this and other BP chronotherapies. (See Glasser et al. 2003⁵³ for details of the extent and nature of the dosing-time differences in BP control by diltiazem.)

A multicenter 24-hour ABPM study of 429 essential hypertensive patients documents the statistically significant reduction of both peak and trough-time SBP and DBP for the 120-, 240-, 360- and 540-mg doses of diltiazem when ingested at bedtime.⁵³ Substantially enhanced BP reduction was achieved between 6 A.M. and noon across all the dose strengths. A sub-study involving the 360-mg dose, a dose that is claimed to control BP in 85% of hypertensive patients,⁵⁴ illustrates the statistically significantly greater SBP- and DBP-lowering effect of diltiazem between 6 A.M. and noon when ingested at

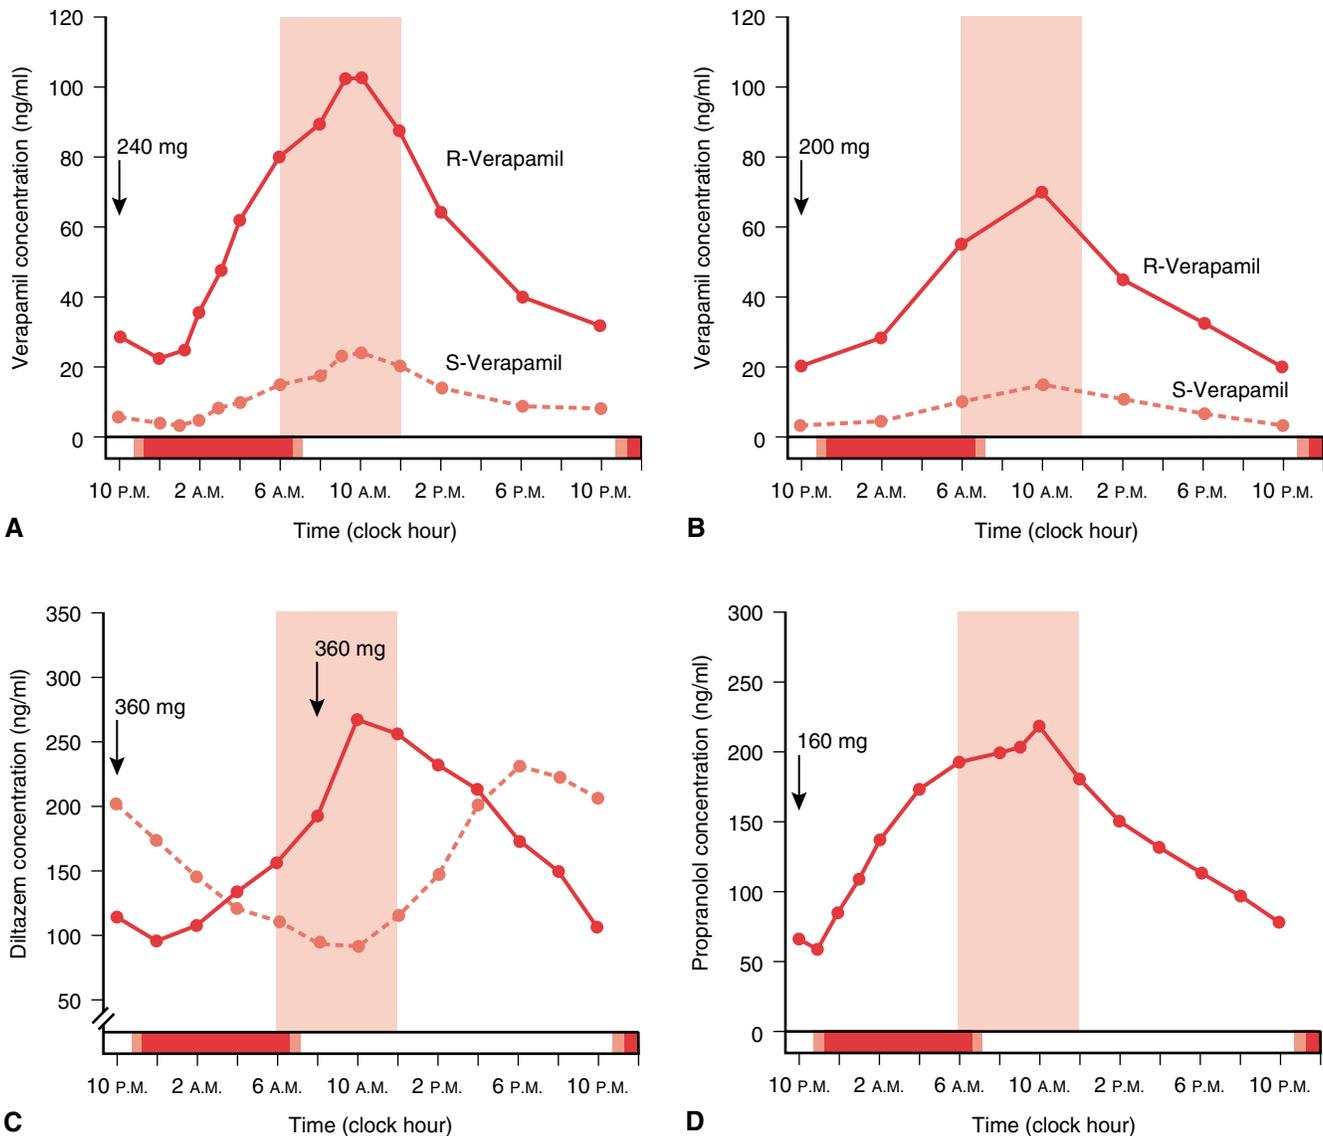

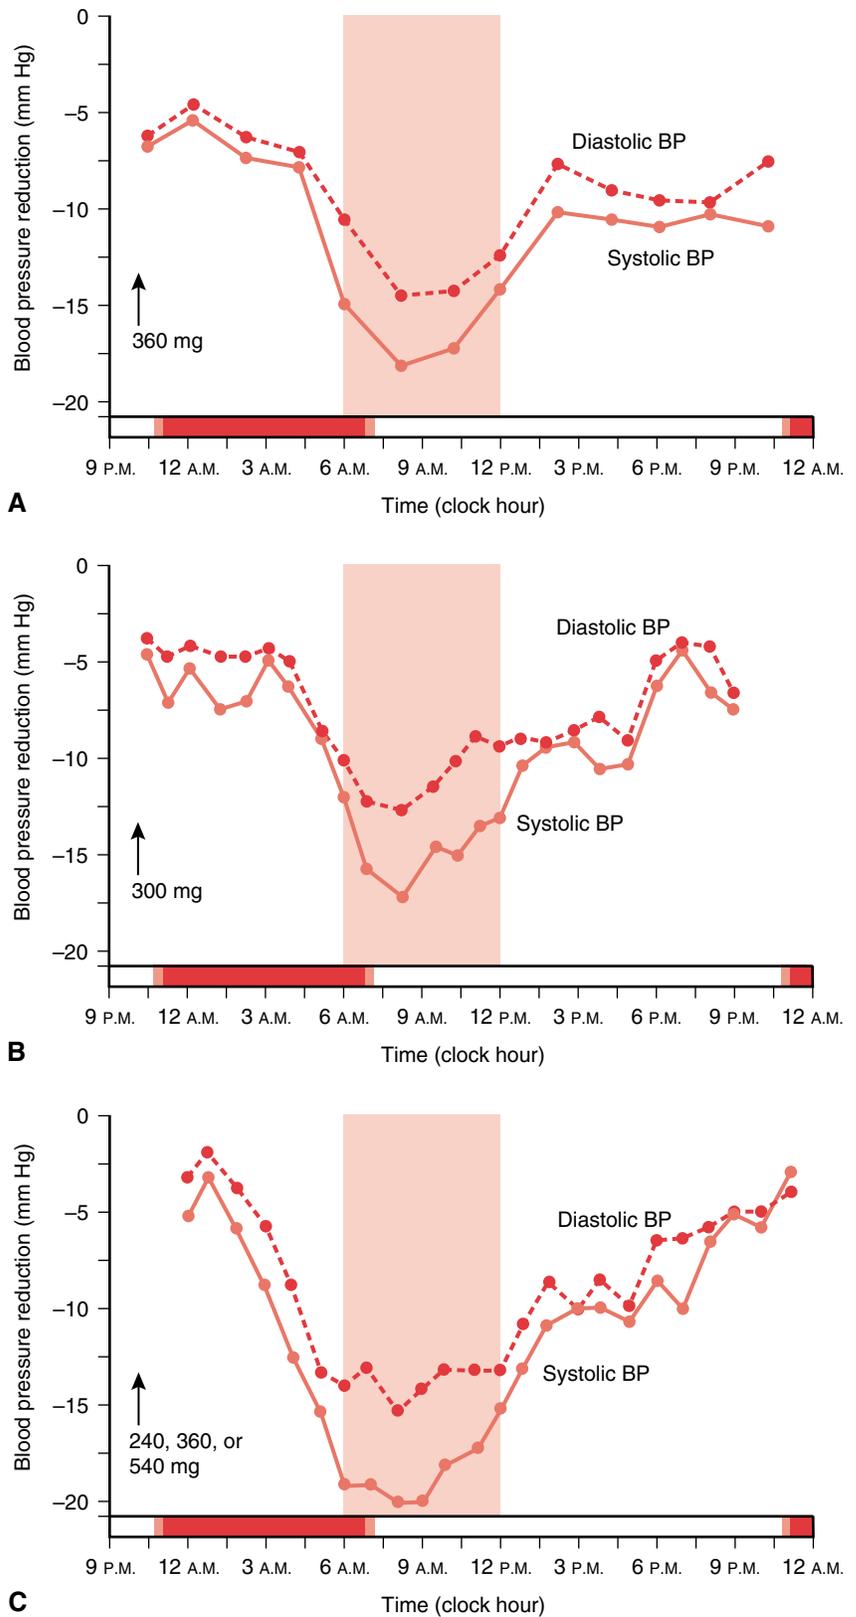

Figure 51-2 Steady-state pharmacokinetics of the hypertension chronotherapies of **A**, 240 mg COER-verapamil; **B**, 200 mg CODAS-verapamil; **C**, 360 mg diltiazem; and **D**, 160 mg propranolol. Bedtime ingestion of the chronotherapies as recommended results in peak drug concentrations in the morning during the initial hours of daytime activity, generally between 6 and 10 A.M. when SBP and DBP in EH attain peak or near-peak values, and in trough drug concentration during the first 4 to 5 hours of nighttime sleep when SBP and DBP decline to lowest or near-lowest values during the 24 hours. Note that dosing diltiazem chronotherapy at the wrong time of the day (i.e., in the morning at 8 A.M.) results in mismatch of diltiazem concentration relative to biologic need as defined by the circadian BP rhythm in EH. Studies show dosing this, and presumably any other, chronotherapy of hypertension at an inappropriate time of the day (e.g., morning) significantly compromises BP control in the morning and afternoon.* Dark and light regions of the horizontal time axis indicate, respectively, the spans of nighttime sleep and daytime activity. (**A** adapted from Gupta SK, Yih BM, Atkinson L, et al. bedtime as opposed to in the morning on awakening.⁵³ Bedtime dosing of diltiazem has been found to be safe; the incidence of adverse events in the 120-, 240-, 360-, and 540-mg treatment groups was dose-independent and comparable with that of the placebo-treated groups. The most frequent side effects, independent of dose, were headache (11.7%), upper respiratory infection (5.6%), and lower limb edema (5.4%). No episodes of bradycardia and no episodes of first-degree atrioventricular heart block requiring dismissal from the clinical trials occurred in any of the diltiazem treatment groups.⁵⁵ Finally, another multicenter trial found bedtime diltiazem in doses of up to 540 mg/day to be significantly more effective in controlling morning SBP, DBP, heart rate (HR), and rate-pressure product ($\text{SBP} \times \text{HR}$ = surrogate measure of left ventricular work and myocardial oxygen demand) than the angiotensin-converting enzyme inhibitor (ACEI) ramipril ingested at bedtime in doses of up to 20 mg/day.⁵⁶

β -Antagonist

The β -antagonist propranolol (Innopran XL, Reliant Pharmaceuticals) was approved by the FDA in 2003 for use in chronotherapy. Multiple-dose study⁵⁷ of this capsule medication shows that its ingestion at bedtime as recommended results in trough drug concentration toward the latter hours of nighttime sleep (~4 A.M.) due to the intentional delay of propranolol release for 4 to 5 hours, peak drug concentration between 4 and 10 A.M., and an elevated plateau of drug concentration in the afternoon and early evening (Figure 51–2, D). Unpublished findings (Dr. Joel Neutel, Integrium, Tustin, CA, personal communication) from 24-hour ABPM trials of this β -antagonist chronotherapy document its potent SBP and DBP reduction in the morning with persistence of significant BP-lowering activity for the entire 24-hour dosing interval.

CHRONOPHARMACOLOGY IN THE BLOOD PRESSURE-LOWERING EFFECTS OF CONVENTIONAL ONCE-A-DAY ANTIHYPERTENSIVE MEDICATIONS

Appreciable administration-time differences in the kinetics (i.e., chronokinetics) of BP-lowering and cardiac medications are well known.^{58–62} They result from circadian rhythms in gastric pH and emptying; gastrointestinal motility; biliary function and circulation; blood flow to the duodenum, liver, and kidney; and liver enzyme activity, among other factors.^{63,64} In some instances it is the chemistry and/or physics of the drug-delivery system of the tablet and capsule medications that is vulnerable to circadian influences, while in others it is the chemistry of the medication that is vulnerable. Clinically relevant administration-time differences in the beneficial and adverse effects (termed *chronodynamics*) of BP-lowering medications are also known. These result from the chronokinetics of the medications as well as circadian rhythms in the drug-free fraction, rate-limiting steps of key metabolic pathways, receptor number and conformation and/or second messenger dynamics, culminating in temporal disparities in the concentration-effect relationship.⁶⁵ Examples of administration-time differences in the BP-lowering effects of various types of antihypertensive medications—CCBs, ACEIs, angiotensin receptor blockers (ARBs), α_1 -adrenoceptor antagonists, and even aspirin—are presented

in Table 51–1. The dosing time-dependent difference in the BP-lowering effect of some of these medications is so great that it merits detailed discussion in the following sections.

Morning vs. Evening Isradipine Therapy of Nondipper Pattern Hypertension

Nocturnal hypertension, characterized by the loss or even reversal of the expected 10% to 20% sleep-time BP decline, increases the risk of cardiovascular and cerebrovascular events, nephrosclerosis, and progression to ESRD in renal patients. Nondipper BP patterns are more frequent in hypertension secondary to specific medical conditions, such as chronic renal failure, diabetes, and autonomic nervous system dysfunction, than in uncomplicated primary hypertension. Normalization of the circadian BP rhythm is considered to be an important clinical goal of pharmacotherapy because it may slow the advance of renal injury and avert ESRD.^{66–68}

One of us⁶⁹ explored the relative advantage of evening vs. morning once-a-day treatment with a conventional sustained-release isradipine formulation on the nondipping 24-hour pattern of SBP and DBP in 16 chronic renal failure patients. Participants were randomized into two groups according to the order, morning at 8 A.M. vs. evening at 8 P.M., of the 4-week-long, 5-mg/day isradipine treatment regimen. The 24-hour pattern of BP was determined by ABPM before and after each treatment-time schedule. Both isradipine treatment schedules were equally effective in reducing the mean 24-hour BP. However, it was the 8 P.M. dosing schedule that best reduced and normalized nocturnal SBP and DBP.

The findings of this study demonstrate that in nondipping chronic renal failure patients, an evening, as compared with a morning, 5-mg/day sustained-release isradipine treatment schedule is more likely to effectively reduce the 24-hour mean SBP and DBP and restore the normal nocturnal dipping and circadian BP patterning.

Low-Dose Aspirin Chronoprevention of Preeclampsia/Gestational Hypertension in High-Risk Pregnancy Patients

Several small investigations established that low-dose aspirin (acetylsalicylic acid [ASA]) is safe to use in pregnancy and suggested that it might reduce the risk of preeclampsia in high-risk pregnancies. However, several subsequent large randomized clinical trials, while documenting the safety of low-dose ASA use in pregnancy, were unable to corroborate its protective action against preeclampsia.⁷⁰ Review of the published studies revealed several potential methodologic flaws. Trials did not always involve high-risk obstetric patients; low-dose ASA intervention often was not initiated until late in pregnancy, not until 28 to 32 weeks' gestation; and nowhere in the published articles was the ingestion time of the daily ASA dose specified.

Hermida et al.⁷⁰ wondered if the time of drug ingestion might have significantly affected the outcome of the previous clinical trials. He and his colleagues conducted a prospective double-blind, randomized, controlled-trial of the administration-time-dependent differences in the protective effect of low-dose ASA initiated early in pregnancy. A total of 341 pregnant (181 primipara) normotensive women, at high risk of developing gestational hypertension and preeclampsia, were recruited. These medication-free women were

Table 51-1 Administration Time Differences in BP-Lowering Effects of Various Antihypertensive Medications

Medication (authors)	Dose (mg)	Dosing Times (conditions)	Subjects (no. and type)	Differential Rx Time Effect on 24 BP Pattern
Benazepril (Palatini et al., 1993) ⁸⁶	10	9 A.M. vs. 9 P.M. (single dose)	10 EH	9 A.M. dose exerted greater BP-lowering effect. Duration of therapeutic effect shortened by 5 hours with 9 P.M. dosing.
Ramipril (Myburgh et al., 1995) ⁸⁷	2.5	8 A.M. vs. 8 P.M. (4 weeks)	33 EH	8 P.M. dosing improved nocturnal BP-lowering effect.
Enalapril (Witte et al., 1993) ⁸⁸	10	7 A.M. vs. 7 P.M. (single dose)	8 EH	7 A.M. dose significantly reduced daytime but not nighttime BP; 7 P.M. dose exerted stronger BP-lowering overnight and morning but had no effect on afternoon BP.
Quinapril (Palatini et al., 1992) ⁸⁹	20	8 A.M. vs. 10 P.M. (4 weeks)	18 EH	No dosing-time difference on daytime BP; 10 P.M. dosing reduced nocturnal BP more than 8 A.M. dosing.
Perindopril (Morgan et al., 1997) ⁹⁰	4	9 A.M. vs. 9 P.M. (4 weeks)	18 EH	9 P.M. dosing markedly lowered BP (particularly SBP) during nocturnal sleep but was associated with ~33% shortening of SBP and DBP-lowering effect during the 24-hour dosing interval.
Captopril + HTZ (Middeke et al., 1991) ⁹¹	25/12.5	7–8 A.M. vs. 6–8 P.M. (3 weeks)	13 EH	Evening dosing resulted in attenuation of daytime BP-lowering. Evening dose reduced BP during daytime (6 A.M.–6 P.M.) equal to that achieved by a q12h dosing schedule (equal to twice the dose/24 hours) of the combination medication.
Diltiazem Retard (Kohno et al., 1997) ⁹²	100–200	8 A.M. vs. 7 P.M. (3 weeks)	7 EH	8 A.M. dosing better reduced BP during nighttime sleep; 8 P.M. dosing exerted greater daytime BP-lowering effect and inhibition of morning BP rise.
Isradipine (Portaluppi et al., 1995) ⁶⁹	5	8 A.M. vs. 8 P.M. (4 weeks)	16 RP	8 P.M. dosing best lowered both day and nighttime BP and normalized the non-dipping circadian BP pattern of renal patients.
Cilnidipine (Kitahara et al., 2004) ⁹³	~10	Morning vs. bedtime	13 EH	Bedtime, but not morning, dosing significantly reduced nocturnal SBP and DBP. Daytime BP lowering was not dosing-time dependent.
Valsartan (Hermida et al., 2003c) ⁹⁴	160	Morning vs. bedtime (3 months)	90 EH	No dosing-time difference in reduction of 24-hour mean BP. Bedtime dosing best normalized nondipper BP patterns.
Doxazosin (Hermida et al., 2004) ⁹⁵	4	Morning vs. bedtime (3 months)	91 EH	Morning dosing exerted little nocturnal BP-lowering and had only minor effect on 24-hour mean BP. Bedtime dosing exerted full 24-hour BP control and, compared with morning dosing, several-fold greater reduction in 24-hour mean BP.
Aspirin (Hermida et al., 2003a) ⁷⁰	100	Morning vs. afternoon vs. bedtime (~6 months)	174 pregnant women at risk for preeclampsia and gestational hypertension	Bedtime, but not morning, dosing commencing ~12–16 weeks' gestation reduced the occurrence of preeclampsia, gestational hypertension, intrauterine-growth retardation, and preterm delivery.

Continued

Table 51-1 Administration Time Differences in BP-Lowering Effects of Various Antihypertensive Medications—cont'd

Medication (authors)	Dose (mg)	Dosing Times (conditions)	Subjects (no. and type)	Differential Rx Time Effect on 24 BP Pattern
Aspirin (Hermida et al., 2003b) ⁷¹	100	Awakening vs. bedtime (3 months)	50 stage 1 EH	Morning dosing had little effect on BP, while bedtime dosing significantly reduced 24-hour mean SBP and DBP by 6 and 4 mm Hg, respectively.

EH, essential hypertensive patients; RP, renal (nondialysis) hypertensive patients; BP, blood pressure; SBP, systolic blood pressure; DBP, diastolic blood pressure.

randomized to one of six different groups, each composed of 55 to 59 pregnant women, specific to the types of treatment: placebo or 100 mg ASA and the times of treatment: on awakening in the morning, 8 hours after awakening (lunch), or before going to bed. BP was assessed every 20 minutes between 7 A.M. and 11 P.M. and every 30 minutes overnight for 48 hours by ABPM first at the time of recruitment, between 12 to 16 weeks' gestation, and thereafter at 4-week intervals until delivery.

The BP-lowering effect of the low-dose ASA was nil and comparable with the placebo when ingested on awakening. In contrast, the daily ingestion of ASA in the early afternoon (8 hours after morning awakening) resulted in significantly lower average 24-hour mean SBP and DBP compared to placebo after the first month of dosing, with the difference between the two treatments at the time of the delivery amounting to decreases of 4.4 mm Hg for SBP and 3.5 mm Hg for DBP. The BP-lowering effect of ASA compared with placebo was strongest when it was dosed at bedtime; the effect of ASA on the 24-hour mean SBP and DBP was again apparent after the first month of treatment, with the difference between the two treatments at the time of delivery now amounting to decreases of 9.7 mm Hg for SBP and -6.5 mm Hg for DBP.

The protective effect of the low-dose ASA against preeclampsia, gestational hypertension, intrauterine growth retardation, and preterm birth varied dramatically according to its time of ingestion. The incidence of preeclampsia was roughly 12% on average in the placebo-treated groups. Morning low-dose ASA was not at all protective (15% incidence), whereas afternoon and bedtime dosing was very protective (1% incidence). Gestational hypertension occurred in nearly 30% of the placebo-treated women. Morning ASA dosing again exerted little protection (25% incidence), whereas afternoon (9% incidence) and bedtime (7% incidence) dosing did protect against gestational hypertension. Intrauterine growth retardation occurred in roughly 18% of the placebo-treated women. As before, morning ASA dosing exerted little protection (16% incidence), whereas afternoon (7% incidence) and, especially, bedtime (3% incidence) dosing did protect. Finally, the incidence of preterm birth was approximately 14% in the placebo-treated women. Morning low-dose ASA again was not protective (12% incidence), whereas afternoon (3% incidence) and, in particular, bedtime (0% incidence) dosing was protective.

Morning vs. Evening Low-Dose Aspirin in Stage 1 Hypertension

Hermida et al.,⁷¹ motivated by the findings of the ASA study of high-risk pregnancies, assessed the potential BP-lowering

effect of conventional low-dose (100 mg/day) ASA tablet therapy in mild hypertension as a function of its ingestion time. A total of 170 (66 men and 104 women) stage 1 hypertensives were randomly divided into three groups. One group served as a control and was prescribed an exercise and diet regimen (EDR), a second group was prescribed the identical EDR plus 100 mg/day ASA on awakening, and a third group was prescribed the identical EDR plus 100 mg/day ASA at bedtime. BP was assessed by ABPM for 48 hours, both before and after 3 months of treatment. The 3-month EDR intervention in the control group had no BP-lowering effect. Moreover, EDR plus morning low-dose ASA treatment exerted but little BP-lowering effect; the average decrease in the 24-hour mean SBP and DSP amounted to only 2.2 and 1.1 mm Hg, respectively. In contrast, EDR plus bedtime low-dose ASA reduced BP significantly; the average decline in the 24-hour mean SBP and DBP amounted to 7.1 and 4.4 mm Hg, respectively.

The studies by Hermida and colleagues involving low-dose ASA clearly demonstrate just how important the ingestion time of medications can be in determining their therapeutic effects. In the case of low-dose ASA, the dosing time determined whether it was protective against gestational hypertension and preeclampsia in high-risk pregnancies and whether it exerted a meaningful BP-lowering effect in stage 1 hypertension.

DISCUSSION

The concepts of chronopharmacology and chronotherapeutics are not new to clinical medicine. The chronotherapy of conventional tablet corticosteroid medications, daily or alternate-day morning prednisone and methylprednisolone dosing, was introduced in the United States in the 1960s² and is still extensively used today. In the 1980s, special drug-delivery technology made possible the chronotherapy of theophylline (Uniphyll, Purdue Pharma in the United States; Uniphyllin, Knapp in England/Munipharma in Germany; Euphyllong, Byk Gulden in Germany) to achieve highest drug concentration during nighttime sleep to avert nocturnal asthma.⁶⁰ Knowledge of the circadian rhythms in symptom intensity of chronic diseases,⁴ along with the chronopharmacology of medications, has been used to optimize conventional once-a-day H₂-receptor antagonists for peptic ulcer disease,⁷² H₁-receptor antagonists for allergic rhinitis,⁷³ nonsteroid antiinflammatory drugs for rheumatoid arthritis and osteoarthritis,⁷⁴ cholesterol-lowering agents such as simvastatin,⁷⁵ and even cancer medications to lessen their toxicity and enhance therapeutic outcome.⁷⁶

The chronotherapy of hypertension commenced in 1996 with the introduction of COER-verapamil. Three other chronotherapies of hypertension (a diltiazem calcium antagonist, a propranolol β -antagonist, and another verapamil calcium antagonist) have since been introduced in the United States. The common features of these four chronotherapies are bedtime dosing, reliance on unique drug-delivery technology to retard the dispersal of medication for approximately 4 to 5 hours following ingestion, graded or slow release of medication thereafter during a portion of the 24-hour dosing interval, and drug half-life that makes possible the progressive stepwise reduction of morning peak blood level in close synchrony with the expected circadian pattern of BP in essential hypertension. Improved BP control at the beginning of daily activity may also benefit from a more favorable concentration-response relationship in the morning as compared with other times of the day as exemplified by the β -antagonist medication propranolol.⁷⁷ Clinical trials show that the chronotherapies of hypertension are much more effective than most conventional medications in attenuating both the morning rate of rise and level of BP and are as effective as most conventional BP formulations in maintaining BP control throughout the remainder of the 24-hour dosing interval. Enhancement of morning BP-lowering is accomplished by incorporating a roughly 4- to 5-hour delay in drug-release following bedtime ingestion of the chronotherapy. The equivalent 15% to 20% of the 24-hour dose that would ordinarily circulate from continuous release once-a-day conventional formulations during this time span, when BP is typically lowest in essential hypertension, is redistributed by design to the morning when more aggressive antihypertensive therapy is required to manage expected peak or near-peak SBP and DBP. Clinical trials show that the four chronotherapies are well tolerated, perhaps better than the respective conventional formulations of the same dose when routinely ingested in the morning as recommended. The major side effect of the verapamil chronotherapies is dose-dependent constipation. Bradycardia and heart block with the verapamil and diltiazem chronotherapies are uncommon, even with the very highest dose of 540 mg/day. The low incidence of this side effect with these CCB dosage forms may be related to the purposeful reduction in drug concentration during the sleep span when heart rate and impulse conduction through the cardiac tissue are slowest.

The awareness by clinicians of the temporal variation in BP and potential role of its accelerated rise in the morning as a trigger of cardiovascular events has increased significantly in recent years.⁴⁰ Indeed, an unpublished 2002 Gallup poll of 200 American family practitioners (Biovail Pharmaceuticals, personal communication) found that 99% of them knew that BP varied during the 24 hours, and 97% believed the temporal variation resulted, at least to some degree, from circadian rhythms. The 2002 survey further revealed that the majority of doctors today believe that highest BP is achieved in the morning (55%) or afternoon (19%). The survey also found that 88% of the surveyed clinicians recommended that patients take their antihypertensive medications at a certain time of day. Most of those who gave such advice recommended their patients take antihypertensive medicines either immediately on awakening (22%) or sometime in the morning (46%). However, studies show that the dosing of many popular conventional once-a-day antihypertensive medications immediately on awakening or

later during the morning is too late to optimally attenuate the peak or near-peak BP at this time of the day; this is especially true for medications with short half-lives that do not maintain therapeutic effects for the full 24 hours.⁴⁷

Even though a majority of doctors recommend that their hypertensive patients take BP-lowering medications on awakening or later in the morning, the idea of dosing antihypertensive medicines at bedtime is gaining popularity with American clinicians. At the time of the 2002 Gallup poll, about 15% of the surveyed American family practitioners stated they recommended dosing antihypertensive agents at night, presumably even conventional slow-release once-a-day drugs. A separate yet unpublished pharmaceutical company-sponsored Gallup poll of 600 American hypertensive patients (Biovail Pharmaceuticals, personal communication) found that, although most people take their BP-lowering medications on awakening (19%) or sometime in the morning (64%), an appreciable proportion do so either at night (7%) or at bedtime (7%). The 18% of patients surveyed who took antihypertensive medications twice a day stated that they ingested their second dose of medication either in the afternoon (9%), in the evening (50%), or at bedtime (27%). Many doctors and patients are unaware that the effects of certain antihypertensive medications may differ significantly according to the (circadian) time they are ingested, as exemplified by the entries of Table 51-1 for ACEIs, CCBs, and angiotensin receptor antagonists. Even low-dose ASA shows dramatic administration-time-dependent differences in its effect on the 24-hour BP mean of stage 1 essential hypertensive patients, and the administration-time-dependent differences in the effect of low-dose of aspirin in the prevention of preeclampsia and gestational hypertension of at-risk pregnancies are even more dramatic.

Our knowledge of the therapeutic potency and safety of antihypertensive medications is derived from the conduct of clinical trials designed and sponsored by pharmaceutical companies. The goal of these trials is to demonstrate to governmental agencies that the therapy in question is effective and safe for the indication trialed and that it is suitable for marketing to consumers. The labeling instructions regarding the dose and timing of medications are based on the conditions and findings of such trials. Generally, once-a-day medications that are proven to be efficacious and safe are approved and labeled for the dosing time selected for the clinical trials. Unless a pharmaceutical company seeks and substantiates its claim for bedtime labeling, information about the efficacy and safety of the medication when taken at this time will be unknown. Adherence to the recommended time of day of dosing on the drug label is seldom appreciated by clinicians and patients as a crucial attribute of compliance.⁵⁹

Only a very few conventional medications have been studied for their therapeutic impact and safety when dosed at different times of the day.^{56,78,79} Knowledge of the extent to which the safety and therapeutic effect of the majority of conventional once-a-day antihypertensive medications are affected by ingestion (circadian) time is far too sparse to support any broadscale practice of bedtime dosing of the large number of BP-lowering formulations. In fact, nocturnal hypotension, perhaps aggravated by the dosing of certain antihypertensive medications at bedtime, increases the risk of ischemic ocular disorders in glaucoma patients³⁶ and perhaps nocturnal stroke.³⁷ Moreover, evening ingestion of

certain β -adrenoceptor blocker medications, such as atenolol and propranolol, has been shown to attenuate or even abolish the nocturnal secretion of melatonin,⁸⁰⁻⁸² a key component of the circadian clock network. The consequence of a chronically attenuated or altered circadian rhythm of melatonin awaits clinical assessment.

Sander and Klingelhofer⁸³ using conventional medications showed that drug-induced normalization of the pathologic circadian BP profile of patients with hemodynamic brain infarction resulted in progressive recovery of the blood-brain barrier. In addition, several endpoint studies document that normalization of the nondipping circadian BP rhythm of hypertensive patients may slow the advance of renal injury and avert ESRD.⁶⁶⁻⁶⁸ Numerous clinical trials of the marketed chronotherapies of hypertension clearly document their improved control of morning SBP and DBP without compromise of BP control throughout the remainder of the 24-hour dosing interval. Moreover, COER-verapamil and long-acting diltiazem, which are approved for the management of chronic stable angina pectoris, evidence enhanced control of coronary ischemia in the morning—when it is most common—without loss of effect during the remainder of the 24 hours.^{41,42,55} Yet at present there are no data to substantiate the hypothesis that these special chronotherapeutic formulations are more effective than conventional ones in the prevention of cardiovascular events in at risk patients.

The first proposed large-scale assessment of verapamil chronotherapy was the 5-year international multicenter (Controlled Onset Verapamil INvestigation of Cardiovascular Endpoints: CONVINCE) trial involving 15,000 hypertensive patients with identified cardiovascular risk. This trial was designed to compare the degree of BP control and protection against cardiovascular events afforded by a regimen of conventional β -blocker and diuretic medications vs. the COER-verapamil chronotherapy.⁸⁴ This community-based outcomes study was terminated prematurely not because of inadequate performance of the chronotherapy, but because of financial and corporate considerations of the pharmaceutical company that acquired the rights to the medication. Because the trial was terminated early, there were far too few cardiovascular events to carry out a valid scientific assessment of the advantage, if any, of verapamil chronotherapy in hypertension.⁸⁵ Thus, the relative merit of chronotherapy vs. conventional therapy in preventing cardiovascular events remains unresolved. The great majority of doctors, pharmacists, and public health officials have misinterpreted the premature termination of the CONVINCE trial and lack of significant differences in cardiovascular events between the trialed medications as evidence against the utility of chronotherapeutics in hypertension. Obviously, well-designed future trials are required to gauge the merit of the chronotherapy of hypertension in reducing the risk of morning cardiovascular accidents and improving patient quality of life.

Comorbid Conditions and Special Populations in Hypertension

Chapter 52

Diabetes Mellitus and the Cardiovascular Metabolic Syndrome: Reducing Cardiovascular and Renal Events

Jay Lakkis, Matthew R. Weir

This chapter provides perspective about identifying and treating patients with diabetes mellitus and the cardiovascular metabolic syndrome. Most patients are diagnosed late in the course of disease, which creates substantial difficulties in managing their cardiovascular disease (CVD) burden. This often requires multiple medications and complex medical care requirements. We need better screening tests to recognize higher-risk patients sooner so that prevention strategies can be optimized. It is likely that this will be the most cost-effective approach.

Our chapter is laid out in three parts. First, we define the problem and address the epidemiologic factors that are involved. Next, we focus on risk stratification and look at the individual factors that contribute to total risk. We conclude with a section focused on strategies to curb cardiovascular and renal disease risks in these patients.

DEFINITIONS

Diabetes Mellitus

In January 2004, the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus of the American Diabetes Association (ADA) published a set of practice recommendations, including criteria for the diagnosis of diabetes mellitus modified from those previously recommended by the World Health Organization (WHO) (Box 52–1). These revised criteria are symptoms of diabetes plus random plasma glucose (PG) concentration ≥ 200 mg/dl (classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss); fasting plasma glucose (FPG) ≥ 110 mg/dl, with fasting defined

as no caloric intake for at least 8 hours; or 2-hour PG ≥ 200 mg/dl during an oral glucose tolerance test (OGTT) performed using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water. The Committee did not recommend the OGTT for routine clinical use, however. In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.

The Expert Committee also identified an intermediate group of persons whose glucose levels, although not meeting criteria for diabetes, are nevertheless too high to be considered altogether normal. This group is defined as having impaired fasting glucose with FPG levels ≥ 110 mg/dl but < 126 mg/dl or impaired glucose tolerance with 2-hour values on OGTT of ≥ 140 mg/dl but < 200 mg/dl.¹

Type 1 diabetes comprises approximately 10% of all cases of diabetes and its hallmark is total dependence on exogenous insulin for survival. Type 2 diabetes comprises 90% of all people with diabetes and is characterized by insulinopenia and/or insulin resistance.

The Metabolic Syndrome

The metabolic syndrome, originally described by Reaven in 1988 (see Chapter 13), refers to a clustering of several component disorders, at the center of which lay central obesity and insulin resistance. Two definitions have been proposed: one by the National Cholesterol Education Program's Third Report of the Expert Panel on the Detection, Evaluation and Treatment of High Blood Cholesterol in Adults (NCEP-ATP III) and another by the WHO (Table 52–1). The clinical spectrum of this syndrome has been defined by the NCEP-ATP III

Box 52-1 Criteria for the Diagnosis of Diabetes Mellitus*

1. Symptoms of diabetes plus casual plasma glucose concentration ≥ 200 mg/dl (11.1 mmol/L). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

2. FPG ≥ 126 mg/dl (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.

or

3. 2-hour postload glucose ≥ 200 mg/dl (11.1 mmol/L) during an OGTT. The test should be performed as described by WHO, using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.

Adapted with permission from Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. American Diabetes Association: Clinical practice recommendations 2004. *Diabetes Care* 27:S5-S10, 2004.

*In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The third measure (OGTT) is not recommended for routine clinical use.

to include abdominal obesity defined by a waist circumference >102 cm or 40 inches in men and >88 cm or 35 inches in women, androgenic dyslipidemia reflected by an elevated triglyceride level >150 mg/dl, small low-density lipoprotein (LDL) particles or low high-density lipoprotein (HDL) cholesterol level (<40 mg/dl in men and <50 mg/dl in women), raised blood pressure (BP) $>130/85$ mm Hg, insulin resistance with or without glucose intolerance or fasting blood sugar >110 mg/dl, and prothrombotic and proinflammatory states.² The WHO defines the metabolic syndrome as either

impaired glucose tolerance or diabetes or an FPG >110 mg/dl, hyperinsulinemia or insulin resistance plus at least two other components: hypertension defined by an arterial BP $>140/90$ mm Hg or the administration of antihypertensive drugs; dyslipidemia defined as a serum triglyceride >150 mg/dl or an HDL cholesterol <35 mg/dl in men or <39 mg/dl in women; abdominal central obesity defined by a waist:hip ratio >0.90 in men or >0.85 in women or a waist circumference >94 cm or 37 inches or a body mass index (BMI) >30 kg/m²; or microalbuminuria >20 μ g/min or an albumin:creatinine ratio >30 mg/g.³

This constellation of metabolic disorders makes the affected individual highly prone to develop CVD, including coronary heart disease (CHD), cerebrovascular disease, and peripheral vascular disease, and hence the nomenclature has been appropriately expanded to “the cardiovascular metabolic syndrome.” In the NHANES III (Third National Health and Nutrition Examination Survey 1988-1994) data set, the cardiovascular metabolic syndrome has also been linked to an increased risk for both microalbuminuria and chronic kidney disease (CKD; estimated GFR <60 ml/min/1.73 m²).⁴

EPIDEMIOLOGY

Diabetes Mellitus

The prevalence of diabetes has been rising over the past few decades.^{5,6} NHANES III (1988-1994) data from a subsample of 6587 adults, 20 years of age or older, for whom FPG values were obtained, and a subsample of 2844 adults between 40 and 74 years of age who received an OGTT, demonstrated that the prevalence of diagnosed diabetes was estimated to be 5.1% (10.2 million people). Using ADA criteria, the prevalence of undiagnosed diabetes (FPG ≥ 126 mg/dl) was 2.7% (5.4 million), and the prevalence of impaired fasting glucose (110-125

Table 52-1 Clinical Identification of the Cardiovascular Metabolic Syndrome

Risk Factor	Defining Level
Abdominal obesity* (waist circumference) [†]	
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglycerides	≥ 150 mg/dl
High-density lipoprotein cholesterol	<40 mg/dl
Men	<50 mg/dl
Women	
Blood pressure	$\geq 130/\geq 85$ mm Hg
Fasting glucose	≥ 110 mg/dl

Adapted with permission from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. Executive Summary of the Third Report of The National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol In Adults (Adult Treatment Panel III). *JAMA* 285(19):2486-2497, 2001.

*Overweight and obesity are associated with insulin resistance and the cardiovascular metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body mass index (BMI). Therefore, the simple measure of waist circumference is recommended to identify the body weight component of the syndrome.

[†]Some male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased (e.g., 94-102 cm [37-40 inches]). Such patients may have strong genetic contribution to insulin resistance and they should benefit from changes in life habits, similarly to men with categorical increases in waist circumference.

mg/dl) was 6.9% (13.4 million). Based on ADA criteria, the prevalence of diabetes (diagnosed plus undiagnosed) in the total population 40 to 74 years of age increased from 8.9% in the period 1976-1980 to 12.3% by 1988-1994. A similar increase from 11.4% and 14.3% was found when WHO criteria were applied.⁶

The National Diabetes Clearing House estimates that 16.9 million or 8.6% of adults, 20 years of age or older, have diabetes, and the prevalence increases among adults, age 65 years or older, to 7 million or 20.1%.⁷

Cardiovascular Metabolic Syndrome

Several analyses of data from the NHANES III data set provide insight into the magnitude of the problem presented by the cardiovascular metabolic syndrome. With the adoption of the NCEP-ATP III definition, analysis of data from 8814 men and women aged 20 years or older estimated the unadjusted and age-adjusted prevalences of the syndrome to be 21.8% and 23.7%, respectively. The syndrome was more prevalent among Mexican Americans (31.9%) and the prevalence seemed to increase proportionally with age. Prevalence of the cardiovascular metabolic syndrome increased from 6.7% among participants aged 20 through 29 years to 43.5% and 42.0% for participants aged 60 through 69 years and aged at least 70 years, respectively. Using 2000 census data, about 47 million U.S. residents have the cardiovascular metabolic syndrome.⁸ Another analysis adopting the NCEP-ATP III definition evaluated 3305 Black, 3477 Mexican American, and 5581 white men and women aged 20 years and older and revealed a prevalence of 22.8% and 22.6% of U.S. men and women, respectively. Similarly, the age-specific prevalence was highest in Mexican Americans and lowest in Blacks of both sexes.⁹ In a third analyses of data from 8608 participants aged 20 years or older, the age-adjusted prevalence overall was 23.9% using the NCEP-ATP III definition and 25.1% using the WHO definition. Estimates differed substantially for some subgroups; for example, in African American men, the WHO estimate was 24.9%, compared with the ATP III estimate of 16.5%.¹⁰

Comorbid Conditions: Obesity and Overweight

The epidemic of obesity and overweight is one of the most alarming health disorders in the United States and the Western hemisphere today. Obesity and overweight may be assessed by BMI, waist circumference, or waist:hip ratio. The Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults recommend that waist circumference be measured and compared with sex-specific cutoffs (>102 cm or 40 inches in men and >88 cm or 35 inches in women) in adults with a BMI between 25 and 34.9 kg/m².¹¹

The prevalence of obesity and overweight was evaluated in the NHANES among 4115 adult men and women recruited in 1999 and 2000. The age-adjusted prevalence of obesity was 30.5% in NHANES compared with 22.9% in NHANES III (1988-1994); the prevalence of overweight also increased during this period from 55.9% to 64.5%, and extreme obesity (BMI \geq 40) also increased from 2.9% to 4.7%. Such an increase occurred in both sexes, all age

groups, and all racial and ethnic groups. Among women, the prevalences of obesity and overweight were highest among non-Hispanic Black women, with more than half of those aged 40 years or older being obese and more than 80% overweight.¹²

Comorbid Conditions: Hypertension

It has been estimated that 24% of the U.S. adult population, representing 43.186 million persons, had hypertension, based on NHANES III data (1988-1994) from 9901 participants 18 years of age and older.¹³ The prevalence of hypertension is rising, as subsequent data showed an increase in age-adjusted hypertension prevalence among NHANES participants (1999-2000) to 28.7%.¹⁴

High BP is more prevalent in the diabetic population. In fact, 100% of diabetic patients that progress to end-stage renal disease (ESRD) are hypertensive; 55% of diabetics are not controlled to a goal of <140/90 mm Hg; and only 12% patients are controlled to <130/85.¹⁵ Even fewer diabetics reach the ADA recommended goal of 130/80 mm Hg.¹⁶

Comorbid Conditions: Dyslipidemia

Similarly, dyslipidemia tends to be more prevalent in the diabetic population and in patients with the cardiovascular metabolic syndrome.

RISK STRATIFICATION

It should be emphasized that the presence of one of these components of the syndrome almost always puts the patient at a higher risk for clustering of the other components, the end result being that these disorders individually or interactively affect cardiovascular and renal outcomes. In fact, the risk of these disorders is additive if not synergistic. Based on this and on the evidence to be presented, it is essential that all affected patients, be it with diabetes mellitus or the cardiovascular metabolic syndrome, must be stratified in the highest risk category for cardiovascular and renal disease.

Diabetes Mellitus, Impaired Glucose Tolerance, Hyperinsulinemia, and Insulin Resistance

Diabetes mellitus is an established independent risk factor for microvascular disease and macrovascular disease, namely CVD. The presence of diabetes mellitus or the cardiovascular metabolic syndrome in a patient enhances the risk of thrombotic events and atherosclerosis, especially in the coronary arteries, and is associated with endothelial dysfunction, both of which may contribute to myocardial ischemia. CVD is the leading cause of mortality in diabetic persons. A diabetic person has at least a twofold to fourfold higher risk for a cardiovascular event than an age-matched nondiabetic subject, and if he or she does have an event, will fare worse. CVD is ominous in this population for being premature, more extensive, and diffuse at time of diagnosis and carries a higher mortality and morbidity after a myocardial infarction (MI) than age-matched controls.¹⁷ Consequently, diabetes is considered a CVD-equivalent.

However, a definite causal relationship between diabetes mellitus and macrovascular disease or CVD has not been fully elucidated in major clinical trials, that is, the Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS).

The ADA and the American College of Cardiology published a Consensus Development Conference Report, including indications for cardiac testing in diabetic subjects and choosing the most appropriate test to detect CVD in each individual patient (Figures 52–1 and 52–2). They added that the presence of autonomic cardiac dysfunction in a patient, aged more than 35 years, with diabetes for more than 25 years warrants cardiac testing.¹⁷

Hyperinsulinemia, often viewed as a surrogate of insulin resistance, is also an independent risk factor for CHD in patients with diabetes mellitus,^{18–27} as well as an independent risk factor and predictor of the development of type 2 diabetes mellitus and hypertension.^{18,21}

Similarly, diabetes mellitus (both type 1 and 2) is an established risk factor for microvascular complications, including renal disease.^{28,29} In fact, diabetes mellitus is the major cause of ESRD in the United States.³⁰ The incidence of ESRD would increase at an even greater rate were not the competing hazards of CVD and stroke causing mortality in these patients. Furthermore, as mentioned earlier, the majority of patients with diabetes have hypertension as an important contributing factor to the progression of their kidney and heart disease.

Obese or Overweight Patient

Insulin resistance, hyperinsulinemia, diabetes mellitus, hypertension, and dyslipidemia are all much more prevalent in persons with central obesity than in nonobese subjects. Obesity causes cardiac and vascular disease through hypertension, type 2 diabetes, and dyslipidemia; furthermore, obesity is an independent predictor of cardiovascular risk factors, morbidity, and mortality.^{31–34} Other contributing factors to this increased risk may include mediators of chronic inflammation and hypercoagulation.

Obesity is a cause as well as a consequence of abnormal kidney function (see Chapter 44). In the obese patient, there is an increase in renal tubular sodium reabsorption, resulting in volume expansion, elevated arterial pressure, and a hypertensive shift of pressure natriuresis associated with activation of the renin-angiotensin and sympathetic nervous systems, as well as physical compression of the kidneys due to accumulation of intrarenal fat and extracellular matrix.³⁵ With time, glomerular hyperfiltration and increased arterial pressure increase glomerular capillary wall stress, which along with activation of neurohumoral systems and obesity-associated dyslipidemia and glucose intolerance, cause glomerular cell proliferation and matrix accumulation, with the end result of glomerulosclerosis and loss of nephron function in the early phases of obesity. This creates a slowly developing vicious cycle that requires additional increases in arterial pressure to maintain sodium balance and therefore makes effective antihypertensive therapy more difficult.³⁵ Elevated circulating leptin levels may play a role in the sympathetic activation. Elevation in leptin was also associated with impaired vascular function in healthy adolescents, independent of the metabolic and inflammatory disturbances associated with obesity.³⁶ In addition, obesity increases the risk of renal cancer and is a known cause of proteinuria, focal segmental glomerulosclerosis and occult diabetic nephropathy.³⁷

Hypertension

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) recommends a goal BP in patients with diabetes mellitus or CKD of less than 130/80 mm Hg.³⁸ In the diabetic population, hypertension increases the risk and accelerates the progression of CHD, left ventricular hypertrophy (LVH), congestive heart failure (CHF), cerebrovascular disease, peripheral vascular disease, and kidney disease. Studies in animal models reveal that hyperinsulinemia and hyperleptinemia occur concurrently in obese subjects, and

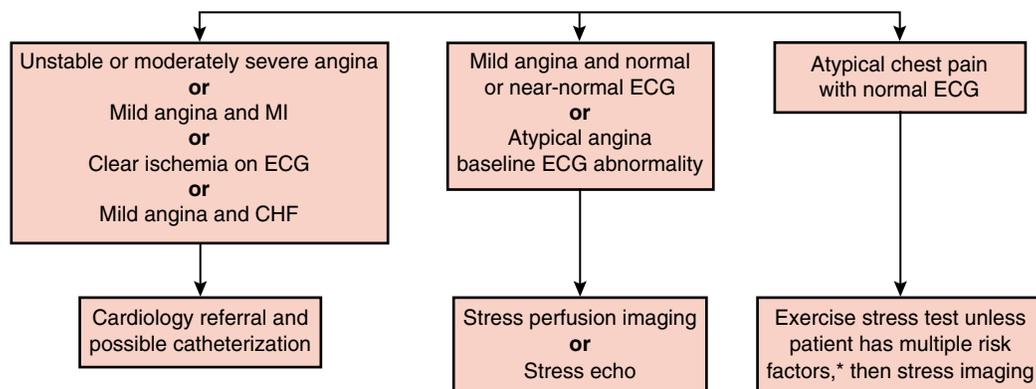

Figure 52–1 Cardiac testing of the symptomatic diabetic patient. In patients with diabetes and symptoms that are either clearly related to ischemia or atypical in nature but suspected to be of cardiac origin, testing can be undertaken using this algorithm. *A multiple risk factor patient is defined as an individual with two or more risk factors. MI, myocardial infarction; ECG, electrocardiogram; CHF, congestive heart failure. (Adapted from Consensus Development Conference on the Diagnosis of Coronary Heart Disease in People with Diabetes: 10–11 February 1998, Miami, Florida. American Diabetes Association. *Diabetes Care* 21:1551–1559, 1998.)

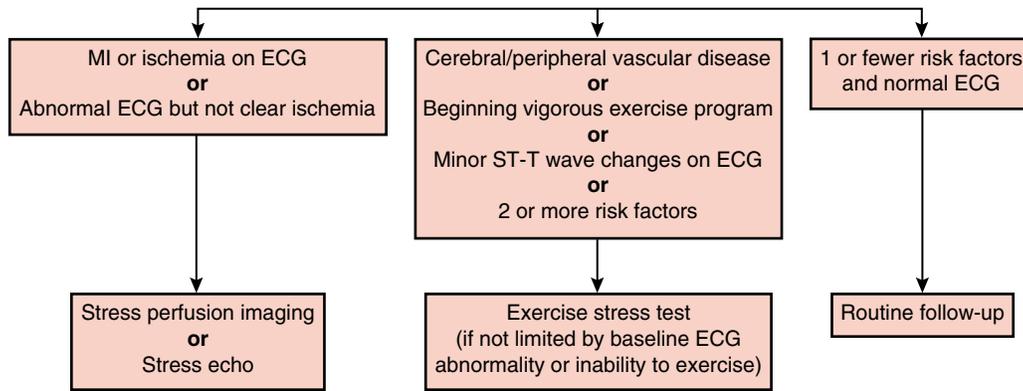

Figure 52-2 Cardiac testing of the asymptomatic diabetic patient. Asymptomatic patients with diabetes and one or fewer risk factors and a normal ECG do not require cardiac testing. Patients with two or more risk factors or those beginning a vigorous exercise program should have an exercise stress test. In patients with clear or suggestive evidence of ischemia or myocardial infarction (MI) on ECG, stress perfusion imaging or stress echo should be used. If expertise with both modalities is available, perfusion imaging would be preferred. MI, myocardial infarction; ECG, electrocardiogram. (Adapted from Consensus Development Conference on the Diagnosis of Coronary Heart Disease in People with Diabetes: 10-11 February 1998, Miami, Florida. American Diabetes Association. *Diabetes Care* 21:1551-1559, 1998.)

both have been suggested to mediate increased BP associated with excess weight gain.³⁹

There is a clear relationship between higher levels of BP and increased cardiovascular morbidity and mortality in the general population.⁴⁰⁻⁴² Epidemiologic studies demonstrate clearly that increasing systolic BP (SBP) and diastolic BP (DBP) correlate with increasing cardiovascular morbidity and mortality for the first 50 years of life with no evidence of any “threshold” below which lower levels were not associated with lower risks of stroke and of CHD. These results suggest that for the large majority of individuals, a lower BP should eventually confer a lower risk of vascular disease.⁴³ However, after 50 years of age, SBP is a more valid measure of cardiovascular risk; wider pulse pressure associated with higher SBP correlates well with cardiovascular morbidity and mortality⁴⁰⁻⁴² (see Chapters 3 and 22). Similarly, data from the Framingham Risk Study indicate that there is a graded relationship between BP and cardiovascular events, which extends below the traditional hypertensive threshold. Persons with SBP <120 mm Hg had fewer cardiovascular events than their counterparts with SBP of 120 to 129 or 130 to 139 mm Hg.⁴⁴ Although these are observational and not interventional studies, they do suggest that lower BP goals may be advantageous. This is likely the case in patients with more cardiovascular risk factors, such as diabetics.

Hypertension is both a cause and a consequence of renal disease. BP elevation is a strong independent risk factor for ESRD as has been shown by several trials.^{45,46} Hypertension is the second most common cause of ESRD in the United States and the most common in the African American population.³⁰ In fact, results from the Multiple Risk Factor Intervention Trial (MRFIT) showed that the increase in risk for ESRD associated with higher BP was graded and continuous throughout the distribution of BP readings above the optimal level.⁴⁵ This raises some question about what are optimal BP goals in the diabetic. Schrier et al.⁴⁷ reported a 5-year prospective, randomized controlled trial of 480 “normotensive” type 2 diabetic patients. Compared with a group with

mean BP controlled to 137/81 mm Hg, patients with intensive BP control of 128/75 mm Hg had not only slowed progression from normoalbuminuria to microalbuminuria, and microalbuminuria to overt albuminuria, but also decreased their risk for stroke and progression of retinopathy. In a study by Viberti et al.,⁴⁸ a modest 4/2-mm Hg reduction of BP with angiotensin-converting enzyme (ACE) inhibitor therapy in type 1 and type 2 diabetics with a baseline BP of 124/77 mm Hg resulted in a 50% reduction in progression from microalbuminuria to clinical proteinuria.^{48,49}

Microalbuminuria or Macroalbuminuria

Microalbuminuria is defined >30 mg but <300 mg albumin excreted per 24 hours (Table 52-2). The presence of microalbuminuria is the most important factor in predicting progression to macroalbuminuria or overt nephropathy in both type 1 and type 2 diabetics.⁵⁰⁻⁵² Microalbuminuria is also predictive of cardiovascular mortality in both diabetic and nondiabetic populations.^{50,53-55}

To screen for microalbuminuria, a spot urine albumin:creatinine ratio is preferred due to its simplicity and reduced probability of collection error compared with timed urine specimens.⁵⁶⁻⁵⁸ However, it should be noted that as a screening test, it is a poor predictor of quantitative albuminuria, and has a higher false-positive rate in older populations. Repetitive measurements (at least three) of first morning void urines provide a more accurate assessment. The ratio of albumin to creatinine in a spot or timed-urine collection can be helpful for quantifying 24-hour urine albumin excretion, because the creatinine output in the urine on a daily basis remains relatively constant.

Microalbuminuria may ultimately prove to be one of the most important risk factors for predicting cardiovascular events in both diabetic and nondiabetic patients. This has certainly been demonstrated to be the case in the Heart Outcomes Prevention Evaluation (HOPE) study (Figure 52-3).⁵⁹

Table 52-2 Definitions of Abnormalities in Albumin Excretion

Category	Spot Specimen (mg/g creatinine)	24-Hour Specimen (mg/24 hour)	Timed Collection (mg/min)
Normal	<30	<30	<20
Microalbuminuria	30-300	30-300	20-200
Clinical albuminuria	>300	>300	>200

*Because of variability in urinary albumin excretion, two of three specimens collected over a 3- to 6-month period should be abnormal before considering a patient to have crossed these diagnostic thresholds. Exercise within 24 hours, infection, fever, congestive heart failure, marked hyperglycemia, marked hypertension, pyuria, and hematuria may elevate urinary albumin excretion over baseline values.

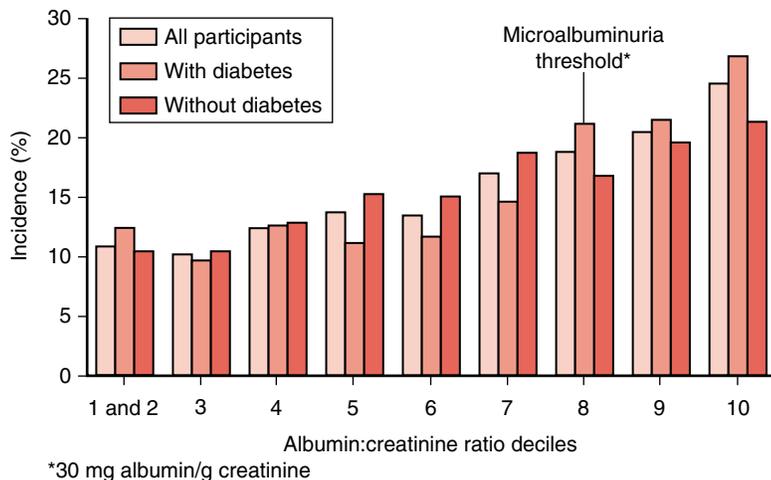

Figure 52-3 Cardiovascular events by the degree of albuminuria in the HOPE study. (From Gerstein HC, Mann JF, Yi Q, et al. Albuminuria and risk of cardiovascular events, death, and heart failure in diabetic and nondiabetic individuals. *JAMA* 286:421-426, 2001.)

Dyslipidemia

NCEP-ATP III recommends that diabetes mellitus should be considered a CHD risk equivalent, for risk factor management. The Expert Panel recommended the treatment of LDL cholesterol in patients with diabetes mellitus to levels <100 mg/dL.²

In type 2 diabetes, the most characteristic pattern of dyslipidemia is elevated triglycerides and decreased HDL cholesterol levels, although all lipoproteins have compositional abnormalities. Surprisingly few good prospective studies of lipoprotein levels in relation to CHD have been performed in diabetic subjects. Available observational studies suggest that low HDL cholesterol may be the most important risk factor for CHD. In studies in which total cholesterol and triglycerides were measured, both were risk factors for CHD, with triglycerides often a stronger predictor. The strength of triglycerides as a risk factor for CHD may depend partially on their association with other variables (e.g., hypertension and plasminogen activator inhibitor 1 [PAI-1]).⁶⁰

Experimental evidence suggests that lipid abnormalities may contribute to the progression of kidney disease. In humans, there is limited clinical trial evidence for this hypothesis.⁶¹

STRATEGIES TO REDUCE CARDIOVASCULAR RISK

Having established that all patients with diabetes mellitus or the cardiovascular metabolic syndrome are at highest risk for cardiovascular and renal events, it is imperative to devise preventive and therapeutic strategies to reduce such events and disease progression in this patient population.

Nonpharmacologic Interventions: Dietary Modification

Dietary modification in the diabetic population should include reductions in carbohydrates, in salt for those with associated hypertension, and in fat for those with dyslipidemia.

Nonpharmacologic Interventions: Physical Activity and Weight Loss

Over the past few decades, there have been trends in the general population towards more sedentary lifestyles. This has contributed to the epidemic of obesity and the cardiovascular metabolic syndrome. Initiation of a graded exercise program

is highly recommended.^{62,63} However, in diabetic patients, aged 35 years or older, who have been previously sedentary, it is recommended that cardiac testing be performed prior to initiation of a vigorous exercise program.¹⁷

Nonpharmacologic Interventions: Tobacco Cessation

Tobacco use is an established independent risk factor for cardiovascular morbidity and mortality in all patients. Furthermore, there is evidence from several clinical trials of an enhanced risk for microvascular and macrovascular disease, as well as premature mortality from the combination of smoking and diabetes. Patients with diabetes should be continuously counseled about smoking cessation, the combined risks of smoking and diabetes for morbidity and mortality; and the proven efficacy and cost-effectiveness of cessation strategies.⁶⁴

Pharmacologic Interventions: Aspirin Therapy

Atherosclerosis and vascular thrombosis are major contributors to cardiovascular morbidity and mortality in patients with diabetes and the cardiovascular metabolic syndrome. Aspirin blocks the synthesis of thromboxane, a potent vasoconstrictor and platelet aggregant, by acetylating platelet cyclooxygenase. The Early Treatment Diabetic Retinopathy Study (ETDRS) proved the safety of aspirin use in the diabetic population.⁶⁵ The ADA published a Position Statement on Aspirin Use in Diabetes recommending enteric-coated aspirin in doses of 81 to 325 mg/day as a secondary prevention strategy in diabetics with evidence of large vessel disease, such as a history of MI, vascular bypass procedure, stroke or transient ischemic attack, peripheral vascular disease, claudication, or angina. Aspirin therapy should also be utilized for primary prevention in high-risk diabetic patients with a family history of CHD, cigarette smoking, hypertension, obesity defined by >120% desirable weight or a BMI >27.3 kg/m² in women or >27.8 kg/m² in men, microalbuminuria or macroalbuminuria, total cholesterol >200 mg/dl, LDL cholesterol ≥100 mg/dl, HDL cholesterol <45 mg/dl in men and <55 mg/dl in women, triglycerides >200 mg/dl, and age >30 years.^{66,67}

Pharmacologic Interventions: Glycemic Control

Atherosclerosis occurs earlier in people with diabetes than it does in those without elevated blood glucose levels. In the Diabetes Control and Complications Trial (DCCT), 1441 patients with type 1 diabetes were randomized to either standard or intensive care. Mean follow-up was 6.5 years. The intensive treatment group achieved a mean hemoglobin A_{1c} (HbA_{1c}) of approximately 7%, whereas the standard care group maintained an approximate HbA_{1c} of 9%. Improved glycemic control was associated with reduced cardiovascular events, but the difference was not statistically significant. However, this may be because the population studied consisted of young adults and therefore the event rate was very low.²⁸

The UKPDS, which recruited 5102 patients with newly diagnosed type 2 diabetes between 1977 and 1991 and followed them for an average of 10 years, showed no increase in cardiovascular events or death with either insulin or sulfonylurea

drugs, despite the fact that both agents led to greater weight gain and higher plasma insulin levels than conventional treatment. The UKPDS showed strong associations between better blood glucose control and lower risk of CVD morbidity and mortality, but no statistically significant effect of lowering blood glucose on cardiovascular complications. There was a 16% reduction (not statistically significant, $p = .052$) in the risk of combined fatal or nonfatal MI and sudden death in the intensively treated group and a continuous association between the risk of cardiovascular complications and glycemia, such that for every percentage point decrease in HbA_{1c} there was a 25% reduction in diabetes-related deaths, a 7% reduction in all-cause mortality, and an 18% reduction in combined fatal and nonfatal MI.²⁹

In obese patients with diabetes mellitus type 2, the UKPDS has shown that initial single-agent intensive therapy with metformin results in a risk reduction of combined diabetes-related endpoints, diabetes-related deaths, all-cause deaths, and MI by about one third when compared with the conventionally treated patients. This risk reduction rate was statistically significant. Metformin was notably associated with an absence of weight gain.⁶⁸

In the Diabetes Mellitus Insulin-Glucose Infusion Acute Myocardial Infarction (DIGAMI) study, 620 diabetic patients with acute MI were randomized to receive insulin-glucose infusion followed by multidose subcutaneous insulin for at least 3 months, and 314 to conventional therapy. After 1 year, the group that received insulin-glucose infusion followed by a multidose insulin regimen had a 29% reduction in mortality.⁶⁹

In conclusion, both the DCCT and the UKPDS showed trends in reducing the risk of cardiovascular events with better glycemic control, but these trends were not statistically significant. Neither study proved definitively that intensive therapy, which lowered blood glucose levels, reduced the risk of cardiovascular complications compared with conventional therapy. Thus, the role of hyperglycemia in cardiovascular complications of diabetes is still unclear.

Pharmacologic Interventions: Blood Pressure Control

The UKPDS showed that in the “tight blood pressure control group,” lowering BP to a mean of 144/82 mm Hg significantly reduced stroke, diabetes-related death, and heart failure, and there was a continuous relationship between the risk of such outcomes and SBP (i.e., there was no evidence of a threshold for these complications above an SBP of 130 mm Hg). However, the risk reduction rate seen in MI (21%) was not statistically significant.⁷⁰

The UKPDS also compared antihypertensive treatment with an ACE inhibitor to that with a β -blocker. Both drugs were equally effective in lowering BP, although patients on β -blockers had slightly better BP control (a 1–mm Hg systolic and 2–mm Hg diastolic improvement). Neither drug was superior to the other in any outcome measured, including diabetes-related death, MI, and all microvascular endpoints. Also, there were no significant differences in microalbuminuria or proteinuria ($p = .09$ for microalbuminuria to microalbuminuria for captopril vs. β -blocker). However, because of the low prevalence of nephropathy in the population studied, it is unclear whether there were sufficient events

to observe a protective effect of either drug on the progression of nephropathy. We conclude that both drugs used to reduce BP are equally effective and safe, and that either can be used with great benefit to treat uncomplicated hypertension in patients with type 2 diabetes. Both conventionally and intensively treated blood glucose study patients had equal benefit from BP lowering. Likewise, the tightly and less tightly controlled BP study patients had equal benefit from blood glucose lowering.⁷¹

In the Captopril Prevention Project (CAPPP) subanalysis, captopril was found to be superior to a diuretic/ β -blocker antihypertensive treatment regimen in preventing cardiovascular events in hypertensive diabetic patients.⁷² Similar results have been observed in the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) study, which included 1513 type 2 diabetic patients with early renal insufficiency and macroalbuminuria. Compared with placebo, the angiotensin receptor blocker (ARB) losartan was shown to reduce new onset CHF, with a statistically insignificant trend for reducing MI.⁷³ A meta-analysis of the data from the IRMA-2 (Irbesartan MicroAlbuminuria Type II Diabetes in Hypertensive Patients), IDNT (Irbesartan Diabetic Nephropathy Trial), and RENAAL trials demonstrated that ARB-based therapy provided a 15% risk reduction ($p = .03$) for cardiovascular events in type 2 diabetics compared with conventional antihypertensive therapy despite equal BP reduction.⁷⁴ Overall, these studies suggest that using a renin-angiotensin-aldosterone system (RAAS) blocking drug as part of an effective antihypertensive regimen in type 2 diabetics provides more cardiovascular risk reduction than a non-RAAS blocker-based medical regimen.

Using an ACE inhibitor or an ARB as part of the antihypertensive regimen clearly provides a distinct advantage for preventing progression of cardiovascular or renal disease, particularly in diabetics. However, it is important to remember that most patients will require multiple drugs for BP control, and that strong data support the use of thiazide diuretics to reduce cardiovascular events in diabetics in both the Systolic Hypertension in the Elderly Program (SHEP) and the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).^{75,76} The reality is, most diabetic hypertensive patients will likely require anywhere from two to five drugs to achieve a SBP goal of 130 mm Hg. Based on the clinical trial evidence, thiazide diuretics and a RAAS-blocking drug are indicated. Many patients will gain additional benefits from both β -blocker and calcium channel blocker (CCB) therapy to achieve lower BP goals. For example, when combined with an ACE inhibitor, the CCB amlodipine was shown to reduce BP, as well as morbidity and mortality, in diabetic hypertensives.⁷⁷ Moreover, the results of ALLHAT validated amlodipine as a useful drug to reduce CVD mortality and a safe antihypertensive drug. In addition, an analysis from the RENAAL study demonstrated that CCB therapy did not attenuate the risk reduction for renal disease progression associated with losartan.⁷⁸ In RENAAL, most patients taking CCBs were on a dihydropyridine.

Pharmacologic Interventions: Microalbuminuria or Macroalbuminuria

Microalbuminuria is predictive of cardiovascular mortality in both diabetic and nondiabetic populations.^{50,53-55} The pres-

ence of microalbuminuria indicates a widespread disturbance of endothelial function, resulting in an enhanced risk for the development of atherosclerosis.⁷⁹⁻⁸² It may thus serve as a useful biomarker for systemic vascular disease.

Once a patient is diagnosed with microalbuminuria, a lower BP goal should be considered because of the greater risk for cardiovascular events. Subgroup analyses of diabetics enrolled in major outcome trials indicate that more intensive control of BP, particularly SBP to <130 mm Hg with blockade of the RAAS as part of the regimen, provides the optimal strategy for both cardiovascular risk reduction^{72,77} and preventing progression from microalbuminuria to macroalbuminuria, and from macroalbuminuria to overt nephropathy.⁸³

Microalbuminuria is a very useful and important screening technique for CVD. It also indicates a need for more intensive BP control, <130/80 mm Hg, preferably including agents that block the RAAS. The presence of microalbuminuria indicates a need for more intensive cardiovascular risk reducing strategies, including attention to lipids, glucose, and platelet function. The ADA recommends yearly microalbuminuria screening for all diabetics. It may also be appropriate to recommend expansion of screening to include all patients in whom we suspect the cardiovascular metabolic syndrome.

Pharmacologic Interventions: Correction of Dyslipidemia

In clinical trials that included diabetics, LDL reduction with statins has led to significant improvements in CHD incidence and cardiovascular and overall mortality. The Helsinki Heart Study recruited 4081 asymptomatic middle-aged men (40 to 55 years of age) with primary dyslipidemia and randomized them to gemfibrozil versus placebo. Gemfibrozil led to a 34% reduction in the incidence of CHD in all patients. Similar results were observed in the 135 diabetic participants in posthoc subgroup analysis, were not statistically significant perhaps, because of small sample size.^{84,85} The Scandinavian Simvastatin Survival Study (4S) recruited 4444 patients with angina pectoris or previous MI, 202 of whom were diabetics, and randomized them to simvastatin or placebo. The statin was associated with a 42% reduction in cardiovascular mortality and a 30% reduction in overall mortality among all subjects.⁸⁶ Posthoc subgroup analyses showed a 55% reduction in major coronary events in diabetic subjects.⁸⁷ These results were reproduced in the Cholesterol and Recurrent Events Trial (CARE), which recruited 4159 patients with MI, 586 of whom were diabetic. Pravastatin resulted in a 24% reduction in CHD events in all patients, and posthoc subgroup analyses showed similar reduction rates in diabetics (25%) and nondiabetics (23%).^{88,89}

The very positive results of statin trials point to LDL cholesterol as being a major predictor of CHD risk in diabetic patients. Therefore, the primary target of therapy in diabetic patients is lowering LDL cholesterol (and possibly, non-HDL cholesterol). Based on the aforementioned results, statins are the preferred pharmacologic agent in this situation. Reduction of LDL levels should take priority over reduction of triglycerides in combined hyperlipidemia because of the proven safety of the statin class of drugs, as well as greater reduction in CHD incidence. Once LDL cholesterol levels have been lowered, attention can be given to treatment of residual hypertriglyceridemia and low HDL.⁶⁰ However, it is

still not known whether an LDL goal below the currently recommended 100 mg/dl, such as 70, 80, or 90 mg/dl will provide more cardiovascular risk reduction in the diabetic.

STRATEGIES TO REDUCE KIDNEY DISEASE RISK

Nonpharmacologic Interventions to Preserve Kidney Function in Diabetics

Lifestyle intervention should focus on dietary modification, including low-saturated fat and low-salt diets, weight reduction and increased physical activity, cessation of tobacco use, and moderation in alcohol consumption. Because the majority of patients with diabetes have hypertension, nonpharmacologic interventions to assist in the reduction of BP will help preserve kidney function.

Increasing salt intake attenuates the antihypertensive and antiproteinuric effects of ACE inhibitors and ARBs.⁹⁰ In hypertensive humans, high-salt intake increases glomerular filtration fraction.^{91,92} In a diabetic rat model of renal insufficiency, salt restriction reduces hyperfiltration, renal enlargement, and albuminuria.⁹³ Thus, salt restriction should be encouraged in the hypertensive diabetic patient. Clinical trials need to assess the relationship of salt intake and risk for renal disease progression in diabetics to provide specific guidelines for optimal dietary approaches.

Moderate protein restriction has been shown to reduce albuminuria, progression of renal disease, and improve outcome in type 1 and type 2 diabetes. This benefit is described in addition to the beneficial effect of antihypertensive treatment.^{94,95} A 4-year follow-up of 82 type 1 diabetic patients with macroalbuminuria suggested that patients on a low-protein diet (0.6 g/kg/day) had significantly slower ($p = .01$) progression to death, dialysis, or transplant compared with a usual protein diet group (1.02 g/kg/day).⁹⁶ Increasing protein in the diet causes glomerular capillary hypertension, which provides the rationale as to why lower protein intake is beneficial in reducing progression of renal disease in diabetics. However, the implementation of protein restriction in patients with kidney disease is controversial in part, because many patients with advanced kidney disease have poor nutrition. While theoretical reasons and some clinical data support the benefits of this intervention, this recommendation has not been uniformly accepted in the United States.

Pharmacologic Interventions: Glycemic Control

Several major trials have shown that glycemic control preserves kidney function and delays the development of renal damage in diabetics. This, along with the fact that hypertension is far more prevalent in the diabetic population, highlight two major strategic interventions to preserve kidney function in these patients: strict glycemic control and optimal BP control.

In patients with type 2 diabetes, the UKPDS confirmed that improved blood glucose control reduces the risk of developing microvascular complications, including nephropathy. The overall microvascular complication rate decreased by 25% in patients receiving intensive therapy (median HbA_{1c} 7.0%) versus conventional therapy (median HbA_{1c} 7.9%). There was

a continuous relationship between the risk of microvascular complications and glycemia, such that for every percentage point decrease in HbA_{1c}, there was a 35% reduction in the risk of microvascular complications. There was no evidence of any glycemic threshold above a normal HbA_{1c} level of 6.2%; therefore the results of the UKPDS mandate that treatment of type 2 diabetes include aggressive efforts to lower blood glucose levels as close to normal as possible.

Pharmacologic Interventions: Blood Pressure Control

As mentioned earlier, JNC 7 recommends a goal BP in patients with diabetes mellitus of <130/80 mm Hg.³⁸ JNC 7 estimates that most patients with hypertension will require two or more antihypertensive medications to achieve this goal BP; if the BP is more than 20/10 mm Hg above goal, it is best to consider initiating therapy with two agents.³⁸ In fact, the average number of antihypertensive agents needed to achieve optimal BP control in patients with CKD is estimated at 2.6 to 4.3 agents.⁹⁷ Several clinical trials have supported the conclusion that the vast majority of hypertensive patients, even in the absence of diabetes, will need more than one antihypertensive medication to control their BP. In diabetic patients, there is evidence that the achievement of optimal BP is a major strategy to preserve renal function and delay the progression of renal disease.

The UKPDS showed that lowering BP by 10/5 mm Hg to a mean of 144/82 mm Hg significantly reduced microvascular complications that there was a reduction in the risk of microvascular outcomes compared with less aggressive treatment. They also noted that there was a continuous relationship between the risk of microvascular outcomes and SBP; that is, there was no evidence of a threshold for these complications above a SBP of 130 mm Hg.⁷⁰

The choice of the appropriate antihypertensive agent for the individual patient should be based on an educated decision after evaluating evidence from controlled clinical trials. In the treatment of the diabetic patient, the antihypertensive regimen should include an ACE inhibitor or an ARB. Aldosterone receptor antagonists also might have a role but need to be studied in more detail.^{98,99}

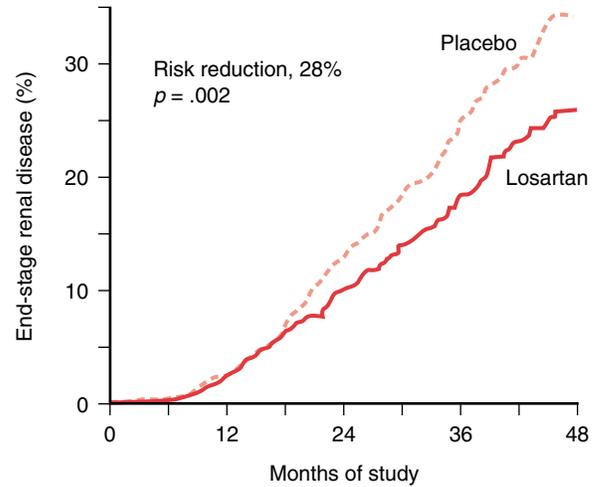

There are excellent clinical data demonstrating the advantage of lower BP goals in preventing renal disease progression in diabetics. A series of studies in microalbuminuric patients clearly provide evidence of the advantage of lower BP goals combined with RAAS blockade. Viberti et al.⁴⁸ studied 92 normotensive type 1 and type 2 diabetic patients whose mean BP before therapy was 124/77 mm Hg. After 2 years of follow-up, captopril-treated patients (BP reduction of 4/2 mm Hg) had significantly decreased progression to clinical proteinuria compared with a placebo group.⁴⁸ In another study, 94 patients with a mean pretreatment BP of 130/80 mm Hg were followed for 7 years. Patients on enalapril 10 mg had a 42% risk reduction for nephropathy compared with those taking a placebo.¹⁰⁰ Similar data have shown that ARB (irbesartan 300 mg) therapy provided a 70% risk reduction versus placebo for progression of microalbuminuria to clinical proteinuria in hypertensive type 2 diabetics.¹⁰¹ Another trial in type 2 diabetics compared valsartan and amlodipine and demonstrated a BP-independent antimicroalbuminuric effect of the ARB.¹⁰² In patients with clinical proteinuria the Collaborative Study

Group conducted the definitive trial demonstrating the advantage of the ACE inhibitor captopril in preventing ESRD in the type 1 diabetic.¹⁰³

Studies with ARBs confirm the renoprotective effects of these drugs in patients with nephropathy associated with type 2 diabetes. The RENAAL study included 1513 type 2 diabetic patients with early renal insufficiency and macroalbuminuria. Compared with placebo, the ARB (losartan) was demonstrated to reduce proteinuria and ESRD.⁷³ RENAAL was the first trial to show that any therapy could significantly reduce the incidence of ESRD in type 2 diabetes (Figure 52–4). The IDNT trial also demonstrated the significant benefit of a multidrug regimen including irbesartan 300 mg compared with traditional multidrug therapy or an amlodipine-based regimen to reduce the composite endpoint of doubling of serum creatinine, ESRD, or death in 1715 patients with type 2 diabetes, clinical proteinuria, and early renal insufficiency (Figure 52–5).^{103,104}

Because diabetic hypertensive patients often require multidrug regimens for adequate BP control, one needs to consider other therapies that are safe, well tolerated, and work well with the ACE inhibitor or ARB in reducing blood BP. Thiazides, or loop diuretics if there is renal insufficiency, facilitate the antihypertensive properties of the ACE inhibitor or ARB. Likewise, CCBs have demonstrated important and robust antihypertensive effects,⁷⁷ which make them useful adjuvant therapy in most diabetic hypertensives. β -Blockers are also useful adjuvants in the diabetic because of their important effects in reducing cardiovascular events, particularly in patients with angina, post-MI, and with systolic dysfunction.

Microalbuminuria is one of the most important factors in predicting progression to macroalbuminuria or overt nephropathy in both type 1 and type 2 diabetics.⁵⁰⁻⁵² Microalbuminuria indicates early renal damage, and the consequent need for more stringent BP control, preferably with drugs that block the RAAS, as these drugs provide both antihypertensive and antiproteinuric effects. Microalbuminuria is also an indicator of systemic vascular disease, as well as a risk factor for cardiovascular events. Consequently, once a patient is diagnosed with microalbuminuria, a lower BP goal should be applied, in addition to intensive control of glucose

No. at risk	0	12	24	36	48

Figure 52–4 Kaplan-Meier curves of the percentage of patients with end-stage renal disease (ESRD). (Adapted from Brenner BM, Cooper ME, de Zeeuw D, et al. Effects of losartan on renal and cardiovascular outcomes in patients with type 2 diabetes and nephropathy [RENAAL]. *N Engl J Med* 345:861-869, 2001.)

and lipids, with the ultimate goal being to prevent cardiovascular events. Normalization of urine microalbumin may serve as a clinical clue that optimal BP control is being achieved. This theoretical construct is based on evidence from clinical trials that reduction of microalbuminuria is associated with less likelihood for progression to macroalbuminuria and diminished risk for progression of kidney disease.

Pharmacologic Interventions: Correction of Dyslipidemia

Bianchi et al.⁶¹ conducted a prospective, controlled open-label study to evaluate the effects of 1-year treatment with atorvastatin versus no treatment on proteinuria and progression of

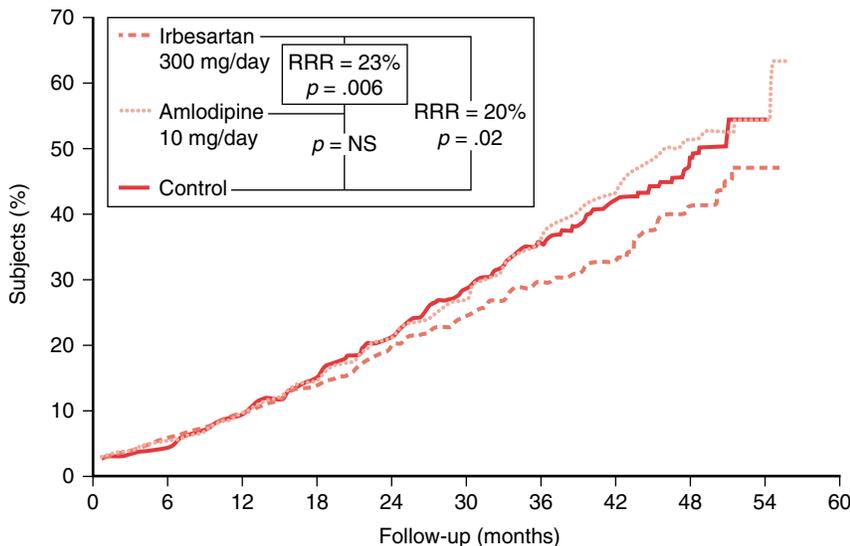

Figure 52–5 IDNT primary endpoint: time to doubling of serum creatinine, end-stage renal disease (ESRD), or death. (From Lewis EJ, Hunsicker LG, Clarke WR, et al., for Collaborative Study Group. Renoprotective effect of the angiotensin-receptor antagonist irbesartan in patients with nephropathy due to type 2 diabetes. *N Engl J Med* 345:851-860, 2001.)

kidney disease in 56 patients with CKD. Before randomization, all patients had already been treated for 1 year with ACE inhibitors or ARBs and other antihypertensive drugs. By the end of 1 year of treatment, urine protein excretion decreased from 2.2 ± 0.1 g to 1.2 ± 1.0 g every 24 hours ($p < .01$) in patients treated with atorvastatin in addition to ACE inhibitors or ARBs. By contrast, urinary protein excretion did not decrease significantly (from 2.0 ± 0.1 g to 1.8 ± 0.1 g every 24 hours, $p =$ not significant) in patients who did not receive atorvastatin in addition to an ACE inhibitor or ARB. During this time, creatinine clearance decreased only slightly and not significantly (from 51 ± 1.8 ml/min to 49.8 ± 1.7 ml/min) in patients treated with atorvastatin. By contrast, during the same period of observation, creatinine clearance decreased from 50 ± 1.9 to 44.2 ± 1.6 ml/min ($p < .01$) in patients who did not receive atorvastatin. The authors concluded that treatment with atorvastatin in addition to a regimen including ACE inhibitors or ARBs may reduce proteinuria and the rate of progression of kidney disease in patients with CKD, proteinuria, and hypercholesterolemia.⁶¹ Although these patients were not all diabetic, it is likely that the benefit would be extrapolatable to diabetic populations. The same could be said for improving glycemic control, as a recent study comparing

intensive versus less intensive strategies to control BP, lipids, and glucose by the Steno group demonstrated the benefit of intensive therapy on the development of nephropathy, autonomic neuropathy and cardiovascular death (Figure 52–6).¹⁰⁵

SUMMARY

The approach to the patient with diabetes mellitus or cardiovascular metabolic syndrome should combine early detection of comorbid risk factors and target organ damage, design of prevention strategies and lifestyle modification, and multitargeted pharmacologic interventions. This requires that all such patients should have their BMI, and waist circumference, and waist:hip ratio checked periodically. They should also be screened periodically for tobacco use, presence of high BP, dyslipidemia, and microalbuminuria or macroalbuminuria.

Prevention strategies should aim at a well-designed exercise program and weight loss to achieve a BMI <30 kg/m², a waist:hip ratio <0.90 in men and <0.85 in women, or a waist circumference <102 cm or 40 inches in men and <88 cm or 35 inches in women. Cardiac evaluation may be needed in diabetic patients 35 years or older who have been previously

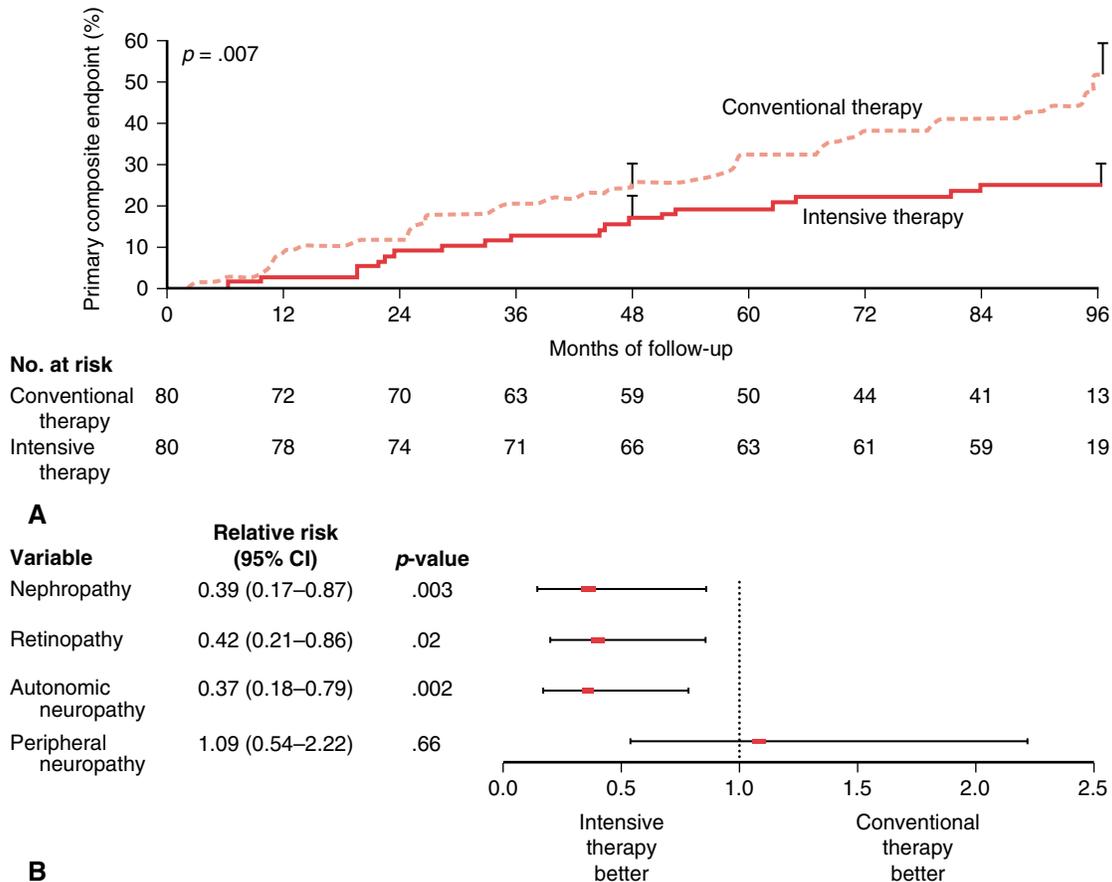

Figure 52–6 (A), Kaplan-Meier estimates of the composite endpoint of death from cardiovascular causes. **(B)**, Relative risk for each variable based on type of therapy. (From Gaede P, Vedel P, Larsen N, et al. Multifactorial intervention and cardiovascular disease in patients with type 2 diabetes. *N Engl J Med* 348:383-393, 2003.)

sedentary. Dietary modification should aim at salt reduction in the hypertensive patient, low-carbohydrate diet in the diabetic patient, and low-fat diet in the dyslipidemic patient. Moderate protein reduction is also recommended. Alcohol consumption should be reduced to moderate levels or abstinence. Patients should be counseled at every clinic visit about tobacco cessation and all possible help should be offered to achieve it.

Pharmacologic interventions should include aspirin in doses of 81 to 325 mg/day. Glycemic control should target a goal $HbA_{1c} < 7\%$. Metformin may be of added benefit in the obese patient when compared with other agents. BP control to a goal $< 130/80$ mm Hg and normalization of microalbuminuria or macroalbuminuria with a multidrug regimen to include an ACE inhibitor in type 1 diabetics and an ARB in type 2 diabetics should be aggressively pursued. Dyslipidemia should be corrected; hydroxymethylglutaryl-coenzyme A reductase inhibitors (statins) may be used to achieve an LDL cholesterol level < 100 mg/dl. Once LDL cholesterol levels is lowered to optimal levels, lowering non-LDL cholesterol to < 130 mg/dl and lowering triglycerides to normal, and increasing HDL cholesterol level to > 40 mg/dl in males and > 45 mg/dl in women should be pursued. Fibrates may be a useful adjunct for the latter purposes, with special attention to the increased risk of myositis with these agents.

Diabetic patients will derive greater cardiovascular and renal risk reduction benefits from these approaches if they are initiated early. This will require multiple medications, good compliance, and a multidisciplinary effort.

Hypertension in Patients on Renal Replacement Therapy

Todd W. B. Gehr, Domenic A. Sica

PREVALENCE OF HYPERTENSION IN DIALYSIS PATIENTS

The prevalence of hypertension in patients with end-stage renal disease (ESRD) ranges between 70% and 90%.^{1,2} Hypertension prevalence in ESRD (in other comorbid conditions such as diabetes) is definitionally dependent. In a survey of 2535 clinically stable adult hemodialysis patients, hypertension—as defined by either a systolic blood pressure (SBP) of >150 mm Hg or a diastolic blood pressure (DBP) >85 mm Hg or use of antihypertensive medications—was documented in 86% of the cohort.¹ These prevalence rates are in striking contrast to those of the general U.S. population for whom National Health and Nutrition Examination Survey (NHANES) data report a hypertension prevalence rate of 28.7%.³

The prevalence of hypertension in ESRD also appears to vary in keeping with population demographics. In the ESRD population, not unlike the general population, males and African Americans have a higher prevalence of hypertension. Also, during the first year of dialysis the prevalence of hypertension often declines only to return as dialysis goes on. The timing of specific blood pressure (BP) measurements (as determinants of the presence of hypertension) in ESRD can complicate the designation of a patient as being hypertensive. The point in time of BP measurement becomes less of an issue when ambulatory BP monitoring (ABPM) is employed as the diagnostic medium.⁴ ABPM can be both a diagnostic tool and a means for determining adequacy of BP control in ESRD. For example, in a cohort of 53 hypertensive ESRD patients, only 15% maintained BP readings consistently <150/90 mm Hg over a 48-hour interdialytic period despite being actively treated for their hypertension.⁵

HYPERTENSION AND DIALYSIS MODALITY

The prevalence of hypertension in renal replacement therapy (RRT) patients may also be dependent on the dialysis modality. For example, the prevalence of hypertension in peritoneal dialysis (PD) is viewed as being less than in hemodialysis (HD) patients with early reports showing that continuous ambulatory peritoneal dialysis (CAPD) provided more effective control of volume overload and hypertension.^{6,7} PD also appeared to offer some distinct advantages over intermittent HD in that the hemodynamic perturbations with PD were less disruptive and antihypertensive medication pharmacokinetics more predictable.⁸ Accordingly, in the short term, BP control on CAPD proved superior (particularly as relates to SBP)⁹ to that of HD as long as the CAPD patient maintained some residual renal function¹⁰ and peritoneal ultrafiltration capacity was intact.¹¹

However, peritoneal transport characteristics may be important in determining the BP pattern of the CAPD patient. For example, when 24-hour ABPM was performed in a group of 25 CAPD patients and related to peritoneal transport characteristics, patients who were “high transporters” (reflecting high glucose absorption and poor ultrafiltration) had higher SBP and DBP values both during the day and at night. Left ventricular mass index was also higher in this group when compared with “low transporters.”¹² Thus, it is not surprising that more long-term studies have shown a less-favorable hemodynamic profile for CAPD patients, particularly since the common scenario of insidious volume expansion would be expected to lead to BP increase and thereby left ventricular hypertrophy (LVH) more than with intermittent HD.^{13,14} However, this deterioration in hemodynamic profile (compared with HD patients) can be prevented if volume status is strictly controlled in the long-term CAPD patient.¹⁵

A number of factors favorably influence both the prevalence and severity of hypertension in the HD patient. Two such modifications of the dialysis prescription include quotidian (daily) forms of dialysis: (1) short daily or (2) long nocturnal dialysis, 6 times per week.^{16,17} Because the interdialytic period is shorter with quotidian dialysis, fluid shifts are minimized, as are the negative effects on cardiac function and hemodynamics. Patients on daily hemodialysis have been shown to obtain better BP control and a greater reduction in LVH.¹⁸ The London Daily/Nocturnal Hemodialysis Study has also shown that patients treated with quotidian dialysis experienced significant reductions in BP even as they took fewer antihypertensive medications.¹⁶ Observational studies with nocturnal hemodialysis bear out these findings.^{19,20}

CARDIOVASCULAR DISEASE IN END-STAGE RENAL DISEASE

Cardiovascular disease (CVD) and cerebrovascular disease account for more than 50% of all ESRD deaths, a figure that is remarkably similar around the world^{21,22} (Figure 53–1). In fact, Clyde Shields, the first patient on long-term dialysis, died from a myocardial infarction (MI) in 1970, aged 50 years, 11 years after starting hemodialysis.²³ LVH is the most frequent cardiac abnormality in patients with ESRD²⁴ and, if left untreated, all too often progresses through phases of diastolic dysfunction, ventricular dilation, and systolic dysfunction, to death.²⁵ In addition to hypertension, episodic sodium and water retention, chronic volume and flow overload, associated with anemia and/or arteriovenous shunting, as well as non-hemodynamic factors, such as hyperparathyroidism and increases in angiotensin II (Ang II) and endothelin, also contribute to the development of LVH.²⁶

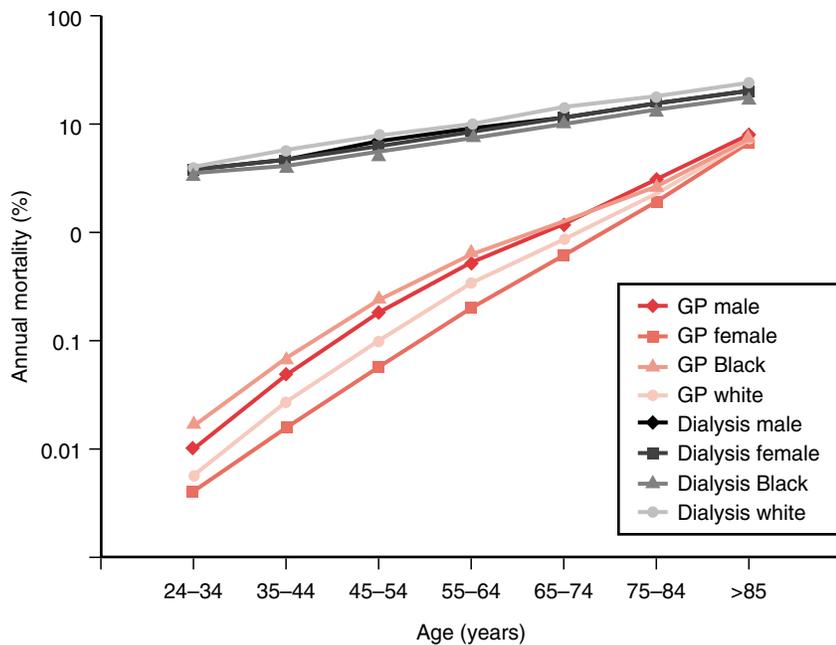

Figure 53-1 Annual cardiovascular mortality by age group in the general population (GP) and in patients on dialysis. (From Foley RN, Parfrey PS, Sarnat MJ. Clinical epidemiology of cardiovascular disease in chronic renal disease. *Am J Kidney Dis* 32:S112-S119, 1998.)

HYPERTENSION AND CARDIOVASCULAR DISEASE IN END-STAGE RENAL DISEASE

Whereas the general population has experienced a significant reduction in age-adjusted risk of death from CVD and cerebrovascular disease, this has not been the case for ESRD patients.^{27,28} Any direct relationship between hypertension and cardiovascular mortality remains poorly defined, in part, because there are no prospective interventional trials in dialysis patients examining this issue.^{29,30} Because of the increased number of cardiovascular risk factors in patients on dialysis, it would seem reasonable that lowering the BP in these persons would reduce cardiovascular risk. In one study of a select group of ESRD patients, normal BP values without antihypertensive therapy (in the setting of a higher than usual dose of dialysis) were associated with a reduction in cardiovascular mortality.³¹ However, few observational studies have associated hypertension with a shorter survival and good/excellent BP control with increased survival.³²

Surprisingly, several studies have even suggested the contrary (i.e., they have failed to identify hypertension as having a major influence on cardiovascular risk in large cohorts of ESRD patients³³⁻³⁴ and have often found “U-shaped” correlation for more frequent cardiovascular deaths at very high and very low BP values.³⁵ This relationship was explored for predialysis and postdialysis SBP/DBP in an observational study of 4499 U.S. hemodialysis patients as part of the Case Mix Adequacy Study of the U.S. Renal Data System (USRDS). Patients with a predialysis SBP <110 mm Hg had an elevated adjusted mortality rate; however, predialysis systolic hypertension was not associated with excess mortality risk, although there was an increase in cerebrovascular deaths in this group. Low and high (>180 mm Hg) postdialysis SBP values (as compared with midrange SBP) were associated with increased mortality.³⁰

The relationship between BP and cardiovascular risk is further confounded by the lack of agreement on which BP

values—predialysis, postdialysis, off-dialysis day, and/or pulse pressure—provide the greatest predictive accuracy for cardiovascular risk/protection.^{36,37} A large representative sample of patients undergoing maintenance hemodialysis have been found to have an increased risk of death in association with a widened pulse pressure (Figure 53-2).³⁸ Further confusing this issue is the observation that routine dialysis unit BP determinations (oftentimes obtained by poorly trained staff) can systematically exceed standardized readings. In one study, 55% of surveyed patients were noted to have postdialysis SBP measurements greater by at least 10 mm Hg than standardized readings obtained by trained evaluators.³⁹

PATHOGENESIS

A number of pathogenic factors contribute to the development of and/or persistence of hypertension in patients on RRT. Because mean arterial pressure is a product of both cardiac output and peripheral vascular resistance, both factors play an important role in the pathogenesis of ESRD-related hypertension. Another important determinant of BP (in particular, SBP and pulse pressure) in ESRD is vessel compliance and pressure wave reflectance.⁴⁰

In most dialysis patients, multiple factors typically contribute to the pathogenesis of their hypertension. Despite this, a sensible approach to sorting out the pathogenesis of hypertension in a dialysis patient can be arrived at by classifying it into volume-dependent and volume-independent categories based on the response to ultrafiltration. Volume-dependent hypertension is by far the more common of the two and is usually characterized by normal to low plasma renin activity with a reduction in BP with either dietary sodium restriction or gradual net volume removal during consecutive dialysis sessions. Volume-independent forms of hypertension in ESRD are accompanied by a relative, if not, an absolute increase in the activity of the renin-angiotensin system (RAS), as well as limited BP reduction in response to volume removal and/or

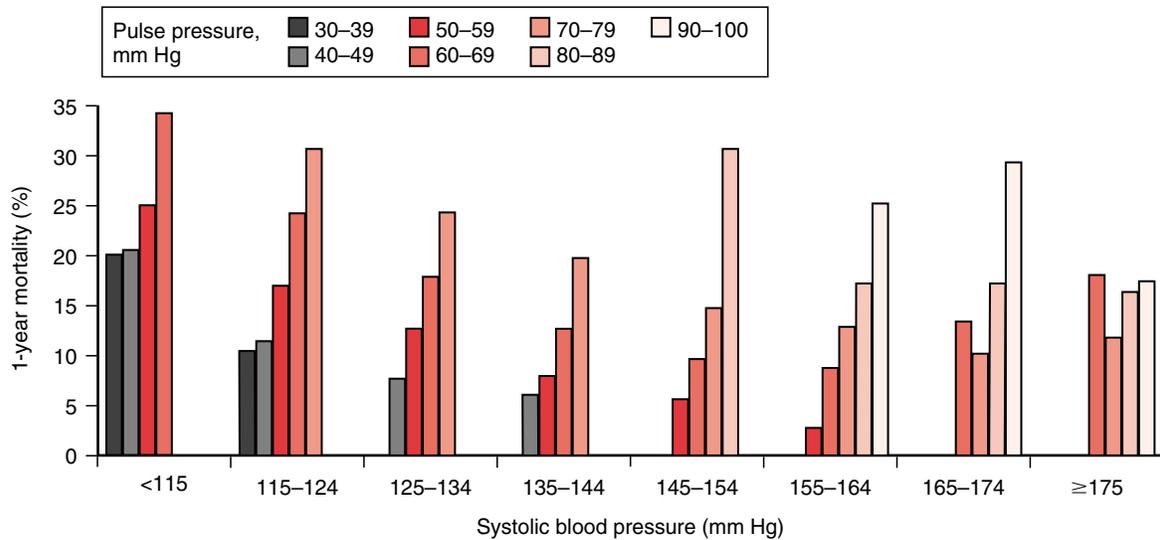

Figure 53-2 Percentage of patients who died at 1 year within categories of postdialysis systolic blood pressure (SBP) and pulse pressure. Categories with fewer than 10 patients are not shown. Within each category of SBP, the grouped columns indicate death percentage as pulse pressure increases. Within each pulse pressure category, the death percentage can be followed across categories of increasing SBP. (From Klassen PS, Lowrie EG, Reddan DN, et al. Association between pulse pressure and mortality in patients undergoing maintenance hemodialysis. *JAMA* 287:1548-1555, 2002; with permission.)

dietary sodium restriction. In its most extreme form, bilateral nephrectomy has been required to control BP in ESRD.⁴¹

Although it is clinically useful to divide ESRD hypertension into these broad categories, additional factors play a role in its pathogenesis. Such factors should always be considered in the context of a patient's prevailing volume status/hemodynamic profile. Moreover, ESRD-related hypertension can reflect a carryover of pathogenic factors from the pre-ESRD period. As mentioned, volume and sodium excess are prime factors in the pathogenesis of hypertension in chronic kidney disease (CKD) and persist in ESRD.

Early phases of hypertension in CKD are generally marked by an increase in cardiac output and low to normal peripheral vascular resistance. Progressive renal disease is regularly accompanied by the onset of anemia and/or creation of an arteriovenous fistula, circumstances that reinforce the high cardiac output state. Changes in cardiac output can be attenuated with correction of anemia,⁴² in which case the continued presence of hypertension becomes a function of increased peripheral vascular resistance, which positively correlates with the increase in exchangeable sodium that underscores the progression to ESRD.⁴³ Finally, the BP response to changes in sodium/volume status may be influenced by disturbances in the activity of and response to various neurohumoral pathways.⁴⁴

Activation of the renin-angiotensin-aldosterone axis is a frequently cited factor in the pathogenesis of ESRD-related hypertension, but it is the predominant factor in only a handful of patients. The significance of this activation lies more in failure of appropriate renin suppression in the volume-expanded environment, typical of most ESRD patients.⁴⁵ Tissue-based Ang II production may also be implicated in the hypertension and CVD of the ESRD patient; however, this has not been directly studied.⁴⁶ Aldosterone (as both an autocrine and paracrine substance) is also increasingly viewed as a con-

tributor to the pathobiology of CVD. However, its exact pathogenic role in the ESRD patient has yet to be determined.⁴⁷

Increased activity of the sympathetic nervous system (SNS) may be either directly or indirectly involved in ESRD-related hypertension.^{48,49} Simple techniques for measurement of sympathetic activity are not available; and much has been wrongly inferred from relatively nonspecific indicators of sympathetic activity, such as the physical findings BP and pulse rate and/or the biomarker plasma norepinephrine concentration. The latter is particularly difficult to interpret in CKD, because plasma catecholamine concentrations are approximately doubled in the advanced stage of this disease.⁵⁰ Sympathetic nerve recordings are more accurate measures of sympathetic activation. Converse et al.⁵¹ found that peroneal nerve sympathetic discharge was 2.5 times higher in hemodialysis patients than in normal persons and could be normalized by bilateral nephrectomy, suggesting that reduced sympathetic nerve discharge may be one mechanism by which bilateral nephrectomy reduces BP. Moreover, neuropeptide Y, a 36-amino acid vasoactive peptide, is released during sympathetic stimulation, as in volume overload⁵² and is independently associated with LVH and systolic dysfunction in ESRD.⁵³ An increase in neuropeptide Y is one of several pathways by which SNS activation indirectly influences cardiovascular structure and function.

A host of other factors have been suggested as contributors to the pathogenesis of hypertension in ESRD. A full discussion of all such factors would exceed the scope of this chapter, and the reader is directed to several authoritative reviews on this theme.^{2,44} The roles of nitric oxide (NO), circulating inhibitors of Na⁺,K⁺-ATPase and the calcium-phosphate axis in the pathogenesis of hypertension in ESRD are discussed briefly here.

NO deficiency occurs in ESRD and has been proposed as one of several factors contributing to hypertension in this

population.⁵⁴ NO production by the vascular endothelium is inhibited by asymmetric dimethylarginine (ADMA). Levels of ADMA are 6- to 10-fold higher in hemodialysis patients than in healthy persons. Although ADMA levels are reduced by up to 65% during a standard 5-hour hemodialysis session, any reduction in plasma levels is transient.⁵⁵ In persons whose plasma ADMA levels fall with dialysis, a decrease in mean 24-hour ambulatory BP has been observed.⁵⁶ Of note, higher levels of exhaled NO are found in hemodialysis patients prone to low BP.⁵⁷

Circulating natriuretic substances (including digoxin-like immunoreactive substances) appear to accumulate in CKD and in so doing could bring about a generalized inhibition of Na⁺,K⁺-ATPase. The ensuing rise in intracellular Na⁺ concentration in vascular smooth muscle cells could then diminish Na⁺/Ca²⁺ exchange and thereby increase intracellular calcium concentration, resulting in a persistent state of vasoconstriction.⁵⁸ Consistent with these data, both false-positive digoxin levels (relating to digoxin-like immunoreactive substances)⁵⁹ and circulating Na⁺,K⁺-ATPase inhibitors have been identified in hemodialysis patients and are correlated with interdialytic weight gain.⁶⁰

Defects in calcium metabolism are ubiquitous in dialysis patients and are typically manifest by secondary hyperparathyroidism, which may increase BP via entry of calcium into vascular smooth muscle cells.⁶¹ Allosteric activators of the calcium-sensing receptor, which reduce parathyroid hormone levels in the setting of secondary hyperparathyroidism, are associated with a reduction in BP.⁶²

TREATMENT AND BLOOD PRESSURE GOALS IN HYPERTENSIVE END-STAGE RENAL DISEASE PATIENTS

BP goals in ESRD patients remain controversial, since no randomized, prospective outcome trials have expressly examined the issue of what represents an optimal BP in ESRD patients. This information void makes an evidence-based medicine approach to BP control unfeasible in ESRD patients. Recommendations advising BP goals below those currently advocated for the general population are occasionally forthcoming. These suggestions should not be widely applied based on the unique and highly individualized nature of the hypertension in this population.

The target BP in hypertensive ESRD patients with classic systolic/diastolic hypertension (without intradialytic hypotension) should not differ from that recommended for the general population, <140/90 mm Hg.⁶³ Certain high-risk patient groups such as diabetics should be treated to the currently suggested goal BP of <130/80 mm Hg. However, this recommendation often requires a deft touch in clinical practice since orthostatic hypotension is not uncommon in the hypertensive ESRD patient with diabetes.⁶⁴

Hypertension in ESRD patients is mainly systolic, reflecting a loss of aortic distensibility and premature vascular aging.⁶⁵ The recommended BP goal for ESRD patients with predominantly systolic hypertension (with a widened pulse pressure) is a matter of personal opinion. These patients can be treated empirically to a goal SBP according to current guidelines, with the final SBP goal being influenced by several factors, including: drug tolerance, coexisting coronary and/or cerebrovascu-

lar disease, and/or how much the SBP is reduced. The clinician should be mindful of the U-shaped correlation for cardiovascular mortality in this population.

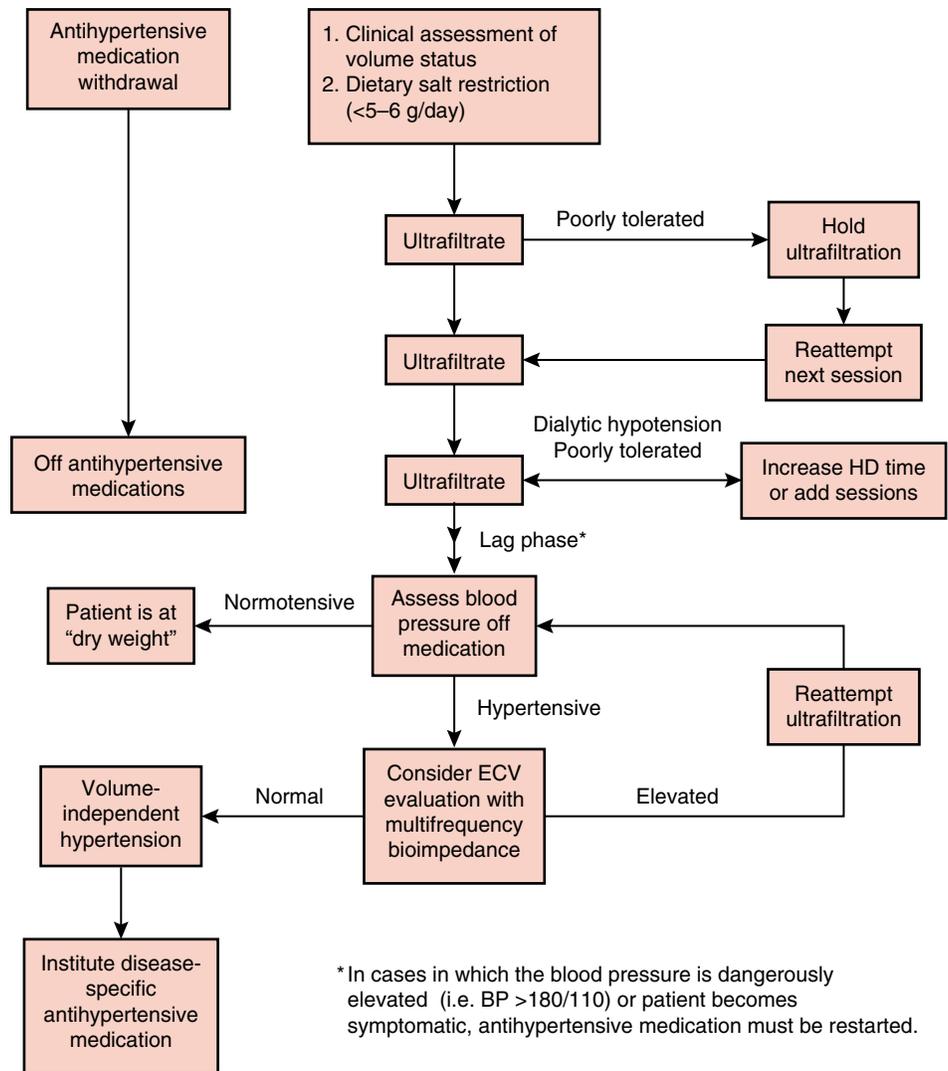

Nonpharmacologic Treatment

Irrespective of the individual patient's "mechanism" of hypertension, the first step in the nonpharmacologic management of hypertension is to set and achieve a true target or "dry weight." The term *dry weight* does not have a consensus definition, however.⁵⁸ Various definitions have been employed: (1) the weight at which there is an absence of overt physical findings of volume overload, such as peripheral edema, rales, or neck vein distension; (2) the weight at which the patient cannot tolerate the associated BP and symptom profile⁶⁶; and (3) the postdialysis weight at which the patient is persistently normotensive without antihypertensive medications and despite interdialytic weight gain.^{67,68} Noninvasive methods, such as ultrasound measurement of inferior vena cava diameter and multifrequency bioimpedance hold some promise for evaluating volume status, but access to these techniques, proficiency of use by staff, and cost are limiting factors in their application.^{69,70}

The most stringent criterion for having reached a patient's "dry weight" is that of BP being controlled throughout the interdialytic period without the need for antihypertensive medications, but even this has several caveats attached to its broad-based application, including (1) There is a limited correlation between interdialytic weight gain and BP.⁷¹ (2) Excessive weight reduction can activate the RAS and SNS and alter cardiac hemodynamics in such a way that certain patients experience a paradoxical increase in BP despite falling below their dry weight.^{72,73} (3) The nutritional status of the ESRD patient is ever-changing and it is not uncommon that lean body weight occasionally decreases; however, unlike normal renal function patients where such lean body weight loss can be recognized by a fall in body weight, the ESRD patient sees no such fall in body weight since interdialytic volume gains "substitute" for muscle mass lost. Consequently, maintenance of a constant body weight in such an ESRD patient reflects an ongoing gradual expansion of extracellular volume replacing lost muscle weight.^{58,66} (4) Reduction in extracellular volume via ultrafiltration does not immediately translate into BP reduction because there is a nonlinear relationship between extracellular volume status and BP. This "lag phase" is such that BP is not immediately controlled after ultrafiltration to a dry weight, especially in patients who are chronically volume overloaded.^{5,58,74}

As previously mentioned, the initial phase of hypertension therapy in the ESRD patient entails the clinical assessment of volume status and an attempt to reach a patient's dry weight with a combination of dietary sodium restriction and dialysis-related ultrafiltration. During the initiation stage of hemodialysis, a patient's true dry weight is probed as weight begins to fall in tandem with efforts at ultrafiltration. It is of the essence that antihypertensive medications be tapered and withheld as this optimal weight is being sought. Failure to withhold medications can lead to a confusing picture characterized by assorted clinical scenarios of hypotension and hypertension. There can be a lag phase of several weeks before the full effect of volume removal on the BP is evident (Figure 53–3).

Figure 53-3 Schematic for the control of blood pressure (BP) in the end-state renal disease (ESRD) patient on hemodialysis. (From Khosla UM, Johnson RJ. Hypertension in hemodialysis patients and the “lag phenomenon”: Insights into pathophysiology and clinical management. *Am J Kidney Dis* 43:739-751, 2004.)

Several alternatives to traditional dialysis may facilitate BP control. For example, thrice-weekly hemodialysis is the most commonly used form of RRT; however, there is an emerging body of evidence that frequent intensive hemodialysis—such as short daily or nocturnal dialysis, six times a week—offers superior uremic toxin clearance, BP control, and improvement in cardiovascular outcomes.¹⁶⁻²⁰ Such departures from the routine dialysis prescription have been integrated into the treatment plan for hypertension in only a handful of ESRD patients.

BP control may seem simplified in patients receiving CAPD because of the continuous nature of fluid removal; however, this impression proves to be an oversimplification of the real situation in these patients. Suboptimal fluid removal remains a clinical problem in many CAPD patients translating into higher BP values and the need for additional antihypertensive medications. For example, in a retrospective study of 66 CAPD patients selected for symptomatic fluid retention, peripheral edema, pulmonary congestion, pleural effusions, and systolic/diastolic hypertension occurred in the large majority of patients, resulting in a significant increase in hospitalization rate.⁷⁵ In addition, numerous studies have documented poor BP control in CAPD patients despite extensive use of antihypertensive medications.^{76,77}

Traditional nonpharmacologic measures that assist in BP management are often overlooked in the dialysis population. These include a reduction in body weight in obese patients, regular exercise and the careful use (if not avoidance) of drugs causing hypertension such as nasal decongestants, migraine headache medications, and weight loss compounds.^{78,79} In one study by Miller et al.,⁷⁹ patients performed stationary cycling during each hemodialysis treatment. Predialysis BPs, postdialysis BPs, and antihypertensive medication use were recorded during a 6-month period. Costs of the medication were analyzed at the end of the study. The average relative benefit of exercise was a 36% reduction in antihypertensive medications with an average annual cost savings of \$885 per patient per year in the exercise group compared with a nonexercise control group (Figure 53-4).⁷⁹

Pharmacologic Management of Hypertension

When volume control through aggressive ultrafiltration and/or sodium and fluid restriction fails to control BP, pharmacologic therapy becomes necessary. These patients represent volume-independent hypertensives and are in the minority of all

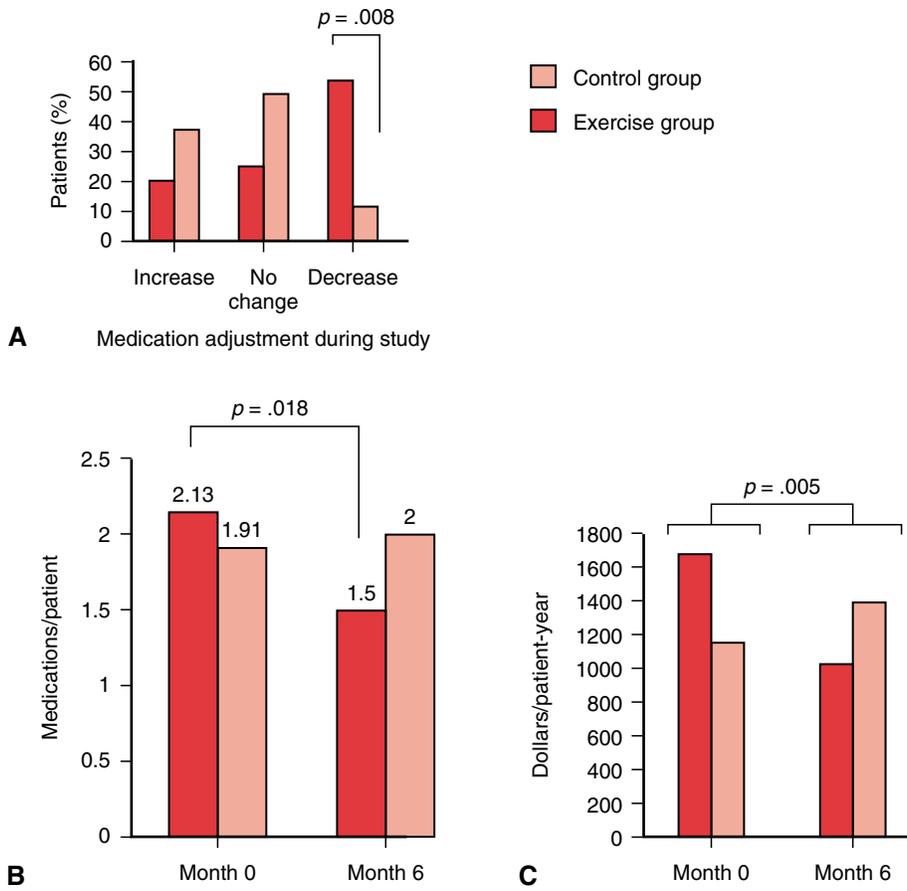

Figure 53-4 (A) Status of patients' antihypertensive medication at 6 months compared with baseline. $p = .008$ by chi-square test among exercise and control group at 6 months. **(B)** Number of antihypertensive medications taken per patient at month 0 and month 6 for exercise and control groups. **(C)** Annualized cost of antihypertensive medications per patient based on use at month 0 and month 6. Exercise patients ($n = 24$); control patients ($n = 32$). (From Miller BW, Cress CL, Johnson ME, et al. Exercise during hemodialysis decreases the use of antihypertensive medications. *Am J Kidney Dis* 39:828-833, 2002.)

hypertensive ESRD patients. Antihypertensive therapy should be directed toward the presumed underlying mechanism of the hypertension, but is often easier said than done, because an explicit mechanism is often hard to identify. That being said, considerable treatment experience exists with many of the more commonly used antihypertensive drug classes, and some comment will be provided for the more commonly used drug classes. However, the final medication regimen settled on should be individualized and directed towards decreasing patient morbidity and mortality while assisting in the management of comorbid conditions (Table 53-1).

Diuretics

As long as some level of residual renal function exists in an ESRD patient, diuretics may be employed to aid in the short-term regulation of fluid balance and thereby facilitate BP control.⁸⁰ Diuretics have not been shown to reduce BP in ESRD patients independent of their ability to promote diuresis.⁸¹ Typically, high doses of a loop diuretic, alone or together with a thiazide diuretic, are needed to establish and sustain a diuretic response. Diuretic therapy can provide an interdialytic bridge for fluid removal, reducing the need for an overly restrictive fluid prescription. However, the initial and sometimes rewarding diuretic effect in the ESRD patient will gradually taper off as the underlying renal disease advances. The progression of renal disease in an ESRD patient should be expected, and generally is marked by a decrease in interdialytic urine volume, signaling the need to discontinue diuretic therapy.⁸⁰

β -Blockers

β -Blockers are used regularly in the patient with ESRD for the treatment of hypertension^{1,82-85} and/or for their cardioprotective effects.⁸⁵⁻⁸⁸ The BP-lowering effect of β -blockers in the ESRD population can be attenuated by interdialytic weight gain.⁸³ The selection of a β -blocker in an ESRD patient should take place with some knowledge of the elimination characteristics (renal, hepatic, hepatic/renal) of the selected drug, as well as whether the compound is dialyzable and/or has active metabolites.^{89,90} Accumulation of a β -blocker in an ESRD patient does not generally improve BP control, but β -blocker accumulation can be associated with more frequent side effects. If such side effects occur, two options exist: first, to continue the offending β -blocker with empiric dose reduction, or second, to convert to a hepatically cleared β -blocker such as metoprolol. Data from the USRDS Waves 3 and 4 Study show β -blocker use to be associated with lower mortality with and without adjustment for comorbidities.⁸⁵ Several pharmacologic features of β -blockers can be offered as possible explanations for these protective effects, including: decreasing sympathetic hyperactivity, reducing stroke volume, remodeling the myocardium, having antiarrhythmic effects, and/or (for nonselective β -blockers) increasing fasting serum potassium concentration.^{49,86,87,91}

Calcium Channel Blockers

Calcium channel blockers (CCBs) have demonstrated efficacy in patients with diverse cardiovascular conditions, including

hypertension, angina pectoris, supraventricular arrhythmias, and diastolic dysfunction. These cardiovascular conditions are widely prevalent in the ESRD patient, which explains the liberal use of CCBs in this population.^{1,84,92,93} In general, the pharmacokinetics of CCBs are comparable in CKD/ESRD patients and persons with normal renal function. Therefore, dose adjustment based on pharmacokinetic considerations and/or dialysis clearance is not necessary with CCBs.⁹²

In an analysis of the USRDS Wave 2 cohort, nondihydropyridine CCBs were associated with a reduced risk of cardiovascular death (hazard ratio, 0.78; 95% confidence interval, 0.62-0.97), and among ESRD patients with preexisting cardiovascular disease, both dihydropyridine and nondihydropyridine CCBs were associated with reduced risk of all-cause and cardiovascular mortality.⁸⁴ These data are important because they lessen the reliance in this patient population on medical evidence extrapolated from non-ESRD populations.

CCB-related side effects may be particularly bothersome in these patients. ESRD patients tend to be constipated, and this can be aggravated by verapamil.⁹² Also, CCBs can produce peripheral edema on a vasodilatory basis. This form of peripheral edema is not distinguished by weight gain. When a true volume-expanded form of peripheral edema exists—as is often the case in ESRD—and a CCB is administered, any edema that develops cannot be viewed as an accurate reflection of the patient's volume status unless it is accompanied by weight gain.⁹⁴

ACE Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors and more recently angiotensin receptor blockers (ARBs) have become popular therapies for the ESRD patient.^{95,96} The ability of either of these drug classes to reduce BP in the ESRD patient is well accepted; however, there is considerably less information available to guide the clinician in the safe and effective use of these drugs in the ESRD patient with congestive heart failure (CHF) and/or coronary artery disease.

Head-to-head comparisons of BP effects and/or target organ protection in the ESRD patient are lacking for both drug classes. ACE inhibitor therapy has been suggested to decrease access failure rate and to improve survival in the ESRD population (see references cited here for a more comprehensive discussion).^{95,96} However, drug classes other than ACE inhibitors appear to offer survival benefits, and it is not yet proven that ACE inhibitors are superior to other drug classes—such as CCBs—in survival benefits for patients with ESRD.

Several pharmacokinetic factors, including dialyzability and the propensity for systemic accumulation, can influence drug selection. ACE inhibitors and ARBs have nonpressor effects that are beneficial for patients with ESRD. These include their ability to decrease thirst drive and erythropoiesis.⁹⁵ The ACE inhibitors have a unique adverse effect profile, which includes cough and, less frequently, angioneurotic edema. In the ESRD population, so-called anaphylactoid dialyzer reactions can occur in conjunction with ACE inhibitor use.⁹⁵ ARBs carry less risk than ACE inhibitors and have a preferred pharmacokinetic profile—limited dialyzability and minimal systemic accumulation. These attributes favor the increased use of ARBs in this population.⁹⁶

SUMMARY

Hypertension in the RRT patient is a common phenomenon. Its pathophysiologic basis relates to a unique set of hemodynamic and volume changes, which are characteristic of ESRD. The treatment of ESRD-related hypertension is at the start heavily dependent on the adequacy of ultrafiltration and the stepwise attainment of a patient's target weight. Thereafter, as pharmacotherapy may become necessary, any of the full range of medication choices provides suitable options. Heavy emphasis is generally placed on the use of CCBs, ACE inhibitors, and/or ARBs, although outcomes data supporting the preferential use of one or the other of these drug classes are currently lacking. Choosing specific antihypertensive agents for a hypertensive ESRD patient is as much an art as a science—issues such as a patient's dialysis shift, dialyzer drug clearance, and altered drug pharmacokinetics are some of the factors that make consistent 24-hour BP control difficult. The goal BP for the hypertensive ESRD patient is a matter of debate, because specific outcomes studies have yet to be performed in this patient population. Moreover, there is evidence of a U-shaped relationship for BP reduction and mortality in the ESRD patient.

Ischemic Heart Disease

George S. Chrysant, Suzanne Oparil

Cardiovascular disease (CVD) continues to be the leading cause of death in the United States, accounting for 946,000 deaths in the year 2000, which represents 39% of all deaths for that year. Many of the 62 million Americans with CVD have both coronary heart disease (CHD) (13 million) and hypertension (50 million). CHD was responsible for 515,000 deaths in the United States in 2000 representing approximately 75% of all CVD deaths that year.¹ Although the burden of CHD, including all forms of angina and myocardial infarction (MI), remains great, there has been a steady decline in CHD death rates since 1950. Between 1970 and 2000, the CHD death rate declined by 51.2%. Acute myocardial infarction accounted for 193,000 deaths in the year 2000. The indirect and direct costs of CHD to the United States are a staggering \$111.8 and \$58.2 billion, respectively.¹ For hypertension, the indirect and direct costs are \$47.2 and \$34.4 billion, respectively.² Hypertension is a major risk factor for CHD, as well as other forms of target organ damage. It both accelerates the progression of atherosclerotic disease and leads to left ventricular hypertrophy (LVH), which results in a diminished coronary reserve that exacerbates the ischemic effects of obstructive CHD. Through its associated target organ damage, hypertension can contribute to CHD and overall CVD mortality (between 200,000 and 205,000 deaths in 2000).¹

EVALUATION OF CORONARY HEART DISEASE AND HYPERTENSION

The first step in evaluating persons with hypertension and CHD is to perform a thorough history and physical examination. This should include evaluation of risk factors and family history. The frequency, intensity, and duration of anginal episodes should be determined with the knowledge that 2% to 4% of the general population will have silent ischemia. Routine laboratory tests, including hemoglobin/hematocrit, potassium, creatinine, calcium, fasting lipid profile, and a urinalysis should be obtained, as recommended by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).³ An electrocardiogram (ECG) should be performed because of its potential to predict in-hospital complications as well as long-term prognosis in patients with CHD. The most powerful predictor of poor prognosis on the initial ECG is sinus tachycardia. In the setting of an acute coronary syndrome (ACS), the sum of ST deviation (– and +), Q waves, and prolonged QRS duration has been correlated with an increase in mortality.^{4,5}

Exercise ECG testing is the initial diagnostic test in patients at intermediate risk for having CHD. However, the ECG may be uninterpretable in individuals with preexcitation, left bundle branch block, pacing rhythm, LVH with >1 mm ST depression, or taking digoxin, and these patients should undergo stress testing with an imaging component. The Duke

Treadmill Score gives prognostic information in terms of 4-year survival.⁶ The 379 individuals studied with a score of ≥ 5 , had a 4-year survival rate of 99% (low risk). The survival rate was 95% for the 211 persons scoring between –10 and +4 (intermediate risk). The individuals scoring < -10 had a 79% 4-year survival rate (high risk). Thus, a reasonable strategy would be to send high-risk patients for coronary angiography and revascularization if indicated, and to treat low-risk patients with medical therapy. For intermediate-risk patients, clinical judgment with the possibility of a stress imaging test could be used to guide decision making in regard to coronary angiography referral.

Echocardiography is the gold standard for detecting LVH, as well as the mechanical complications of MI, such as free wall rupture, pseudoaneurysm, papillary muscle rupture, and/or ventricular septal defect. Stress echocardiography combined with either exercise or dobutamine is widely used for the noninvasive detection of myocardial ischemia. The sensitivity of stress echocardiography (exercise ~85%, dobutamine ~88%) is lower than comparable nuclear cardiac stress tests; however, the specificity is higher, particularly for dobutamine stress echocardiography (Table 54–1). Dobutamine stress echocardiography is a valuable tool for predicting functional improvement in patients who undergo revascularization procedures.^{7,8} Nuclear cardiac imaging with exercise, adenosine/dipyridamole, or dobutamine for stress combined with thallium and/or technetium sestamibi (^{99m}Tc) is another widely used noninvasive modality for detecting myocardial ischemia. These tests are usually more sensitive and less specific than stress echocardiography.

Newer modalities such as cardiac magnetic resonance imaging (MRI) and computed tomography (CT) have emerged as future contenders with the current “gold standard” of coronary imaging, conventional coronary angiography with fluoroscopic guidance. Although most of the literature on electron beam CT (EBCT) focuses on its role in coronary artery calcification scoring, some data support its potential use in coronary imaging. EBCT has been shown to identify lesions >50% with reasonable sensitivity (74%-92%) and specificity (79%-100%) compared with invasive coronary angiography.^{9,10} Multirow detector CT (MDCT) or spiral CT has also been used with some success to image coronary arteries (Figure 54–1). Approximately 73% of the proximal segments of the coronary arteries can be visualized without significant motion artifacts. Sensitivity and specificity for 4-detector-row MDCT range from 37% to 85% and 76% to 99%, respectively, for the detection of >50% stenoses compared with invasive coronary angiography.^{11,12} This is likely to improve with 16-, 32-, and 64-detector-row MDCT. MDCT is currently being evaluated for possible use in the detection of in-stent restenosis.¹³ Major problems with EBCT include motion artifacts, breathing artifacts, and limited views of vessels due to heavy calcification. Distal arteries are difficult to visualize with EBCT and MDCT.

Table 54-1 Sensitivity and Specificity of Noninvasive Tests for the Detection of Coronary Artery Disease

Diagnostic Test	Sensitivity % (range)	Specificity % (range)	Number of Studies Analyzed	Number of Patients
Thallium scintigraphy	89	80	2	28,751
Exercise echocardiography	85	79	58	5000
Persantine thallium	85	91	11	<1000
Dobutamine echocardiography	88	84	5	<1009

From Poon M, Fuster V, Fayad Z. Cardiac magnetic resonance imaging: A “one-stop-shop” evaluation of myocardial dysfunction. *Curr Opin Cardiol* 17:663-670, 2002.

MDCT has several drawbacks, including breathing and motion artifacts and a requirement for a high dose of radiation (6-10 mSv per study). Successful studies with MDCT usually require administration of a β -blocker to slow the heart rate to below 70 beats/min. Another problem is that both CT modalities require nephrotoxic contrast agents in the dose range of 125 to 150 ml.

Coronary MRI has been evaluated more extensively than CT angiography (Figure 54-2). Nine studies comparing MRI with invasive coronary angiography in 387 patients have revealed a sensitivity of 77% and a specificity of 71% for stenoses >50%.^{9,14,15} The requirement for multiple long breath holds, claustrophobia, breathing and motion artifacts, and the presence of any metal such as a pacemaker, automatic implantable cardioverter defibrillator, aneurysm clips, or metal prostheses limit the ability to perform the test and the success of the test. Intracoronary stents do not appear to be affected in any way by MRI, contrary to the package inserts that accompany the stents. No heating, migration, or subacute thrombosis of the stents during MRI has been reported.^{16,17} Both CT and MRI are used in many centers around the world

to diagnose CHD; however, they are currently not an alternative to invasive coronary angiography (Table 54-2).

Cardiac MRI is emerging as a viable method for the evaluation and diagnosis of ischemic heart disease. Cardiac chamber structure (left ventricular mass), function (contractile function), flow (shunts), and both myocardial perfusion and myocardial viability can all be examined with cardiac MRI techniques. This makes cardiac MRI a potential “one-stop shop” as Fayad and Fuster have postulated.⁸ Detection of infarcted tissue by delayed hyperenhancement of contrast agent (gadolinium) has been demonstrated in several teaching centers and appears to be very sensitive. Stress imaging with dobutamine and adenosine has also been demonstrated effectively; however, this discussion is beyond the scope of this chapter.

Coronary angiography is the “gold standard” for coronary imaging. In the 20 years from 1979 to 2000, the number of cardiac catheterizations increased by 341%. More than 2 million of these procedures were performed in 2000 at a cost of \$23 billion.^{18,19} The overall risk of the procedure is <2%, with only the inability to consent freely being an absolute contraindication if needed urgently or emergently.²⁰ The guide-

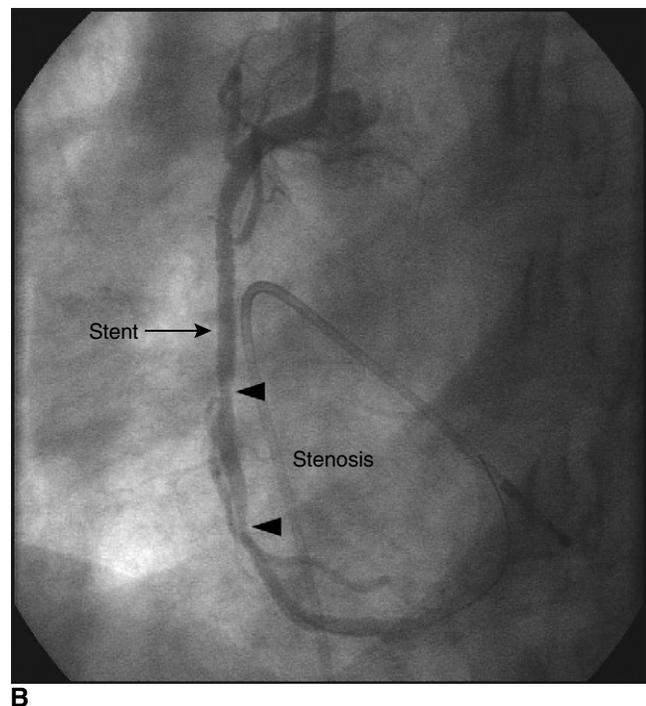

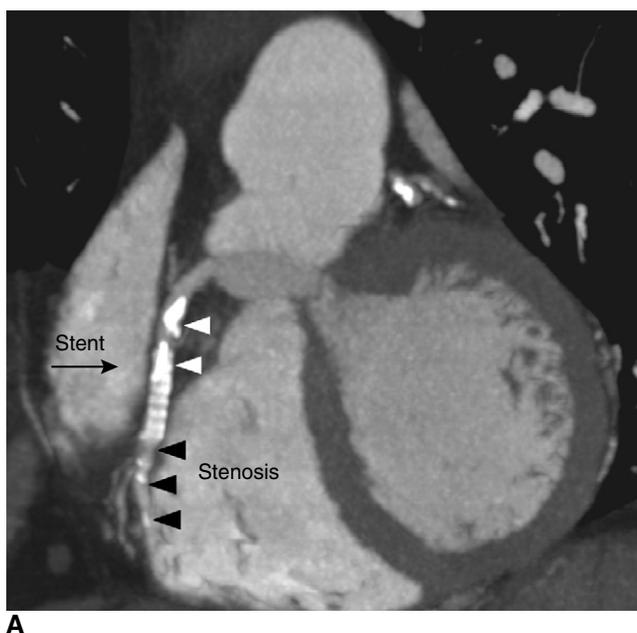

Figure 54-1 (A) MDCT angiogram of RCA showing the presence of an intracoronary stent and a 50% stenosis. (B) X-ray angiogram of RCA of the same patient as in part A.

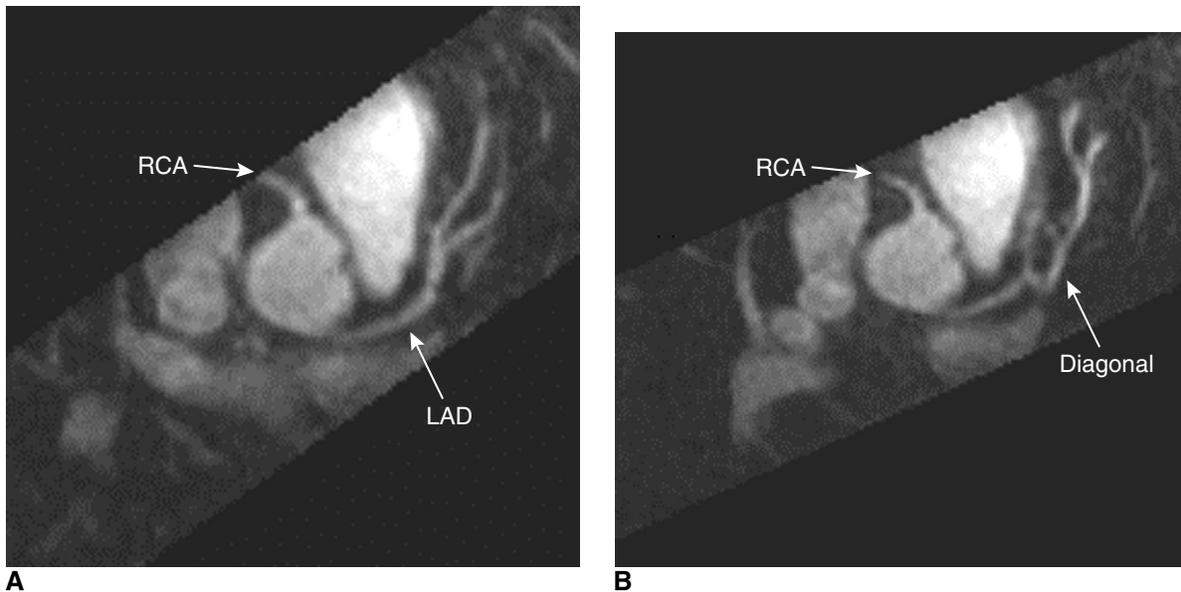

Figure 54-2 Coronary magnetic resonance angiograms of the proximal RCA, LAD, and diagonal arteries

lines for coronary angiography published by the American College of Cardiology are explicit in outlining the indications for performance of the procedure.²¹ Coronary angiography requires the injection of nephrotoxic iodinated contrast, which has become increasingly safer over the last several years. There is also exposure to radiation for both the patient and the operator and staff. In spite of these drawbacks, coronary angiography continues to be widely used and is currently the definitive way to image the coronary arterial tree.

TREATMENT OF CORONARY HEART DISEASE AND HYPERTENSION

Medical Therapy

Chronic Stable Angina and Silent Ischemia

Angina pectoris is characterized as chest discomfort of short duration (minutes) that is usually retrosternal in location and relieved by rest, removal of stress, and/or the administration of nitroglycerin.²² Approximately 24% of the male and 26% of the female population of the United States have angina pectoris.¹ As many as 40% of those persons with CHD experience

silent ischemic episodes (>1-mm ST-segment depression for at least 1 minute on 48-hour Holter monitoring).²³ Silent ischemic episodes have been demonstrated in clinical studies using 24- to 48-hour ambulatory monitoring in persons with known stable angina on antianginal drug regimens.²⁴ The choice of treatment depends on the underlying pathophysiologic process, concomitant risk factors, and comorbid conditions that could exacerbate anginal symptoms and potentially lead to adverse cardiac events. Treatment of hypertension, correction of lipoprotein abnormalities, and smoking cessation are important aspects of risk factor modification and therapy.²⁵ All persons with CHD should be taking aspirin in a dose between 81 mg and 325 mg unless contraindicated or an allergy is present. Aspirin is well studied and has a proven mortality benefit, as well as benefit in the prevention of CHD-related events.

Due to the enhanced myocardial oxygen demand created by increases in blood pressure (BP)—systolic BP (SBP) in particular—and heart rate, hypertensive patients with chronic stable angina are at particular risk. A study of 25 patients with known CHD who underwent simultaneous electrocardiographic and ambulatory BP monitoring (ABPM) showed that a majority of silent ischemic episodes were preceded by an average increase in SBP of 10 mm Hg, as well as a significant increase in heart rate.²⁶ Therefore, persons with both stable angina (with or without silent ischemic episodes) and hypertension derive particular benefit from treatment with β -blockers and calcium channel blockers (CCBs).

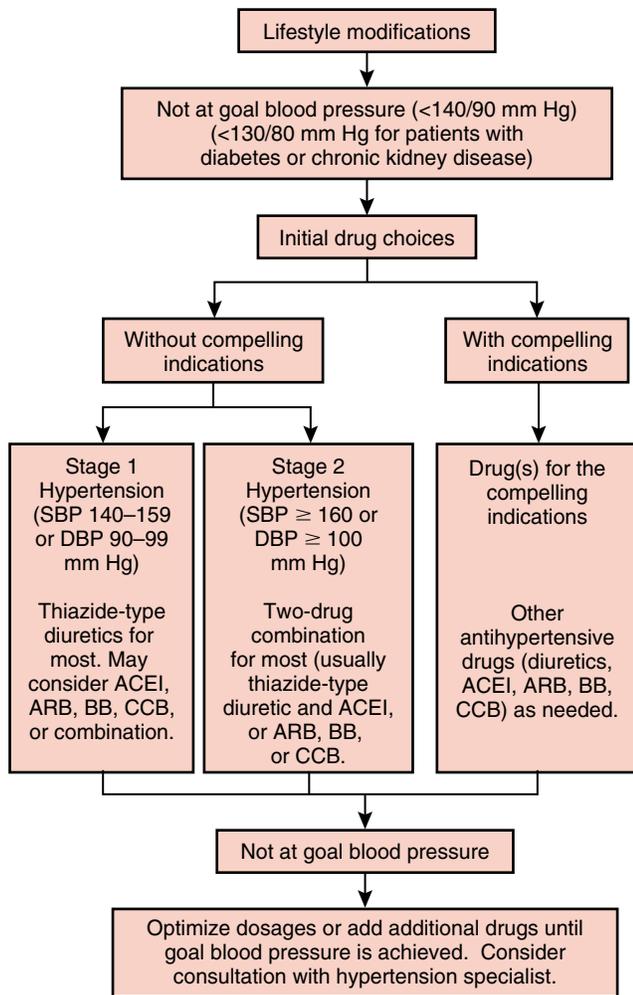

The goals of treating patients with CHD and hypertension are to lower BP, relieve angina, reduce ischemia, and prevent future cardiovascular (CV) events (Figure 54-3). First-line therapy should be with a β -blocker without intrinsic sympathomimetic activity unless contraindicated, because these agents are indicated as first-line treatment for both hypertension and CHD. β -Blockers reduce myocardial oxygen consumption and heart rate and help enhance coronary flow. Thus, they are particularly helpful in reducing angina in the hypertensive patient.

If angina continues on β -blocker therapy, then long-acting CCBs can be added to the regimen. CCBs decrease total

Table 54-2 Comparison of Coronary Magnetic Resonance Angiography and Computed Tomography Angiography with Angiography for the Detection of Coronary Artery Disease

Modality	Subjects	Sensitivity (mean)	Specificity (mean)

peripheral resistance, which leads to decreases in BP and in wall tension, thus reducing myocardial O_2 consumption. CCBs also decrease coronary resistance (helpful in relieving spasm, which may be associated with Prinzmetal's angina) and enhance poststenotic coronary perfusion, which increases myocardial O_2 supply. Nondihydropyridine CCBs have the additional benefit of decreasing heart rate. Short-acting dihydropyridine CCBs should be avoided due to increased mortality, particularly in the setting of acute MI.²⁷ Although nondihydropyridine CCBs can be used as antianginals in combination with a β -blocker, there is associated risk due to the potential for severe bradycardia and/or heart block. Long-acting dihydropyridine CCBs are effective antianginal agents and do not share the disadvantage of bradycardia/heart block. Therefore, if a CCB is needed in addition to a β -blocker to control angina in a hypertensive patient, it should be a long-acting dihydropyridine CCB. If angina is still not controlled on this two-drug regimen, nitrates can be added.²⁸

The use of angiotensin-converting enzyme (ACE) inhibitors as antiischemic therapy continues to be controversial. More than 20 studies have examined whether these agents are or are not useful in preventing ischemia, but only two of these included large groups of patients. In the Perindopril Therapeutic Safety Collaborative Research Group study, 490 hypertensive patients with CVD and/or risk factors for CVD were randomized to treatment with an ACE inhibitor (perindopril) or placebo. Persons in the perindopril group had significantly less ST depression during maximal treadmill exercise testing and fewer anginal episodes ($p < .05$ for both anginal episodes and maximal ST depression).²⁹ The quinapril antiischemia and symptoms of angina reduction (QUASAR) trial was a study of 336 patients with stable CHD who were randomized to an ACE inhibitor (quinapril) or placebo. Approximately half of the study population had medically treated hypertension, and all were examined for ischemic events with treadmill testing, ambulatory ECG monitoring, and the Seattle Angina Questionnaire. No significant difference was demonstrated between the two groups either at 8 or 16 weeks.³⁰ Based on currently available evidence, the use of ACE inhibitors as antiischemic/antianginal agents is not indicated.

Acute Coronary Syndromes: Unstable Angina, Non-ST-Elevation Myocardial Infarction, and ST-Elevation Myocardial Infarction

In the setting of an acute coronary syndrome (ACS), the goal of therapy is to pacify the unstable coronary plaque, relieve anginal pain, control BP and heart rate, and assist in the restoration of flow in the coronary arterial system. All patients with an ACS should immediately receive a crushed aspirin, oxygen, and an intravenous β -blocker (unless contraindicated). If the ACS is an ST-elevation acute MI in a setting where primary percutaneous coronary intervention cannot occur within 1 to 2 hours, reperfusion therapy with thrombolytics is indicated; otherwise, primary percutaneous coronary intervention should be performed (Figure 54–4).³¹ Intravenous heparin should also be administered. If BP is appropriate and right ventricular infarction has been ruled out, intravenous nitroglycerin and narcotic agents can be given safely. If the ACS is unstable angina/non-ST-elevation MI, and certain features such as dynamic ECG changes, positive cardiac biomarkers, and/or uncontrolled pain are present, the use of a GP IIb/IIIa agent (either enoxaparin or tirofiban, not abciximab) is indicated^{32,33} (Figure 54–5). The Thrombolysis in Myocardial Infarction (TIMI) risk score has been used to guide therapy and to predict future events and outcomes.³⁴ CV events increase dramatically with each increment in the TIMI Risk Score.

β -Blockers (nonintrinsic sympathomimetic activity) are first-line agents for both acute MI and hypertension (Figure 54–6). They help limit infarct size, decrease the risk of recurrent MI, improve survival, and decrease the incidence of sudden cardiac death secondary to fatal arrhythmias.^{35–39} Patients should receive early intravenous β -blocker therapy (metoprolol 5 mg every 5 minutes for three doses) within 12 hours of onset of the event, followed by an oral β -blocker (within the first 2 days) unless contraindicated (e.g., by bradycardia, bronchospasm, or hypotension). Both intravenous and oral β -blockers during and after acute MI have been studied extensively and have been proven to reduce mortality and the incidence of reinfarction.³¹ The choice of agent, and the short-

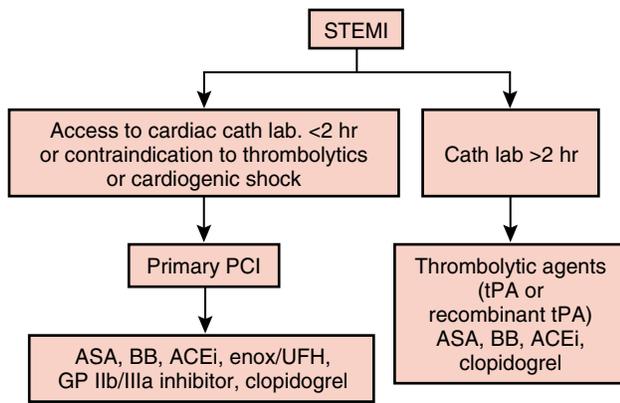

Figure 54-4 Algorithm for the management of patients with ST-segment elevation myocardial infarction.

and long-term dosing goal, have varied substantially in clinical trials. In general, the dose of β -blocker should be that which achieves adequate reduction in heart rate and BP while still being tolerated by the patient.

The Carvedilol Post-Infarct Survival Control in Left Ventricular (LV) Dysfunction (CAPRICORN) trial, carried out in 1959 post-MI patients with LV dysfunction, is the first study to demonstrate the beneficial effects of β -blockers post-MI in the postreperfusion era, and in patients with LV dysfunction (a population excluded from prior β -blocker trials in acute MI).⁴⁰ All participants had a proven MI and LV ejection fraction (LVEF) $\leq 40\%$, and $>50\%$ had hypertension. After a mean follow-up of 1.3 years, all-cause mortality ($p = .031$), CVD mortality ($p = .024$), nonfatal MI ($p = .014$), and all-cause mortality or nonfatal MI ($p = .002$) were lower in the carvedilol group than in the placebo (usual therapy) group. The 23% observed reduction in mortality was in addition to ACE inhibitor (prescribed in 98% of participants) and reperfusion (prescribed in 46%) therapies.

Figure 54-5 Algorithm for the management of patients with unstable angina or non-ST-segment myocardial infarction. (From Braunwald E. Application of current guidelines to the management of unstable angina and non-ST-elevation myocardial infarction. *Circulation* 108:III28-III37, 2003.)

CCBs can be used for acute MI in situations in which β -blocker therapy is inadequately controlling angina, BP, and/or heart rate (e.g., supraventricular tachycardia), or if β -blockers are poorly tolerated or contraindicated. In the setting of unstable angina and concomitant β -blocker use, long-acting dihydropyridine CCBs are preferred over nondihydropyridine CCBs due to the possibility of excessive bradycardia or heart block associated with the latter agents. Short-acting dihydropyridine CCBs should be avoided in patients with acute MI, pulmonary edema, or LV dysfunction.^{40a-43} Several trials have demonstrated that these agents increase mortality and the rate of reinfarction. Specifically, compared with patients treated with other antihypertensive agents (diuretics and β -blockers), hypertensive patients treated with short-acting CCBs have been shown to have a 60% higher risk of MI.²⁷

Randomized trials of nondihydropyridine CCBs (verapamil and diltiazem) in patients with acute MI have shown benefit in preventing CVD events, but no significant influence on overall mortality. In the Danish Verapamil Infarction Trial II, verapamil use was associated with a 20% ($p = .03$) reduction in first major CVD event (death and reinfarction).⁴⁴ In a meta-analysis of 28 randomized trials in approximately 19,000 post-MI patients, verapamil use resulted in a significant 19% decrease in reinfarction (relative risk, 0.81; 95% confidence interval, 0.67-0.98).⁴⁵ However, in these and other trials, no significant decrease in mortality has been shown. A large trial of diltiazem therapy (the Multicenter Diltiazem Postinfarction Trial [MDPIT]) demonstrated no reduction in mortality or reinfarction.⁴⁶ In patients with depressed LV function and/or pulmonary edema, diltiazem use was associated with a 41% increase in CVD events (death from a cardiac cause and nonfatal MI). Therefore, CCBs are not recommended in the setting of acute MI except in situations in which β -blockers are poorly tolerated or inadequate to control concomitant conditions (e.g., BP, angina, or supraventricular tachycardia).³²

ACE inhibitors are indicated in all patients with acute MI who can tolerate them. In a hemodynamically stable (SBP ≥ 90 -100 mm Hg) patient post-MI, an oral ACE inhibitor should be initiated, generally within 24 hours of onset of the event, particularly if the infarct is anterior and associated with depressed LV function (LVEF $< 40\%$) and/or heart failure.⁴⁷⁻⁵⁰ Creatinine and electrolytes should be checked prior to initiation of ACE inhibitor therapy and periodically until the highest tolerated dose of the agent has been given and the patient has shown stable renal function. Use of ACE inhibitors after acute MI has led to significant reductions in mortality.⁵¹⁻⁵³ The large clinical trials have shown that the greatest benefit occurs in patients who are at highest risk (Killip class 2 or 3, heart rate ≥ 100 beats/min). The hemodynamic effects and overall benefit of ACE inhibition are seen early. Approximately 40% of the 30-day increase in survival is observed in days 0 to 1, 45% in days 2 to 7, and approximately 15% after day 7.^{47,50} These findings help support the current recommendation that ACE inhibitors should be initiated routinely after acute MI and continued for an indefinite period.³²

Angiotensin receptor blockers (ARBs) have been proven to be effective as antihypertensive agents for both hypertension and heart failure and are now used in persons who are ACE inhibitor intolerant or allergic. Emerging data appear to support the use of ARBs in MI. The ARB valsartan was compared with the ACE inhibitor captopril in the (VALIANT) trial, a double-blind trial in which patients were randomized to

valsartan (4909 patients), valsartan plus captopril (4885 patients), or captopril (4909 patients).⁵⁴ During the 2-year follow-up, 979 patients in the valsartan group died compared with 941 in the combination group and 958 in the captopril group. There was no statistically significant difference in the primary endpoint of death from any cause, and valsartan was shown to have noninferiority compared with captopril in regard to mortality ($p = .004$). The combination group had the most drug-related adverse events and did not show improved survival.

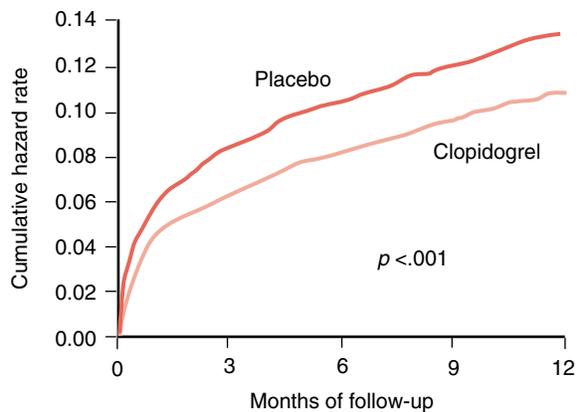

Aldosterone receptor antagonists have been proven to reduce mortality and morbidity in patients with severe heart failure who are already on ACE inhibitor therapy. Aldosterone blockade is believed to prevent ventricular remodeling and collagen formation in the ventricles of persons with severe LV dysfunction.⁵⁵ A large randomized, double-blind, controlled trial comparing eplerenone (a newer and more selective aldosterone antagonist) with placebo (conventional therapy) in 6632 patients who were less than 2 weeks from an MI complicated by LV dysfunction demonstrated a mortality and morbidity reduction in favor of eplerenone.⁵⁶ Total deaths, deaths from a CV cause, and the combined endpoint of CV death or hospitalization for CV illness were all significantly lower in the eplerenone group ($p = .008$, $p = .005$, $p = .002$, respectively). Hypertensive patients ($p = .05$) and those with a widened pulse pressure ($p = .01$) experienced a significant benefit. This important study has led to the U.S. Food and Drug Administration's approval of this novel agent for use as

an alternative to conventional therapy in the setting of acute MI with LV dysfunction.

Other General Considerations

Antiplatelet Therapy

Antiplatelet therapy is a mainstay of medical therapy for CHD and ACS regardless of whether or not an invasive strategy is planned. Multiple studies have proven the benefit of aspirin, a cyclooxygenase-1 inhibitor. The most striking data supporting the use of aspirin come from the Second International Study of Infarct Survival (ISIS-2) trial in which aspirin and streptokinase, a thrombolytic agent, were found to independently equally reduce mortality (9.2% for streptokinase, 9.4% for aspirin).⁵⁷ Thienopyridine therapy has also become a mainstay of therapy, particularly in those patients who go on to percutaneous coronary intervention (PCI) with coronary stenting. Ticlopidine and clopidogrel are equally effective, but clopidogrel is better tolerated and exhibits a more favorable side effect profile.⁵⁸ The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) and Clopidogrel for the Reduction of Events During Observation (CREDO) trials have provided convincing evidence of benefit from clopidogrel treatment in preventing CVD events in the setting of ACS, coronary artery bypass grafting (CABG), or PCI (Figure 54–7).^{59–61} The length of clopidogrel treatment and the decision of when to start the drug remain controversial. If the coronary anatomy is unknown, there is a risk that

No. at risk					
Placebo	6303	5780	4664	3600	2388
Clopidogrel	6259	5866	4779	3644	2418

Figure 54-7 Cumulative hazard rates for the first primary outcome of cardiovascular death, nonfatal myocardial infarction, or stroke during the 12 months of the CURE trial. (From Yusuf S, Zhao F, Mehta SR, et al. Effects of clopidogrel in addition to aspirin in patients with acute coronary syndromes without ST-segment elevation. *N Engl J Med* 345:494-502, 2001.)

urgent CABG may be needed and will have to be delayed due to clopidogrel use. Therefore, it is recommended that clopidogrel be administered to patients with ACS in combination with aspirin unless the patient has undefined coronary anatomy and/or is at risk of excess bleeding.^{32,33}

Low-Molecular-Weight Heparin and Glycoprotein IIb/IIIa Receptor Antagonists

Low-molecular-weight heparin (LMWH) has been shown to be more effective than unfractionated heparin (UFH) in ACS because it has a higher anti-Xa:IIa ratio than UFH and is very predictable and easy to use.⁶²⁻⁶⁴ The Efficacy and Safety of Subcutaneous Enoxaparin in Unstable Angina and Non-Q-Wave MI (ESSENCE) trial compared the LMWH enoxaparin with UFH in 3000 patients with ACS.⁶² Outcome (death, MI, repeat revascularization) rates were significantly lower for enoxaparin at 14 and 30 days.

A higher risk group of 3910 patients (ST-segment depression, positive cardiac enzymes) with ACS was randomized to enoxaparin or UFH in the TIMI 11B trial.⁶³ The primary endpoint of death, MI, recurrent ischemia, and need for revascularization was significantly reduced by enoxaparin treatment. A subsequent meta-analysis of ESSENCE and TIMI 11B showed an advantage for enoxaparin over several time points up to 43 days.⁶⁴ A meta-analysis of clinical trials involving 13,320 patients with non-ST-elevation ACS comparing LMWH and UFH demonstrated no significant differences in either efficacy or safety.⁶⁵

A presumed advantage of LMWH is a reduction in the “rebound” phenomenon that was associated with abrupt cessation of UFH. An increase in CV events presumed to be due to increased platelet adhesion has been shown in the first 24 to 48 hours after UFH has been stopped. However, it appears that cardiac ischemic events occur within 24 hours of LMWH cessation, as well. This was demonstrated in an analysis of the TIMI 11B and ESSENCE trials.⁶⁶ Groups receiving UFH and

short-term enoxaparin (≤ 8 days) were compared with a group that received long-term enoxaparin (43 days). The long-term LMWH group had significantly fewer ischemic events following cessation compared with the UFH group ($p < .0001$) and the short-term enoxaparin group ($p < .0003$). LMWH is recommended by the ACC/AHA guidelines for use in unstable angina, non-ST-elevation MI, and acute MI. UFH may also be used. In the setting of PCI, LMWH and UFH can be used safely and effectively.

The use of platelet glycoprotein IIb/IIIa inhibitors in unstable angina/non-ST-elevation MI is controversial. Persons who are going to be treated with an early invasive strategy and who have positive cardiac enzymes and/or ECG changes benefit the most from the use of these agents. In a meta-analysis of more than 30,000 patients with unstable angina or non-ST-elevation MI, the 5847 patients who underwent early invasive management with revascularization had a 21% reduction in death or MI when treated with these agents. The 25,000+ patients who did not undergo an early invasive procedure had only a 3% reduction in death or MI with glycoprotein IIb/IIIa inhibitor treatment.⁶⁷ The ACC/AHA guidelines support the use of glycoprotein IIb/IIIa inhibitors in high-risk patients (particularly troponin positive) who are likely to have early angiography.

HMG-CoA Reductase Inhibitors

All patients with an ACS should be discharged on an hydroxymethyl glutaryl-coenzyme A (HMG-CoA) reductase inhibitor (i.e., statin) because this class of medications has been shown to decrease CHD events and mortality.⁶⁸⁻⁷⁰ Current National Cholesterol Education Program (NCEP) guidelines specify a goal LDL level in patients with known CHD of < 100 mg/dl. A great number of patients will require pharmacologic intervention to achieve this goal.⁷¹ Above and beyond LDL lowering, studies are now demonstrating positive effects of statins on endothelial function, oxidative stress, and biomarkers of inflammation.⁷²⁻⁷⁴ Statin therapy has been shown in trials to significantly lower levels of C-reactive protein, in association with a significant reduction in CVD event rates.^{75,76}

Invasive Therapy

In patients presenting with ACS, there is now ample evidence to support an early invasive strategy whereby individuals are taken to the cardiac catheterization laboratory for coronary angiography within the first 24 to 48 hours, followed by revascularization as dictated by the anatomy. Prior to the “stent era,” prospective randomized trials showed no benefit from an early invasive strategy compared with early conservative therapy.^{77,78} Both TIMI IIIIB and the Veterans Affairs non-Q-wave infarction strategies in hospital (VANQWISH) trial showed no significant difference between the two strategies.

“Stent-era” trials including the Fragmin and Fast Revascularization During Instability in Coronary Artery Disease (FRISC) II trial, the Randomized Intervention Trial of Unstable Angina (RITA) III trial, and the Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy—Thrombolysis in Myocardial Infarction (TACTICS-TIMI) 18 trial, showed benefit (reduction in death or MI) at 4 to 12 months of follow-up in patients randomized to an early invasive strategy.⁷⁹⁻⁸¹ These studies support an early invasive strategy for all patients with ACS who do not have a contraindication to cardiac catheterization (Figure 54-8). Adjunctive therapy to PCI after diagnostic angiography includes several proven

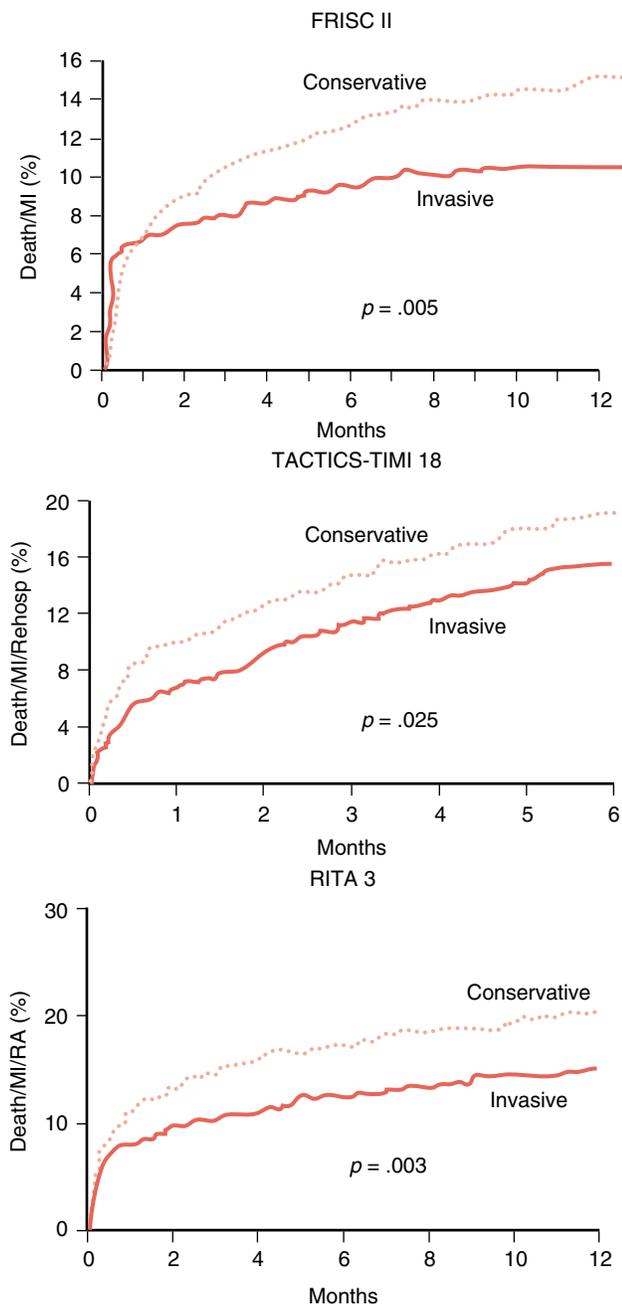

Figure 54-8 Rates of adverse cardiac events according to assignment to either a conservative strategy or an early invasive strategy over time (6-12 months) in the FRISC II study, the TACTICS-TIMI 18 trial, or the RITA 3 trial. (From Wallentin L, Lagerqvist B, Husted S, et al. Outcome at 1 year after an invasive compared with a noninvasive strategy in unstable coronary artery disease: The FRISC II invasive randomized trial. *Lancet* 356:9-16, 2000; Cannon CP, Weintraub WS, Demopoulos LA, et al. pharmacologic agents. However, a formal discussion of the pros and cons of using GP IIb/IIIa inhibitors, LMWH, or bivalirudin in their setting is very controversial and beyond the scope of this chapter.

Percutaneous Coronary Intervention versus Coronary Artery Bypass Grafting

Limited clinical trial data support the use of multivessel stenting as an alternative to CABG in patients with multivessel CHD⁸²⁻⁸⁴ (Table 54-3). With the emergence of drug-eluting stent technology, the higher rates of revascularization in the PCI groups will decrease, making multivessel stenting an even more attractive alternative to CABG. In the setting of acute MI, only the “culprit” vessel should undergo PCI. According to ACC/AHA guidelines, intervening on a “nonculprit” vessel in the setting of acute MI is a class III indication.⁸⁵

Drug-Eluting Stents

Drug-eluting stents such as the sirolimus-eluting Cypher stent and the paclitaxel-eluting Taxus stent have revolutionized PCI by keeping in-stent restenosis in the single digits; thus, helping to eliminate PCI’s Achilles heel, the need for repeat intervention and target vessel revascularization (Figure 54-9). Studies involving the sirolimus-eluting stent have demonstrated mortality rates <2%, target vessel revascularization rates of <9%, and in-stent restenosis rates <3% at 6 months.^{86,87} At 2 years, the in-stent lumen assessed with intravascular ultrasound has remained essentially unchanged in a group of 30 patients with sirolimus-eluting stents.⁸⁸ Similarly, rates of restenosis (0% at 6 months), target vessel revascularization (3% at 6 months), and major adverse cardiac events such as death and MI (0% at 12 months) for the paclitaxel-eluting stent have been very low.⁸⁹ In the setting of acute MI, the sirolimus-eluting stent was shown to be safe in 96 patients enrolled over 6 months.⁹⁰ At 300 days post-MI, sirolimus-eluting stents have had lower overall adverse event rates compared with bare stents without an increase in subacute stent thrombosis.⁹¹ Now that the “stent era” has developed into “the drug-eluting stent era,” it is likely that PCI will become an option for even more patients previously thought to require CABG (Figure 54-10).

HYPERTENSION AND PERIPHERAL VASCULAR DISEASE

Persons with symptomatic peripheral vascular disease (PVD) have a 15-fold increased rate of mortality from CVD and a high rate of concomitant coronary artery disease and/or cerebrovascular disease.⁹² Hypertension, diabetes, and smoking are major risk factors for PVD. CHD and renovascular disease often occur together, with as many as 28% of hypertensive patients undergoing cardiac catheterization having renal artery disease. Therefore, the threshold for noninvasive screening for both disease processes in these persons should be low⁹³ (Table 54-4).

Relatively little attention has been devoted to PVD as an endpoint in controlled trials of antihypertensive therapy, and the sparse data that are available are disappointing. For example, in the United Kingdom Prospective Diabetes Study Group (UKPDS) trial, tight BP control (mean achieved BP = 144/82 mm Hg vs. 154/87 mm Hg in the less tight control group) in patients with hypertension and diabetes led to

Table 54-3 Comparison of Coronary Artery Bypass Grafting with Multivessel Stenting

Trial	CABG	MVS Mortality	CABG TVR Mortality	MVS TVR

ARTS	10.8%	10.2%	4.8%†	19.7%
SoS	9%	10%	6%‡	21%

* $p < .002$; † $p < .001$; ‡ $p < .0001$. CABG, coronary artery bypass grafting; MVS, multivessel stenting; TVR, target vessel revascularization.

significant reductions in risk of death ($p = .019$) and in complications related to diabetes ($p = .005$), stroke ($p = .013$), and microvascular disease ($p = .009$), but no significant decrease in PVD risk ($p = .17$).⁹⁴

Antihypertensive drug treatment is also ineffective in relieving symptoms of PVD. Vasodilator agents such as ACE inhibitors, CCBs, α -adrenergic blockers, and direct vasodilators have not been shown to improve walking distance or symptoms of claudication in patients with PVD.⁹⁵⁻⁹⁷ Whether this is due to the inability of diseased vessels to dilate further because they are maximally dilated during exercise, to a “steal” phenomenon, and/or to the possibility that systemic BP reduction decreases forward blood flow due to a loss of “driving” pressure is unknown. β -Blockers are generally thought to precipitate peripheral vasoconstriction and increase the frequency of intermittent claudication, and thus to be relatively contraindicated in patients with PVD. However, studies have shown that β -blockers do not reduce walking distance or calf blood flow in patients with intermittent claudication due to PVD.⁹⁸ Thus, if needed for CHD, β -blockers can be used in these patients.

Sirolimus-eluting stents versus standard stents in patients with stenosis in a native coronary artery. *N Engl J Med* 349:1315-1323, 2003.)

Because no class of antihypertensive medications offers particular benefits to the patient with PVD, treatment choices should be made based on concomitant conditions (CHD, diabetes, heart failure). In patients with PVD and no concomitant condition, a thiazide diuretic is the agent of first choice, followed by a β -blockers. If CHD is present, a β -blocker should be the first choice, followed by a thiazide diuretic. In patients with CHD, diabetes and/or heart failure, ACE inhibitor therapy is indicated. Renovascular disease should be excluded in this high-risk population before initiation of ACE inhibitor treatment. If the aforementioned agents fail to control BP and/or are poorly tolerated, or if the patient has Raynaud’s phenomenon, CCBs (preferably nondihydropyridine CCBs) can be used.⁹⁹

Table 54-4 Percentage of Patients with Coronary Artery Disease or Peripheral Vascular Disease Who Have Atherosclerotic Renal Artery Disease

Hypertension in the Elderly

Jan N. Basile, Renee P. Meyer

The elderly, defined as individuals 65 years of age and older, represent the most rapidly growing segment of the U.S. population. In 1990, they accounted for 13% of the population and are expected to account for 20% of the population by the year 2040.¹ While approximately 40 million Americans will be 65 years or older by the year 2010, the number of “old elderly” (i.e., those older than age 85) is projected to reach 16 million by the middle of the twenty-first century.²

Hypertension, defined as a systolic blood pressure (SBP) at or above 140 mm Hg and a diastolic blood pressure (DBP) at or above 90 mm Hg, remains the most common primary office diagnosis in the United States, with more than 35 million visits per year.³ Hypertension is a powerful, independent, and modifiable risk factor whose presence increases the risk of atherosclerotic cardiovascular disease (CVD), including stroke, coronary heart disease (CHD), congestive heart failure (CHF), peripheral vascular disease (PVD), renal failure, dementia, and death.³ Affecting approximately 58 million Americans, elevations in blood pressure (BP) exert a strong, continuous, and graded relationship with no threshold of risk for developing CVD.³ High BP in the elderly confers a threefold to fourfold increase in risk for CVD compared with younger individuals.³ In 1999-2000, prevalence data from the National Health and Nutrition Examination Survey (NHANES) found that about 30% of Americans 40 to 59 years of age and 65% of Americans older than 60 years of age were hypertensive, with 80% of older Blacks and 70% of older Mexican Americans and whites affected.⁴ In addition, the prevalence of hypertension has increased significantly in older Americans between 1988 and 2000.⁴ More than 90% of people will develop hypertension within their lifetime, usually after 55 years of age.⁵ For persons 40 to 70 years of age, the risk of CVD begins at 115/75 mm Hg and doubles with each increase of 20/10 mm Hg up to 185/115 mm Hg.⁶ While both SBP and DBP are independently predictive of cardiovascular risk up to age 50, for those older than 50 years of age, SBP is a better predictor of CVD risk than DBP.⁷

More people today are aware of and are on therapy for their hypertension than in previous years. Since the late 1970s, the minimum goal for BP reduction for patients with hypertension has been less than 140/90 mm Hg. In its seventh report on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), the Joint National Committee recommended an even lower goal, to less than 130/80 mm Hg, for higher-risk patients, including diabetics and those with renal impairment.³ While BP control rates are improving, BP is controlled in only one in every three persons in the United States, with control rates even worse in the elderly, of whom only 27% are controlled.⁴

ISOLATED SYSTOLIC HYPERTENSION

As we age, elevation of SBP predicts the risk of CVD better than increases in DBP.⁷ Although this was observed more than three decades ago, no attempt was made to translate this evidence into practice until 1993, when the Fifth Joint National Committee Report (JNC V) recognized isolated systolic hypertension (ISH) as an important target for BP control.^{8,9} ISH, defined as a SBP of ≥ 140 mm Hg and a DBP of < 90 mm Hg, represents the most common form of hypertension in the elderly and its prevalence increases with age; two thirds of individuals 60 years of age and older, and three fourths of those older than 75 years of age, have ISH.¹⁰ In NHANES III, among persons 70 years of age and older, more than 90% of those who were inadequately treated had ISH, whereas in those less than 40 years of age who were inadequately treated, only 22% had ISH.¹¹ More than 25% of adults 60 years of age or older have stage 1 ISH (SBP of 140-159 mm Hg with DBP < 90 mm Hg). It is the predominant form of hypertension in the elderly and often goes untreated.¹¹

SBP is easier to measure than DBP in the elderly, and knowing the SBP allows more appropriate risk stratification. In an analysis of the Framingham Heart Study, knowing only the SBP correctly classified the stage of BP in 99% of adults older than the age of 60, while knowing only the DBP allowed 66% to be correctly classified.¹²

Age-related pathophysiologic changes explain the frequent development of ISH. While DBP elevation is caused by constriction of the smaller arterioles, ISH is caused by the loss of distensibility of the larger arteries, especially the aorta.¹³ In younger persons, the aorta is highly distensible, expanding during systole to minimize the rise in BP. The majority of elderly individuals, however, develop progressive stiffening of their arterial tree with age. This reduces the compliance of the aorta during systole and leads to a progressive elevation in SBP. Because the smaller arterioles are not involved in this process, the DBP remains normal or tends to decrease, contributing to a higher pulse pressure (SBP-DBP) with age.¹³ Accordingly, the elevated SBP increases both left ventricular work and the risk for left ventricular hypertrophy (LVH), while the decreased DBP may compromise coronary blood flow.¹⁴ This increase in pulse pressure is a stronger predictor of cardiovascular risk than either SBP or DBP elevation in the elderly. As there is no trial-based evidence that a reduction in pulse pressure reduces cardiovascular risk, and because SBP reduction improves CVD outcomes and remains the major risk component of pulse pressure, treatment of SBP should continue to be targeted to reduce cardiovascular risk in the elderly patient.¹⁵

APPROPRIATE GOALS OF THERAPY IN THE ELDERLY

Treatment Benefits

The optimal BP level in the elderly individual with hypertension has not yet been conclusively determined.³ In general, BP goals depend on the type of elevation (isolated systolic versus systolic/diastolic) and the presence of diabetes or renal disease. Clinical trials over the past 35 years have proven the benefits of antihypertensive therapy in reducing the rates of stroke, heart failure, and heart attack. Several large, prospective clinical trials conducted over the past several decades in older patients with combined systolic-diastolic hypertension have demonstrated the benefits of treating hypertension in the elderly (Table 55–1). Based on diastolic entry criteria, they showed significant decreases in the rates of stroke, heart failure, and heart attack, as well as mortality when treating to a DBP goal of less than 90 mm Hg. These treatment benefits are notably greater in older compared with younger individuals, due to the greater absolute risk for CVD outcomes in older individuals.¹⁶ Small reductions in BP are associated with large reductions in cardiovascular events and stroke.¹⁷ While cardiovascular events have been decreased by treatment of hypertension in the elderly, the demonstrated benefit has been even larger for the prevention of stroke and stroke-related mortality. Several meta-analyses found a 38% reduction in stroke, 16% reduction in heart attack, 52% reduction in heart failure, 21% reduction in cardiovascular death, and a 35% reduction in LVH in drug-treated compared with placebo or control participants.^{18–21} The Blood Pressure Treatment Trialists' Collaboration evaluated 29 trials (162,341 participants with a mean age of 65 years) and found that reduction in BP with any of the commonly used regimens reduced the risk of cardiovascular events, and the larger the reduction in SBP, the larger the reduction in risk.²²

In the most recent controlled clinical trials, including the Hypertension Optimal Treatment (HOT),²³ Antihypertensive, and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),²⁴ and the Controlled Onset Verapamil Investigation of Cardiovascular Endpoints (CONVINCE)²⁵ trials, 90% of participants had their DBP reduced to <90 mm Hg, but only about 60% had SBPs reduced to <140 mm Hg. Accordingly, it is usually the inability to reduce SBP effectively that prevents BP targets from being reached.

Table 55–1 Percent Event Reduction in Clinical Hypertension Trials in Older Patients

	Stroke	CAD	CHF	All CVD
Australian	33	18	—	31
EWPHE	36	20	22	29*
STOP	47*	13†	51*	40*
MRC	25*	19	—	17*
HDFP	44*	15*	—	16*

*Statistically significant.

†Myocardial infarction only.

CAD, coronary artery disease; CHF, congestive heart failure; CVD, cardiovascular disease.

Randomized placebo-controlled trials have demonstrated significant benefit from drug treatment in elderly patients with ISH. In those with a SBP \geq 160 mm Hg and a DBP <90 to 95 mm Hg at baseline, a 35% to 40% reduction in stroke, up to a 50% reduction in heart failure, a 30% reduction in coronary events, and a 10% to 15% reduction in mortality were achieved with antihypertensive treatment (Table 55–2). In order to achieve this benefit, SBP was reduced by at least 20 mm Hg from baseline, to a level below 150 or 160 mm Hg. In none of the trials was an average SBP <140 mm Hg achieved (Table 55–3).

Is there clinical trial evidence to recommend a goal SBP of <140 mm Hg in patients with ISH? Only a few clinical trials have specifically attempted to randomize patients to different target levels of BP as a primary intervention. Many recommendations to achieve a specific target BP come from epidemiologic observation or posthoc analyses of clinical trial data. One such posthoc analysis was published almost 10 years after the original results of the SHEP trial.²⁶ In this analysis, performed on the original 4736 participants 60 years of age or older with SBP of \geq 160 mm Hg and DBP <90 mm Hg, the risk of stroke was calculated according to on-treatment BP during follow-up. With a targeted SBP <160 mm Hg and at least a 20-mm Hg reduction from baseline, those on-treatment had a 33% reduction in stroke. The patients who achieved a SBP <150 mm Hg did even better, with a 38% reduction in stroke risk. The group who achieved a SBP <140 mm Hg had a 22% reduction in stroke risk, which did not reach statistical significance because of the smaller numbers of participants involved. These data should not be interpreted to mean that achieving SBP <140 mm Hg is less beneficial than achieving a higher SBP level. They do suggest, however, that if SBP is reduced by at least 20 mm Hg from baseline, even if not to the presently recommended goal of <140 mm Hg, clinical outcome is improved.

The cardiovascular risk associated with stage 1 ISH (140-159 mm Hg) is well established, but no outcome-based trial has tested whether treatment reduces event rates. Nevertheless, JNC 7³ and a consensus statement from the National High Blood Pressure Education Program recommend achieving a SBP <140 mm Hg based on epidemiologic rather than trial-based data.¹⁰

It should be noted that clinical trials in elderly patients with hypertension tend to underestimate the actual benefit of treatment for several reasons. First, patients with severe hypertension, who stand to benefit the most from treatment because of their greater absolute risk, are often excluded. In addition, many study protocols follow an “intention-to-treat” design, where patients in the placebo group are treated once their BP reaches a designated threshold, thus minimizing the treatment benefits in the active therapy group. In the Systolic Hypertension in the Elderly Program (SHEP), for example, by the end of the study, 44% of patients in the placebo group were receiving active treatment. Finally, a relatively short (3-5 year) trial duration may not allow treatment-related reductions in CHD events to be realized, because cerebrovascular endpoint benefits may occur sooner and cause the trial to be stopped early.²⁷ Accordingly, benefits of antihypertensive treatment seen in practice may be greater than those achieved in clinical trials.

Is there any age at which one would not treat the elderly patient with hypertension? A subgroup meta-analysis of effects of antihypertensive treatment on very old participants enrolled in randomized controlled trials supports the benefit of antihypertensive therapy even in patients 80 years of age and older, at least with respect to prevention of stroke, major cardiovascular events, and heart failure.²⁸ There was no treatment benefit for cardiovascular death, and a nonsignificant excess of all-cause mortality in the active treatment group, suggesting a need for a large-scale trial of antihypertensive treatment in the very elderly. In the interim, there is no justification for withholding antihypertensive treatment based on advanced age (Box 55-1).

Clinical Evaluation

A thorough history and physical examination should be performed, as in the younger patient with hypertension. Patients should be specifically questioned about the use of any prior antihypertensive medication and how well their BP was controlled. In addition, they should be asked about the use of nonsteroidal antiinflammatory agents and over-the-counter medications, including nasal sprays and cold remedies, both of which may

Box 55-1 General Guidelines Related to Antihypertensive Treatment in the Elderly

- Therapy in older individuals with hypertension should begin with lifestyle modification.
- Weight loss and sodium restriction may decrease the need for antihypertensive medication in this population.
- The starting dose of medication should be one half of that used in younger patients.
- In the elderly patient with hypertension and no compelling indications, a thiazide-type diuretic is recommended as initial therapy.
- α -Blocker therapy should not be used as initial therapy but it can be used as additive therapy to further help reduce blood pressure (BP).
- Although BP reduction should occur more gradually in the older patient with hypertension, the goal for effective BP control is similar to those younger in age.
- The minimum goal for BP control is <140/90 mm Hg; while in those with diabetes and renal disease the goal is <130/80 mm Hg.
- Patients with ISH should reduce their SBP to <140 mm Hg.
- Caution should be exercised when lowering DBP to <55 mm Hg when treating the older patient with ISH
- The effects of hormone replacement therapy (HRT) on BP are unclear. BP should be monitored closely if the patient is on HRT.
- HRT should not be used for cardiovascular disease (CVD) prevention. HRT should only be considered for the short-term treatment of menopausal symptoms.

raise BP. Questioning should also occur concerning alternative therapies, including ephedrine-containing nutraceuticals such as Ma Huang, which has been associated with stroke.

As in the younger patient, the diagnosis of hypertension should be based on the average of two standardized measurements taken over separate office visits. This is even more important in the elderly because BP is often more variable in this group than in younger persons. In addition, measurement of BP can pose special problems in the elderly. Pseudohypertension should be suspected in those with persistently high BP without any evidence of target organ damage or when antihypertensive medication causes hypotensive symptoms in elderly patients with continually elevated cuff-determined BP. In these individuals, the brachial arteries may be thickened and stiff and the BP measurement may be an overestimation of actual intraarterial pressure.

BP should be measured in the supine, sitting, and standing positions as the elderly are more prone to postural hypotension, especially after a meal. The occurrence of postural hypotension often limits the ability to control systolic hypertension and affects the ability to use sitting pressures to determine BP control. The standing BP, therefore, should often be used in the elderly to determine the dose of antihypertensive medication required and if BP is controlled.

Most elderly patients with hypertension are asymptomatic. Target organ damage is more likely to occur in the elderly,

but very few elderly patients have a reversible, secondary form of hypertension. When an elderly patient presents with new-onset of severe hypertension or the sudden loss of what was previously well-controlled hypertension, a secondary cause should be considered. It is neither cost-effective nor rewarding to perform an extensive workup on every elderly patient with hypertension in hopes of finding a secondary cause. Although renovascular hypertension is more common and often unrecognized in the elderly, it is rarely cured by surgical or percutaneous (angioplasty with stent) intervention. Accordingly, if BP is controlled and renal function remains normal, there is little benefit from knowing that renal artery stenosis is present.

Two often unrecognized conditions in the elderly that lead to poor BP control are sleep apnea and obstructive uropathy. To make a presumptive diagnosis of sleep apnea, ask the patient and his or her sleeping partner whether the patient snores or gasps for air while sleeping, and whether the patient has daytime hypersomnolence. A positive answer indicates that the patient may need further evaluation such as a formal sleep study (see Chapter 73). A second cause of poor BP control is obstructive uropathy. A full bladder can cause discharge of sympathetic neurons and make BP control difficult. Catheterization is often curative.

The initial dose of antihypertensive drug(s) in the elderly should often be one half that used in the younger subject. This allows for the reduced renal or hepatic drug metabolism that often occurs in the elderly. The dose should be slowly increased until the maximum BP reduction occurs at the dose with the fewest side effects. Additional agents should be added until the BP goal is attained.

Options for Therapy: Lifestyle (Nonpharmacologic) Changes

Lifestyle changes—in particular, weight loss and reduced sodium intake—are beneficial in controlling BP in the elderly hypertensive and are associated with a reduced need for pharmacologic therapy. Weight reduction is the most effective lifestyle intervention for lowering BP, especially in the elderly hypertensive who is overweight. Older hypertensive patients are often more salt sensitive than younger ones, and successful salt reduction can be achieved, in part by limiting a variety of high-salt-containing processed foods. The Trial of Nonpharmacologic Interventions in the Elderly (TONE) during 30-months of follow-up found that restricting salt to 80 mmol (2 g) per day reduced SBP by 4.3 mm Hg and DBP by 2 mm Hg. The combination of weight loss and salt restriction reduced BP more than either strategy by itself, and, when used together, enabled almost half the elderly participants to stop antihypertensive drug therapy. These individuals were unsuccessful in long-term weight reduction, with a high recidivism rate at 6 to 12 months.²⁹

Additional lifestyle changes include adopting the Dietary Approaches to Stop Hypertension (DASH) diet. This diet, which is low in fat but rich in fruits, vegetables, and low-fat dairy products, has been successful in reducing BP in older hypertensive patients even when consuming an average salt intake.³⁰ Reducing alcohol intake and increasing physical activity should also be integral parts of BP control in the elderly.

Options for Therapy: Pharmacologic Treatment of ISH

Several placebo-controlled randomized outcome trials have tested whether pharmacologic treatment of ISH can reduce cardiovascular events and stroke. In the SHEP trial, performed in 4736 patients at least 60 years of age with a SBP 160 mm Hg or above and a DBP below 90 mm Hg, initial therapy with a thiazide-type diuretic with or without a β -blocking agent reduced first stroke by 36%, and cardiovascular events by 27%.³¹ Heart failure was reduced by 49% overall, with an 81% reduction in those with either a history or evidence of a prior myocardial infarction (MI) on the electrocardiogram.³² In the 583 SHEP patients with type 2 diabetes, major cardiovascular events were reduced by 34%.³³ The benefit of diuretic therapy was lost if the serum potassium level was not kept above 3.5 mg/dL.³⁴

The European Trial on Isolated Systolic Hypertension (Syst-Eur) in the elderly randomized 4695 patients 60 years of age or older with SBP 160 to 219 mm Hg and DBP <95 mm Hg (European definition of ISH) to the moderately long-acting dihydropyridine calcium channel blocker (CCB) nitrendipine, with the addition of the angiotensin-converting enzyme (ACE) inhibitor enalapril, and a thiazide-type diuretic as necessary, or to matching placebos. Over a median of 2 years of follow-up, active treatment reduced stroke by 42% and all cardiovascular events by 31%.²⁷

A meta-analysis of eight placebo-controlled trials in the elderly with ISH, which included 15,693 patients 60 years of age and older followed for an average of 3.8 years, found that active treatment reduced coronary events by 23%, stroke by 30%, cardiovascular death by 18%, and total death by 13%.³⁵ In those patients older than 70 years of age, the absolute benefit was particularly high. Treating 19 patients for 5 years prevented one major fatal or nonfatal cardiovascular event.

In a prespecified subgroup analysis of the Losartan Intervention For Endpoint Reduction (LIFE) trial, losartan-based therapy was superior to β -blocker (atenolol) based therapy in the 14% of patients with ISH. All participants enrolled in LIFE had electrocardiographic evidence of LVH (ECG LVH). Over 4.7 years of follow-up, a 25% reduction in the combined endpoint of cardiovascular death, acute MI, and stroke occurred in the group randomized to losartan. Of note, hydrochlorothiazide was added in almost all patients in both treatment groups.³⁶

In summary, in those with ISH, initial therapy with a thiazide-type diuretic or dihydropyridine-type calcium-antagonist therapy has been found to be superior to placebo-based therapy. In addition, in those with ECG-LVH, an angiotensin receptor blocker (ARB)-based strategy was more effective than a β -blocker-based regimen. Only 60% of elderly patients treated for ISH were controlled on a single agent in reported clinical trials. Accordingly, the majority of elderly patients with hypertension, including those with ISH, will require at least 2 to 3 drugs to achieve the SBP goal of <140 mm Hg.

Pharmacologic Treatment of Systolic/Diastolic Hypertension

Although all classes of antihypertensive agents effectively lower combined SBP/DBP elevation in the elderly, the majority of

outcome-based trials showing a reduction in cardiovascular morbidity and mortality have used diuretics and, when necessary, additional β -blocker therapy. A meta-analysis of outcome trials of antihypertensive treatment has suggested that the initial agent chosen likely does not have a unique status for event rate reduction, and that the SBP reduction achieved appears more important.²²

The open-label Second Swedish Trial in Old Patients with Hypertension (STOP-2) compared the use of an ACE inhibitor, a CCB, or a diuretic with or without β -blocker therapy in 6628 participants 70 to 84 years of age with combined SBP/DBP elevation.³⁷ Similar BP reduction was achieved in all three treatment groups. There was no difference in cardiovascular mortality (the primary outcome) among the three randomized groups.

The open-label Nordic Diltiazem (NORDIL) trial, with an average participant age of 60 years, found a similar rate for the primary outcome of combined fatal and nonfatal stroke, MI, and cardiovascular death in participants randomized to the CCB diltiazem compared with those assigned to diuretic and/or β -blocker therapy.³⁸ Although fewer strokes occurred in the diltiazem arm, there was a trend toward more MIs and heart failure with diltiazem.

The double-blinded International Study of Intervention as a Goal In Hypertension Treatment (INSIGHT) trial enrolled men and women 55 to 80 years of age, 75% of who were older than the age of 60. It found that nifedipine GITS (GastroIntestinal Therapeutic System) and diuretic therapy had similar overall CVD outcomes.³⁹

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the largest outcome trial of antihypertensive therapy ever performed, was designed to determine whether the occurrence of fatal CHD or nonfatal MI (primary outcome) in high-risk patients with hypertension is lower when treated with a representative dihydropyridine CCB (amlodipine), or a representative ACE inhibitor (lisinopril), each compared with a representative long-acting thiazide-type diuretic (chlorthalidone).²⁴ The third active comparator arm involving an α -blocker (doxazosin) was stopped early because of a 25% greater cardiovascular event rate, principally a twofold greater risk of heart failure when compared with chlorthalidone, as well as a vanishingly small chance of finding a difference in the primary endpoint between the two treatment groups. Those results were interpreted as showing that an α -blocker should not be used as first-line therapy for hypertension in a relatively high risk, ALLHAT-like population.⁴⁰

ALLHAT, with a mean follow-up of 4.9 years, enrolled 33,357 men and women aged 55 years or older (mean age 67) with at least one additional coronary risk factor. On entry, participants had stage 1 or stage 2 hypertension (BPs 140-180/90-110 mm Hg). More than 90% of patients were on one or two BP-lowering agents that were stopped prior to entry into the study. In the final analysis, 15,255 patients were randomized to chlorthalidone (12.5-25 mg once a day); 9048 to amlodipine (2.5-10 mg once a day); and 9054 to lisinopril (10-40 mg once a day). If the participant did not achieve the goal BP of <140/90 mm Hg after up-titration to the highest dose of the step 1 drug open-label step 2 drugs were added. Step 2 drugs included atenolol (25-100 mg/day), clonidine (0.1-0.3 mg twice a day), or reserpine (0.05-0.2 mg/day);

the only step 3 agent was hydralazine (25-100 mg twice a day). Amlodipine and lisinopril were both compared with chlorthalidone. No comparison was valid between amlodipine and lisinopril.²⁴

Baseline risk factors were nearly identical in the three treatment groups. Of the participants, 47% were women, 35% were Black, 19% were Hispanic, 22% were smokers, 36% were diabetic, 25% had preexisting CHD, and 47% had preexisting CVD.⁴¹ Mean seated BP on entry (usually on some antihypertensive medications) was 146/84 mm Hg in all three groups and was 134/75 mm Hg, 135/74 mm Hg, and 136/75 mm Hg in the chlorthalidone, amlodipine, and lisinopril groups respectively, at 5 years of follow-up. At the initial visit, 27% were at or below the BP goal of <140/90 mm Hg. After 5 years of follow-up, 68%, 66%, and 61% were below SBP goal in the chlorthalidone, amlodipine, and lisinopril groups, respectively.²⁴ In contrast, more than 90% had reached the DBP goal, reinforcing the relative unimportance of DBP in older hypertensive patients.

Adherence to therapy fell from 87% to 80% for chlorthalidone, 88% to 80% for amlodipine, and 82% to 73% for lisinopril from the first through the fifth year of follow-up. Adherence to initial therapy was different only between those on lisinopril and chlorthalidone.

A total of 2956 patients experienced a primary outcome event and there was no difference among the groups. Neither amlodipine nor lisinopril was superior to chlorthalidone in preventing major coronary events or improving overall survival. For both the primary and secondary outcomes, there was no difference between the amlodipine and chlorthalidone groups except that those randomized to chlorthalidone had a significant 38% reduction in the risk of heart failure that was seen within all the prespecified subgroups (old and young, men and women, Black and non-Black, diabetic and nondiabetic). Compared with chlorthalidone, amlodipine was not associated with excess gastrointestinal bleeding or cancer death—concerns that had been raised from past observations.

In comparing chlorthalidone and lisinopril, those on chlorthalidone had a 15% reduction in the risk of stroke with a mean 2-mm Hg lower SBP overall. In Blacks, who had a 4-mm Hg greater reduction in SBP on chlorthalidone compared with lisinopril, a 40% reduction in stroke risk occurred in those randomized to chlorthalidone compared with the lisinopril group. The risk of heart failure was reduced by 19% in those on chlorthalidone compared with lisinopril.

Thiazide-type diuretics were unsurpassed in reducing clinical events and lowering BP and were as well tolerated as CCB and ACE inhibitor therapy in ALLHAT. Accordingly, they are recommended as initial therapy in the elderly patient with hypertension. If a compelling comorbid condition exists, other initial therapy may be justified.³ If not used initially, a thiazide-type diuretic should be included in most regimens to enhance the efficacy of other BP-lowering agents.

BP control rates can be improved, but more than one drug will usually be required to do so. Although two of every three ALLHAT participants were controlled to <140/90 mm Hg, only 30% were controlled on single-agent therapy.⁴² The degree of BP (particularly SBP) reduction and not the individual antihypertensive drug used appears more important for improving outcome in the older individual.²²

J-CURVE HYPOTHESIS

The J-curve hypothesis describes the concern that lowering DBP below a certain critical value increases the risk of cardiovascular death and morbid events in the elderly hypertensive. Prospective data validating this hypothesis are lacking. The bulk of the evidence available comes from retrospective trials, which are associated with inherent observational bias.⁴³ As an increased occurrence of ischemic events has been prospectively observed in both placebo and actively treated patients with very low DBP, a low DBP is thought to serve more as a marker than a cause of cardiovascular events in those with underlying coronary disease.^{44,45}

The Hypertension Optimal Treatment (HOT) study was designed to test whether intensive BP lowering was helpful or harmful in preventing cardiovascular events and death.⁴⁶ This Prospective, Randomized, Open with Blinded Endpoint evaluation (PROBE) trial randomly assigned 18,790 hypertensive patients (mean age 61.5 years) from 26 countries to a target DBP <80 mm Hg, <85 mm Hg, or <90 mm Hg and followed them for an average of 3.8 years. It found no increased cardiovascular risk for the DBP goal <80 versus <90 mm Hg.

A retrospective analysis of the SHEP trial, however, suggested that in the few patients whose DBP was lowered to <55 mm Hg with drug treatment, there was no benefit in outcome when compared with the placebo group.⁴⁷ This suggests that we exercise caution in lowering DBP to <55 mm Hg when treating older individuals with ISH.

Hormone Replacement Therapy and Hypertension

After years of observational studies supporting use of hormone replacement therapy (HRT) in postmenopausal women for prevention of CVD, controlled clinical trials have provided no evidence for cardiovascular benefit and have noted the occurrence of serious adverse effects for those on HRT. The Hormone Estrogen Replacement Study (HERS) followed 2763 postmenopausal women with known CHD who were randomized to estrogen and progestin or placebo. It found an increased incidence of CHD for those on active therapy in the first year of follow-up and a reduction of CHD in years 3 through 5. No overall benefit in preventing cardiovascular events could be identified.⁴⁸ To determine whether the later risk reduction for CHD seen during years 3 through 5 in the HERS trial persisted, HERS II followed women from the original study for a total duration of 6.8 years. No significant decrease in cardiovascular events was seen during HERS II. The authors of the study stated that their findings support not recommending HRT to reduce CHD risk in postmenopausal women.⁴⁹

Subsequent analysis of HERS data identified 11 risk factors for CVD among the participants, and assessed preventative measures.⁵⁰ Six factors that increased risk were identified by history: nonwhite ethnicity, lack of exercise, treated diabetes, angina, CHF, and more than one previous MI. The remaining five were obtained by measurement: uncontrolled hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, elevated Lp(a) lipoprotein level, and low creatinine clearance. Controlled hypertension was not a risk factor. In this cohort with known CHD, and therefore already at risk for another cardiovascular event, these 11 risk factors increased subsequent risk sixfold. Only three of the risk factors were potentially reversible: lipid lowering, exercise, and BP control. BP

and lipid-lowering agents were used in a minority of qualified enrollees at the onset of the HERS study and continued during the 4-year follow-up. The underuse of proven therapies in the HERS middle-aged to elderly female population is an important but not isolated finding. Inadequate secondary prevention measures have been observed in other studies of the elderly.⁵¹⁻⁵³

The Women's Health Initiative (WHI) included in its complex design a randomized, double-blind clinical trial that compared a combination of 0.625 mg equine estrogen and 2.5 mg medroxyprogesterone acetate with placebo in more than 16,000 apparently healthy women 50 to 79 years of age.⁵⁴ The trial was stopped early after an average follow-up of 5.2 years because of an increased incidence of breast cancer in the estrogen plus progestin group. The number of cases of CHD (CHD deaths plus nonfatal MIs), stroke, pulmonary embolism, and venous thromboembolic disease were all increased in those on combined hormone replacement. HRT was associated with a 44% increased risk of ischemic stroke in women with and without hypertension.⁵⁵ A slight increase in SBP was noted in the HRT treatment group: 1 mm Hg higher after 1 year, increasing to 1.5 mm Hg at 2 years. Analysis of BP data at the time of enrollment in the trial revealed that current HRT use was associated with a 25% greater likelihood of developing hypertension than nonuse when adjusted for age, smoking, alcohol intake, cholesterol, physical activity, body mass index, family history, and other comorbidities.⁵³ The same report, focusing on the adequacy of BP control among WHI participants with hypertension, found that despite the fact that those 70 to 79 years of age were as likely to be on antihypertensive treatment as the younger 50 to 69 year old participants, a significantly lower percentage of the older age group had adequate BP control, with almost two thirds of the oldest women having BPs >140/90 mm Hg despite the fact that they had often seen a healthcare provider in the past year (Figure 55-1).

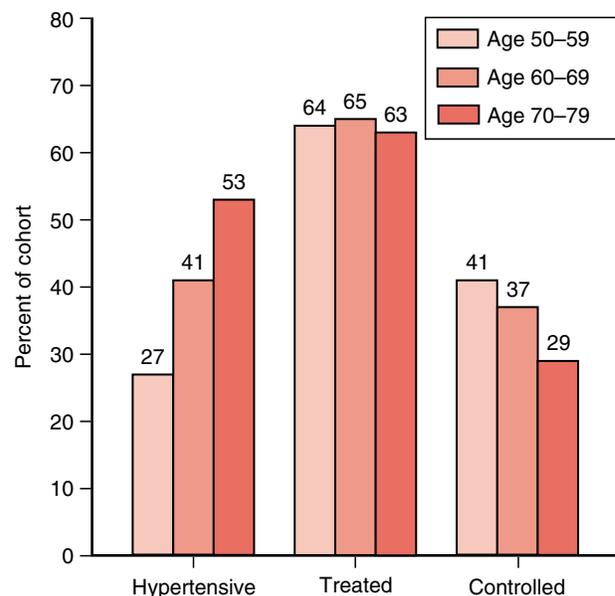

Figure 55-1 The Women's Health Initiative—prevalence and treatment status by age. From Wassertheil-Smoller S, Anderson G, Psaty B, et al. Hypertension and its treatment in postmenopausal women. Baseline data from the Women's Health Initiative Hypertension 36:780-789, 2000.

In contrast to the aforementioned studies, which found an increase in BP on HRT, the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial, which studied younger postmenopausal women who were normotensive on entry, found no difference in BP among any of four HRT treatment groups and placebo after 3 years of follow-up.⁵⁶ Furthermore, in the Baltimore Longitudinal Study on Aging, which followed 226 healthy postmenopausal women over an average 5.7 years, SBP increased 3 mm Hg more in the two thirds of participants on placebo compared with those that received HRT, with no change in DBP noted.⁵⁷

There is no clear consensus about the direct effects of HRT on BP. HRT-related changes in BP are likely to be modest and should not preclude hormone use in normotensive or hypertensive women. Because of the adverse cardiovascular outcomes noted previously, HRT should not be given to prevent any adverse cardiovascular outcome in postmenopausal women⁵⁸ regardless of the presence of hypertension. If used, HRT should only be used for the short-term treatment of menopausal symptoms. In those with hypertension, BP should be monitored closely, both on initiation of HRT therapy and at 6-month intervals thereafter.³

Management of Hypertension in Black Populations

Ernest F. Johnson III, Jackson T. Wright, Jr.

Hypertension is the major risk factor for cardiovascular morbidity and mortality in African Americans.¹ An estimated 50 million Americans are affected with roughly 2 million new diagnoses annually. With almost 6 million hypertensives, African Americans have the highest rate of hypertension, among the lowest rates of control to goal blood pressure (BP), and the highest risk of complications from hypertension of any ethnic group in the United States. Multiple theories have been proposed to explain this disparity. Potential patient-related barriers include lack of awareness, socioeconomic status, and genetic predisposition. Physician-related barriers have included an overall lower expectation of treatment as well as the limitation of available clinical trial data to guide management. This chapter reviews the epidemiology, potential mechanisms, and management of hypertension in the African American population.

EPIDEMIOLOGY

African Americans, compared with U.S. whites, develop hypertension at an earlier age, have more severe hypertension, and manifest more clinical sequelae of target organ damage. In the most recent National Health and Nutrition Examination Survey (NHANES), a total of 5448 participants were surveyed, including 1049 non-Hispanic Blacks (Table 56–1).² Non-Hispanic Blacks had a higher age-adjusted prevalence of hypertension than the general population in 2000 (33.5% vs. 28.7%). Consistent with previous NHANES data, both non-Hispanic Black men (30.9%) and women (35.8%) had a higher prevalence of hypertension compared with non-Hispanic white men (27.7%) and women (30.2%). Despite concerted efforts, hypertension awareness in the African American community has remained virtually unchanged since 1988, with rates of 73.3% and 73.9% in phases I and III of NHANES III. Although overall treatment rates in the United States have improved from 55.8% to 63.0%, a smaller percentage (28.1% vs. 33.4%) of African American hypertensives was controlled to BP <140/90 mm Hg. Among African American hypertensives, women (29.4%) had higher control rates than men (26.5%). As in other populations, both systolic BP (SBP) and diastolic BP (DBP) increase with age through the fifth decade of life (Figure 56–1). Subsequently, DBP stabilizes or trends downward while SBP (and thus pulse pressure) continues to increase.

The Atherosclerosis Risk in Communities (ARIC) study evaluated cardiovascular risk factors in 14,062 participants including 3694 African Americans, aged 45 to 64 between 1987 and 1997.³ ARIC reported a hypertension prevalence of 56% in African American women and 53% in African American men, compared with 25% in whites. The

African American component of ARIC continues to be followed as part of the Jackson Heart Study.⁴ The Meharry Cohort Study (MCS) was begun in 1958 as a longitudinal study of the incidence of hypertension in 433 African American medical students at Meharry Medical College.⁵ A parallel study was conducted at Johns Hopkins University with white students. The prevalence of hypertension rose to 44% in the Meharry cohort compared with 7% in the Johns Hopkins cohort over 26 years of follow-up.

Differences in prevalence of hypertension and stroke have also been noted by race and region of the country, suggesting that southern residence is associated with increases in both hypertension and stroke. Obisesan analyzed regional and urbanized data from NHANES III in 6278 non-Hispanic whites and Blacks age 40 to 79 to determine whether differences in hypertension prevalence might explain the disproportionate number of strokes in the southeastern part of the United States known as the “Stroke Belt.”⁶ A significant regional difference in hypertension prevalence was noted between southern and nonsouthern non-Hispanic Black males age 40 to 59 (44.1% vs. 36.7%), as well as a trend toward higher rates in southern versus nonsouthern African American females in the same age group (45.6% vs. 39.4%). Regional differences were also reported in 5115 men and women age 18 to 30 (~39% African American) in the Coronary Artery Disease Risk Development In Young Adults (CARDIA) study, extending the regional disparity to younger African American adult males.⁷ Although there was no baseline regional difference in hypertension, both African American and white men in Birmingham, Alabama had significantly higher incidences of elevated BP (>130/85 mm Hg) by the seventh year compared with men in the Midwest and far West. This was especially true for African American men in Birmingham, who had the highest incidence (20%) of hypertension of any racial/gender/regional group.

Because most surveys of secondary hypertension prevalence have used clinic-based rather than population-based data, the epidemiology of secondary hypertension in African Americans is uncertain. Thus, the true incidence of renovascular disease in African Americans remains a matter of controversy.^{8–10} Svetkey et al.¹⁰ prospectively evaluated 167 hypertensives with clinical features of renovascular hypertension. Renal artery stenosis was found in 27% of whites and 19% of African Americans, and renovascular hypertension (defined by BP response to intervention) was diagnosed in 18% of whites and only 9% of African Americans. However, the criteria used to select patients for evaluation for secondary hypertension (i.e., resistant hypertension and early onset of hypertension) more commonly occur with essential hypertension in African Americans. Therefore, surveys using these selection criteria tend to oversample essential hypertension in African Americans.

Table 56-1 Trends in Hypertension Prevalence, Awareness, Treatment, and Control in the United States (NHANES)

Ethnic Group	Prevalence %	Awareness %	Treated %	Controlled %
Non-Hispanic White				
1988-1991	25.9	70.6	53.9	25.6
1991-1994	25.6	67.5	51.9	22.7
1999-2000	28.9	69.5	60.1	33.4
Mexican American				
1988-1991	17.2	54.4	34.1	13.7
1991-1994	17.8	62.0	43.5	16.3
1999-2000	20.7	57.8	40.3	17.7
Non-Hispanic Black				
1988-1991	28.9	73.3	55.8	24.4
1991-1994	32.5	72.6	56.4	23.3
1999-2000	33.5	73.9	63.0	28.1

MECHANISMS OF HYPERTENSION

Multiple theories have been proposed to account for the higher incidence and severity of hypertension in African American persons. These include differences in socioeconomic status (SES) and other environmental factors, increased sympathetic nervous system activity, deficiency of renal vasodilators, higher rates of low birth weight (LBW), increased salt sensitivity, and genetic susceptibility (Box 56-1). No single mechanism is fully explanatory. On the contrary, it is likely that the true explanation will involve a combination of factors.

SES has received a considerable amount of attention over the years.¹¹⁻¹³ The MCS attempted to eliminate the potential role of SES by including only physicians, thus individuals with roughly equivalent income and living environment. The racial difference in hypertension incidence was unaffected.⁵ Other studies have reported that controlling for differences in SES dramatically reduces the racial differences in the epidemiology of hypertension and its consequences.¹⁴ The effect of SES on health outcomes is complex and gross estimates provided by current markers (e.g., income, education, employment, insurance status, place of residence) probably oversimplify its significance.

Increased release of endothelin-1 (ET-1), a 21-residue peptide, has been associated with hypertension in African Americans.¹⁵⁻¹⁷ Ergul et al.¹⁶ measured resting plasma concentrations of ET-1 in African American and white hypertensives. In 50 hypertensive and 50 normotensive individuals, divided into categories by race and ethnicity, blood ET-1 levels in African American hypertensives were nearly eightfold higher compared with their normotensive counterparts and nearly fourfold higher compared with white hypertensives. Treiber et al.,¹⁸ in 23 white and 18 African American adolescent males with family histories of hypertension, reported greater cardiovascular reactivity and higher levels of ET-1 in African Americans in response to acute physical or mental stress.

Lower activity of endogenous renal vasodilators such as kallikrein, atrial natriuretic peptide (ANP), prostaglandin, and

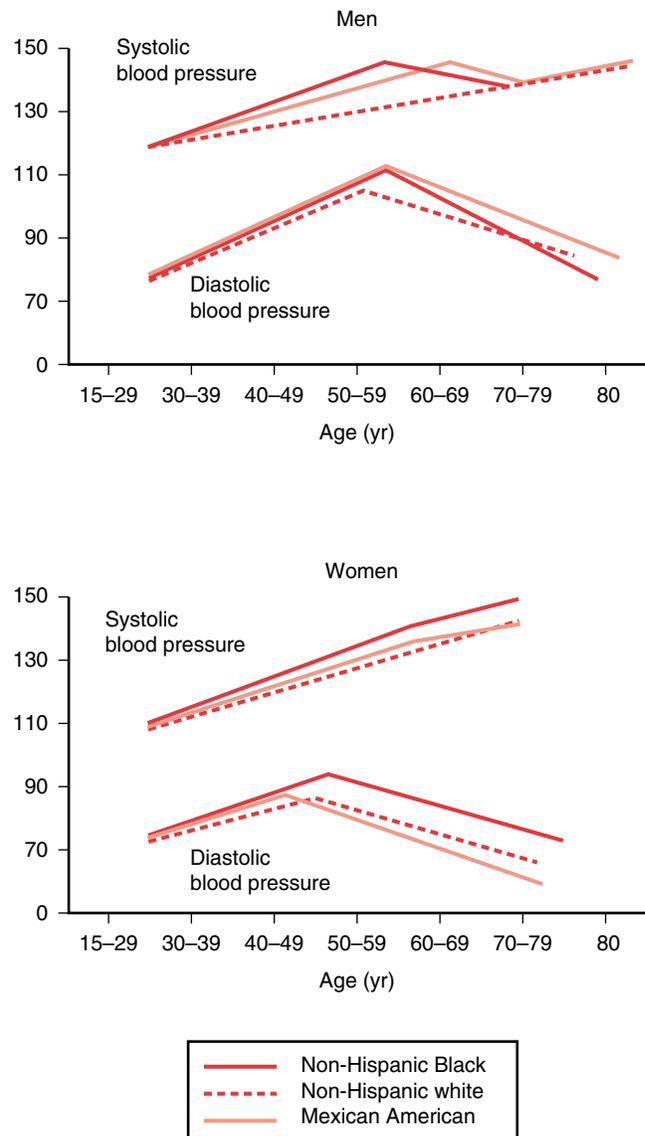

Figure 56-1 Changes in systolic (SBP) and diastolic blood pressure (DBP) with age, SBP and DBP by age and race or ethnicity for men and women over 18 years of age in the U.S. population. (Data from Burt VL, Whelton P, Roccella EJ, et al. Prevalence of hypertension in the US adult population. Results from the Third National Health and Nutrition Examination Survey, 1988-1991. *Hypertension* 25:305-313, 1995.)

nitric oxide has also been reported in African Americans. African Americans, regardless of BP, were found to excrete less urinary kallikrein than whites.¹⁹⁻²² This association may be familially aggregated, as Zinner et al.²³ found that kallikrein excretion tends to be lower in children of families with the highest BPs. In another study, Ferrari et al.²⁴ observed markedly reduced levels of ANP during salt loading in children of hypertensive compared with normotensive parents. In addition, salt-sensitive African Americans have been found to exhibit a paradoxical decrease in ANP in response to increased dietary-salt intake.²⁵ Further exploration of the potential role of these systems in the development of essential hypertension may prove important.

Box 56-1 Proposed Mechanisms of African American Hypertension

SES
 Increased endothelin-1
 Low birth weight
 Salt sensitivity
 Obesity
 Physical inactivity
 Low dietary potassium
 Genetic susceptibility
 Decreased activity of renal vasodilators
 Obstructive sleep apnea

Multiple studies have reported lower activity of the renin-angiotensin system (RAS) in African Americans compared with whites in response to changes in vascular volume or BP.²⁶⁻²⁹ Thus, hypertension in African Americans is more often classified as low renin; this is associated with a lesser response to antihypertensives directed at inhibiting the RAS.

Several epidemiologic studies have raised the possibility that LBW may influence disease later in life.³⁰⁻³² The increased incidence of hypertension in African Americans has been proposed to be related to a higher incidence of LBW and an associated nephron deficit acquired in utero that is not recovered after birth.³² The nephron deficit is postulated to lead to the development of glomerular sclerosis, salt sensitivity, and subsequent hypertension. This hypothesis was supported by a study in almost 5000 persons that reported a statistically significant inverse relationship between SBP at all ages beyond birth and LBW.³¹ Babies weighing ≤ 3180 g at birth had a 4- to 12-mm Hg higher SBP than those weighing >3860 g, and by ages 64 to 71 there was a 5.2-mm Hg increase in SBP for every 1-kg decrease in birth weight.^{31,32}

Racial differences in salt handling have been described and are proposed as a potential explanation for the increased incidence of African American hypertension. An abnormal renal pressure-natriuresis relationship resulting in altered sodium handling has been suggested by multiple studies reporting that African Americans have a higher incidence of salt sensitivity and low plasma renin activity compared with white Americans.³³⁻³⁶ Luft et al.³⁵ studied 68 age-matched persons before and after a 2-L saline infusion and reported that African Americans not only excreted sodium less effectively following the salt load, but also had lower renin levels 20 hours after salt load despite identical levels immediately postsaline.

Weinberger et al.,³⁴ using a similar protocol, evaluated 198 essential hypertensives and reported a salt sensitivity prevalence of 73% in African Americans compared with 56% in whites. However, many previous studies reporting racial differences in salt sensitivity either did not report or control for differences in age, hypertension severity, renal function, and levels of obesity. Differences in these characteristics may result in differences in salt sensitivity. A study in which gender, age, renal function, hypertension status, and weight were closely matched found no racial difference in prevalence of salt sensitivity.³⁷ However, the magnitude of BP increase was greater in African American than white hypertensives; this racial difference was not seen in normotensive persons.

A defect in sodium transport is one proposed mechanism for the altered sodium metabolism.³⁸ African American adults have 10% to 20% higher intracellular sodium than whites.^{39,40} African Americans also have up to a 30% depression in Na^+ , K^+ -ATPase pump activity.⁴¹ Elevated intracellular sodium may trigger a cascade of compensatory events that lead to elevated intracellular calcium, increased vascular reactivity, and eventual hypertension.⁴² The clinical implication of all of these findings is that multiple factors other than race per se may contribute to the racial difference in salt sensitivity and the lower renin levels seen in African Americans.

The question of whether or not there is a genetic contribution to African American hypertension remains to be answered. As a major component of the RAS, angiotensinogen (AGT) has a major influence on both salt and water homeostasis and vascular tone. The AGT gene has been linked to essential hypertension in families of European descent.⁴³ Moreover, a molecular variant of AGT known as T235 has been associated with higher AGT levels, as well as essential hypertension.⁴⁴ Although the frequency of T235 is twice as high in African Americans as in whites,⁴⁵ an association with hypertension has been found only in peoples of African origin living in the Caribbean.⁴⁶ T235 may not be a surrogate marker in African Americans due to its high prevalence.⁴⁷ Bloem et al.⁴⁷ investigated potential haplotypes more likely to serve as potential markers based on their ability to increase AGT levels. Of the three haplotypes examined, only T-1074 showed a significant association with serum AGT level. African Americans heterozygous for T-1074 had higher AGT levels than those with no copy. In addition, African Americans had a higher frequency (0.2 vs. 0.12) of T-1074 compared with whites. Therefore, AGT remains a candidate gene contributing to hypertension in both racial groups.

CLINICAL SEQUELAE OF HYPERTENSION

African Americans have the highest morbidity and mortality from hypertension of any population group in the United States.⁴⁸ Mortality related to hypertension is four to five times higher in the African American community, and the risk of end-stage renal disease (ESRD), left ventricular hypertrophy (LVH), coronary heart disease (CHD), congestive heart failure (CHF), and stroke is increased two to four times in African Americans compared with U.S. whites. Better understanding of the potential mechanisms of hypertension in conjunction with earlier initiation of effective treatment is needed to reduce or prevent hypertension-related complications.

Ethnic minorities, especially African Americans and Native Americans have a threefold to fourfold higher prevalence of ESRD than whites. Of the 335,915 total and 60,923 new ESRD patients in the United States in 2002, African Americans comprised 28.9% of the entire ESRD population and 16,568 of all new diagnoses. In 2001, this rate was 4.4 times higher for African Americans compared with whites. Hypertension has been a long established risk factor for the development of chronic kidney disease (CKD) and ultimately ESRD.⁴⁸⁻⁵² Until the turn of the century, when overtaken by diabetes, hypertension was the most common cause of ESRD in African Americans. Therefore, suboptimal BP control in African Americans may have a dual negative effect on renal

function via the development of hypertensive nephrosclerosis, as well as exacerbating other underlying disease.

In the year 2000, cardiovascular disease (CVD) resulted in 33.5% and 40.6% of African American male and female total deaths, respectively. LVH is a major independent risk factor for CVD. Several studies, including Evans County and the Hypertension Detection and Follow-up Program (HDFP), have reported a higher prevalence of LVH in African American than in white hypertensives using electrocardiogram (ECG) criteria.⁴⁸ Other studies using echocardiogram have shown a similar prevalence in both races.⁵³⁻⁵⁶ As a result, the validity of ECG to determine LVH in hypertensive African Americans is now in question. Using echocardiogram as the reference standard, Lee et al.^{54,56} assessed this racial difference in ECG accuracy in 122 African American and 148 white hypertensives. Although the prevalence of ECG LVH was 2.4 to 6 times higher in African Americans, specificity was consistently lower and ranged from 73% to 94% compared with 95% to 100% in whites. The reason for this overestimation is unknown, but the data suggest that using ECG algorithms for defining LVH in African American patients will require restandardization.

CHD, CHF, and stroke are also more prevalent in African Americans than in whites due in part to hypertension. Among non-Hispanic Blacks older than age 20, 7.1% of men and 9.0% of women have CHD as opposed to 6.9% and 5.4% of white men and women (American Heart Association [AHA], Stat Fact Sheet 2000). Whereas the overall death rate for CHD was 186.9 in 100,000 in 2000, death rates for African Americans were 262.4 in 100,000 for men and 187.5 in 100,000 for women. Furthermore, CHD tends to develop nearly 5 years earlier in African Americans.¹ The prevalence rate for CHF is 1.3% for African Americans aged 35 to 44 versus 0.4% and 0.3% for similar-aged white men and women.

Hypertension is a major risk factor for stroke, the third leading cause of death in the United States. (AHA, Stat Fact Sheet 2000) The overall death rate for stroke in 2000 was 60.8 of 100,000. The relative risk of a first event in African Americans is almost twofold greater than in whites. Despite declining total stroke mortality in the United States, African Americans have maintained a higher stroke mortality rate than whites, with African American males experiencing the highest rate (87.1 of 100,000 vs. 78.1 of 100,000 for women). This increased risk is most notable among African Americans aged 35 to 54 (4.0 times higher) and diminishes in the elderly (1.2 times higher for ages 75-84).

TREATMENT OPTIONS

Lifestyle Modification

Clinical trial data have shown that lifestyle modification (especially salt and caloric restriction, the Dietary Approaches to Stop Hypertension [DASH] eating plan, regular physical activity, and moderation of alcohol) is effective in lowering BP in African Americans.^{37,58-60} Weight loss is a particularly important lifestyle modification in the African American population because of the greater prevalence of obesity, especially among women. More than 60% of non-Hispanic Black men and 77% of non-Hispanic Black women are overweight (body mass index ≥ 25).⁶¹ African Americans also exercise less often than whites. Approximately half of African American adults (44.1% of men, 55.2%

of women) report no participation in any leisure-time physical activity.⁶² Furthermore, African Americans, like whites, consume excess salt.⁶³ Lifestyle modification is essential in treating African Americans with hypertension.

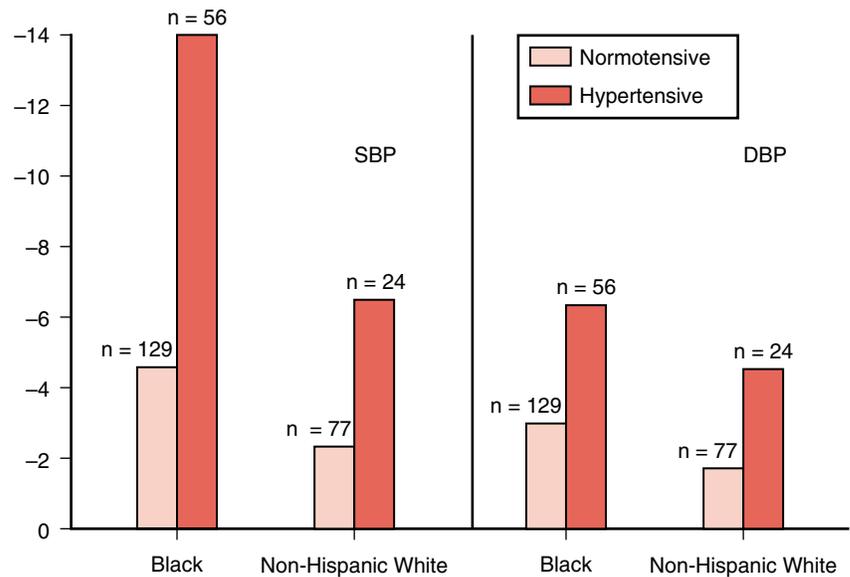

The DASH study included 459 participants (60% African American), who were randomized to one of the following diets: a control diet typical of the average American; a diet rich in fruits and vegetables; or a combination diet low in fat and rich in fruits, vegetables, and low-fat dairy products—the DASH eating plan (see Chapter 43).⁶⁴ The combination diet yielded the greatest BP-lowering effect. This effect was most notable in African American hypertensives, who exhibited a decrease of BP of 13.2/6.1 mm Hg (Figure 56-2). A subsequent study combining the DASH eating plan with sodium restriction found an additional BP-lowering effect.⁵⁸ This benefit again was more pronounced in African Americans.

Pharmacologic Intervention

The majority of patients with hypertension, especially African Americans, will require two or more antihypertensive drugs to achieve their BP goal.^{59,65-67} However, studies clearly document that a majority of hypertensives, including African American hypertensives, can achieve even the most aggressive BP goal.^{59,65,66} Although multiple studies have shown that all of the available antihypertensive agents are effective in African Americans, monotherapy with drugs that inhibit the RAS (i.e., angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], and β -blockers) consistently produces attenuated BP lowering in this population.^{59,68-71} Saunders et al.⁶⁸ compared the efficacy of atenolol, captopril, and verapamil sustained-release (SR) in a cohort of 394 African American patients with mild to moderate hypertension over a period of 11 to 13 weeks. Goal BP ($<140/90$ mm Hg or <10 mm Hg decrease) was achieved in 65.2% of those randomized to verapamil SR compared with 55.1% and 43.8% of those randomized to atenolol and captopril, respectively. Likewise, the Veterans Affairs (VA) Cooperative Studies Group followed 1092 men (533 African Americans) included in the VA Cooperative Trial to compare the efficacy of hydrochlorothiazide, atenolol, diltiazem SR, captopril, prazosin, and clonidine in BP reduction by region of the country.^{69,70} African Americans were less likely to achieve target BP with atenolol or captopril. This racial difference is eliminated when RAS blockers and β -blockers are used in combination with diuretics or calcium channel blockers (CCBs).^{48,72-74}

The VA Cooperative trial, with 42% African American participants employing a regimen of hydrochlorothiazide, reserpine, and hydralazine and conducted more than 35 years ago, and the HDFP trial, with 44% African Americans completed 25 years ago using chlorthalidone, reserpine, methyldopa, and hydralazine, both documented the benefit on clinical outcomes of lowering elevated BP in African American hypertensives with a thiazide-type diuretic-based regimen.^{75,76} The Systolic Hypertension in the Elderly Program (SHEP) trial (14% African American) using chlorthalidone and atenolol also produced similar results in both African Americans and whites with isolated systolic hypertension.⁷⁷ Results of hypertension outcome trials involving nondiuretic-based treatment with significant minority representation have become available more recently. Because of data indicating reduced BP-lowering efficacy in African Americans, evaluation of the effects of RAS

Figure 56–2 Joint effect of race and hypertension status on blood pressure (BP) response to the Dietary Approaches to Stop Hypertension (DASH) combination diet. HF, heart failure; CKD, chronic kidney disease; MI, myocardial infarction; CCB, calcium channel blocker; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB, β -blocker. (From Svetkey LP, Simons-Morton D, Vollmer WM, et al. Effects of dietary patterns on blood pressure: Subgroup analysis of the Dietary Approaches to Stop Hypertension [DASH] randomized clinical trial. *Arch Intern Med* 159:285-293, 1999.)

inhibitors on clinical outcomes in African Americans are especially important.

The African American Study of Kidney Disease (AASK) was the first to evaluate the effect of a CCB and an ACE inhibitor on a clinical outcome in African Americans.⁷⁸ The objectives of AASK were to determine whether lowering of BP below the goal recommended to prevent cardiovascular events or choice of antihypertensive regimen mattered in slowing the progression of hypertensive kidney disease. A total of 1094 African Americans with hypertensive renal disease (glomerular filtration rate 20–65 ml/min) were randomized to receive either ramipril or amlodipine, comparing both with metoprolol. Participants were also randomized to a usual mean arterial pressure goal of 102 to 107 mm Hg or a lower goal of 92 mm Hg or less. No significant difference in renal outcomes was detected between the two BP groups. However, the ACE inhibitor ramipril was significantly more effective in slowing the progression of kidney disease compared with amlodipine or metoprolol. Thus, the benefit of ACE inhibitors in preventing renal outcomes in African American hypertensives was demonstrated.

The effects of ACE inhibitors and other nondiuretic-based regimens in preventing cardiovascular events in African Americans were not addressed by AASK. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was the first study to evaluate the relative benefit of newer agents on cardiovascular outcomes in African American hypertensives.^{79,80} A total of 42,418 participants (35% African American) aged 55 or older were randomized to receive chlorthalidone, amlodipine, lisinopril, or doxazosin. Compared with amlodipine, SBP averaged 1 mm Hg lower in the chlorthalidone arm in both African Americans and whites. The chlorthalidone-lisinopril difference was 2 mm

Hg in white and 4 mm Hg in Black ALLHAT participants. Although there was no difference between treatments in occurrence of the primary outcome (myocardial infarction or fatal CHD) or on all-cause mortality, chlorthalidone proved superior in reducing CHF versus doxazosin, amlodipine, and lisinopril. Chlorthalidone also reduced combined CVD and stroke compared with doxazosin and lisinopril. These differences in outcome were even greater in the African American cohort. Additionally, the higher risk of angioedema in African Americans treated with ACE inhibitors was also confirmed in this trial. Thus, ALLHAT did not support the use of α -blockers or ACE inhibitors in African American hypertensives over diuretics or CCBs (in hypertensives unable to take a diuretic) as initial treatment in the absence of CKD or CHF.

The Losartan Intervention for Endpoint (LIFE) Reduction in Hypertension study was the first to compare ARB-based treatment with an active comparator (β -blocker-based treatment) in reducing cardiovascular morbidity and mortality in a high-risk population that included more than 9000 patients (11% African American) with essential hypertension and LVH by ECG.⁸¹ Participants were randomized to 50 to 100 mg/dl of either atenolol or losartan to achieve a target BP of <140/90. Additional antihypertensive drugs were added as necessary, and approximately 90% of participants were also receiving a thiazide-type diuretic by the end of the trial. BP reduction was similar between groups, with 49% of the losartan group and 46% of the atenolol group reaching the target. Contrary to the overall results of the study, losartan was less effective than atenolol in reducing cardiovascular risk (17% vs. 11%) in African Americans.⁸² This difference in outcome of African Americans versus whites was independent of BP and had no other biologically plausible explanation. This finding must be

viewed with caution, since the size of the African American sample and the number of events occurring in African Americans were small. The mechanism of this apparent racial difference in outcome is unclear and merits further investigation in trials that include larger numbers of African Americans.

RECOMMENDATIONS

The recommendations outlined in JNC 7 are especially pertinent to the African American hypertensive (Figure 56–3). The definition of prehypertension and emphasis on lifestyle modification as integral to the treatment and prevention of hypertension in African Americans are shared by JNC 7 and the guidelines of the International Society of Hypertension in Blacks (ISHIB).^{59,60} African Americans have a higher prevalence of obesity and physical inactivity, and the effects of sodium restriction and the DASH diet were greatest in the African American population. The consideration of multi-drug therapy as initial treatment for those more than 20/10 mm Hg above target BP is also consistent with both guidelines.

ACE inhibitors and ARBs should be used as first-line therapy in hypertensives, including African American hypertensives, with CKD or CHF. Along with the α -blockers and all other agents in the antihypertensive armamentarium, ACE inhibitors and ARBs should be used as needed as add-on agents to achieve the BP goal in African Americans. The JNC 7 recommends that thiazide-type diuretics should be considered first and form the cornerstone of pharmacologic therapy in most hypertensives. This recommendation especially applies to the African American hypertensive.^{59,71,79} In African American hypertensives, a thiazide-type diuretic was unsurpassed in lowering BP and in preventing clinical events.⁷⁹ A CCB produced similar lowering of BP and was equally effective in preventing most clinical outcomes, but was associated with a substantially greater risk of CHF. CCBs are a reasonable alternative first-line choice in African American hypertensives unable to take a diuretic. Although recommended as equivalent or preferable to diuretics in African American diabetics in the ISHIB guidelines,⁶⁰ in the absence of renal disease or CHF, it is difficult to justify the selection of an ACE inhibitor or ARB over a diuretic (or CCB) as initial therapy in this patient population.

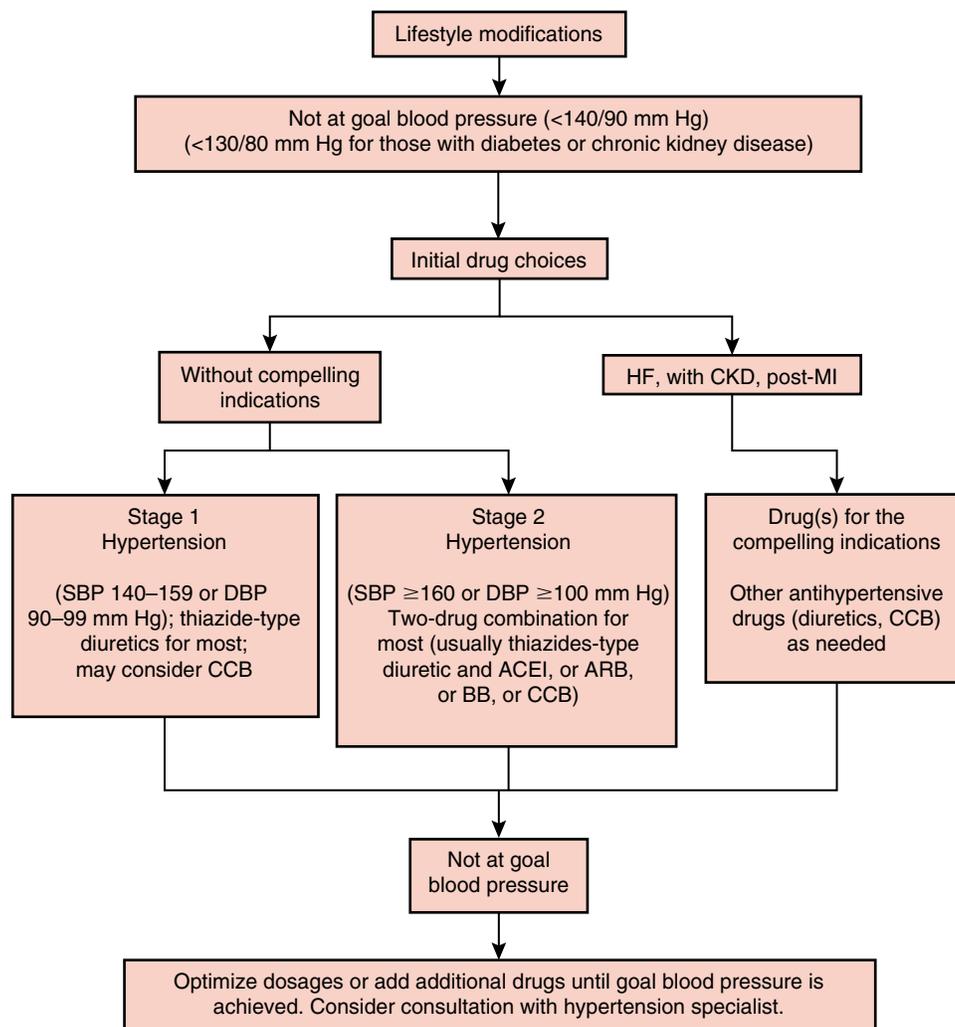

Figure 56–3 Algorithm for treatment of hypertension. HF, heart failure; CKD chronic kidney disease; MI, myocardial infarction. (Modified from JNC 7, JAMA 2003.)

SUMMARY

African Americans develop hypertension at an earlier age and with a higher overall prevalence than whites. Despite similar rates of awareness, African American hypertensives not only are more likely to have more severe hypertension, but are also less well controlled once treatment is initiated. The etiology of hypertension in African Americans remains unknown. The approach to treatment should be multidisciplinary and should include both lifestyle modification and pharmacologic intervention. For the majority of hypertensives, especially African Americans, multiple agents will be required to achieve target BP. Although all classes of antihypertensive are effective, thiazide-based regimens should be considered as first line treatment in the absence of compelling indications for alternative regimens. CCBs are recommended as initial therapy in African American hypertensives who cannot take a diuretic. Monotherapy with ACE inhibitors, ARBs, or β -blockers is less effective in African Americans compared with other population groups. This racial difference disappears with the addition of a diuretic or CCB. ACE inhibitors or ARBs should be included in antihypertensive regimens prescribed for African American hypertensives with renal disease or CHF. In the absence of these conditions, ACE inhibitors or ARBs should be added to a regimen containing a thiazide-type diuretic and/or CCB in order to achieve the desired BP goal. Aggressive treatment of BP to recommended goals can have a significant impact on preventing CVD, stroke, and ESRD in African Americans.

Hypertension in Pregnancy

Sandra J. Taler

INTRODUCTION

The key to managing hypertension in pregnancy rests on early detection and accurate disease classification to distinguish preeclampsia, a pregnancy-specific syndrome of reduced organ perfusion, from preexisting chronic hypertension. Although the cause of preeclampsia remains unknown, the pathophysiologic mechanisms and associated risks and therefore management differ from chronic hypertension. Classification is based on the work of the American College of Obstetricians and Gynecologists Committee on Terminology, with minor revisions by the U.S. National High Blood Pressure Education Program in 2000. Hypertension in pregnancy is classified into one of five categories (Table 57–1): chronic hypertension, preeclampsia-eclampsia, preeclampsia superimposed on chronic hypertension, gestational hypertension, and transient hypertension.¹

Hypertensive disorders are estimated to occur in 6% to 8% of pregnancies in the United States. Preeclampsia is more common in nulliparous women, occurring in up to 10% of first-time pregnancies. Chronic hypertension occurs in up to 5% of pregnant women, although rates may vary by the population studied. With recent societal trends to delay childbearing to older maternal ages and the increasing use of fertility drugs resulting in multiple gestation pregnancies, the incidence of preeclampsia increased 40% between 1990 and 1999 and will likely continue to rise.² Risk factors for preeclampsia are listed in Box 57–1. Older maternal age may contribute to preeclampsia risk because of an increased frequency of chronic hypertension. The prevalence of preeclampsia increases to 25% in women with chronic hypertension and is even higher in the setting of renal or other systemic diseases.

Following their initial presentation, hypertensive disorders have a high rate of recurrence (20%-50%) in subsequent pregnancies.³ Risk factors for recurrence are shown in Box 57–2. Although gestational hypertension has long been known to predict subsequent essential hypertension, studies suggest that women with preeclampsia also have a greater tendency than women with normotensive pregnancies to develop hypertension later in life.^{3,4}

CHRONIC HYPERTENSION IN PREGNANCY

Chronic hypertension complicates pregnancy by increasing the risk of adverse outcomes, including premature birth, intrauterine growth retardation, fetal death, placental abruption, and cesarean delivery. The incidence of these conditions is related to the severity and duration of the hypertension prior to conception, the presence of target organ damage or coexistent renal disease, and the higher risk for superimposed preeclampsia. Pregnancy may present additional risks to the

woman with chronic hypertension by the added stress of volume expansion on compromised cardiac function or by increases in proteinuria that accelerate renal decline. Women with chronic hypertension may be at higher risk for adverse neonatal outcomes independent of the development of preeclampsia.^{5,6} The risks of fetal loss and acceleration of maternal renal disease increase at serum creatinine levels above 1.4 mg/dl at conception, although it may be difficult to delineate the effects of pregnancy from progression of the underlying renal disease.^{7,8}

PREPREGNANCY EVALUATION

Ideally, women with chronic hypertension should seek evaluation prior to pregnancy to define the severity of their hypertension, adjust medications, and plan for potential lifestyle changes (Table 57–2). If the systolic blood pressure is ≥ 180 mm Hg or diastolic pressure is ≥ 110 mm Hg or if treatment requires multiple antihypertensive agents, it is particularly important to search for a potentially reversible cause. Some practitioners would change to antihypertensive medications known to be safe during pregnancy even before conception. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) may cause oligohydramnios, fetal renal failure, and neonatal death and should be discontinued before conception or as soon as pregnancy is confirmed.

Women with a history of hypertension over several years should be evaluated for target organ damage, including retinopathy, left ventricular hypertrophy, and renal disease. If present, they should be advised that pregnancy may worsen these conditions. Risk factors for superimposed preeclampsia include renal insufficiency, a history of hypertension for more than 4 years, or hypertension in a previous pregnancy.

Planning for pregnancy may require lifestyle changes. Hypertensive women are advised to restrict aerobic exercise during pregnancy based on theoretical concerns that reduced placental blood flow may increase the risk of preeclampsia.⁹ Weight reduction is not recommended during pregnancy, even in obese women. Sodium restriction may be continued for women who have been successfully treated by this approach prior to pregnancy. As in all pregnancies, alcohol and tobacco use is strongly discouraged.

TREATMENT OF CHRONIC HYPERTENSION IN PREGNANCY

Most women with chronic hypertension in pregnancy have stage 1 hypertension (systolic blood pressure of 140-159, diastolic pressure of 90-99 mm Hg, or both). In the short time frame of pregnancy, the risk of cardiovascular complications

Table 57-1 Classification of Hypertension in Pregnancy

Chronic hypertension	<ul style="list-style-type: none"> • BP \geq140 mm Hg systolic or 90 mm Hg diastolic before pregnancy or before 20 weeks' gestation • Persists >12 weeks postpartum
Preeclampsia	<ul style="list-style-type: none"> • BP \geq140 mm Hg systolic or 90 mm Hg diastolic with proteinuria (>300 mg/24 hr) after 20 weeks' gestation • Can progress to eclampsia (seizures) • More common in nulliparous women, multiple gestation, women with hypertension for \geq4 years, family history of preeclampsia, hypertension in previous pregnancy, renal disease
Chronic hypertension with superimposed preeclampsia	<ul style="list-style-type: none"> • New-onset proteinuria after 20 weeks in a woman with hypertension • In a woman with hypertension and proteinuria before 20 weeks' gestation: <ul style="list-style-type: none"> • Sudden twofold to threefold increase in proteinuria • Sudden increase in BP • Thrombocytopenia • Elevated AST or ALT
Gestational hypertension	<ul style="list-style-type: none"> • Hypertension without proteinuria occurring after 20 weeks' gestation • Temporary diagnosis (only during pregnancy) • May represent pre-proteinuric phase of preeclampsia or recurrence of chronic hypertension abated in midpregnancy • May evolve to preeclampsia • If severe, may result in higher rates of premature delivery and growth retardation than mild preeclampsia
Transient hypertension	<ul style="list-style-type: none"> • Retrospective diagnosis (only after pregnancy) • BP normal by 12 weeks' postpartum • May recur in subsequent pregnancies • Predictive of future essential hypertension

AST, aspartate aminotransferase; ALT, alanine aminotransferase.

is low. Because there is no evidence that pharmacologic treatment leads to improved neonatal outcomes and blood pressure usually falls during the first half of pregnancy, these women can be monitored with no or reduced drug therapy.¹⁰ Some centers manage chronic hypertensives by stopping antihypertensive medications under close observation. Women with evidence for target organ damage or taking multiple agents may be able to taper medications based on blood pressure readings. Medications should be continued if needed to maintain blood pressure control. There is evidence that antihypertensive treatment will prevent progression of chronic

hypertension to severe levels during pregnancy. Treatment should be reinstated if blood pressure reaches levels of 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic.

Complete secondary hypertension evaluation is usually postponed during pregnancy. All hypertensive women should still be screened for pheochromocytoma at the time of hypertension diagnosis because of the high morbidity and mortality associated with this condition if not diagnosed before delivery. When the hypertension is severe, further evaluation for secondary causes may be indicated and treatment may save the life of the fetus. Ultrasound and magnetic resonance scanning techniques offer safe modalities for renal artery or adrenal imaging. Laparoscopic adrenalectomy has been successfully performed during the second trimester in settings of primary aldosteronism, resulting in excellent fetal survival.^{11,12}

Box 57-1 Maternal Risk Factors for Preeclampsia

Primigravida
 Positive family history (maternal or paternal)
 Multiple gestations
 Diabetes mellitus
 Insulin resistance/obesity
 Chronic hypertension
 Preexisting renal disease
 Extremes of reproductive age
 Hydatidiform disease
 History of severe early preeclampsia in a prior pregnancy
 Collagen vascular disease
 Black race
 Increased circulating testosterone
 Thrombophilias

ANTIHYPERTENSIVE DRUG SELECTION

The goal of treating chronic hypertension is to reduce maternal risk by using agents that are safe for the fetus. Methyldopa

Box 57-2 Risk Factors for Recurrent Hypertension in Pregnancy

Early onset of hypertension in a prior pregnancy
 Chronic hypertension
 Persistent hypertension beyond 5 weeks postpartum
 High baseline blood pressure early in pregnancy

Table 57-2 Management of Chronic Hypertension in Pregnancy

Before conception	
Evaluation for secondary hypertension	Pheochromocytoma
Evaluation for target organ damage	Other causes if severe
Change to medications safe for pregnancy	Cardiac function, LVH (echocardiography)
Lifestyle planning	Renal disease (serum creatinine, proteinuria)
Baseline laboratory testing	Taper early
	Titrate later
	Restrict aerobic exercise
	Avoid weight reduction
	Moderate sodium intake
	Avoid all alcohol and tobacco
	Hematocrit, hemoglobin, platelet count, serum creatinine, uric acid, urinalysis
During pregnancy	
Selection of medications safe for pregnancy	Table 57-3
Thresholds for treatment	150-160 mm Hg systolic
Laboratory monitoring	100-110 mm Hg diastolic
	Hematocrit, hemoglobin, platelet count, serum creatinine, uric acid, AST, ALT, quantification of urine protein, serum albumin, LDH, peripheral blood smear, coagulation studies
Delivery	
Maternal indications	Gestational age ≥ 38 weeks
	Platelet count $< 100,000$ cells/mm ³
	Deterioration in hepatic or renal function
	Suspected placental abruption
	Severe headache or visual changes
	Severe epigastric pain, nausea, or vomiting
Fetal indications	Severe fetal growth restriction
	Concerning fetal testing results
	Oligohydramnios
Acute/parenteral therapy	Table 57-5
Postpartum	
Lactation	Withhold antihypertensive medication
	Taper medication dosage
	Selection of safe medications
	Close monitoring for adverse effects
Late issues after hypertensive pregnancy	
Persistent hypertension	Evaluation for secondary causes
Long-term risk	Change medication
	Monitor blood pressure for future hypertension
	Treat cardiovascular risk factors

LVH, left ventricular hypertrophy; AST, aspartate aminotransferase; ALT, alanine aminotransferase; LDH, lactate dehydrogenase.

is preferred by many as first-line therapy, based on reports of stable uteroplacental blood flow and child development studies out to 7.5 years showing no long-term adverse effects.¹³ Other treatment options are listed in Table 57-3. For all medication choices, there are concerns regarding safety in pregnancy. In a meta-analysis of 45 randomized controlled trials of treatment of mild to moderate hypertension in pregnancy when using methyldopa, β -blockers, thiazide diuretics, hydralazine, calcium antagonists, and clonidine, there was a direct linear relationship between treatment-induced fall in mean arterial pressure and the proportion of small-for-gestational-age infants.¹⁴ Neither type of hypertension, type of agent, nor duration of therapy explained this relationship.

There are no placebo-controlled trials evaluating the treatment of severe hypertension in pregnancy, and none are like-

ly to be performed because of ethical concerns. Historical experience with severe chronic hypertension in the first trimester describes fetal loss rates of 50% and significant maternal mortality, primarily occurring in pregnancies complicated by superimposed preeclampsia.¹⁵

PREGNANCY IN WOMEN WITH RENAL DISEASE

Women with renal diseases likely to progress should be encouraged to complete their childbearing while their renal function is well preserved. For women with mild renal disease (serum creatinine below 1.4 mg/dl), fetal survival is moderately reduced and the underlying disease does not generally

Table 57-3 Oral Treatment of Hypertension in Pregnancy

Agent	Comments
Methyldopa	Preferred based on stable utero-placental blood flow and long-term child development studies ¹³
β-Blockers	Reports of intrauterine growth retardation (atenolol) ^{42,43} Generally safe
Labetalol	Increasingly preferred to methyldopa due to reduced side effects
Clonidine	Limited data
Calcium antagonists	Limited data Most experience with nifedipine and isradipine No increase in major teratogenicity with exposure ⁴⁴
Diuretics	Not first-line agents Probably safe Most experience with thiazide diuretics
Angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists	Contraindicated ^{45,46} Reports of fetal toxicity and death

worsen. In moderate or severe renal insufficiency, pregnancy may accelerate the hypertension and the renal disease.^{7,16,17} A decrease in birthweight correlates directly with rising maternal serum creatinine concentration.¹⁷ As renal failure progresses, hypertension may worsen because of volume overload, requiring treatment with diuretics or dialysis. Conception should be discouraged in chronic dialysis patients, as pregnancy is associated with significant maternal morbidity. Renal transplant recipients are advised to wait 1.5 to 2 years after successful transplantation and undertake pregnancy only if renal function is stable, with creatinine of 2.0 mg/dl or less. All pregnancies in transplant recipients are considered high risk, with high rates of prematurity. No increase in structural malformations has been reported in these infants, and in the majority of cases, maternal graft function does not deteriorate.¹⁸

PRECLAMPSIA

Preeclampsia is a pregnancy-specific syndrome of reduced organ perfusion caused by vasospasm and activation of the coagulation cascade. Although the pathologic changes are primarily ischemic, the cause of preeclampsia remains unknown. Current hypotheses focus on impaired placentation of the trophoblast and incomplete vascular remodeling as underlying pathogenic processes. Failure to develop the normal low-resistance, high-flow vascular connections between endovascular trophoblasts and the maternal spiral arteries results in reduced placental perfusion and a generalized disturbance in endothelial function. Postulated causes include inadequate immune tolerance, activation of inflammatory cytokines, and genetic mechanisms. Research efforts have been restricted by the lack of a de novo animal model and the difficulties inherent in

predicting which women will develop preeclampsia before it presents.

Clinically preeclampsia is manifest by hypertension and proteinuria. Generalized vasoconstriction and reduced plasma volume lead to systemic hypoperfusion and reduced blood flow to multiple organs. The degree of blood pressure elevation may be mild, not reflective of the severity of the disease in the various vascular beds. Proteinuria is defined as the urinary excretion of 300 mg protein or greater in a 24-hour urine collection (usually equivalent to a dipstick measure of 30 mg/dl, “1+ dipstick” or more). A random urine protein:creatinine ratio has been shown to correlate closely with 24-hour urine protein measurements in pregnancy.¹⁹ Preeclampsia should be suspected in the absence of proteinuria when other symptoms or signs are present (Table 57-4).

PREVENTION

Prevention of preeclampsia has been frustrated by lack of knowledge of its underlying cause. Current strategies focus on identifying women at higher risk as targets for early disease recognition, close monitoring, and delivery when indicated. Although early small trials suggested benefit, several large multi-center trials of low-dose aspirin failed to demonstrate a protective effect over placebo.²⁰⁻²² Based on subgroup analysis, selective treatment for certain women at higher risk (specifically women with the antiphospholipid syndrome) may be reasonable. Calcium supplementation has effectively reduced the incidence of preeclampsia in third world women with low calcium intake but offers no benefit for low-risk women in the United States.^{23,24} Recent attention has focused on a potential role for antioxidant vitamins to defend against oxidative stress as a mediator of preeclampsia.

TREATMENT

Treatment for preeclampsia is palliative, because it does not alter the underlying pathophysiology of the disease. Delivery is always appropriate therapy for the mother but may not be so for the fetus, particularly when the fetus is very premature (< 32 weeks' gestation). For a preterm fetus without evidence of fetal compromise in a woman with mild disease, valuable time may be gained by postponing delivery under close monitoring. Regardless of gestational age, delivery should be strongly considered when there are signs of fetal distress or intrauterine growth retardation or signs of maternal risk, including severe hypertension, hemolysis, elevated liver enzymes, and low platelet count (termed the *HELLP syndrome*), deteriorating renal function, visual disturbance, headache, or epigastric pain (see Table 57-4). Vaginal delivery is preferable to cesarean delivery to avoid the added stress of surgery. Antihypertensive therapy is prescribed only for maternal protection. It does not improve perinatal outcomes and may reduce uteroplacental blood flow. The choice of agent and route of administration depend on anticipated timing of delivery. If it is likely to be more than 48 hours until delivery, an oral agent is selected (see Table 57-3). Methyldopa is preferred based on its safety record, with labetalol increasingly used as an effective alternative with few side effects. If delivery is imminent, parenteral agents are used. Appropriate agents and initial dosages are listed in Table 57-5.

Table 57-4 Clinical Characteristics and Laboratory Tests Used to Discriminate Preeclampsia from Chronic Hypertension

	Preeclampsia	Chronic Hypertension
Age	Extremes of age	Older (≥ 30 yrs)
Parity	Nulliparous	Often multiparous
Time of diagnosis of hypertension	After 20 weeks	Before 20 weeks
Maternal risk factors for preeclampsia	Yes	No
Hypertension/preeclampsia in prior pregnancies	Yes	Yes
Proteinuria (>300 mg/24 hours)	Yes	No
Serum uric acid	Elevated (≥ 5.5 mg/dl)	Normal to low
Elevated liver enzymes	Yes	No
Thrombocytopenia	Yes	No
Headache, blurred vision, epigastric abdominal pain	Yes	No
Persistent hypertension >12 weeks postpartum	No	Yes

Treatment is initiated for persistent diastolic levels of 105 to 110 mm Hg or higher before induction, aiming for diastolic pressures of 95 to 105 mm Hg. Although hydralazine has been considered first-line parenteral therapy, a recent meta-analysis of randomized trials of short-acting antihypertensive treatment suggested greater maternal and fetal complication rates with hydralazine as compared with labetalol or nifedipine.²⁵

TREATING HYPERTENSION DURING LACTATION

Although all studied antihypertensive agents are excreted into human breast milk, differences in lipid solubility and extent of ionization of the drug at physiologic pH affect the milk:plasma ratio.²⁶ Breast-feeding can usually be done safely with attention to antihypertensive drug choices. For mildly hypertensive mothers who wish to breast-feed for a few months, medication may be withheld with close monitoring of blood pressure. Following discontinuation of nursing, therapy can be restarted. For patients with more severe blood pressure elevation, the clinician may consider reducing drug dosages while monitoring mother and infant. No short-term adverse effects have been reported from exposure to methyldopa or hydralazine. If a β -blocker is

Table 57-5 Acute/Parenteral Treatment of Hypertension in Preeclampsia

Hydralazine	5-mg IV bolus, then 10 mg every 20 to 30 minutes to a maximum of 25 mg, repeat in several hours as necessary
Labetalol (second-line)	20-mg IV bolus, then 40 mg 10 minutes later, 80 mg every 10 minutes for two additional doses to a maximum of 220 mg
Nifedipine (controversial)	10 mg PO, repeat every 20 minutes to a maximum of 30 mg Caution when using nifedipine with magnesium sulfate, can see precipitous blood pressure drop Short-acting nifedipine is not approved by FDA for managing hypertension
Sodium nitroprusside (rarely when others fail)	0.25 μ g/kg/min to a maximum of 5 μ g/kg/min Fetal cyanide poisoning may occur if used for more than 4 hours

indicated, propranolol and labetalol are preferred. Diuretics may reduce milk volume and thereby suppress lactation. ACE inhibitors and ARBs should be avoided based on reports of adverse fetal and neonatal renal effects. Given the scarcity of data, it is important to monitor all breast-fed infants of mothers taking antihypertensive agents for potential adverse effects.

RISK FOR HYPERTENSION AND ATHEROSCLEROSIS AFTER A HYPERTENSIVE PREGNANCY

Past epidemiologic studies failed to relate preeclampsia or eclampsia with first pregnancy to a greater future risk of hypertension or cardiovascular disease.²⁷⁻²⁹ Rates of subsequent hypertension among women who had eclampsia as multiparas were higher, but the prevalence among nulliparous eclamptic women was reported to be no greater than in the general population. Hypertension or preeclampsia/eclampsia in any subsequent pregnancy predicted a threefold to fourfold higher rate of cardiovascular death.²⁸ In contrast, it is well established that transient hypertension recurs in a high proportion of subsequent pregnancies and predicts later development of chronic hypertension at recurrence rates of 80% to 90%.³⁰⁻³²

A growing body of evidence indicates higher risk for future development of hypertension after a hypertensive pregnancy for women with a family history of hypertension, more severe hypertension during pregnancy, and multiparity.³³⁻³⁵ Of 238 women followed 7 to 12 years after a hypertensive pregnancy, 26% had hypertension and another 10% borderline hypertension as compared with 2% and 6.5%, respectively, in a group of matched controls.³⁶ Systolic blood pressure in early pregnancy was the single most important factor predicting systolic blood pressure at follow-up. In contrast, in a series of 26 pairs of primiparous women matched for age, race, weight, and year of delivery, no difference in frequency of hypertension was reported at

a mean of 10 years later.³⁷ Microalbuminuria, a marker of increased risk for cardiovascular disease, has been reported at higher frequency after preeclampsia than after normotensive pregnancy with or without hypertension in women with no evidence for diabetes mellitus.^{38,39} Preeclampsia has been linked to other markers of persistent endothelial dysfunction including increased plasma levels of von Willebrand factor, fibrinogen, cholesterol, triglycerides, and very-low-density lipoprotein.⁴⁰

Few data address the late cardiovascular consequences of hypertensive pregnancy. A review of maternity records on 7543 Icelandic women reported higher death rates from ischemic heart disease (IHD) among women with any hypertension in pregnancy (RR 1.47, 95% CI 1.05-2.02), based on death certificates, autopsy, and hospital records over the next 43 to 60 years.⁴¹ In contrast to earlier reports, the relative risk of IHD death was higher among eclamptic women and those with preeclampsia than those with hypertension alone. These data suggest that the endothelial dysfunction seen in the uterine spiral arteries during a hypertensive pregnancy may manifest as ischemic heart disease later in life. It is evident from a number of follow-up studies that women whose pregnancies are normotensive are a select group, less likely to develop chronic hypertension than the general population. Thus, pregnancy may be considered a screening test for chronic hypertension. Based on these findings, a recent consensus document concluded that women who have had preeclampsia are more prone to hypertensive complications in subsequent pregnancies; the risk is higher for recurrence with earlier presentation during the index pregnancy; recurrence rates are higher for those experiencing preeclampsia as multiparas as compared with nulliparous women; and preeclampsia reappearance rates may be population specific.¹

Hypertension in Children

Bonita Falkner

Hypertension may occur at any phase of childhood, from the newborn period through adolescence. The literature on hypertension generally regards hypertension in children and adolescents as a “special population” problem that should be approached as a unique issue. Compared with hypertension in adults, childhood hypertension is defined differently and occurs less frequently. Secondary causes of hypertension are detected more frequently in children than in adults, which often requires a different approach in evaluation of the hypertension. Childhood hypertension also has some striking similarities to hypertension in adults. Severe untreated hypertension in children has as poor an outcome as it does in adults.¹ Children with essential hypertension can express the same risk factors for cardiovascular disease (CVD) as adults; and children with hypertension can benefit from interventions to control the blood pressure (BP). An important aspect of BP surveillance in the young is to distinguish between elevated BP signaling an underlying disease (i.e., secondary hypertension), and when elevated BP in childhood is an early expression of primary (essential) hypertension.

DEFINITION OF HYPERTENSION IN CHILDHOOD

The definition of hypertension in adults is based on the level of BP that is linked with an increase in risk for cardiovascular events. Although the risk for cardiovascular events increases as systolic blood pressure (SBP) rises above 115 mm Hg,² hypertension continues to be defined as BP that exceeds 140/90 mm Hg regardless of adult age or gender. However, in children, with the exception of extreme hypertension noted previously, there are not yet data that link a level of BP with subsequent cardiovascular events. In the absence of such data, hypertension is defined statistically. The results of several large epidemiologic studies that measured BP in healthy children³⁻⁷ provide data from which the normal distribution of BP in healthy children and adolescents in the United States has been established.⁵ An analysis of BP data on healthy children in Europe describes a very similar BP distribution pattern in childhood.^{8,9}

There is a progressive rise in the BP level with increasing age concurrent with the normal age-related increase in height and weight throughout childhood. Thus there is a consistent relationship of BP with body size in childhood, and there is a normal upward shift in BP with growth. A gender difference in BP distribution emerges in adolescence that is concurrent with a gender difference in height.

Hypertension is defined as BP at or above the 95th percentile on the BP distribution for age and sex.³ This definition delineates the top segment of the normal BP distribution at each phase of childhood. With the expansion of the epidemiologic data, and with further analysis of the growth-related determinants of BP in childhood, the 95th percentile is further adjusted for height.⁵ The present definition of hyperten-

sion in children and adolescents is SBP and/or diastolic blood pressure (DBP) that is equal to or greater than the 95th percentile for age, sex, and height. High normal BP or “prehypertension” is SBP or DBP that is between the 90th and 95th percentile for age, sex, and height. Normal BP is SBP and DBP that is less than the 90th percentile for age, sex, and height. Table 58–1 provides the level of BP for the 95th and 90th percentile for age, sex, and height for boys, and Table 58–2 provides the same percentile levels for girls.⁵

Hypertension can also occur in newborn infants. There are limited data on normal levels of BP in newborns and very young infants.^{6,7,10} When daily BP measurement in healthy newborns is examined, there is a rapid and consistent increase in BP from day of birth through the first 5 days of life.¹¹ This upward shift in BP over a few days reflects the normal hemodynamic transition from intrauterine to extrauterine life. Similar observations were made in a larger study on newborn infants that included a broad range of birth weight and gestational age.¹² There is a direct relationship of BP with both birth weight and gestational age at birth. Regardless of birth weight or gestational age at birth, there is a transition, reflected by a progressive increase in BP that occurs during the first 5 days of postnatal life. Subsequently, BP is directly related to body weight and age, in terms of gestation or postconceptional age. This relationship is depicted in Figure 58–1. As can be seen in the figure, the upper 95% confidence limit (CL) for a term infant (40 weeks' postconceptional age) is 90 mm Hg for SBP. BP levels that exceed 90 mm Hg are considered to be hypertensive in a term infant, and by 4 to 6 weeks of age (44 to 46 weeks postconceptional age), a SBP that exceeds 100 mm Hg is hypertension.

MEASUREMENT OF BLOOD PRESSURE IN THE YOUNG

Measurement of BP in children and adolescents should be performed in a standardized manner that is similar to the methods used in the development of the BP tables. In the ambulatory clinic setting, the preferred method for BP measurement in children is by auscultation with a standard sphygmomanometer.

Correct BP measurement in children requires the use of a cuff that is appropriate for the size of the child's upper arm.¹³ A technique that can be used to select a BP cuff size of appropriate size is to select a cuff that has a bladder width that is approximately 40% of the arm circumference midway between the olecranon and the acromion. This will usually be a cuff bladder that will cover 80% to 100% of the circumference of the arm. Most manufacturers of BP cuffs provide lines on the cuff that are useful in choosing the correct cuff size for a given child. The equipment necessary to measure BP in children 3 years of age through adolescence includes three pediatric cuffs of different size, as well as a standard adult cuff, an

The 90th percentile is 1.28 SD, the 95th percentile is 1.645 SD, and the 99th percentile is 2.326 SD over the mean.

Reproduced from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics* 114:555-576, 2004.

oversized cuff, and a thigh cuff for leg BP measurement. The latter two cuffs may be needed for use in obese adolescents.

BP measurement in children should be conducted in a quiet and comfortable environment after 3 to 5 minutes of rest. With the exception of acute illness, the BP should be measured with the child in the seated position with the cubital fossa supported at heart level. It is preferable that the child has her or his feet on the floor while the BP is measured, rather than her or his feet dangling from an examination table. Overinflation of the cuff should be avoided due to discomfort, particularly in younger children. The BP should be measured and recorded at least twice on each measurement occasion.

SBP is determined by the onset of the auscultated pulsation or first Korotkoff sound. The disappearance of Korotkoff sounds or fifth Korotkoff sound (K5) is the definition of DBP in adults. In children, particularly preadolescents, a difference of several millimeters of mercury is often present between the fourth Korotkoff sound, the muffling of Korotkoff sounds, and K5.¹⁴ The substantial body of normative BP data in children indicates that K5 can be used as the measure of DBP in children, as well as adults.

The measured BP level in a child is interpreted by comparing the child's BP to the BP tables. Precise interpretation requires plotting the BP according to the child's height percentile, as well as age and sex. The child's height is measured and plotted on the standard child growth curves. The height

percentile is used in the tables, wherein the BP level for the 90th and 95th percentile at the child's age, sex, and height percentile are compared with the child's measured BP.

Elevated BP measurements in a child or adolescent must be confirmed on repeated visits before characterizing a child as having hypertension. A more accurate characterization of an individual's BP level is an average of multiple BP measurements taken for weeks or months. A notable exception to this general guideline for asymptomatic generally well children would be situations in which the child is symptomatic or has profoundly elevated BP. Children with elevated BP on repeated measurement should also have the BP measured in the leg as a screen for coarctation of the aorta. To measure the BP in the leg, a thigh cuff or an oversized cuff should be placed on the thigh and the BP measured by auscultation over the popliteal fossa. Coarctation is suspected if the SBP measured in the thigh is 10 mm Hg or more lower than the SBP measured in the arm.

There continues to be an increase in the use of automated devices to measure BP in children. Situations in which use of automated devices is acceptable include BP measurement in newborn and young infants in whom auscultation is difficult, as well as in an intensive care setting, where frequent BP measurement is necessary. The reliability of these instruments in an ambulatory clinical setting is less clear because of the need for frequent calibration of the instruments and the current lack of established reference standards.

The 90th percentile is 1.28 SD, the 95th percentile is 1.645 SD, and the 99th percentile is 2.326 SD over the mean. Reproduced from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. Pediatrics 114:555-576, 2004.

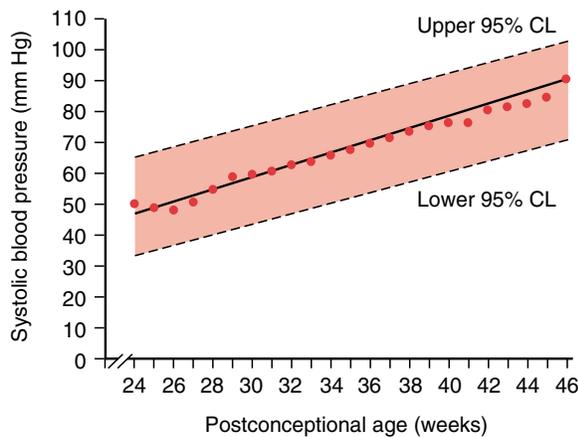

Figure 58-1 Postconceptional age (gestational age in weeks + weeks after delivery) is computed daily for each infant (8566 daily records) and regressed against mean SBP and DBP. Regression lines and equations are presented in terms of postconceptional weeks, which is more useful clinically. Regression equations are SBP = (0.255 × postconceptional age in weeks × 7) + 6.34, $r = 0.61$, $p < .0001$ and DBP = (0.151 × postconceptional age in weeks × 7) + 3.32, $r = 0.46$, $p < .0001$. Observed means of SBP and DBP for each postconceptional week are also plotted. CL, confidence limits. (From Zubrow AB, Hulman S, Kushner H, et al. Determinants of blood pressure in infants admitted to neonatal intensive care units: A prospective multicenter study. J Perinatol 15:470-479, 1995.)

CAUSES OF HYPERTENSION IN THE YOUNG

Secondary Hypertension

Underlying causes of hypertension, or secondary hypertension due to an underlying renal or endocrine disorder, occur more frequently during childhood than in adults. Prior to the development of normative data on BP levels in children, BP was measured infrequently. When elevated BP was detected in children, the hypertension was, by current standards, quite severe. Because secondary hypertension is generally characterized by marked BP elevation, this led to the belief that hypertension in children was *always* secondary. This concept has now changed, largely due to better understanding of normal levels of BP in the young and the practice of regularly measuring the BP in children as part of health assessment and health maintenance. The prevalence of secondary hypertension in the young varies according to the age and severity of hypertension. Hana et al.¹⁵ identified a secondary cause of hypertensive in 90% of children that were younger than 10 years of age and only 10% of these young children were considered to have essential hypertension. A report on a series that included both children and adolescents with hypertension describes secondary hypertension in 65% of the adolescents, with 35% of the adolescents having essential hypertension.¹⁶

Young children, younger than 12 years of age, with sustained hypertension are more likely to have a secondary cause for the hypertension. The degree of hypertension is also an important

clue, as severe BP elevation in a young child is most likely to be due to an underlying abnormality. In general, a child that has either SBP or DBP that is consistently 8 to 10 mm Hg above the 95th percentile has significant hypertension, and a child that has either SBP or DBP that is consistently 15 mm Hg or more above the 95th percentile has severe hypertension. Children and adolescents with this degree of hypertension should have a careful evaluation for a possible cause of the hypertension and also for evidence of target organ damage from the hypertension. Although the list of conditions that can cause hypertension in the young is quite long, the majority of the identifiable causes of hypertension in the young are related to renal disorders. Box 58–1 provides a list of underlying causes for chronic hypertension in the young, as well as the conditions associated with acute hypertension in the young.

Hypertension is uncommon in healthy newborn infants. However, certain infants have conditions that increase the risk for hypertension. Some newborn infants require treatment in intensive care units where umbilical artery catheterization may be required for vascular access. The umbilical artery catheters are a risk for thromboembolic events.^{17,18} Low-birth-weight infants, with respiratory distress syndrome, can progress to bronchopulmonary dysplasia and develop sodium retention from chronic steroid therapy.¹⁹ The most commonly identified

causes of hypertension in the newborn infant are renal artery thrombosis, renal artery stenosis, congenital renal malformations, coarctation of the aorta, and bronchopulmonary dysplasia.⁴ In some critically ill newborn infants with hypertension, an underlying cause may not be identified. Regardless of whether a cause for the hypertension is determined, BP control and monitoring in these infants is important.

For children up to 10 years of age, the leading causes of hypertension are renal parenchymal diseases, coarctation of the aorta, and renal artery stenosis. Coarctation of the aorta, a congenital cardiac anomaly that can be missed in infants and toddlers, should be considered in a hypertensive child.^{20–22} In later childhood, essential hypertension also occurs. The disorders that cause acute hypertension include postinfectious glomerulonephritis and hemolytic uremic syndrome. Some conditions such as hemolytic uremic syndrome may cause permanent renal scarring that results in chronic hypertension.

During the adolescent years the most common cause of hypertension is essential hypertension. The secondary causes of hypertension that are detected most frequently in adolescents are renal parenchymal diseases, such as chronic pyelonephritis, focal segmental glomerulosclerosis (FSGS), and other types of chronic glomerulonephritis. Adolescent behaviors that may contribute to high BP are illicit substance

Box 58–1 Secondary Causes of Hypertension

Chronic Hypertension

Renal

- Chronic glomerulonephritis
- Interstitial nephritis
- Collagen vascular diseases
- Reflux nephropathy
- Polycystic kidney disease
- Medullary cystic disease
- Hydronephrosis
- Hypoplastic/dysplastic kidney

Cardiac and Vascular

- Coarctation of aorta
- Renal artery stenosis
- Takayasu arteritis

Endocrine

- Hyperthyroidism
- Pheochromocytoma
- Primary aldosteronism

Drugs

- Corticosteroids
- Alcohol
- Appetite suppressants
- Anabolic steroids
- Oral contraceptive
- Nicotine

Syndromes

- Alport's syndrome
- Williams syndrome (renovascular lesions)
- Turner's syndrome (coarctation or renovascular)
- Neurofibromatosis (renovascular)
- Adrenogenital syndromes
- Little syndrome

Acute Hypertension

Renal

- Postinfectious glomerulonephritis
- Schönlein-Henoch purpura
- Hemolytic uremic syndrome
- Acute tubular necrosis

Vascular

- Renal or renal vascular trauma

Neurogenic

- Increased intracranial pressure
- Guillain-Barré syndrome

Drugs

- Cocaine
- Phencyclidine
- Amphetamines
- Jimson weed

Miscellaneous

- Burns
- Orthopedic surgery
- Urologic surgery

use, especially cocaine and amphetamine-related compounds.^{23,24} Other substances that have been associated with high BP in adolescents include appetite suppressants (both prescription and over-the-counter remedies), oral contraceptives, excessive alcohol intake, and use of anabolic steroids for body building.²⁵

Essential Hypertension

Essential hypertension has been considered to be a disorder of adulthood. The concept that essential hypertension has its roots in childhood can be inferred from BP tracking data that demonstrate that children with elevated BP will continue to have elevated BP as adults.⁵ Classic risk factors for hypertension such as overweight and a positive family history of hypertension or CVD may be present in childhood. The combination of higher BP and typical risk factors has been considered indicative of risk for future hypertension. Recent reports indicate, however, that this condition is more than a risk for future problems. Effects of high BP on left ventricular mass in children and adolescents have been investigated. Using echocardiography and appropriate childhood reference values for cardiac structure, left ventricular hypertrophy (LVH) has been reported in 30% to 40% of children and adolescents with hypertension.^{26,27} Longitudinal data are now becoming available that demonstrate a direct link between risk factors in childhood, including BP level, with evidence of target organ injury, including greater intima-media thickness of carotid arteries.^{26,28,29} Essential hypertension in childhood should be considered an early phase of a chronic disease.

Children and adolescents with essential hypertension generally demonstrate several clinical characteristics or associated risk factors. The degree of BP elevation is generally mild, approximating the 95th percentile and there is often considerable variability in BP over time. Laboratory and observational studies have demonstrated a marked cardiovascular response to stress, characterized by increased heart rate and BP responses to stimuli.³⁰⁻³³ A consistent clinical observation in children exhibiting mild essential hypertension is a positive history of hypertension in parents and/or grandparents.^{30,34,35}

In both children and adults, greater body weight and increases in body weight correlate with higher BP.^{36,37} Essential hypertension in children is frequently associated with obesity, which appears to be a contributory factor because even a modest reduction in excess adiposity is associated with a reduction in BP.^{38,39} The cluster of mild BP elevation, a positive family history of hypertension, and obesity is a typical pattern in children and adolescents with essential hypertension.⁴⁰

Currently the prevalence of childhood obesity is increasing⁴¹ and has more than doubled in the past 20 years.⁴² Obesity has an adverse effect on risk for CVD and warrants attention for disease prevention and health promotion. In a study by Daniels et al.²⁷ cardiac structure was examined by echocardiography in young adolescents with essential hypertension. These investigators found a significant incidence of LVH. The adolescents who had echo criteria of cardiac hypertrophy, despite mild BP elevation, were all obese. Rocchini et al.^{38,39} have demonstrated augmented BP sensitivity to sodium intake in obese adolescents, and a significant dampening in the BP response to sodium following weight reduction.

Over the past two decades, the literature on hypertension and CVD in adults has focused on the overlap of hypertension,

non-insulin-dependent diabetes mellitus, atherosclerosis, and obesity. This constellation within individuals and within populations has been described as the insulin-resistance syndrome.⁴³⁻⁴⁵ Children, as well as adults, may exhibit characteristics of the insulin-resistance syndrome.^{39,46,47} Some investigators have detected the insulin-resistance syndrome in nonobese offspring of hypertensive parents,^{48,49} indicating a hereditary component to the syndrome. The characteristics of the insulin-resistance syndrome are also congruent with the overweight child having a strong family history of hypertension or early heart disease. These children often have high BP.⁵⁰ Although these children are not at risk for immediate adverse effects of the higher than normal BP, they should be considered at risk for future CVD.⁵¹ These children can benefit from health behavior changes that improve insulin action, including an increase in physical activity, diet modifications, and control of excess adiposity.

The cause of essential hypertension is believed to be multifactorial and the outcome of an interplay of genetic and environmental factors. Barker et al.⁵² have proposed an alternative cause of hypertension based on observations of an association of hypertension and ischemic heart disease in adults with a low recorded birth weight. These investigators propose that lower birth weight reflects alteration in the intrauterine nutritional environment. Impaired fetal growth effects an alteration in organ structure and impairment in organ function in later life.^{52,53} Higher BP is the link between compromised intrauterine growth and the long term risk for CVD.⁵² Despite the reports, based on retrospective data that support the low-birth-weight-high BP hypothesis,⁵²⁻⁵⁵ this concept is in conflict with the body of data in childhood, as well as adulthood, which consistently demonstrates a direct relationship between body weight and BP,⁵⁶⁻⁵⁹ and BP tracking in childhood.^{34,60-65} Reports from studies on small cohorts have not detected a significant correlation.^{58,59} When the body of reports on the association of birth weight with future BP is examined, the effect of birth weight on future BP is in the range of 2- to 3-mm Hg BP reduction for each 1-kg increase in birth weight. When the current child or adult weight is taken into consideration the birth weight effect is minimal.⁶⁶ Although the birth weight hypothesis has some appeal, clinical investigations have not yet firmly demonstrated that birth weight has a substantial effect on future BP.

EVALUATION OF HYPERTENSION IN CHILDREN AND ADOLESCENTS

When sustained hypertension is established in a child by repeated BP measurements that are at or above the 95th percentile, additional evaluation is needed. The extent of the diagnostic evaluation is determined by the type of hypertension that is suspected. When a secondary cause is considered, a more extensive evaluation may be necessary. On the other hand, when the patient's elevated BP is more likely to be an early expression of essential hypertension, a few screening studies may be sufficient. The medical history and physical examination is key in determining whether the characteristics of a patient's presentation indicate essential hypertension or reflect a secondary, and potentially correctable, cause.

Children or adolescents with severe hypertension, in particular very young children, generally have an identifiable under-

lying cause. As noted previously, the higher the BP and the younger the child, the more likely a secondary cause is present.

A particular symptom complex revealed in the history or findings on physical examination may also prompt a thorough investigation. In these patients, the direction of the evaluation is dictated by the particular symptom or physical examination findings. Any pediatric patient who is hypertensive and is not growing normally should also undergo an evaluation for secondary causes. A sudden onset of elevated BP in a previously normotensive child should always prompt a search for secondary causes. Absence of a positive family history of hypertension should increase the level of suspicion for an underlying disorder.

Another set of findings characterizes children and adolescents with essential hypertension. These characteristics include slight to mild elevations in BP, a strong family history of essential hypertension, elevated resting heart rate, variable BP readings on repeated measurement, and obesity. If no other abnormalities are found on history or physical examination, these children require less extensive evaluations than those in whom secondary causes are suspected.

Medical History

The medical history and physical examination are used to detect clues to determine whether the BP elevation is secondary or essential. It is also helpful to determine whether the hypertension is longstanding or of acute onset. The family history is particularly important. In both first- and second-degree relatives, the family history of essential hypertension, myocardial infarction (MI), stroke, renal disease, diabetes, and obesity should be obtained. It can be relevant to the diagnosis in a hypertensive child if relatives had an onset at an early age of any of the aforementioned conditions. Parents should also be asked about conditions in family members that are inheritable and have hypertension as a component (e.g., polycystic kidney disease, neurofibromatosis, pheochromocytoma). Another familial type of hypertension is glucocorticoid-remediable aldosteronism, an autosomal-dominant condition that should be considered when multiple family members have early-onset hypertension associated with hypokalemia or stroke.^{67,68}

Details about previous health problems such as history of urinary tract infections are important as there may be associated reflux nephropathy, renal scarring, and resultant hypertension. A history of medications and over-the-counter products used can be helpful.^{69,70} Information should be obtained about health-related behaviors such as usual diet, amount of physical activity, or athletic participation. Other adverse adolescent lifestyles to consider are use of “street” drugs, smokeless tobacco, oral contraceptive pills, cigarette smoking, diet aids, ethanol, and anabolic steroids.

Physical Examination

The physical examination of a hypertensive child should be comprehensive. An assessment of the child’s general growth rate and growth pattern should be made. Weight, height, and body mass index (BMI) should be plotted according to age and sex on the child growth charts. Abnormalities in growth that are associated with hypertension can be seen with chronic renal disease, hyperthyroidism (causing primarily systolic

hypertension), pheochromocytoma, adrenal disorders, or certain genetic abnormalities such as Turner’s syndrome.

To rule out coarctation of the aorta, the evaluation of every child for hypertension should include upper- and lower-extremity BP measurements taken with appropriately sized cuffs. Normally the leg BP levels are slightly higher than the arm BP levels. A child with coarctation will have systolic hypertension in an upper extremity, sometimes absent or decreased femoral pulses, and a BP differential greater than 10 mm Hg between the upper and lower extremities.^{20,22}

There are other physical clues that could suggest a secondary etiology for child hypertension.⁷¹ Abnormal facies or dysmorphic features may suggest a syndrome, some of which are associated with specific lesions causing hypertension. For example, both Turner’s and Williams syndromes are associated with renovascular or cardiac lesions that cause hypertension. Renal vascular lesions may sometimes cause an audible abdominal bruit detectable by auscultation of the abdomen. Skin lesions are sometimes the first manifestations of disorders such as tuberous sclerosis and systemic lupus erythematosus.

Diagnostic Testing

When the history and physical examination provide clues for a specific underlying cause for the hypertension, such as an endocrine or cardiac disorder, the testing should be directed to the area of clinical suspicion. Other important historical information such as a history of urinary tract infections might dictate studies to evaluate vesicoureteral reflux and renal scarring. In the absence of clues, however, renal parenchymal disease should be considered a likely cause, because this diagnosis is the most frequent cause of secondary hypertension in the pediatric population. The initial studies to screen for renal abnormalities include a full urinalysis, electrolytes, creatinine, complete blood count, urine culture, and renal ultrasound.

The other component of the evaluation includes an assessment of target organ injury. The presence of target organ injury provides a measure of chronicity and severity (characteristics sometimes difficult to ascertain from the history) and will aid in deciding whether pharmacologic therapy should be instituted. Echocardiography is a sensitive means to detect interventricular septal and posterior ventricular wall thickening.⁷²⁻⁷⁵ Chest radiograph and electrocardiography (ECG) are much less sensitive measures of LVH in children. An ophthalmologic examination can also be helpful. In a study of 97 children and adolescents with essential hypertension, Daniels et al.⁷⁶ found that 51% displayed retinal abnormalities. The usefulness of microalbuminuria, sometimes used as a marker for renal injury in adults,⁷⁷ has not been determined for children. The remainder of the evaluation should be directed by specific findings on history and physical examination, as well as results of initial screening studies.

The use of 24-hour ambulatory BP monitoring (ABPM) has become increasingly common in the evaluation of adults with hypertension.⁷⁸ Some population standards for ambulatory BP values in children and adolescents are now available,⁷⁹ and there are some situations in which this information can be quite helpful.⁸⁰ ABPM is useful in determining how consistently BP readings are elevated over a 24-hour period and can aid in assessing the need for implementing pharmacologic therapy.

TREATMENT OF HYPERTENSION IN CHILDREN AND ADOLESCENTS

Health-related behavior changes in diet, physical activity, and weight control improve BP control in adults. Children may also benefit in these lifestyle changes. Children and adolescents with a mild elevation of BP and without target organ damage, should begin treatment with nonpharmacologic interventions that include weight reduction or control, exercise, and diet modification.

Obesity is often associated with mild hypertension in childhood and weight reduction has benefit in obese children. Using a program of both behavior modification and parental involvement, Brownell et al.⁸¹ showed that weight loss in obese adolescents was associated with a significant decrease in BP. There is also evidence that exercise training lowers BP in both school-aged children and adolescents.⁸²⁻⁸⁴ Rocchini et al.³⁸ showed that a program that included both caloric restriction and exercise produced a decrease in BP and a reversal of structural changes in forearm resistance vessels. Weight reduction can be extremely difficult and generally requires multiple strategies that include the input of a nutritionist, dietary education, emotional support, information about exercise, and family involvement. Power weight-lifting should be discouraged in hypertensive adolescents due to its potential to induce marked BP elevation. Participation in other sports should be encouraged as long as BP is under reasonable control, regular monitoring of BP occurs, and a thorough examination has been conducted to exclude cardiac conditions.²⁵

The guidelines for dietary modifications in the pediatric population are less clear than in adults. Information on the effects of salt on BP in children are not as definitive as in adults. There does seem to be a subset of adolescents, particularly those who are obese, who demonstrate BP sensitivity to salt as well as other risk factors for hypertension.³⁸ Because the usual dietary intake of sodium for most children and adolescents in the United States far exceeds nutrient requirements, it is reasonable to restrict sodium intake to less than 4 g/day by decreasing fast-food consumption and refraining from adding salt to cooked foods.⁸⁵

Current information on the effects of potassium and calcium intake on BP in children is even less definitive. Some reports suggest that a diet high in potassium and calcium may help lower BP,⁸⁶ yet no study has definitively shown this effect in children or adolescents. The dietary intervention clinical trial, Dietary Approach to Stop Hypertension (DASH) reported results that could be relevant to diet benefits in children. This study, which was conducted in adults with normal BP or stage 1 hypertension, demonstrated a significant reduction in both SBP and DBP when a diet high in fruits, vegetables, and low-fat dairy products was consumed compared with the BP in the same subjects when consuming the usual diet. These results indicate that a benefit in BP occurs from diets that are high in potassium, calcium, magnesium, and other vitamins.⁸⁷ A similar approach may be of benefit for children and investigations to examine this issue would be appropriate.

Pharmacologic therapy is indicated if nonpharmacologic approaches are unsuccessful, or when a child is symptomatic, has severe hypertension, or target organ damage. Children with diabetes mellitus or chronic renal disease may receive renoprotective benefits from BP reduction. For children with

these disorders it is reasonable to use pharmacologic therapy to lower BP to a level that is below the 90th percentile for age, sex, and height.

Most of the medications used for adults can be used for children. However, efficacy data, as well as long-term safety data, are limited for the pediatric population. The choice of antihypertensive medication must be individualized and depends on the child's age, the cause of the hypertension, the degree of BP elevation, adverse effects, and concomitant medical conditions. In most patients therapy is begun with a single agent. The dose is titrated upward until control of the BP is attained. BP control, in most instances, is defined as maintaining SBP and DBP below the 90th percentile. If control cannot be achieved using the maximum dose of a single agent, a second medication can be added or, alternatively, another agent from a different class selected. The more commonly used medications for chronic antihypertensive therapy in children are listed in Table 58-3 and those for use in acute, hypertensive emergencies in Table 58-4. Presently, the dosing recommendations for children have been largely based on practitioner experience, not on large, multicenter trials. Some clinical trial work is now being conducted on the medications that are already approved and prescribed for hypertension in adults. This information, as it becomes available will provide more information on efficacy, safety, and dosing in children.

β -Adrenergic blockers, such as propranolol, metoprolol, and atenolol, are good choices in some nonasthmatic children, but may not be well tolerated by athletes in whom exercise capacity could be decreased. More frequently, first-line medications are either angiotensin-converting enzyme (ACE) inhibitors or calcium channel blockers (CCBs). ACE inhibitors rarely cause side effects (e.g., cough, rash, neutropenia) in children, are usually well tolerated, and many formulations have the advantage of once-a-day dosing. Not only are they effective at controlling BP, but may have beneficial effects on renal function, peripheral vasculature, and cardiac function.⁸⁸ Importantly, children with diabetes and those with chronic renal disease may be at special risk for progressive renal deterioration and may benefit from ACE inhibitors.^{89,90} Because of their vasodilator effects on the efferent arteriole, ACE inhibitors can severely reduce glomerular filtration and should therefore be used with caution in patients with renal artery stenosis, a solitary kidney, or a transplanted kidney.⁹¹ ACE inhibitors are contraindicated during pregnancy because of teratogenic effects on the lungs, kidneys, and brain of the fetus.⁹² Therefore, these agents should be used with special caution in adolescent females. Angiotensin receptor blockers (ARBs) also interact with the renin-angiotensin system (RAS) and have benefits similar to the ACE inhibitors. Some experience is now being developed with these agents in treatment of children with hypertension.

Several of the CCBs are being used in children. In children, the CCBs can be used as initial therapy or as the second or third medication when more than one drug is needed to control BP. As with most of the oral antihypertensive preparations, the appropriate dose for small children is often lower than the strength of available tablets, which makes initial dose determinations challenging. Both short-acting and longer-acting forms are available. Use of short-acting CCBs should be limited to children with acute hypertension, such as occurs with acute glomerulonephritis. When CCBs are

Table 58-3 Treatment of Chronic Hypertension in Children

Drug	Dose	Frequency	Available Preparations
Diuretics			
Chlorothiazide	20-30 mg/kg/day Max: 500 mg/day	q12-24h	Tablets: 250, 500 mg Solution: 250 mg/5 ml
Hydrochlorothiazide	1-4 mg/kg/day Max: 50 mg/day	q12-24h	Tablets: 25, 50, 100 mg
Metolazone	0.1-0.5 mg/kg/day Max: 20 mg/day (Zaroxolyn)	q24h	Tablets: 2.5, 5, 10 mg (Zaroxolyn)
Furosemide	0.5-1 mg/day (Mykrox) 0.5-4 mg/kg/day Max: 80 mg/dose	q24h q6-24h	Tablets: 0.5, 1.0 mg (Mykrox) Tablets: 20, 40, 80 mg Solution: 10 mg/ml, 40 mg/5 ml, 80 mg/10 ml
Spirolactone	1-3.0 mg/kg/day Max: 100 mg/day for hypertension	q8-24h	Tablets: 25, 50, 100 mg
β-Adrenergic Antagonists			
Nonselective: Propranolol	0.5-5 mg/kg/day Max: 640 mg/day	q6-12h	Tablets: 10, 20, 40, 60, 80 mg Long-acting capsules: 60, 80, 120, 160 mg Solution: 20, 40 mg/5 ml
Nadolol*	40-240 mg/day	q24h	Tablets: 20, 40, 80, 120, 160 mg
Selective:			
Atenolol	0.5-2 mg/kg/day Max: 100 mg/day	q24h	Tablets: 25, 50, 100 mg
Metoprolol	1-6 mg/kg/day Max: 200 mg/day	q12-24h	Tablets: 50, 100 mg
Bisoprolol/HCTZ	2.5/6.25 mg/day Max: 10/6.25 mg/day	q24h	Tablets: 2.5/6.25, 5/6.25, 10/6.25 mg
α-Adrenergic Antagonists			
Prazosin	0.02-0.5 mg/kg/day Max: 20 mg/day	q6-12h	Tablets: 1, 2, 5 mg
Complex Adrenergic Antagonists			
Labetalol	2-3 mg/kg/day initially Max: 20 mg/kg/day	q8-12h	Tablets: 100, 200, 300 mg
Central α-Adrenergic Agonists			
Clonidine	0.05-0.1 mg/dose Max: 2.4 mg/day	q6-12h	Tablets: 0.1, 0.2, 0.3 mg Patches: 0.1, 0.2, 0.3 mg/week
Methyldopa	10-65 mg/kg/day Max: 3 g/day	q6-12h	Tablets: 125, 250, 500 mg Solution: 250 mg/5 ml
Angiotensin-Converting Enzyme Inhibitors			
Captopril	0.05-6 mg/kg/day Max: 200 mg/day	q8-12h	Tablets: 12.5, 25, 50, 100 mg
Enalapril	0.1-0.6 mg/kg/day Max: 40 mg/day	q12-24h	Tablets: 2.5, 5.0, 10, 20 mg
Lisinopril*	0.07-0.6 mg/kg/day Max: 40 mg/day	q24h	Tablets: 5, 10, 20 mg
Quinapril*	5-80 mg/day	q24h	Tablets: 5, 10, 20 mg
Ramipril*	1.25-20 mg/day	q12-24h	Capsules: 1.25, 2.5, 5, 10 mg
Fosinopril	0.1-0.6 mg/kg/day Max: 40 mg/day	q24h	Tablets: 10, 20, 40 mg
Benazepril	0.2-0.6 mg/kg/day Max: 40 mg/day	q24h	Tablets: 5, 10, 20, 40 mg
Vasodilators			
Hydralazine	1-8 mg/kg/day Max: 200 mg/day	q12-24h	Tablets: 10, 25, 50, 100 mg
Calcium Antagonists			
Nifedipine	0.25-3 mg/kg/day Max: 180 mg/day	q6-24h	Capsules: 10, 20 mg Extended release: 30, 60, 90 mg
Isradipine	0.15-0.8 mg/kg/day	q8-12h	Capsules: 2.5, 5, 10 mg
Amlodipine*	0.06-0.34 mg/kg/day Max: 10 mg/day	q24h	Tablets: 2.5, 5, 10 mg
Felodipine ER	2.5-20 mg/day	q24h	Tablets: 2.5, 5, 10 mg
Angiotensin II Receptor Blockers			
Losartan	0.75-1.44 mg/kg/day Max: 100 mg/day	q24h	Tablets: 25, 50, 100 mg
Irbesartan*	75-300 mg/day	q24h	Tablets: 75, 150, 300 mg
Telmisartan*	20-80 mg/day	q24h	Tablets: 40, 80 mg
Candesartan*	2-32 mg/day	q24h	Tablets: 4, 8, 16, 32 mg
Valsartan*	80-160 mg/day	q24h	Tablets: 80, 160 mg

*The pediatric dose is under investigation.

Table 58-4 Treatment of Hypertensive Emergencies in Children

Drug	Dose	Route	Comments
Furosemide	1-4 mg/kg/dose Max: 160 mg/dose	IV, IM, or PO	Nephrotoxic, ototoxic When administered IV, infuse slowly to avoid ototoxicity Onset: 5-20 min
Hydralazine	0.1-0.5 mg/kg/dose Max: 50 mg/dose	IV, IM	Tachycardia, flushing, salt retention Onset: 10-20 min
Diazoxide	1-5 mg/kg/dose q5-15min Max: 150 mg/dose	IV	Pain at injected vein, sodium retention Onset: 2 min
Sodium nitroprusside	0.3-10 µg/kg/min by continuous infusion	IV	Cyanide poisoning in patients with renal failure Onset: seconds
Nifedipine	0.2-0.5 mg/kg/dose Max: 10 mg/dose	PO, sublingual, bite, and swallow	Headaches, edema Onset: 2-3 min
Nicardipine	1-3 µg/kg/min	IV	Dizziness, flushing
Labetalol	0.2-1 mg/kg/dose by bolus over 2-min period or 0.25-3.0 mg/kg/hr Max: 80 mg/dose or 300 mg/total dose	IV q10min Continuous IV infusion	Contraindicated in congestive heart failure, diabetes mellitus, and asthma Onset: 5-10 min
Enalapril	0.05-0.1 mg/kg/dose Max: 1.25 mg/dose	IV bolus	Cough, angioedema, renal failure, hyperkalemia Onset: 15 min

IV, intravenously; IM, intramuscularly; PO, orally.

needed for BP control in chronic hypertension, long-acting preparations are preferred, provided that the correct dosage preparation can be used.

Diuretics are generally recommended as initial drug therapy for uncomplicated hypertension in adults. This recommendation is based on a vast amount of clinical trial data in adults. No such information is available to guide recommendations for pharmacologic management of hypertension in children and adolescents. Unless there is clinical evidence of fluid retention in a hypertensive child, such as may occur when the elevated BP is related to chronic steroid use, diuretics are usually not the preferred first step in drug treatment. Although some hypertensive children may achieve adequate BP control with a thiazide diuretic alone, most will not. Children receiving thiazide diuretics will often develop hypokalemia and require potassium supplements; and for children, taking the potassium supplements is extremely unpleasant. The need to take potassium supplements in turn can lead to compliance problems. Although not favored as an initial drug to treat hypertension in children, low-dose diuretics can be very useful as a second or third drug in those children who require multiple drugs to achieve BP control.

SUMMARY

Essential, or primary, hypertension can occur in childhood. Due to the rising rates of childhood obesity, the expression of essential hypertension in childhood will increase. Despite this trend, the possibility of secondary hypertension should

be considered in a child with documented hypertension. Children with suspected secondary hypertension may require a more extensive evaluation compared with children and adolescents expressing characteristics of essential hypertension. Whether the hypertension is determined to be secondary or essential, these children require careful monitoring, interventions to control the BP, and long-term follow-up. Considering the long-term morbidity and mortality associated with essential hypertension, interventions, including preventive interventions that focus on BP control beginning in the young are needed. Essential hypertension may be found to encompass several distinct pathophysiologic entities, each with its own genetic basis and management approach. As new information develops, improved management strategies can be created for hypertension in the young as well as in adults.

Resistant Hypertension

David A. Calhoun

DEFINITION

Resistant hypertension has traditionally been defined as failure of concomitant use of three or more different antihypertensive agents to achieve goal blood pressure (BP). This definition has generally required that one of the agents be a diuretic and/or that all of the prescribed agents be at maximal or near-maximal doses.¹ It is more practical; however, to define resistant hypertension as concomitant need of three or more antihypertensive agents prescribed at pharmacologically effective doses. The latter definition has several advantages. First, it does not exclude patients who, because of real or perceived adverse effects, are intolerant of diuretics. Second, it is more realistic in not requiring use of maximal doses of all prescribed agents, as adverse effects often preclude titration to the highest recommended dose of a medication. Last, such a definition allows for use of recent clinical trials to estimate the prevalence of resistant hypertension. Such trials provide our best estimates of the true frequency of resistant hypertension, as continued drug titration is mandated by protocol, medications are generally provided at no charge, and adherence is closely monitored with pill counts. Also, as in real-world treatment of hypertension, these outcome studies have not generally required use of a diuretic in all participants.

PREVALENCE

Using the aforementioned definition of concomitant prescription of three or more antihypertensive medications, recent clinical trials indicate that resistant hypertension is common, affecting 20% to 30% of the different study populations. Given the size and diversity of the study population, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) may provide the best estimation of the prevalence of resistant hypertension.² In ALLHAT, more than 33,000 persons 55 years of age or older with a history of hypertension and one other cardiovascular risk factor were randomized to chlorthalidone, amlodipine, or lisinopril. The dose of the randomized medication as titrated first and then nonstudy antihypertensive medications were added as long as the BP was above 140/90 mm Hg. After 5 years of follow-up, 34% of subjects had not achieved goal BP and overall, 27% of participants were receiving three or more medications.³

Other recent outcome studies have documented that resistant hypertension is not rare. In the Controlled Onset Verapamil Investigation of Cardiovascular End Points Trial (CONVINCE), more than 16,600 participants were randomized to COER-verapamil or conventional antihypertensive therapy (atenolol or hydrochlorothiazide [HCTZ]), with other medications added as necessary to reduce BP below 140/90 mm Hg.⁴ After a mean follow-up of 3 years, 33% of participants had not achieved goal BP and 17% to

18% were receiving three or more antihypertensive medications. In the International Verapamil-Trandolapril Study (INVEST), over 22,500 persons with hypertension and known coronary artery disease were enrolled.⁵ At 2 years follow-up, 29% of participants remained uncontrolled at >140/90 mm Hg and approximately 50% required three or more antihypertensive agents. In studies of even more complicated hypertensive patients, controls rates are even worse. In the LIFE Study, which enrolled hypertensive patients with left ventricular hypertrophy (LVH), only 46% to 49% of participants had a BP of <140/90 mm Hg after almost 5 years of intensive antihypertensive treatment.⁶

The above studies, on one hand, likely overestimate the prevalence of resistant hypertension, as they were limited to older, higher-risk patients. However, on the other hand, they likely underestimate the frequency of resistant hypertension, as persons with severe or known drug resistance were excluded from enrolling; a percentage of enrollees were not titrated in spite of lack of BP control; and control rates were not based on recommended lower BP goals for diabetics and/or persons with chronic kidney disease.

Overall, these recent outcome studies suggest that resistant hypertension is not rare with approximately 30% of subjects never achieving goal BP because of drug resistance and/or nonadherence and 20% to 30% enrollees requiring three or more antihypertensive medications.

PATIENT CHARACTERISTICS

In the large majority of patients, resistant hypertension is a consequence of the systolic blood pressure (SBP) remaining uncontrolled. This is indicated by both epidemiologic data and clinical trial results. Cross-sectional data from the Framingham Heart Study demonstrated that among patients being treated for hypertension, 90% had a diastolic blood pressure (DBP) of <90 mm Hg, whereas only 49% had a SBP <140 mm Hg.⁷ Similar discrepancies between systolic and diastolic control rates are seen in clinical trials. In ALLHAT, 92% of participants achieved goal DBP but only 67% achieved goal SBP.² In LIFE, 89% of enrollees a SBP <90 mm Hg, while 45% to 48% had a systolic <140 mm Hg.⁶ These studies clearly demonstrate that the poor BP control is overwhelmingly due to lack of SBP control in treated patients.

Uncontrolled hypertension, which includes untreated and under-treated persons as well as treatment-resistant patients, increases with age. Analyzing data from the third National Health and Nutrition Examination Survey III (NHANES III), Hyman and Pavlik reported that among persons being treated, hypertension was controlled in 65% of those between 25 to 44 years of age, 52% 45 to 64 years of age, and 34% 65 years or older.⁸ In this analysis, the largest relative risk of uncontrolled hypertension was associated with being 65 years of age

or older. In the Framingham Heart Study, cross-sectional analysis indicated that increasing age was significantly associated with lack of SBP control, whereas prospectively, participants ≥ 55 years of age were two thirds as likely to have controlled BP as participants < 55 years age.^{8,9} In ALLHAT, older age predicted a lower likelihood of achieving BP control.³ In participants 55 to 59 years of age, the control rate of SBP was 62%. In those older than 80 years of age, the systolic control rate fell to 49%.

Although there is wide individual variation, in general, the more severe the hypertension, the more medications it will require to effectively reduce BP to goal. In the Framingham Heart Study, higher levels of SBP predicted lower BP control rates. Participants with SBP 140 to 159 mm Hg were 50% as likely to be achieve BP control as participants with SBP < 140 mm Hg, whereas participants with SBP ≥ 160 mm Hg were only 25% as likely to be controlled.⁹ In ALLHAT, similar effects were seen, with higher baseline SBP being strongly associated with a lower likelihood of achieving BP control.³

Other characteristics associated with resistant hypertension include obesity, diabetes, Black race, renal insufficiency, and presence of LVH (Box 59–1). Obesity predicts need for an increasing number of antihypertensive medications and increased likelihood of never achieving adequate BP control.^{3,8} In ALLHAT, Black participants had overall worse BP control than non-Blacks.³ The best control rate was in non-Black men (70%) and the lowest in Black women (59%). Clinical trials indicate that diabetics are more resistant to antihypertensive treatment than nondiabetics, requiring more medications to achieve the same level of BP control.^{3,10,11} Renal insufficiency increases BP, presumably through increased sodium retention and corresponding volume expansion and through increased release of vasoconstrictors such as angiotensin II and norepinephrine. In general, as renal function deteriorates, BP control becomes more difficult to treat.³ Last, LVH is associated with an increased resistance to BP reduction.^{3,7} Whether LVH contributes to drug resistance or reflects underlying severity of hypertension is unknown.

DIAGNOSIS AND EVALUATION

The evaluation of patients with resistant hypertension is generally the same as for all patients with primary hypertension, except that there should be a higher level of suspicion for secondary causes of hypertension. In this regard, acquisition of a 24-hour urine during ingestion of the patient's normal salt diet is recommended. This will allow for simultaneous assess-

- Black race
- Chronic kidney disease
- Diabetes
- Left ventricular hypertrophy

ment of sodium and aldosterone excretion, as well as calculation of creatinine clearance. Special attention should be paid to use of good BP measurement technique, including obtaining the BP after 5 minutes of rest and use of appropriately sized cuffs as falsely high readings may result. Degree of target organ damage should be documented.

ADHERENCE

Poor adherence undoubtedly contributes substantially to poor BP control. In one study based on patient self-report, BP was controlled in 81% of patients who reported taking more than 75% of their medications, but in only 37% of patients who took less than 75% of their pills.¹² In other studies, lack of BP control has been attributed to poor adherence to the prescribed regimen in approximately 50% of cases.¹³ Need for multiple medications and frequent medication changes, as often typifies treatment of resistant hypertension, worsens adherence. In specialty clinics, poor adherence may be less of a problem than among generalized hypertension patients. In an evaluation of patients referred to a university-based hypertension clinic, it was estimated that poor adherence was a contributing factor to treatment resistance in only 10% of patients.¹⁴

Ultimately, poor adherence in the clinical setting can only be confirmed by the patient's self-report. Accordingly, establishing and maintaining good rapport is essential to maintaining effective clinician-patient dialog. Adherence should be queried in a nonthreatening manner, including questions of out-of-pocket costs, dosing convenience, and possible adverse experiences. Input from family members (in the patient's presence) can be solicited. Poor adherence might be suspected in a patient chronically unfamiliar with prescribed medications or dosing regimens or in whom anticipated adverse experiences are absent or denied.

PSEUDOHYPERTENSION

Pseudohypertension refers to the phenomenon whereby vascular stiffening results in falsely high auscultatory BP measurements. Such an occurrence could result in the misdiagnosis of resistant hypertension when intraarterial pressures are actually normal or below normal. Small studies suggest that pseudohypertension may be common among the elderly, but definitive evaluation is lacking.^{15,16} Use of Osler's maneuver (ability to palpate the brachial or radial artery despite ipsilateral occlusion of the artery by a BP cuff inflated to suprasystolic values) has been recommended as a method to screen for pseudohypertension,¹⁷ but other investigators have found the maneuver to have questionable predictive value.¹⁸ Use of infrasonic or oscillometric measurement devices may more accurately reflect intraarterial pressure, but whether this translates into an effective clinical screen for pseudohypertension has not been determined.^{16,19} Pseudohypertension might be suspected if auscultatory BP values remain high in the absence of demonstrable target organ deterioration (i.e., LVH, retinopathy, renal insufficiency) or if patients with seemingly resistant hypertension manifest symptoms of hypotension. Confirmation of pseudohypertension requires direct intraarterial measurement of BP.

WHITE-COAT PHENOMENA

A small number of studies suggest that white-coat or isolated clinic hypertension is as least as common in patients with resistant hypertension as the general hypertensive population, with a prevalence ranging from 28% to 52%.²⁰⁻²² As in the general hypertensive population, persons with resistant clinic hypertension but normal ambulatory BP are at lower cardiovascular risk than those with sustained ambulatory hypertension. For example, in a study of 86 patients with resistant hypertension, defined as a clinic SBP >100 mm Hg during concomitant treatment with at least three antihypertensive agents that included a diuretic, one third were found to have an ambulatory SBP <88 mm Hg.²³ This group had a generally benign prognosis in terms of cardiovascular events during a mean follow-up of 49 months.

White-coat hypertension should be suspected if the patient reports consistently lower home BP levels than is recorded in clinic, if BP elevations persist in the absence of target organ damage, or if symptoms of hypotension develop in spite of persistently high clinic BP measurements. In these situations, ambulatory BP assessment is appropriate to look for a significant white-coat effect. If present, use of home and work BP values should be relied upon to guide therapy.

DIETARY SODIUM

Population-based studies suggest a weak positive relationship between dietary-salt ingestion and BP.²⁴⁻²⁶ However, there are subsets of patients more likely to manifest increased salt-sensitivity, including Blacks, the elderly, and in particular, patients with underlying renal insufficiency. In any patient, excessive sodium ingestion can blunt the antihypertensive benefit of most classes of agents, especially angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and diuretics. Accordingly, dietary-salt reduction should be recommended to all patients with resistant hypertension. In patients with renal insufficiency, an assessment of 24-hour urinary sodium excretion may be helpful in guiding adherence to reduced salt intake. Urinary sodium excretion should be maintained at <100 mEq/24 hours in persons with resistant hypertension.

EXOGENOUS SUBSTANCES

Exogenous substances most often compromising hypertension control include nonsteroidal antiinflammatory drugs (NSAIDs), alcohol, oral contraceptives, decongestants, and less commonly, certain psychotropic drugs (Box 59-2). There is wide individual variation in BP response to the different agents, with most persons being able to tolerate them without significant hypertensive effects. However, a minority of patients may be particularly sensitive to certain agents and withdrawal from the potentially interfering medication should be attempted if possible.

NSAIDs, presumably through inhibition of vasodilating prostaglandins in the kidney, impair natriuresis and induce fluid retention and volume expansion. They can also acutely worsen renal function, particularly in patients with underlying renal insufficiency, including elderly and diabetics, in

Box 59-2 Exogenous Substances That Can Contribute to Development of Resistant Hypertension

- Nonsteroidal antiinflammatory drugs including selective COX-2 inhibitors
- Alcohol
- Oral contraceptives
- Sympathomimetic agents (decongestants, diet pills)
- Caffeine
- Anabolic steroids
- Licorice
- Chemotherapeutic agents
- Corticosteroids
- Cyclosporine
- Erythropoietin
- Tricyclic antidepressants

whom renal dysfunction may be subtle or unrecognized. In addition to directly raising BP, NSAIDs may blunt the antihypertensive effects of certain agents, particularly diuretics, β -blockers, and ACE inhibitors. Although selective cyclooxygenase-2 (COX-2) inhibitors seem to have renal effects similar to nonselective NSAIDs,^{27,28} adverse effects on BP may be less likely, particularly with celecoxib.²⁹⁻³¹

In general, the pressor effects of NSAIDs are dose dependent and modest, with an anticipated increase in mean BP of 4 to 6 mm Hg.^{32,33} However, on an individual basis the compounds can induce acute renal insufficiency, pronounced fluid retention, and severe BP elevations. These effects are more likely to occur in patients with preexisting renal insufficiency. BP and renal function should be monitored closely when initiating NSAIDs use in patients with hypertension. In patients presenting with resistant hypertension, NSAIDs should be withdrawn if possible. Acetaminophen can be substituted for analgesic effect, although it does not provide antiinflammatory benefit.

Sympathomimetic compounds such as decongestants or certain diet pills can elevate pressure and should be avoided in patients with resistant hypertension. Oral contraceptives tend overall to induce a modest increase in BP, but the effect can be more severe in some individuals. Corticosteroids induce fluid retention and consequently may worsen BP control. Tricyclic antidepressants can blunt the efficacy of sympatholytic compounds such as clonidine. Erythropoietin and cyclosporine have well-documented pressor effects, but the option to withdraw such therapies is often limited.

ALCOHOL

Epidemiologic studies indicate that alcohol ingestion is associated with increases in BP with heavy drinking, increasing the risk of hypertension remaining uncontrolled.^{34,35} In a group of patients referred to a Finnish hypertension clinic, 38.5% had elevated γ -glutamyltransferase (GGT) levels, a marker of heavy alcohol ingestion, and among those patients, 22.5% failed to achieve BP control over the subsequent 2 years.³⁶ In contrast, in patients with normal GGT levels, only 7.1% failed to achieve BP control. Among patients with self-admitted heavy alcohol ingestion (>80 g/day), BP remained

uncontrolled in 46.1%. In a prospective study, cessation of heavy daily alcohol ingestion reduced 24-hour systolic and SBP by 7.2 and 6.6 mm Hg, respectively.³⁷

Whether through physiologic effects and/or improvements in adherence, cessation of heavy drinking does improve BP control. Accordingly, in all patients with resistant hypertension, alcohol consumption should be limited to ≤ 1 ounce ethanol/day (i.e., 24 ounces of beer, 10 ounces of wine, or 2 ounces of 100 proof liquor).

OBESITY

BP and weight are directly related, with each 10% increase in weight associated with a 6.5-mm Hg increase in SBP.³⁸ This relationship is continuous throughout the entire range of body weight. The mechanism by which weight gain increases BP is not fully known. Likely contributing factors include increases in cardiac output, peripheral resistance, and sympathetic activation, and increases in circulating insulin, which may induce salt sensitivity.

In observational studies, obesity correlates with lack of BP control. The Framingham investigators have reported that body mass indexes (BMIs) greater than 25 and 30 kg/m² are associated with lack of control of DBP and SBP, respectively.⁷ Cross-sectional studies indicate that increasing BMI independently correlates with increasing number of prescribed antihypertensive medications.³⁹ Last, in ALLHAT, obese subjects, despite receiving more medications, were less likely to achieve goal BP.³ While weight reduction is difficult to accomplish and maintain, it should be recommended to overweight patients with resistant hypertension, because it will likely reduce the need for antihypertensive treatment.

SLEEP APNEA

Epidemiologic studies clearly demonstrate a significant association between obstructive sleep apnea and hypertension. Two large cross-sectional studies have shown that the prevalence of hypertension increases with increases in sleep-disordered breathing.^{40,41} In a prospective evaluation, patients with a high number of nocturnal respiratory events characteristic of sleep apnea were more than three times as likely to develop hypertension as those with no respiratory events.⁴² Furthermore, Logan et al. reported that sleep apnea was very common in patients with drug-resistant hypertension.⁴³ In their study of 41 patients with resistant hypertension, 96% of the men and 65% of women were diagnosed to have previously unrecognized sleep apnea. In a separate study, sleep apnea was found to be an independent predictor of uncontrolled hypertension in patients <50 years of age.⁴⁴ Furthermore, the more severe the sleep apnea, the more likely the accompanying high BP will be resistant to pharmacologic therapy.⁴⁵

Treatment of sleep apnea has generally shown associated reductions in BP, with the benefit being most demonstrable on reductions in nighttime BP.⁴⁶ In one prospective evaluation, nasal continuous positive airway pressure (CPAP) reduced both daytime and nighttime mean BP, but only the nighttime reduction was significantly different from placebo treatment.⁴⁷ While CPAP seems to improve BP control in general, the benefit may be modest, particularly in patients with

severe and/or resistant hypertension. There are other cardiovascular and neurocognitive benefits of CPAP, so it should be prescribed when appropriate, even though large reductions in BP may not occur. For a more complete discussion of sleep apnea, see Chapter 73.

SECONDARY HYPERTENSION

The most common secondary causes of resistant hypertension are hyperaldosteronism, renal parenchymal disease, renal artery stenosis, and sleep apnea (Box 59–3). Retrospective reports have suggested that the prevalence of secondary causes of hypertension among patients referred to a hypertension specialty clinic is approximately 20%.⁴⁸ The prevalence of secondary hypertension increases with age, largely due to the increased prevalence of renovascular disease and renal insufficiency in older persons.⁴⁹ Recent prospective studies indicate that hyperaldosteronism is the most common cause of secondary hypertension.

Hyperaldosteronism

A growing body of evidence indicates that primary aldosteronism (PA) is much more common than thought historically. In an extensive evaluation that included more than 600 hypertensive persons, Mosso et al. found that the prevalence of PA increases according to the severity of the hypertension (Figure 59–1).⁵⁰ Applying JNC VI (Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure) staging criteria to untreated patients, PA was diagnosed in 2% of those with stage 1 hypertension (140-159/90-99 mm Hg), 8% of those with stage 2 hypertension (160-179/100-109 mm Hg), and 13% among patients with stage 3 hypertension (>180/110 mm Hg). Earlier, Lim et al. had reported a PA rate, based on an elevated plasma aldosterone:plasma renin activity ratio (ARR), of 14% among hypertensive patients randomly selected from a family physician database.⁵¹ Loh et al.⁵² reported a prevalence of 18% among 350 unselected hypertensive patients attending primary care clinics in Singapore.

These studies are just a few of many that report PA to be a common cause of hypertension. PA is particularly common in

Box 59–3 Secondary Causes of Resistant Hypertension

Common Causes

- Primary aldosteronism
- Renal artery stenosis (fibromuscular dysplasia, atherosclerotic)
- Renal parenchymal disease
- Sleep apnea

Rare Causes

- Cushing's disease
- Pheochromocytoma
- Coarctation of the aorta
- Hypercalcemia
- Carcinoid syndrome
- Central nervous system tumors
- Acromegaly

patients with resistant hypertension. In a prospective evaluation of Black and white patients with resistant hypertension, defined as uncontrolled hypertension in spite of use of three or more antihypertensive agents, Calhoun et al.⁵³ found an overall prevalence of PA of approximately 20% (see Figure 59–1). These results are consistent with a study from separate investigators reporting a prevalence of PA of 17% among patients referred to hypertension specialists for uncontrolled hypertension.⁵⁴

The reason for the increased prevalence of PA is unknown. Early studies of aldosteronism may have underestimated the prevalence of PA by evaluating small numbers of selected patients, such as those presenting with hypokalemia. The high prevalence of PA is also likely related to expanded screening of hypertensive patients. Recently described associations between obesity, sleep apnea, and aldosteronism suggest a possible mechanistic relationship between body weight and aldosterone excess, but such a relation remains speculative.^{55,56}

As indicated by the aforementioned reports, PA has become the most common secondary cause of hypertension. Accordingly, PA should be excluded in all patients with resistant hypertension. PA responds well to treatment, particularly in the absence of long-standing hypertension, with either resection of the hypersecreting adenoma or with use of aldosterone antagonists such as spironolactone or eplerenone. (See Chapter 75 for a more complete discussion.)

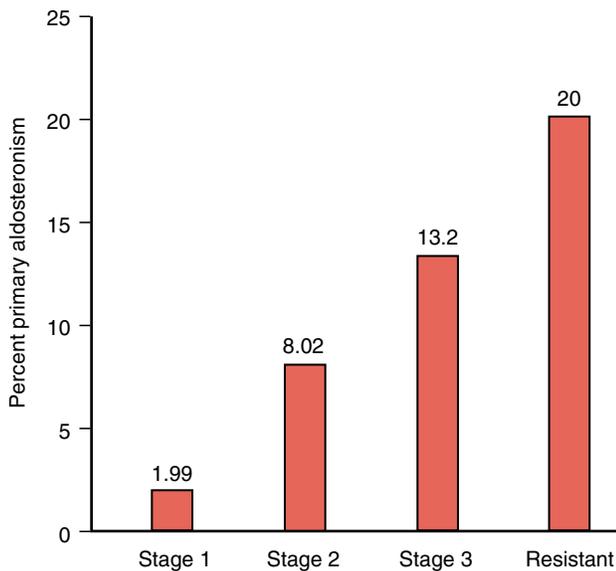

Figure 59–1 Prevalence of primary aldosteronism (PA) according to severity of hypertension (JNC VI stage 1, 140-159/90-99 mm Hg; stage 2, 160-179/100-109 mm Hg; stage 3, >180/>110 mm Hg; resistant, >140/90 mm Hg on three or more antihypertensive medications). (Modified from Mosso L, Carvajal C, Gonzalez A, et al. Primary aldosteronism and hypertensive disease. *Hypertension* 42:161-165, 2003; and Calhoun DA, Nishizaka MK, Zaman MA, et al. High prevalence of primary aldosteronism among black and white subjects with resistant hypertension. *Hypertension* 40:892-896, 2002.)

Renovascular Disease

Fibromuscular dysplasia accounts for less than 10% of cases of renal artery stenosis. It typically affects young women between the ages of 15 and 50. Angioplasty is successful in up to 100% of patients, the majority of whom will have significant improvement in BP.⁵⁷ Restenosis occurs in approximately 10% of cases postangioplasty. Captopril renography is very sensitive in screening for fibromuscular dysplasia.⁵⁷

Atherosclerosis accounts for 90% of the cases of renal artery stenosis. It generally occurs in patients >50 years of age and is more common in smokers and in patients with other atherosclerotic disease, particularly peripheral vascular disease. Patients will often present with exacerbation of previously controlled hypertension. Angioplasty of atherosclerotic renal artery lesions is less successful than with fibromuscular dysplastic lesions, however, with use of stents, short-term success rates approach 100% with restenosis occurring to 11% to 23% of patients at 1 year follow-up.^{58,59} Captopril renography has diminished sensitivity in patients with renal insufficiency, such as elderly patients or those with long standing hypertension. Duplex ultrasonography, gadolinium-enhanced magnetic resonance angiography, or computed tomographic angiography can provide effective screening of atherosclerotic renal disease, depending on institutional experience.

Although revascularization helps preserve renal function, the BP response to angioplasty of atherosclerotic lesions is often limited. Studies suggest that less than one third of those will be cured of their hypertension.⁵⁷ This response rate may be improved with stenting, but prospective studies evaluating outcomes following angioplasty and stenting are needed. (See Chapter 74 for a more complete discussion of renovascular hypertension.)

Renal Parenchymal Disease

Renal insufficiency secondary to renal parenchymal disease commonly contributes to resistant hypertension. The most common causes of renal insufficiency are diabetes and poorly controlled hypertension. Such patients are often volume expanded and have increased sensitivity to salt. Renal insufficiency is generally indicated by an elevated serum creatinine. In patients with reduced muscle mass, such as some elderly patients, significant renal disease may be unrecognized unless creatinine clearance is estimated. An estimate of creatinine clearance in the absence of 24-hour urine collection can be obtained based on prediction equations corrected for age, gender, and body size.^{1,60}

Pheochromocytoma

Pheochromocytoma is a rare cause of resistant hypertension. In the report by Anderson et al.,⁴⁹ pheochromocytoma was diagnosed in 0.3% of 4429 patients referred to their hypertension clinic. Pheochromocytoma is easily screened for by assessment of 24-hour urinary excretion of catecholamines or plasma metanephrines.⁶¹ It should be suspected in patients with sustained or episodic hypertension complicated by headache, palpitations, or diaphoresis. (See Chapter 76 for a comprehensive discussion of pheochromocytoma.)

TREATMENT FOR RESISTANT HYPERTENSION

The best treatment for resistant hypertension is based on identification and reversal of contributing factors. Accordingly, there should be a thorough screening for poor adherence, use of interfering substances, renal insufficiency, and secondary causes of hypertension, in particular aldosteronism. Obesity and sleep apnea, if present, should be treated.

In an evaluation of patients referred to a hypertension specialty clinic, failure of treatment after excluding secondary causes of hypertension, was attributed to ineffective regimens, most commonly inadequate dosing of prescribed agents and lack of appropriate use of long-acting diuretics.¹⁴ Antihypertensive agents should be prescribed in the maximum tolerated dose. Use of combination products improves adherence by reducing pill burden, simplifying the dosing regimen, and reducing out-of-pocket costs to the patient. Unless poorly tolerated, use of long-acting diuretics will significantly enhance BP control, particularly in patients already receiving vasodilators. Unless there is significant renal insufficiency (creatinine clearance <60 ml/min), thiazide diuretics are appropriate. Loop diuretics may be needed in patients with renal insufficiency or who are receiving potent vasodilators. Long-acting agents are preferred; if a short-acting agent such as furosemide is prescribed, it should be taken twice a day.

Use of aldosterone antagonists may provide additional BP reduction, even in patients already receiving a diuretic. It has been observed that low-dose spironolactone, 12.5 to 50 mg daily, when added to a regimen that included a diuretic, ACE inhibitor or ARB, and a calcium channel blocker (CCB) provided significant additional BP reduction (Figure 59–2).⁶² It is interesting to note that BP reduction was achieved even in patients without true PA, suggesting additional diuretic effects of the aldosterone antagonist when added to multidrug regimens, and/or a role for aldosterone in causing resistant hypertension even in the absence of excess hormone levels (Figure 59–3).

In patients in whom BP remains uncontrolled in spite of use of three or more medications, referral to a hypertension specialist is appropriate. A focused evaluation of contributing factors and especially exclusion of secondary causes of hypertension, along with expert tailoring of the prescribed medications should serve to maximize treatment.^{48,63}

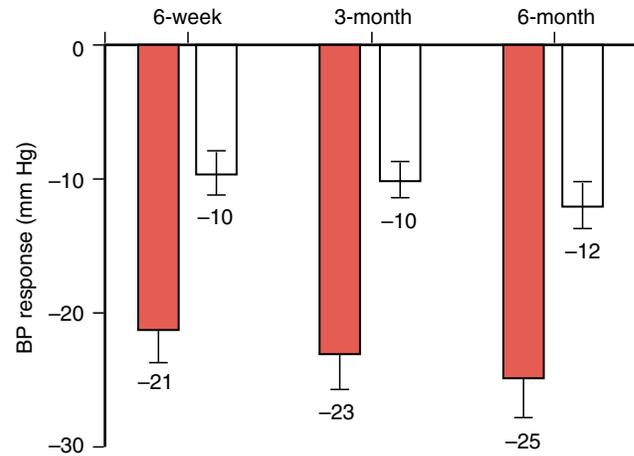

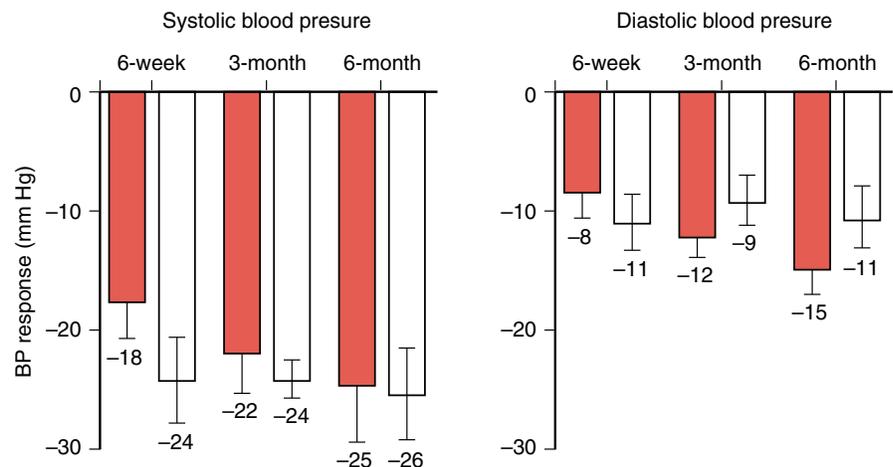

Figure 59–2 Spironolactone-induced reduction in systolic blood pressure (SBP) (filled bars) and diastolic blood pressure (DBP) (open bars) at 6-week, 3-month, and 6-month follow-up in patients with resistant hypertension. BP reduction was significant at all time points compared with the baseline. (Nishizaka MK, Zaman MA, Calhoun DA. Efficacy of low-dose spironolactone in subjects with resistant hypertension. *Am J Hypertens* 16:925-930, 2003.)

SUMMARY

Resistant hypertension is most often a consequence of poorly controlled systolic hypertension. Common reversible contributing factors include nonadherence, obesity, heavy alcohol consumption, and NSAID use. Prevalent secondary causes of resistant hypertension include hyperaldosteronism, renal insufficiency, renal artery stenosis, and sleep apnea. Of these, hyperaldosteronism may be the most common. Pharmacologic treatment of resistant hypertension requires use of maximum tolerated doses of multiple agents including, if possible, a long-acting diuretic. Addition of aldosterone antagonists to multidrug regimens may provide greater BP reduction.

Figure 59–3 Spironolactone-induced reduction in systolic blood pressure (SBP) and diastolic blood pressure (DBP) at 6-week, 3-month, and 6-month follow-up in patients with primary aldosteronism (PA) (filled bars) and without PA (open bars). Blood pressure (BP) reduction was not significantly different between patients with and without hyperaldosteronism.

Orthostatic Hypotension and Autonomic Dysfunction Syndromes

Satish R. Raj, David Robertson

Patients with dysfunction of autonomic cardiovascular regulation often present with extremes of blood pressure (BP) or heart rate (HR), especially when they assume an upright posture. Some have disorders with a well-understood pathophysiologic substrate, whereas others are less well understood and their mechanisms are under intensive investigation. In this chapter we focus on three major dysautonomic categories: (1) severe dysautonomias (pure autonomic failure [PAF] and multiple system atrophy [MSA]), rare conditions in which orthostatic hypotension is present; (2) mild dysautonomias (orthostatic intolerance/postural tachycardia syndrome [POTS] and neurally mediated syncope [NMS]), more common disorders, but with poorly characterized pathophysiologies, in which orthostatic hypotension is intermittent or absent, and in which tachycardia may be present; and (3) baroreflex failure, in which exaggerated BP and HR swings are exacerbated by emotional or physical stress (as opposed to gravity). Clinical features of some autonomic disorders are shown in Table 60–1.

SEVERE DYSAUTONOMIAS

Pure Autonomic Failure (Idiopathic Orthostatic Hypotension)

In 1925, Bradbury and Eggleston¹ described the clinical presentation of severe autonomic failure: orthostatic hypotension with an unchanging HR, supine hypertension, reduced sweating, reduced basal metabolic rate, impotence, nocturia, constipation, and anemia. They demonstrated pharmacologically the failure of both sympathetic and parasympathetic nervous systems, together with denervation hypersensitivity to respective agonists. In these cases, garments that prevented pooling of blood in the lower part of the body helped the patients, and successful symptomatic pharmacotherapy with sympathomimetic amines was soon reported.²

PAF is a disease process primarily involving the ganglion and the postganglionic neurons; central nervous system (CNS) involvement is rare. Lewy bodies have been found in autonomic neurons. The disease tends to progress slowly and has a good prognosis. Compared with normal individuals, patients with PAF have a significantly lower supine level of plasma norepinephrine.

Multiple System Atrophy (Shy-Drager Syndrome)

MSA is a sporadic, progressive, neurodegenerative disease of uncertain cause characterized by predominant autonomic dysfunction and various combinations of extrapyramidal, pyram-

idal, and cerebellar dysfunction.³ MSA is characterized by a progressive loss of neuronal and oligodendroglial cells in multiple sites in the CNS. The cause of MSA is unknown. This rare disorder (prevalence 2–15 per 100,000; men affected more commonly than women) has an age of onset of 55 years with median survival of only 9 years from the first symptom.⁴ Autonomic symptoms often develop first—orthostatic hypotension, urinary incontinence, or erectile dysfunction. Patients who develop Parkinsonian symptoms often demonstrate a poor or temporary response to levodopa therapy. PAF and MSA are compared in Table 60–2.

Orthostatic Hypotension

The orthostatic hypotension in PAF is often extraordinarily severe⁵ (Figure 60–1), being greatest early in the day and after a large meal. In mildly affected individuals, orthostatic hypotension may be present only after a meal. It may be present in the morning but not later in the day or only after climbing stairs or walking up a hill. Even small body temperature elevation (e.g., due to infection) greatly reduces BP. Patients learn to avoid hot environments because they lower BP.⁶

The upright BP may fall by 60/30 mm Hg or more in the most severely affected patients and cannot be accurately measured sphygmomanometrically. For this reason, it is useful to monitor disease severity with the standing time (the length of time a patient can stand motionless before the onset of symptoms of orthostatic hypotension). As soon as the herald symptom of orthostatic hypotension appears, the patient is allowed to sit down and the time is recorded. If the patient is able to stand for 3 minutes without symptoms, a reliable BP determination can then usually be obtained.⁷ Many patients who have small increases in standing time (e.g., from 30–120 seconds) may have a substantial increase in functional capacity. It is important to remember to treat the patient and not the standing BP. Patients can sometimes tolerate a standing systolic blood pressure (SBP) as low as 70 mm Hg without dizziness or syncope, probably because their cerebral blood flow is maintained at an adequate level because of the capacity of their cerebral circulation to undergo autoregulation.⁸

Supine Hypertension in Pure Autonomic Failure/Multiple System Atrophy

Many patients with PAF or MSA also have supine hypertension, even when they are not taking pressor medications. Supine hypertension can be undetected if BP is measured only in the seated position. In a study of 117 autonomic failure patients at our institution, 56% had supine diastolic blood pressure ≥ 90 mm Hg, and in 43% it was ≥ 95 mm Hg.⁹ Supine BPs as high as 228/140 mm Hg were observed. The results of

PAF, pure autonomic failure; POTS, postural tachycardia syndrome; BF, baroreceptor failure.

Table 60-2 Characteristics of Pure Autonomic Failure and Multiple System Atrophy

Feature	Pure Autonomic Failure	Multiple System Atrophy
CNS involvement	No	Multiple
Lesion location	Ganglionic/postganglionic	Central/preganglionic
Progression	Slow	Fast
Prognosis	Good	Poor
Cerebellar signs	No	Common
Extrapyramidal signs	No	Common
Supine plasma NE	Low	Normal
Standing plasma NE	Low	Low
Lewy bodies	Noradrenergic cells	None
BP response to water	↑↑	↑↑↑

CNS, central nervous system; NE, norepinephrine; BP, blood pressure.

this study show that supine hypertension is common in autonomic failure and frequently can be severe. The mechanisms responsible for supine hypertension in these patients are not known. It has been reported that patients with autonomic failure have a normal plasma volume,¹⁰ so an increase in intravascular volume is not likely to be responsible for supine hypertension. We previously found that autonomic failure patients with supine hypertension had a normal cardiac output, so their hypertension was due to increased peripheral vascular resistance.¹¹ Because plasma norepinephrine and renin are low in these patients, it is unlikely that they play a substantial role in this increased vascular resistance. Other mediators that increase smooth muscle tone (vasopressin, endothelin,

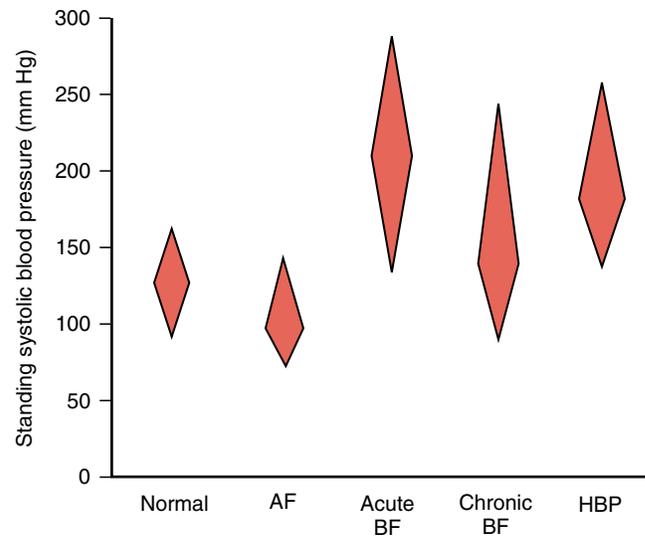

Figure 60-1 Blood pressures (BP) in patients with various dysautonomic syndromes. Standing systolic blood pressures (SBPs) in normal persons and in patients with autonomic failure (AF), acute baroreceptor failure (Acute BF), chronic baroreceptor failure (Chronic BF), and severe essential hypertension (HBP). The widest part of each diamond depicts the most common standing SBP seen in typical patients, while the height depicts the range of pressures seen throughout the day. Patients with AF have the lowest standing BP. Extremely high BPs are seen in acute BF, and these can exceed the BPs seen in severe hypertension. After several months (Chronic BF), the standing SBP is usually near normal, but great variability is still seen. (Reprinted from Robertson RM. Baroreflex failure. In Robertson D, Low PA, Polinsky RJ [eds]. Primer on the Autonomic Nervous System. San Diego, CA, Academic Press, 1996; with permission).

decreased nitric oxide production) need to be addressed in future studies.

Treatment in Pure Autonomic Failure/Multiple System Atrophy

Patients with asymptomatic orthostatic hypotension require no treatment. They should, however, be closely observed for the development of symptoms. Symptomatic patients can be treated nonpharmacologically by applying external support (by bandages firmly wrapped around the legs or by custom-fitted counter-pressure support stockings) and by using physical counter-maneuvers (leg-crossing, squatting, abdominal compression, bending forward or placing one foot on a chair) to reduce venous pooling in upright position.¹² Patients with PAF and MSA demonstrate a very significant pressor response to drinking 16 fluid ounces (480 ml) of room temperature water. This simple therapy can be used throughout the day as needed.¹³ If orthostatic symptoms continue, pharmacologic treatment consisting of the mineralocorticoid fludrocortisone,¹⁴ pressor drugs,¹⁵ or pyridostigmine¹⁶ can be added. As patients with severe autonomic failure have a high incidence of anemia, which may contribute to their symptoms, erythropoietin has been used. This treatment has reversed anemia and improved upright BP.¹⁷ An approach to

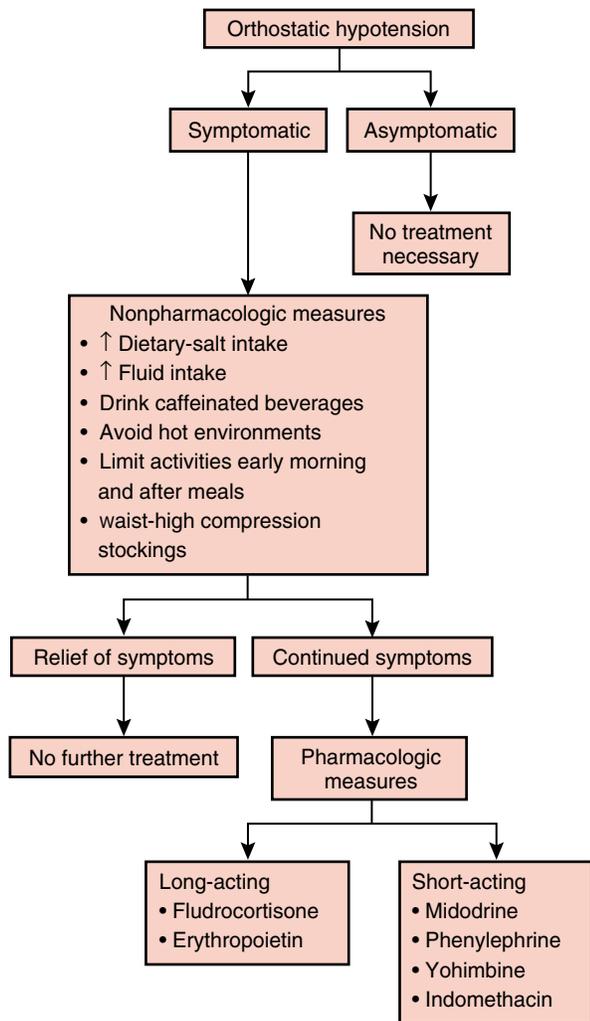

Figure 60-2 A useful strategy for the treatment of orthostatic hypotension. (Adapted from Jordan J, Shannon JR, Biaggioni I, et al. Contrasting actions of pressor agents in severe autonomic failure. *Am J Med* 105:116-124, 1998; with permission.)

treatment of orthostatic hypotension is schematically shown in Figure 60-2.¹⁸

However, these agents also aggravate supine hypertension. One approach for treating orthostatic hypotension in patients with supine hypertension is to use only short-acting pressor agents early in the day.¹⁹ Transdermal nitrates, oral clonidine, and oral hydralazine at bedtime are sometimes effective for the treatment of overnight supine hypertension. Patients are also encouraged to sleep with the head of the bed elevated 6 to 10 inches to avoid supine hypertension.⁹

MILD DYSAUTONOMIAS

Orthostatic Intolerance/Postural Tachycardia Syndrome

Orthostatic intolerance/POTS is the most common disorder of the regulation of BP after essential hypertension. It is present in approximately 500,000 Americans. It tends to occur in

Table 60-3 Contrasting Features Between Pure Autonomic Failure and Postural Tachycardia Syndrome

Feature	Pure Autonomic Failure	Postural Tachycardia Syndrome
Hemodynamic perturbation	Hypotension	Tachycardia
Syncope on standing	Early	Late
Age at onset	>50 years	<35 years
Gender	Male = Female	Female >> Male
Upright norepinephrine	Low	High

younger individuals (most are younger than age 35) and women are affected most often. Homeostatic adjustments to the upright posture²⁰ for some reason fail, and disabling symptoms may occur.²¹ The symptoms are described as dizziness, visual changes, head or neck discomfort, throbbing of the head, poor concentration, tiredness or weakness. Palpitations, tremulousness, fatigue, and anxiety are also seen. Generally, there is little or no fall in BP⁵ (see Figure 60-1). These symptoms are attributed to inadequate perfusion of the CNS.

POTS is very poorly characterized in terms of pathophysiology. In the 1920s it was shown that orthostatic symptoms occur in patients now considered to have PAF.¹ Over the subsequent 80 years, our understanding of the heterogeneity of orthostatic disorders and autonomic failure has improved.⁷ The contrasting features of PAF and orthostatic intolerance/POTS are presented in Table 60-3.

Postural tachycardia, the most constant feature of POTS, has caused investigators to consider several possibilities to explain the syncope. If there were a circulating vasodilator,²² or a reduced “effective” blood volume,²³⁻²⁵ the orthostatic tachycardia might be an appropriate autonomic compensatory response mediated through the baroreflex to maintain adequate BP and cardiac output.²⁶ It is possible that this hemodynamic response may not be sufficient to adequately perfuse the CNS, but a more likely explanation may be dysregulation in local vascular beds. A number of possible vasodilators have been investigated: bradykinin,²² atrial natriuretic factor,²⁷ histamine, and prostaglandin D₂.²⁸ However, it does not appear that vasodilators are a common cause for this disorder.

These largely negative studies have caused investigators to look elsewhere to explain POTS. Some proposed that an abnormally sensitive cardiac β_1 -adrenoreceptor could result in orthostatic tachycardia in situations in which the sympathetic nervous system (SNS) is activated.²⁹ Orthostatic intolerance occurs in many patients with the mitral valve prolapse syndrome.³⁰ Some investigators reported an apparent “supercoupling” of β_2 -adrenoreceptors: Although receptor number and affinity were not abnormal, activation of lymphocyte β_2 -adrenoreceptors from patients resulted in greater cyclic adenosine monophosphate accumulation than in normal persons,³¹ suggesting an abnormal coupling of the receptors to the guanine nucleotide regulatory complex. All of these observations strongly suggest that the major abnormality underlying POTS remains undiscovered.

The elevated normal and raised plasma norepinephrine levels³² and elevated urinary norepinephrine excretion³³ found

in some patients with POTS supports the view that increased SNS activation is responsible for the disorder. On the other hand, the observation of delayed recovery from the bradycardia of phase IV of the Valsalva maneuver and increased HR variability³⁰ suggests that there might be an imbalance in central autonomic regulation, a view that has been strengthened by evidence that there is raised muscle sympathetic nerve traffic even at rest in some patients with POTS.³⁴

It has also been suggested that POTS may be explained, perhaps paradoxically, by impairment in sympathetic function. Loss of the galvanic skin response (a sympathetic marker) on the soles of the feet has been noted.³⁵ The cause of orthostatic intolerance might thus be partial (or selective) denervation of the lower extremities that allows pooling of blood with upright posture. This hypothesis is based on an analogy to certain sensory and motor neurologic disorders, in which selective impairment of neurons may occur distally, with or without more proximal progression. Viral and/or immunologic causes could be operative.³⁶ In addition, patchy impairment of autonomic neuronal function could occur so that some areas remain intact. The heart might, for example, remain normally innervated while the distal extremities could have innervation impaired.³⁷ Observations of reduced clearance of norepinephrine from the circulation in some patients with POTS support this view.³⁸

No pharmacotherapy of POTS is generally effective, although individual agents may be somewhat helpful in selected patients.³⁹ The most widely employed agents are the β -adrenoreceptor antagonists, given to attenuate the symptomatic tachycardia on standing. Patients often respond to very low doses of nonselective β -blockers (e.g., propranolol 1-20 mg two to three times per day). Another approach is to use the α_2 -adrenoreceptor agonists (e.g., clonidine) to minimize sympathetic activation.⁴⁰ Finally, fludrocortisone has been employed in an attempt to increase blood volume.⁴¹ It is noteworthy that all of these drugs have a well-established capacity to lower plasma renin activity in normal persons. If low plasma renin activity contributes to the pathophysiology of orthostatic intolerance,⁴² it is possible that the currently used agents are marginally effective precisely because, along with the primary actions that constitute the rationale for their use, they also have a counterproductive action at the level of the juxtaglomerular apparatus. If this were true, it would mean that therapeutic alternatives that did not suppress renin ought to be sought. One potential alternative that is known to raise renin levels is exercise.⁴³

In summary, orthostatic intolerance/POTS is a final common clinical expression of multiple pathophysiologic processes that alter the normal response to upright posture. Two pathophysiologies seem to represent a substantial proportion of patients with POTS: (1) a partial dysautonomia due to impairment of the peripheral autonomic system and (2) a hyperadrenergic orthostatic intolerance in which the abnormality is in the CNS. With improved dissection of these and other pathophysiologies and improved matching of therapy to pathophysiology, improved therapeutic strategies for management of these patients will emerge.

Neurally Mediated Syncope

Syncope is a sudden, transient loss of consciousness with spontaneous recovery that is associated with a loss of postural tone. It is very common, with conservative estimates that

3% of the general population has experienced at least 1 syncope spell and is responsible for more than 1% of hospital admissions.⁴⁴ Neurally mediated syncope (NMS), or reflex fainting, is the most common cause of syncope, especially in those patients without evidence of structural heart disease. NMS most commonly occurs following prolonged sitting or standing, although it can also occur with exercise (initiation or peak exercise) or with emotional/psychologic triggers (e.g., phlebotomy). In contrast to POTS, NMS is associated with intermittent postural hypotension, with normal orthostatic BPs more than 99% of the time.

The pathophysiology of NMS is not completely understood, but a frequently used pathophysiologic model is shown in Figure 60-3.⁴⁵ The most common hypothesis argues that the initiating event is a pooling of blood in the legs (from prolonged sitting or standing) with a resultant reduction in venous return (preload) to the heart. The fall in BP leads to a baroreceptor-mediated increase in sympathetic tone, with a subsequent increase in chronotropic and inotropic effect. The vigorous cardiac contraction, in the setting of an underfilled ventricle, is thought to stimulate ventricular afferents in the left ventricle that trigger a reflex loss of sympathetic tone and an associated increase in vagal tone. The adrenal gland also releases epinephrine in response to this stress. The result is clinical hypotension and/or bradycardia.

The history and physical examination are at the heart of the diagnosis. A clinical diagnosis can be made with these alone in most cases. The history should focus on the circumstances surrounding the syncope, the associated symptoms before and after the event, and any collateral history from witnesses. The past medical history may contain evidence of structural heart disease and coexisting medical conditions, which both point away from NMS. Medications may provoke syncope, and a family history of sudden death may point to an arrhythmic cause. Historical features of NMS have been found to include a female gender, younger age, associated diaphoresis, nausea, or palpitation, and postsyncope fatigue.⁴⁴ A long duration of spells (from the first lifetime spell) also suggests NMS. The physical examination should focus on ruling out structural heart disease and focal neurologic lesions.

Tilt table testing involves subjecting patients to head-up tilt at angles of 60 to 80 degrees, in an attempt to induce either syncope or intense presyncope, with a reproduction of presenting symptoms.⁴⁶ Passive tilt tests simply use upright tilt for up to 45 minutes to induce vasovagal syncope.⁴⁴ Provocative tilt tests use a simultaneous combination of orthostatic stress and drugs such as isoproterenol, nitroglycerin, or adenosine to provoke syncope with a slightly higher sensitivity, but reduced specificity. There is little agreement about the best protocol. Recent studies with implantable loop recorders have called the value of tilt testing into question.⁴⁷ Tilt tests are contraindicated in patients with severe aortic or mitral stenosis, or critical coronary or cerebral artery stenosis.

Treatment of Neurally Mediated Syncope

Most patients should simply be reassured about the usual benign course of NMS and instructed to avoid those situations that precipitate fainting. They should be taught to recognize an impending faint and urged to lie down (or sit down if that is not possible) quickly. This will not be enough for some patients, and other treatment options may be necessary.

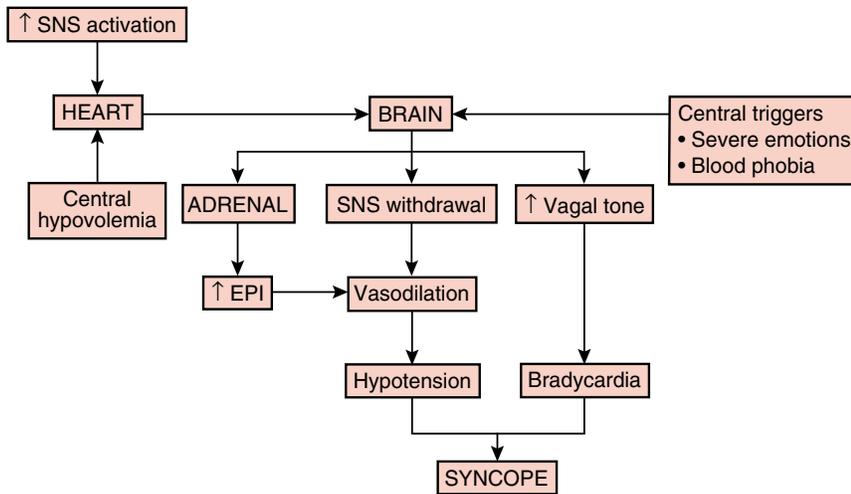

Figure 60-3 Pathophysiologic model of neurally mediated syncope. Multiple potential triggers lead to a loss of sympathetic tone, an increase in vagal parasympathetic tone, and the adrenomedullary release of epinephrine with resultant hypotension and bradycardia leading to syncope. SNS, sympathetic nervous system. (Adapted from Raj SR, Robertson RM. *Neurally mediated syncope*. In Robertson D, Biaggioni I, Burnstock G, et al. [eds]. *Primer on the Autonomic Nervous System*. San Diego, CA, Academic Press; 2003; pp 249-251; with permission.)

Pharmacologic therapy has only inconsistent results.⁴⁴ Although salt replenishment and fludrocortisone have not been rigorously studied, they are both commonly used because of low side effect profile and probable efficacy. β -Adrenergic antagonists are commonly used for this disorder, but with only poor evidence of effectiveness.⁴⁸ The α_1 -agonist midodrine has been found to decrease the rate of recurrent syncope among frequent fainters,⁴⁹ but other agents in this class have not had the same results.⁵⁰ In one well-designed study, the selective serotonin reuptake inhibitor paroxetine was found to be effective.⁵¹ Orthostatic training has been described as an effective nonpharmacologic therapy for patients with recurrent NMS,⁵² but this therapy has not been properly studied. Permanent dual-chamber pacemakers were initially a very promising therapy,⁵³ but recent evidence suggests only a modest benefit.⁵⁴ Pacemaker implantation is not currently a front-line therapy for NMS.

BAROREFLEX FAILURE

Arterial baroreflexes maintain arterial pressure within a narrow range. The baroreflex arc can be damaged at any site: at the baroreceptors (stretch-receptors) in the vasculature (mainly in the carotid sinus), in the course of the glossopharyngeal or vagal nerves, or at the nuclei in the brain stem. In humans, baroreflex failure is a rare disorder, which is usually related to neck surgery, neck irradiation therapy for malignant tumors, brain stem lesions, or bilateral carotid body tumors.⁵⁵ Failure of the baroreflex at any point produces a characteristic clinical syndrome. It is presumably caused by an inability to buffer supramedullary input to cardiovascular control centers in the brain stem.⁵⁵ It has been shown in numerous animal studies and in humans that nearly complete denervation of the carotid and aortic baroreceptors is necessary to cause flagrant baroreflex failure, (i.e., all baroreceptors, both glossopharyngeal and vagus nerves or the brain stem nuclei have to be damaged).^{55,56}

At Vanderbilt University's Autonomic Dysfunction Center we identified 36 patients with arterial baroreflex failure (out of approximately 2700 referred with severe disorders of autonomic function). Reasons for referral were evaluation of essential hypertension, suspicion of pheochromocytoma,

uncontrolled severe hypertension, and assumption that glossopharyngeal or vagal nerves had been damaged. The causes for baroreflex failure included surgery and irradiation of throat carcinoma in three patients, surgical section of the glossopharyngeal nerve for glossopharyngeal neuralgia in a patient with previously sustained injury to the contralateral glossopharyngeal and vagus nerves, the familial paraganglioma syndrome in four patients, and a marked bilateral cell loss in the nuclei of the solitary tract (found at subsequent autopsy) in the setting of a degenerative neurologic disease of medullary and higher structures in one patient. The familial paraganglioma syndrome is a genetic disorder in which affected individuals develop multiple benign noncatecholamine-producing tumors. These tumors physically damage the glossopharyngeal and vagus nerves, leading to baroreflex failure. In two patients no cause could be documented.

Patients usually present with arterial hypertension, usually episodic but occasionally sustained. Labile, episodic hypertension is often seen in patients who develop baroreflex failure gradually (e.g., years after neck irradiation) or with a chronic disorder. In contrast, sustained hypertension is especially severe in patients with acute interruption of the baroreflex arc (see Figure 60-1). Arterial pressures of 310/150 mm Hg have been seen, with resultant hypertensive crises. The clinical picture is often similar to that of pheochromocytoma, where arterial hypertension and tachycardia also occur together. Patients have the same subjective sensations of warmth or flushing, palpitations, headache, and diaphoresis. The diagnosis of pheochromocytoma⁵⁷ can be ruled out by computed tomography scanning, metaiodobenzylguanidine (MIBG) scanning, adrenal arteriography, or venous norepinephrine sampling (see Chapter 76). In contrast to patients with a pheochromocytoma, patients with baroreflex failure show stability or improvement in their hypertension over time.

There is sometimes emotional lability or nervousness in patients with baroreflex failure, more prominent at the time of BP elevation.⁵⁵ The loss of the baroreflex buffering capacity causes much more pronounced effects of cortical influences on the vasomotor centers in patients with baroreflex failure. Pain, emotion, visual attention, or mental arithmetic may have a much greater effect in patients than in normal subjects. Cold pressor test (placing the patient's hand in ice water for 1 minute) in normal persons caused an increase in systolic

arterial pressure of 24 ± 7 mm Hg with the BP normalizing within a few minutes of hand rewarming; in patients with baroreflex failure, responses of 56 ± 14 mm Hg were noted,⁵⁸ and these sometimes persisted for 30 minutes despite hand rewarming (Figure 60-4).

The hallmark diagnostic feature of baroreflex failure is a parallel increase in BP and HR with stress and a substantial parallel decrease with sedation or rest. There is no reflex decrease in HR after pressor agents and no reflex increase in HR after vasodilators. In normal persons an increase in BP of 20 mm Hg with phenylephrine will decrease the HR by 7 to 21 beats per minute (bpm), and a decrease in BP of 20 mm Hg with sodium nitroprusside will increase the HR by 9 to 28 bpm. Patients with baroreceptor failure, however, do not alter their HR by more than 4 bpm with either drug.⁵⁸

Plasma norepinephrine levels parallel the BP changes. During surges of sympathetic activity associated with hypertensive-tachycardic episodes, plasma norepinephrine levels as high as 2260 pg/ml (13.36 nM) have been seen. During quiescent periods, norepinephrine levels may be normal (111-360 pg/ml [0.66-2.13 nM]). There can be diagnostic confusion with POTS, because POTS is sometimes also associated with elevated catecholamines and volatile BP.

Acute administration of clonidine decreases BP, HR, and plasma catecholamine levels in patients with baroreflex failure

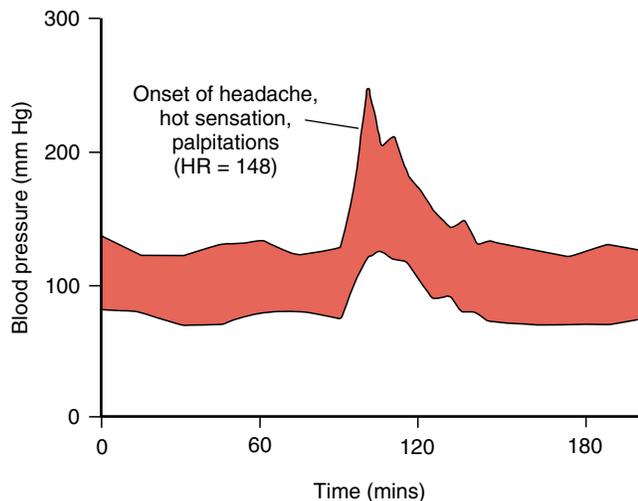

Figure 60-4 Blood pressure (BP) in acute baroreflex failure. BP monitoring over a 200-minute period in a 43-year-old man approximately 2 weeks following surgical removal of a second carotid body tumor, 5 years after removal of the initial (contralateral) carotid body tumor. While BP was being monitored at normal baseline levels, a cold pressor test (immersion of the hand in ice water for 60 seconds) was performed. The BP immediately rose and continued to rise for several minutes following of the cold stimulus. The symptoms appeared during his time and resolved as BP and heart rate (HR) returned to normal over the succeeding half-hour. On some occasions, paroxysms of similar magnitude occurred without obvious exogenous causative stimuli. (Reprinted from Robertson D, Hollister AS, Biaggioni I, et al. The diagnosis and treatment of baroreflex failure. *N Engl J Med* 329:1449-1455, 1993. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)

and is therefore useful as a diagnostic test to distinguish baroreflex failure from pheochromocytoma.⁵⁹ Clonidine is the most effective drug in terms of decreasing the number and the severity of hypertensive crises. Diazepam is used to control stress.

In contrast to the majority of patients with nonselective baroreflex failure (with loss of parasympathetic efferent discharge), occasional patients with this syndrome have intact parasympathetic control of the HR. They have a lesion involving only the afferent arc of the baroreflex (selective baroreceptor failure). In addition to undamped sympathetic tone, they can also have excessive vagotonic reactions. Such patients have phases of severe hypertension and tachycardia alternating with prolonged episodes of severe bradycardia and asystole.⁶⁰ They require unique therapeutic strategies, including medications that attenuate sympathetic nerve traffic, medications that increase BP, and, in some cases, implantation of a cardiac pacemaker.

Individual Drug Classes

Chapter 61

How Hypertensive Drugs Get Approved in the United States

Robert R. Fenichel

This chapter describes the means by which manufacturers gain permission to bring antihypertensive drugs to the U.S. market. Some of the chapter is applicable only to oral antihypertensive formulations intended for long-term use, but much of it applies equally well to intravenous antihypertensive formulations and, indeed, to drugs other than antihypertensives.

Before a drug may be promoted as an antihypertensive on the U.S. market, the claim of antihypertensive efficacy must be approved by the U.S. Food and Drug Administration (FDA). An antihypertensive product might theoretically avoid FDA jurisdiction by never appearing in interstate commerce, but the notion of “interstate commerce” has been so broadly construed that this option is more apparent than real.

Federal regulations do not prevent U.S. physicians from prescribing, or U.S. pharmacists from dispensing, medications (or other substances) for nonapproved uses. Medical insurers, however, frequently refuse to reimburse patients for the cost of such prescriptions. After medical misadventures, physicians may find it difficult to defend a therapeutic choice that was not FDA approved. Perhaps for these reasons, and with the notable exception of immediate-release nifedipine preparations (approved in the United States only for the treatment of chronic stable angina, but widely prescribed as antihypertensives), unapproved products are not frequently prescribed as antihypertensives by U.S. physicians.

Would-be manufacturers have adequate incentives, then, to obtain FDA approval for an antihypertensive claim. To obtain that approval, the sponsor must demonstrate the following:

- The product is of known and stable composition, and can be reliably manufactured and distributed.
- There is an identifiable population in whom the product is reproducibly effective and reasonably safe.
- It is possible to lay out evidence-based instructions for use of the product.

CHEMISTRY AND BIOPHARMACEUTICS

If a product is not of stable composition, then there is little point in discussing its clinical effects. In general, a drug’s manufacturer is required to formalize the work of synthesis, compounding, packaging, and labeling, so that little is left to judg-

mental variation. The manufacturer is also required to establish a system of controls, to verify at various stages of manufacture that things are what they should be. The details of these requirements will not be of interest to most clinicians.

The proposed product must also be studied to determine the pharmacokinetics (absorption, distribution, metabolism, and excretion) of its active ingredient(s). Sometimes development of the to-be-marketed formulation proceeds in parallel with clinical trials; in these cases, special bioavailability trials may need to be done to demonstrate that the to-be-marketed formulation is not substantially different from the formulation(s) tested in clinical trials. In addition, samples of the final product in final packaging must be shown to survive storage for the claimed shelf life.

TOXICOLOGY

FDA consent is required when a novel chemical substance is given experimentally to a human being in the United States. Before that time, the manufacturer of a new antihypertensive will generally have done studies to demonstrate that the new drug is antihypertensive in animals. Such studies are not required,* but in the case of antihypertensives some such studies are almost always performed, to reassure the manufacturer (and the FDA) that antihypertensive efficacy in humans can be plausibly anticipated, justifying the risks and costs of human trials. Once antihypertensive efficacy has been demonstrated in humans, the animal-efficacy data are no longer of great interest.

Toxicologic studies in animals, unlike studies of antihypertensive efficacy, are strictly required. In general, human trials are permitted only after the FDA has reviewed animal studies in which maximal-tolerated doses were administered for as long as, or longer than, the proposed exposure in human trials. Unlike the efficacy studies in animals, some of these toxicology studies retain their importance throughout the

*Because many human illnesses have no animal models, the FDA could not reasonably require demonstrations of efficacy in animals for all drug claims. Even in hypertension (where animal models are available), a drug effective in humans might conceivably not be effective in any nonhuman species.

development process and after approval. In particular, some toxicologic studies (reproductive and carcinogenicity studies) are not analogous to any feasible human trials.

CLINICAL TRIALS

The earliest human trials are those that are traditionally called *phase 1* trials. These studies may be unblinded and nonrandomized; their purpose is not to demonstrate antihypertensive efficacy, but rather to investigate human pharmacokinetics and metabolic pathways, to detect unanticipated adverse effects, and to begin the search for well-tolerated doses with some evidence of antihypertensive activity in humans. The subjects in phase 1 trials are conventionally healthy young adult volunteers; a typical trial might utilize only a dozen or so such volunteers, each exposed once or a few times to one or two doses. If the product is to be taken orally, there will be at least one study to determine the extent to which the rate and extent of absorption are affected by food. More complexly, if metabolism and elimination of the product's ingredients have been found to be dependent on renal function, or on the function of one or another of the cytochrome P450 pathways in the liver or the gut, or if administration of the product results in induction or inhibition of those pathways, then other studies will need to investigate potential interactions between this product and at least a few of the important other products that interact with the same pathways.

Using the results of the phase 1 studies, the *phase 2* studies are generally double-blind, randomized, placebo-controlled trials. In a typical such trial, each of a few dozen patients is randomized to receive a few weeks of treatment with a regimen of placebo or the new drug. In other trials done around this time or a bit later, investigators recruit patients who are diabetic, who have hepatic or renal dysfunction, or who are receiving various unrelated drugs (e.g., antianginal drugs, cholesterol-lowering drugs, oral contraceptives) that are frequently received by reasonably large numbers of hypertensive patients. These various middle-stage trials greatly increase the total accumulated number of patient-days of exposure to the new drug, and sometimes they reveal adverse effects that were not apparent earlier. If all goes well, they suggest which regimens are most worth examining in the definitive trials.

As the phase 2 studies are completed, the trials that are intended to provide definitive proof of efficacy are designed and begun. These *phase 3* trials are typically randomized, double-blind, placebo-controlled, parallel-group trials comparing two or three regimens of the new drug (different doses, different interdosing intervals) with placebo, with each trial following a few hundred hypertensive patients for 2 or 3 months. In the case of a combination product (say, a combination of an angiotensin-converting enzyme [ACE] inhibitor and a thiazide diuretic), the phase 3 trials are typically of parallel-group "factorial" design, in which patients are randomized to each of the possible combinations of (1) one dose from among several possible doses (including placebo) of the first drug and (2) one dose from among several possible doses (again, including placebo) of the second drug. The primary metric of each of these trials is the placebo-corrected change in blood pressure (BP), usually seated diastolic blood pressure (DBP), although systolic blood pressure (SBP) is increasingly of equal importance. One of these trials is said to have succeeded when analysis shows that

one or more regimens have effects that are significantly superior to those seen with placebo. Documentation of the phase 3 trials is usually the last-completed component of the package that an applicant submits to the FDA for marketing approval.

The phase 1/phase 2/phase 3 nomenclature is widely used, but the conventional distinctions are increasingly blurry. In recent years, for example, some investigators have done even their earliest trials using patients, healthy except for hypertension, instead of healthy volunteers.

SUBMISSION OF THE APPLICATION

A typical complete application comprises about 200,000 pages of text and tables, collected into volumes of about 500 pages each. A little more than half of the application is typically devoted to the clinical trials, which usually have involved a total of 1500 to 3000 patients.* Under the Prescription Drug User Fee Act (1997, amended 2002), the application must be accompanied by a filing fee; for 2004, the fee was \$573,500.

Although FDA permission is required for human drug experiments within the United States, there is no requirement that a development program include any U.S. trials at all, so a program based entirely on non-U.S. trials might theoretically not come to the FDA's attention until the moment that the application was submitted. This theoretical possibility has never been realized; sponsors and investigators of new antihypertensives have always availed themselves of the opportunity to meet with the FDA on multiple earlier occasions during development. In an early meeting, the topic might be the order in which various potential claims might best be studied, or what studies might be useful to estimate the importance of a worrisome toxicologic finding. In later meetings, the sponsor and FDA might discuss which drug-drug interactions were most reasonable to explore, or the design of the phase 3 trials. Still later, most sponsors visit the FDA to discuss the formatting of the application and the design of any computer-based aids for the FDA reviewers.

REVIEW OF THE APPLICATION

Some drug products are approved not on the basis of new toxicologic and clinical data, but rather on the basis of chemical identity (and physical near-identity) to previously approved products. Applications describing such products ("generics") are handled by the FDA's Office of Generic Drugs (OGD). The pertinent chemical and biopharmaceutical criteria used by OGD are sufficient to guarantee that new drug/old drug differences are small compared with the expected interpatient and inpatient variability. The details of those criteria will probably be of little interest to readers of this volume.

*No specific requirement for overall patient exposure is present in FDA regulations, but the FDA has accepted as "guidelines" the notions that there should be at least 1500 patients studied, at least 500 followed for at least 6 months, and at least 100 followed for a year or more. These numbers were the consensus recommendations of "harmonization" discussions among the FDA and its counterparts in Europe and Japan. This patient exposure greatly exceeds what is needed for a demonstration of antihypertensive efficacy, and it is determined by the desire to detect adverse effects that might not be apparent in smaller populations.

Applications for new antihypertensive drug products come to the FDA's Division of Cardio-Renal Drug Products (DCRDP). As of late 2003, the staff of DCRDP included 11 physicians (down from 16 in 1999), 13 toxicologists (down from 15), and 12 administrative and technical personnel (up from 11). In addition, there were at that time 8 chemists, 8 biopharmaceutical reviewers, and 5 statisticians who—although not formally members of DCRDP—were assigned full-time to the support of the DCRDP.

Filing

Within 60 days of the arrival of a new application, the DCRDP must decide whether the application is capable of being reviewed at all. Rarely, the DCRDP decides that an application is incomplete on its face,* so review would be impossible. In such cases, the DCRDP formally “Refuses To File” the application, and further processing is omitted. The “Refusal to File” action (like all others) is subject to appeal and reversal; in addition, a manufacturer may insist that an application be filed (and reviewed) despite the initial refusal by the DCRDP.

Criteria of Approvability

Before a product is approved for marketing, the sponsor must have demonstrated to the FDA that the product is produced by a securely repeatable process, and that its bioavailability has been described. The specific requirements in these areas are narrowly technical, and they are probably not of interest to most clinicians.

The clinical and toxicologic requirements are of broader interest. The FDA does not look to the clinical trials for a useful estimate of the magnitude of antihypertensive effect. That magnitude varies, of course, from patient to patient. In the clinical treatment of hypertension, drugs are titrated to effect, and any given drug is used only in patients who appear to respond to it. If a treatment is effective in a given patient, then it is immaterial that its antihypertensive effect in other patients is small or even absent. But because natural variations in BP are often similar in amplitude to the effects of therapy, the clinical trials may be the only setting in which active drugs can reliably be distinguished from placebos, and this distinction is at the center of the clinical review.

To demonstrate superiority to placebo, it is theoretically not necessary to do a placebo-controlled trial. If a new antihypertensive regimen were shown to be unequivocally *superior* to an approved regimen of an approved antihypertensive agent, the new drug could be approved. If, on the other hand, trials seemed to show only that the new drug were *similar* to approved therapy, then interpretation would be much more difficult. Such results might reflect genuine shared superiority to placebo, but they might instead reflect only that the trials had been so poorly executed that even a totally ineffective new drug could not have been distinguished from the approved therapy. In any event, the FDA has never seen an application for approval of an antihypertensive drug in which the major phase 3 trials were not placebo-controlled. The primary met-

ric of each trial is usually the baseline-adjusted seated DBP, but other measurements of BP (seated systolic, supine systolic and diastolic, standing systolic and diastolic) are also performed. Responder rates* are usually recorded, but—in part because of their necessarily arbitrary definitions, in part because of their statistical inefficiency—they have not been used as primary measures. Trials are usually powered to show that each of several doses of test drug is significantly superior to placebo, but sometimes the analysis uses a trend test to show only that taking all of the trial results together, the observed BPs cannot reasonably be believed to have been unrelated to the administered doses of test drug. In factorial trials, where individual cells of the randomization may each receive relatively few patients, a two-dimensional analog of the trend test[†] is especially attractive.

From the widespread adoption of $p \leq .05$ as the threshold of meaningful statistical significance, and from the Federal regulations' requirement (21 CFR §314.126) that approvals be supported by “adequate and well-controlled studies” (note the plural), the FDA has come to expect that any approvable antihypertensive claim would be supported by at least two trials, each successful by the criterion of $p \leq .05$. A single trial with $p \leq .05 \times 0.05 \div 2 = 0.00125$ [‡] could in principle provide equally strong evidence,[§] but no antihypertensive application to date has ever rested its case on such an argument.[§]

FDA policy with respect to antihypertensives is derived from the landmark historical placebo-controlled trials that demonstrated the benefits of treatment with respect to the irreversible outcomes of stroke and similar hard endpoints. As described in Chapters 1 and 29 to 35, these trials employed antihypertensive medications of many different classes, always in stepped-therapy schemes, and usually starting with a diuretic or β -blocker. In every such trial with adequate statistical power to show a difference, antihypertensive therapy was seen to be superior to placebo. While the fractional reduction in event rate was consistently large, the absolute benefit—at least in patients with mild or moderate disease—was generally small, typically only a few averted events per thousand years of patient treatment.

Because the benefits of antihypertensive treatment have been so consistent across such a wide range of regimens, the FDA believes (with Dr. Jan Staessen and the Clinical Trialists Collaborative Group; see Chapter 29) that reduction of BP—however achieved—can be expected to be associated with a reduction in the incidence of irreversible vascular events. Accordingly, the FDA considers antihypertensive efficacy to have been demonstrated when the regimen in question is shown to reduce BP.

*For example, the fractions of patients whose last measured seated diastolic blood pressure (DBP) was below 90 mm Hg or at least 10 mm Hg less than it had been at baseline.

[†]That is, two trials rejecting the null hypothesis with each $p \leq .05$ (0.05×0.05), and both results in the *same* tail of the distribution ($\div 2$).

[‡]As could, say, four trials, each successful with $p \approx .3$.

[§]A treatment that is nontrivially antihypertensive in patients with mild to moderate hypertension can easily be distinguished from placebo in small, short trials (a few hundred patients for a few weeks), so these statistical thresholds (whatever their exact levels) are not much of a hurdle. They are much more of an issue in other clinical areas (e.g., congestive heart failure), and they may become important in hypertension if claims are sought on the basis of the large, hard-endpoint trials.

*For example, one application revealed that during a few months of storage, the to-be-marketed product came to contain large quantities of a degradation product whose carcinogenicity had not been studied in any species.

On the other hand, the small absolute benefit of antihypertensive treatment could easily be outweighed by a small incidence of unrelated toxic effects, possibly an incidence too small to be reasonably estimated from the total experience in a typical package of clinical trials. The clinical and toxicologic reviewers must be satisfied that a new antihypertensive regimen is unlikely to be more toxic than those that, in the hard-endpoint trials, provided a net positive benefit.

Special additional criteria are imposed on fixed-dose combination products. Because any combination therapy exposes the patient to the potential adverse effects of each component, the FDA requires that each component of a combination product contribute to the antihypertensive effect, and that there be well-defined situations in which the combination offers antihypertensive efficacy that is superior to that provided by monotherapy with one or another of the components. Some additional considerations related to fixed-dose combination products were described in a 1994 editorial.²

Why New Hard-Endpoint Trials Are Not Required

To avoid relying on uncertain predictions of long-term toxicity, the FDA could require that before any new antihypertensive regimens could be approved, net benefit would need to have been demonstrated in new hard-endpoint trials. The FDA's adoption of such a requirement has been proposed from time to time, and some of the difficulties of such a policy were discussed at the Cardio-Renal Advisory-Committee meeting of October 20, 1995.

Because most of the reported hard-endpoint trials were performed before the availability of some currently available drugs, and especially because they predated our current knowledge of effective dosing of diuretics, limiting FDA approval to hard-endpoint-trial-based therapy would not result in treatment recommendations that would be acceptable to most modern clinicians. The regimens tested in the hard-endpoint trials were shown to provide net benefit, but our knowledge of these regimens' toxicity* suggests that current recommendations (although not strictly based on hard-endpoint data) are likely to provide greater net benefit.

Also, the very success of the hard-endpoint trials of the 1970s and 1980s makes it ethically impossible to perform similar placebo-controlled trials today. When interventions have been shown to prevent a substantial incidence of irreversible harm, it is no longer permissible to assign patients to inactive

therapy.[†] Without placebo controls, and probably without control regimens identical to any of the creaky, now disfavored regimens of the reported hard-endpoint trials, net benefit would be difficult to demonstrate.

Finally, many of the possible hazards of antihypertensive therapy can be reliably estimated from hard-endpoint trials in other clinical areas. Of course, it is always possible that an antihypertensive regimen will turn out to induce obscure organ toxicity (e.g., agranulocytosis, pancreatitis) whose net effect, integrated over the years of treatment, will negate the benefit of pressure reduction. To the extent, however, that the toxicity of antihypertensive therapy is likely to be directly related to cardiovascular effects (e.g., from excessive rate or extent of pressure reduction), that toxicity can often be assessed by looking at the results of relatively short hard-endpoint trials in which the same therapy was given to patients (e.g., those with myocardial infarctions or congestive heart failure) who might be expected to be unusually sensitive to such effects.

Primary Reviews

In the usual case, the application is formally accepted for filing, and the various sections of the application are reviewed more-or-less independently by specialists from the separate disciplines. In particular, separate primary reviews are contributed by a chemist, a toxicologist, and a biopharmacist. If the proposed product is to be administered parenterally, an additional review is provided by a microbiologist. In each of these disciplines, the primary reviewer's work is not considered complete until it has been cosigned by a supervisor. In many cases, the initial nonclinical reviews reveal various gaps in the manufacturer's documentation of its data and control procedures. The reviews lead to correspondence between the agency and the manufacturer, and thereafter to a (usually) convergent series of supplemental submissions and reviews.

Review of the clinical trials is handled differently. Sometimes there are separate reviews by a statistician and a physician, but more often the statistician and a physician (or two or three physicians) jointly produce a single review, dividing the work among themselves under the direction of a team leader who is then responsible for integrating the group's work into a coherent document. In addition to writing their review(s), the clinical reviewers will usually identify a few trial sites for routine audit by FDA field personnel. Like the nonclinical reviews, a clinical review often leads to correspondence intended to fill in gaps in documentation. In their conclusions, primary clinical reviews attempt to identify the clinical data whose interpretation should lead to approval or nonapproval, with suggestions for labeling in the event of approval.

Secondary Reviews

On average, each volume of an application submitted to DCRDP will cause the generation of about one page of primary review, so the several primary reviews add up to a few hundred pages of text. The primary reviews are then brought together by a team leader (always a physician), who prepares a secondary review of (typically) a few dozen pages, including overall recommendations for approval/nonapproval and labeling. The secondary reviewer's recommendations regarding approval and labeling may differ from those of the primary reviewers, but the primary reviews are not revised on

*They often used doses of hydrochlorothiazide and triamterene up to 100 and 300 mg/day, respectively, and often used hydralazine (up to 200 mg/day) and α -methyldopa (up to 2 g/day) as the first add-ons.

[†] Similar considerations are prominent in other clinical areas in which the goal of treatment is to reduce the incidence of irreversible harm. In congestive heart failure, for example, patients in a typical placebo-controlled trial receive either (an ACE inhibitor and placebo) or (an ACE inhibitor and the test drug). Omission of ACE inhibitors would be impermissible, because ACE inhibitors reduce mortality in this condition.

Despite the use of ACE inhibitors, patients with congestive heart failure have high mortality compared with age-matched controls, so the possibility of additional clinical benefit from an additional drug is not far-fetched. In hypertension, on the other hand, it may be unrealistic to expect that a new drug will provide additional hard-endpoint benefit when it is added to a regimen that is already providing blood pressure control that is thought to be adequate.

this account. In this situation, the secondary reviewer will devote some of the review to discussion of the arguments that were raised by the primary reviewers.

Advisory Committee

At approximately this point in the review process, issues raised by the application may optionally be brought to a public meeting of the FDA's Cardio-Renal Advisory Committee. The Committee comprises 10 to 12 clinicians and statisticians, appointed for 4-year terms. In most years, the Committee will have three or four 2-day meetings, during which a total of 8 to 10 applications will be discussed. Sometimes the DCRDP turns to the Committee for help in reaching a difficult decision about a specific application, but Committee meetings are more often used to bring complex regulatory issues to public awareness, usually (not always) with initial reference to a pending application. At most meetings, the Committee ultimately discusses and votes on a series of formal questions posed to the Committee by the DCRDP. The decisions of the Committee are not binding upon the FDA, but it is unusual for the FDA to contravert strong recommendations from the Committee.

Tertiary and Quaternary Reviews

After the Committee meeting (if any), a tertiary review (usually just a few pages long) is written by the DCRDP Director. If the DCRDP Director disagrees with the secondary reviewer or the Advisory Committee, then his or her review will generally explain the disagreement.

With two other divisions, DCRDP is a component of the FDA's Office of Drug Evaluation I (ODE I). The FDA's decision authority about applications that come to DCRDP is held by ODE I, but this decision authority is often, on a case-by-case basis, delegated to DCRDP for applications (new formulations, new fixed-dose combinations, and so on) that do not involve new chemical substances. Applications for products containing new chemical substances are passed to ODE I for quaternary review.

Action Letters

The tertiary (or quaternary) review describes the FDA's decision as to whether or not the application is approvable, and an "Action Letter" is then sent to the sponsor of the application. An Action Letter describes the application as *Nonapprovable*, *Approvable*, or *Approved*.

A Nonapprovable letter must describe the deficiencies in the application that led to the FDA's negative conclusion. At the other extreme, an Approval letter is usually short and simple. Marketing of the product is not permitted until the issuance of an Approval letter.

The third type of Action Letter, the Approvable letter, was originally used for products that appeared to be safe and effective, but with respect to which there remained minor gaps in the chemistry description, unsettled portions of labeling, or other deficiencies that appeared to be straightforwardly reparable. The typical Approvable letter was then followed by no more than a few weeks of faxes and meetings before the predictable appearance of an Approval letter. More recently, apparently as a response to time constraints imposed upon the FDA by the Prescription Drug User Fee Act, Approvable letters have been less closely coupled to ultimate approval.

The total elapsed time from the DCRDP's receipt of the application to its issuance of the Action Letter averaged about 14 months in the late 1990s. The DCRDP declines to release any newer statistics, and such statistics would in any event be difficult to interpret, in view of recent changes in the use of Approvable letters.

Diuretics: Mechanisms of Action

Mark A. Knepper, Thomas Kleyman, Gerardo Gamba

INTRODUCTION

The regulation of blood pressure is achieved in part through the control of sodium chloride (NaCl) balance, which is largely dependent on regulation of NaCl excretion by the kidney.¹ Accordingly, many forms of blood pressure are associated with abnormalities in Na⁺ and Cl⁻ transport along the renal tubule.² Furthermore, an important staple in the treatment of hypertension has been diuretic agents, which work by directly inhibiting Na⁺ transporters and channels that mediate renal tubule Na⁺ reabsorption. This chapter reviews the mechanism of diuretic action, focusing on the molecular properties of the Na⁺ transporters and channels that they inhibit. We focus on diuretic agents that work by blocking transport and specifically do not discuss mineralocorticoid receptor antagonists, angiotensin II receptor antagonists, and blockers of adrenergic receptors, which work in part by increasing NaCl excretion but do so indirectly.

Fundamentally, there are three main groups of direct-acting diuretic agents (Figure 62–1): (1) “loop diuretics” such as furosemide or bumetanide, which block the type 2 Na⁺, K⁺-2Cl⁻ cotransporter (NKCC2) of the thick ascending limb of Henle (TAL); (2) thiazides and related diuretics, which block the Na⁺-Cl⁻ cotransporter (NCC) of the distal convoluted tubule (DCT); and (3) amiloride and its congeners, which block the epithelial sodium channel (ENaC) expressed in the connecting tubule and collecting duct (CD) portions of the renal tubule. The major portions of this chapter summarize the properties of these transporters and address the mechanisms involved in blockade of these transporters.

Figure 62–1 and Table 62–1 summarize the major renal tubule segments and the major renal tubule transporters expressed in them. A filtrate of blood plasma generated in the renal glomerulus is delivered sequentially to the proximal tubule, the loop of Henle, the distal convoluted tubule, the connecting tubule, and the collecting duct. Each segment reabsorbs a fraction of NaCl delivered to it. The collecting duct carries out the final adjustments in urinary composition and is the site of fine control of Na⁺ transport by aldosterone, angiotensin II, and vasopressin.

Renal tubules are epithelial structures that transport NaCl from their lumens to the interstitium and thereby back to the blood. As is true of all epithelial cells, renal tubule epithelial cells consist of two membrane domains (apical and basolateral) separated by a tight junction that connects each cell to its immediate neighbors. Transcellular transport of Na⁺ across an epithelium therefore requires transport across both the apical and basolateral plasma membranes. The basolateral transport pathway is the same for each renal tubule segment, namely the Na⁺, K⁺-ATPase, which trans-

ports three Na⁺ ions out of the cell and two K⁺ ions into the cell per adenosine triphosphate (ATP) γ -phosphate bond hydrolyzed.³ Na⁺,K⁺-ATPase consist of two subunits, a non-glycosylated α subunit and a chaperone-like β subunit, which is not directly involved in ion transport but is necessary for normal trafficking of the assembled complex to the plasma membrane.⁴ The Na⁺,K⁺-ATPase in the kidney tubule consists of $\alpha_1\beta_1$ complexes.⁵ Hypothetically, drugs that target the Na⁺, K⁺-ATPase such as the cardiac glycoside, ouabain, could serve as diuretics. However, the therapeutic ratio for such drugs is too low for them to be effective diuretics, and they exert toxic effects on the Na⁺, K⁺-ATPase isoform in the heart prior to any significant diuretic effect in the kidney.

The diuretic agents considered in this review increase Na⁺ excretion by blocking Na⁺ transporters in the apical plasma membrane of renal tubule cells. Their efficacy depends on the process of active transepithelial secretion of the drugs from blood to lumen in the late part of the proximal convoluted tubule and early part of the proximal straight tubule.⁶ Because this process concentrates the diuretics at their site of action, the renal tubule lumen, the therapeutic ratio for these agents tends to be very high. Although commonly used diuretics such as the loop diuretics, thiazides, and amiloride can inhibit Na⁺ transport at extrarenal sites, circulating levels necessary for effective inhibition of renal tubule transporters are usually too low to have extrarenal effects, owing to the proximal tubule secretory mechanism. However, acute or chronic renal failure can result in significant impairment of the proximal secretory mechanism, resulting in relative resistance to these diuretics.^{7,8} Under these circumstances, the clinician needs to increase diuretic doses to overcome this resistance, resulting in a greater likelihood of toxicity.

It is interesting that there are no effective diuretics that are targeted to transporters in the proximal tubule, the renal tubule segment that is responsible for two thirds of renal tubule Na⁺ reabsorption. A major reason for the lack of such agents has been revealed in studies of renal tubule function in mice in which the major proximal Na⁺ transporter NHE3 (sodium-hydrogen exchanger, type 3) has been deleted.⁹ These mice do not manifest high rates of salt and water excretion as might be expected. Instead, increased salt and water delivery to the macula densa results in activation of the tubuloglomerular feedback mechanism, which markedly lowers glomerular filtration rate. Therefore NaCl balance is maintained, despite a marked reduction in proximal NaCl absorption in these mice, through a marked decrease in glomerular filtration rate.

In the remainder of this chapter we focus on the properties of the apical Na⁺ transporters and channels that are targets for loop diuretics, thiazide diuretics, and amiloride.

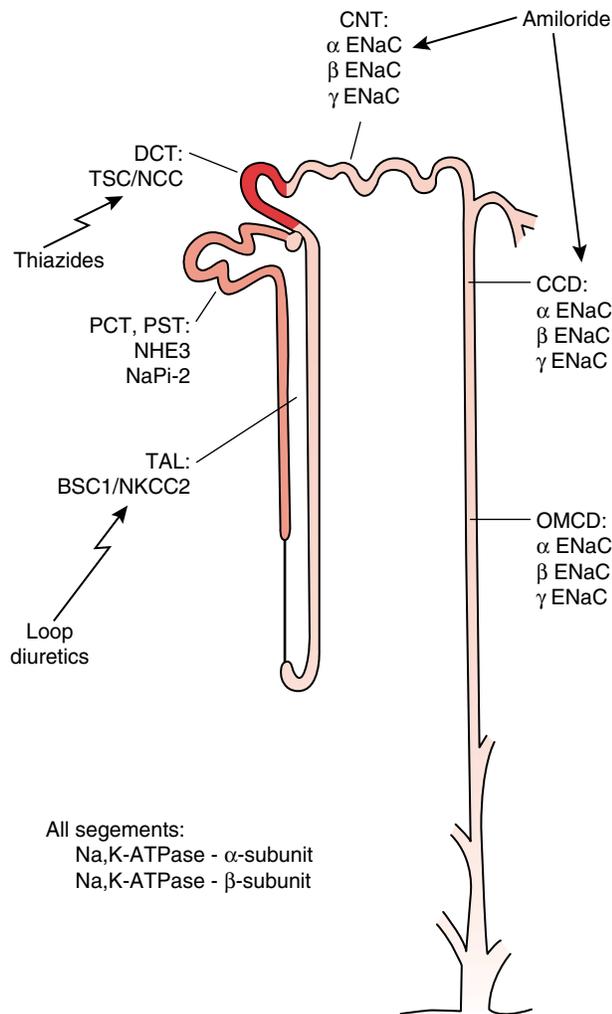

Figure 62-1 Diuretic targets along the renal tubule. The tubule segments and main transporters are depicted. Tubule segments are: PCT, proximal convoluted tubule; PST, proximal straight tubule; TAL, thick ascending limb of Henle’s loop; DCT, distal convoluted tubule; CNT, connecting tubule; CCD, cortical collecting duct; OMCD, outer medullary collecting duct.

LOOP DIURETICS

Transport Mechanisms in the Thick Ascending Limb of the Loop of Henle

The TAL is responsible for the reabsorption of about 15% to 20% of the NaCl in the glomerular filtrate. In addition, the TAL also plays important roles in divalent cation (Ca^{2+} and Mg^{2+}) and ammonium ion (NH_4^+) reabsorption. However, its chief role is regulation of water excretion through the dilution of luminal fluid and the concentration of the surrounding interstitium. Concentration of the interstitium is a result of a process called “countercurrent multiplication”¹⁰ and is critical to the generation of a final urine that is concentrated relative to plasma. This functional capacity is necessary for the survival of land mammals, including humans.

The molecular mechanism of salt reabsorption by TAL is shown in Figure 62-2. As in the rest of the nephron, in TAL the salt is transported from the luminal side to the interstitial space because of the polarized expression of the Na^+ , K^+ -ATPase (the “sodium pump”) to the basolateral membrane. This pump produces a continuous efflux of sodium ions into the interstitial space, reducing the intracellular sodium concentration, thus generating a gradient for sodium transport in which apical sodium is transported into the TAL cells. As shown in Figure 62-2, the major pathway for sodium reabsorption in the apical membrane of the TAL is the Na^+ , K^+ - 2Cl^- cotransporter. This is a secondary carrier that takes advantage of the gradient for Na^+ transport to translocate K^+ and Cl^- from the lumen into the TAL cells against their respective electrochemical gradients. This Na^+ , K^+ - 2Cl^- cotransporter is the main pharmacologic target of loop diuretics (furosemide, bumetanide, ethacrynic acid, torasemide, and piretanide). Loop diuretics exert their action by direct interaction with the Na^+ , K^+ - 2Cl^- cotransporter in the TAL.

As shown in Figure 62-2, salt reabsorption in the TAL requires the simultaneous function of at least six proteins produced by different genes. Salt enters the cell across the apical plasma membrane, together with K^+ , through the Na^+ , K^+ - 2Cl^- cotransporter. The sodium and chloride ions leave the cell in the basolateral membrane through the Na^+ , K^+ -ATPase and the Cl^- channels (CLC-Kb), respectively. The Na^+ , K^+ -ATPase is composed of two subunits: the α - and β -subunits that are

Table 62-1 Major Na Transporter and Na Channel Proteins in the Kidney

Name	Identification	Location*	No. Amino Acids	Actual MW (kDa) [§]
NHE3	Type 3 Na-H exchanger	PT, DL, TAL (apical)	831	84
NKCC2	Type 2 Na, K-2Cl cotransporter	TAL (apical)	1095	163

products of two different genes. The α -subunit is not glycosylated and plays a catalytic and transport role. In contrast, the β -subunit is glycosylated and is required for successful targeting of the Na^+, K^+ -ATPase complex to the plasma membrane. A similar situation occurs with CLC-Kb , since it is also composed of two subunits— CLC-Kb , the pore-forming subunit, and a protein known as *Barttin* that is required to drive CLC-Kb to the basolateral membrane.

Potassium ions entering the cell across the apical plasma membrane are largely returned to the tubular lumen via an inwardly rectifying K^+ channel known as the renal outer medullary potassium channel (ROMK). Potassium recycling into the lumen is required for NaCl reabsorption by the TAL. Because the potassium concentration in the glomerular ultrafiltrate (4 mEq/L) is much lower than that of sodium (145 mEq/L) or chloride (110 mEq/L), without the recycling pathway for potassium, the concentration of this cation in the lumen of the TAL would be rapidly reduced below the minimum required for transport. As a consequence, the function of the Na^+, K^+ - 2Cl^- cotransporter would stop because of depletion of K^+ from the lumen. The recycling, however, assures that potassium concentration within the TAL lumen will always be enough to allow the proper function of the Na^+, K^+ - 2Cl^- cotransporter. The potassium recycling, together with the movement of sodium and chloride to the interstitial space, generates a positive voltage within the TAL lumen that drives the reabsorption of a second cation through the paracellular pathway. Because the tight junctions are permeable to sodium, magnesium, and calcium, all three ions are reabsorbed at rates dependent on their luminal concentrations. Thus the coordinated function of the Na^+, K^+ - 2Cl^- cotransporter, the apical K^+ channels, and the basolateral Cl^- channels makes the TAL epithelial cells thermodynamically more efficient, since two cations are reabsorbed at the expense of the ATP needed to pump one.¹¹

The functional description of the molecular mechanisms for salt reabsorption in the TAL cells helps us to understand the mechanism by which loop diuretics exert their effects in the kidney. By blocking the function of the Na^+, K^+ - 2Cl^- cotransporter, loop diuretics reduce the salt reabsorption rate in the TAL. As a consequence, an increased amount of salt is delivered to the distal nephron, increasing the fractional excretion of salt into urine, thus producing natriuresis and diuresis. Increased delivery of NaCl to the macula densa would normally result in a compensating decrease in

glomerular filtration rate as a result of activation of the tubuloglomerular feedback (TGF) mechanism.¹² Such compensation does not occur when increased NaCl delivery is mediated by loop diuretics because the TGF mechanism is dependent on the function of the bumetanide-sensitive Na^+, K^+ - 2Cl^- cotransporter present in the macula densa cells. This cotransporter has been demonstrated to be same one (NKCC2) as that in the TAL cells.¹³

Greater delivery of NaCl to the connecting tubule and collecting duct results in greater Na^+ reabsorption by the principal cells in these segments, resulting in greater potassium secretion. In addition, the greater rate of sodium transport indirectly cause a greater rate of H^+ secretion by the intercalated cells of the connecting tubule and outer medullary collecting duct. For these reasons, one potential, undesired consequence of loop diuretic administration can be increased fractional excretion of potassium and hydrogen, resulting in hypokalemia and metabolic alkalosis.

Molecular Biology of the Apical Na^+, K^+ - 2Cl^- Cotransporter

Two genes encoding isoforms of the Na^+, K^+ - 2Cl^- cotransporters have been identified. They belong to the family of electroneutral cation-chloride coupled cotransporters, known in the human genome database as SLC12. SLC12A1 gene encodes the renal-specific Na^+, K^+ - 2Cl^- (NKCC2) that is exclusively expressed in the TAL of the kidney. This gene is located in human chromosome 15.¹⁴ SLC12A2 gene encodes the ubiquitous Na^+, K^+ - 2Cl^- cotransporter (NKCC1), which is expressed in several tissues and cell lines and is located on human chromosome 5.^{15,16} NKCC2 shares a basic structural topology with the members of the cation-chloride gene family. As shown in Figure 62-3, A, NKCC2 is a glycoprotein of 1095 amino acids with molecular weight of ~165 kDa featuring a central hydrophobic region containing 12 putative transmembrane domains that are flanked by amino and carboxyl-terminal hydrophilic domains, presumably located within the cell. The extracellular hydrophilic loop between putative transmembrane domains S7 and S8 contains two *N*-glycosylation motifs. Several putative protein kinase A (PKA) and protein kinase C (PKC) phosphorylation sites are present within the amino and carboxyl-terminal domains.

At least six isoforms of NKCC2 are expressed in the mouse kidney because of the combination of two alternative splicing mechanisms.¹⁷ As shown in Figure 62-3, on one hand, two isoforms are produced by truncation of the carboxyl-terminal domain. The longer isoform (Figure 62-3, A) is the 1095 amino acid residue protein, whereas the shorter isoform (Figure 62-3, B) is composed of 770 residues. Interestingly, the longer isoform is the Na^+, K^+ - 2Cl^- cotransporter, whereas the truncated isoform encodes a K^+ -independent but nevertheless furosemide-sensitive Na^+ - Cl^- cotransporter that is activated by hypotonicity and inhibited by cyclic adenosine monophosphate (cAMP) analogs.¹⁸ This truncated isoform seems to be important in salt reabsorption along TAL during water diuresis states. On the other hand, the SLC12A1 gene contains three 96 bp mutually exclusive cassette exons designated A, B, and F^{19,20} that encode for 32 amino acid residues that are part of the transmembrane domain 2 and the connecting segment between transmembrane domains 2 and 3 (see Figure 62-3). Thus this splicing mechanism produces three proteins that are identical,

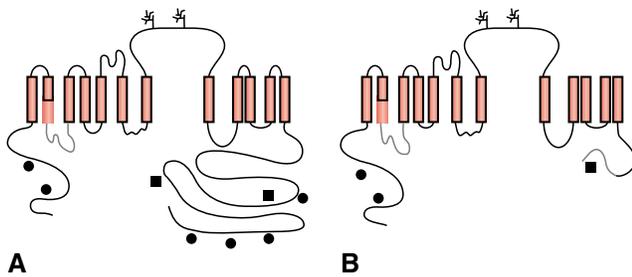

Figure 62-3 Proposed topology and splice variants of the mouse apical, renal-specific $\text{Na}^+, \text{K}^+-2\text{Cl}^-$ cotransporter. **A**, The long isoform that encodes the $\text{Na}^+, \text{K}^+-2\text{Cl}^-$ cotransporter. **B**, The short isoform that encodes the $\text{Na}^+, \text{K}^+-2\text{Cl}^-$ cotransporter contains 55 amino acid residues at the end of the C-terminal domain (highlighted in gray) that are not present in the longer isoform. The region of the transmembrane domain 2 and the interconnecting segment between transmembrane domains 2 and 3 that are highlighted in gray depict the region of the mutually exclusive cassette exons A, B, or F. In this region, both the long and the short isoform can be either A, B, or F. Two glycosylation sites are depicted in the extracellular loop between membrane segments 7 and 8 by two little evergreen bushes. The localization of the putative phosphorylation sites for protein kinase A or C are shown in circles or boxes, respectively.

except in the sequence of these 32 residues that comes from one of the three mutually exclusive exons. Because these two splicing mechanisms can be combined with the carboxyl-terminal domain splicing, six isoforms can be produced: three with long carboxyl-terminal domains (that can be A, B, or F in the second transmembrane domain) and three with short carboxyl-terminal domains (that can be A, B, or F).^{17,21}

The splicing event producing three long carboxyl-terminal domain isoforms named A, B, and F has remarkable effects in the TAL physiology. Early studies on isolated cortical or medullary TAL segments by Burg²² and by Rocha and Kokko²³ clearly showed that medullary TAL transports NaCl more rapidly than the cortical TAL, but the diluting power was greater in the cortical TAL.²⁴ These observations suggested heterogeneity of the transport properties along the TAL. Supporting this conclusion, a higher apparent affinity for Cl^- was observed in cortical than in medullary TALH.²⁵⁻²⁹ In this regard, the splicing isoforms A, B, and F exhibit axial distribu-

tion along the TAL (Figure 62-4). The F isoform is absent in the cortical but present in the medullary TAL, with higher expression in the inner stripe of the outer medulla. The A isoform is present in both cortical and medullary TAL, and the B isoform is present only in the cortical TAL.^{19,20,30} In agreement with this distribution, the affinity for the cotransported ions varies among the three isoforms. The affinity profile is: $B > A > F$.^{31,32} Thus, at the beginning of the TAL, where salt concentration is high, the main isoform is the F, exhibiting the lower affinity, while at the end of TAL, where further dilution is required, the main isoform is the B that exhibits the highest affinity. The A isoform is expressed along the entire TAL and is also the one with the highest capacity for ion transport.³¹ Thus, by producing three isoforms of the $\text{Na}^+, \text{K}^+-2\text{Cl}^-$ cotransporter, alternative splicing of the SLC12A1 gene underlies the heterogeneity of salt transport in the TAL.

Regulation of the $\text{Na}^+, \text{K}^+-2\text{Cl}^-$ Cotransporter

As discussed previously, the NaCl reabsorption in the TAL plays a central role in the regulation of water balance by driving concentrating and diluting processes. Consistent with this role, NaCl transport in this segment is regulated by the antidiuretic hormone vasopressin. As demonstrated in isolated perfused tubule studies, vasopressin has rapid actions to increase NaCl absorption by the TAL.^{33,34} The effect is mediated by cAMP and appears to involve trafficking of the $\text{Na}^+, \text{K}^+-2\text{Cl}^-$ cotransporter, NKCC2, from an intracellular vesicular pool to the apical plasma membrane.³⁵⁻³⁷ It may be dependent in part on phosphorylation of the transporter in the amino-terminal tail region.³⁵ In addition, the stimulatory effect of vasopressin on NKCC2 trafficking appears to be related to inhibition by cAMP of an inhibitory effect of the 770 amino acid short isoform of NKCC2 on trafficking of the full length isoform (vide supra).^{36,37} Other hormones, including parathyroid hormone, calcitonin, and glucagon also increase intracellular cAMP in the TAL cell³⁸ and stimulate concomitant increases in NaCl absorption rate,^{39,40} presumably by the same mechanism as demonstrated for vasopressin. Prostaglandin E2 has been demonstrated to have a short-term inhibitory effect on NaCl absorption in the TAL,⁴¹ presumably via its ability to inhibit cAMP production in TAL cells.⁴² Another mediator that regulates TAL NaCl transport via effects in NKCC2 is nitric oxide (NO), which directly inhibits NaCl absorption in isolated perfused TALs.⁴³

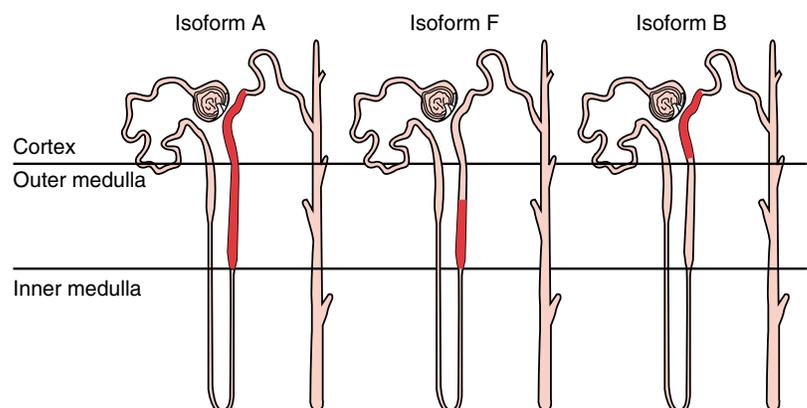

Figure 62-4 Distribution of the isoforms A, F, and B of the $\text{Na}^+, \text{K}^+-2\text{Cl}^-$ cotransporter along the TALH.

In addition to the short-term effect of vasopressin on NKCC2 trafficking or activity, long-term increases in circulating vasopressin levels have been demonstrated to increase the abundance of the NKCC2 protein in TAL cells.⁴⁴ This action results in a long-term potentiation of NaCl transport in the TAL, as demonstrated in isolated perfused tubule studies.⁴⁵

Paralleling the short-term inhibitory effect of prostaglandin E2 on NaCl transport in the TAL, long-term changes in prostaglandin E2 levels appear to modulate NKCC2 expression in the TAL.⁴⁶ In these studies, cyclooxygenase inhibitors indomethacin or diclofenac increased NKCC2 abundance, an effect that was reversed by administration of a prostaglandin E2 analog, misoprostol.

In addition to actions of agents that signal predominantly in the TAL via cAMP, regulatory mediators that signal via other mechanisms also regulate NKCC2 expression in the TAL. For example, NO, which increases cyclic guanosine monophosphate in cells, increases NKCC2 expression as evidenced by observed decreases in abundance in response to inhibition of nitric oxide synthases by *N*-nitro-L-arginine methyl ester (L-NAME).⁴⁷ Furthermore, angiotensin II infusion was also found to increase NKCC2 abundance in the TAL,⁴⁸ although inhibition of angiotensin II type 1 (AT₁) receptors by candesartan⁴⁹ or deletion of AT_{1a} receptors in mice⁵⁰ did not produce the opposite effects. Quite possibly the effect of angiotensin II infusion on NKCC2 expression is indirect and related to local changes in NO or PGE2 levels.

Potential Role of the Na⁺,K⁺-2Cl⁻ Cotransporter in Arterial Hypertension

Because of similarities of Bartter's syndrome to Gitelman syndrome, it was speculated that Bartter syndrome, an autosomal-recessive disorder, was due to reduction in the NaCl transport function of the TAL. Bartter's syndrome is characterized by hypokalemic metabolic alkalosis, with hypocalciuria and normomagnesemia,⁵¹ as well as renal salt wasting, polyuria, arterial hypotension, and nephrocalcinosis. Mutations in at least five genes result in Bartter's syndrome.⁵² Thus this is a monogenic but heterogeneous disease. In all cases, the function of the TAL is affected. Inactivating mutations in the genes encoding the proteins involved in salt reabsorption in TAL produce Bartter's syndrome types I, II, III, and IV. These are the Na⁺,K⁺-2Cl⁻ cotransporter,^{14,53-56} the apical K⁺ channel ROMK,⁵⁷⁻⁶³ the basolateral Cl⁻ channel CLC-Kb,^{64,65} and the chaperon subunit of the Cl⁻ channel known as Barttin,⁶⁶⁻⁶⁸ respectively. In addition, "gain of function" mutations of the calcium-sensing receptor also cause Bartter's syndrome.^{69,70} Activation of the calcium-sensing receptor that is expressed in the basolateral membrane of the TAL reduces the activity of the Na⁺,K⁺-2Cl⁻ cotransporter and the ROMK channels. Thus the participation of all these genes, including the Na⁺,K⁺-2Cl⁻ cotransporter, in the genesis of a syndrome that exhibits arterial hypotension shows that they are among the genes involved in defining the blood pressure levels and thus are potentially involved in hypertension.

Loop Diuretics in the Treatment of Hypertension

Loop diuretics can potentially be used for treatment of hypertension. Because loop diuretics reduce salt reabsorption in the

TAL, their potency as natriuretic agents is superior to thiazides or the K⁺-retaining diuretics. However, in terms of lowering the blood pressure, loop diuretics are less effective than thiazides. In addition, these diuretics have never been tested in outcome trials, and they must be dosed twice daily or more frequently. For all these reasons, loop diuretics, unlike thiazides, are unsatisfactory for the chronic treatment of hypertension and are not recommended for the treatment of stage 1 or stage 2 uncomplicated hypertension. Instead, loop diuretics are very useful to treat essential hypertension complicated by heart failure, edema and/or renal insufficiency. Thus the more common clinical settings in which loop diuretics are prescribed included edematous states caused by congestive heart failure, chronic renal failure, nephrotic syndrome, or chronic liver disease to induce natriuresis and diuresis.

THIAZIDE-TYPE DIURETICS

Transport Mechanisms in the Distal Convulated Tubule

The distal convoluted tubule (DCT) is a specialized segment of the nephron located between the TALH and the collecting duct in which 5% to 7% of the glomerular filtrate is reabsorbed. As is the TAL, the DCT is also involved in calcium excretion and in concentrating urine, in addition to regulating NaCl balance.⁷¹ The molecular mechanism of salt reabsorption in the DCT is shown in Figure 62–5. Similar to most of the renal epithelium, the sodium gradient from lumen to interstitium is generated and maintained by a very intense activity of the Na⁺,K⁺-ATPase that is polarized to the basolateral membrane.⁷² The DCT begins a few cells after the macula densa and is divided in two segments known as "early" and "late" segments.⁷³ Most studies in rat, mouse, rabbit, and human kidney agree that along the whole DCT, the major sodium reabsorption pathway in the apical membrane is the Na⁺-Cl⁻ cotransporter NCC. In the early DCT, this is the only Na⁺ transport pathway identified so far, whereas in late DCT, NCC expression overlaps with that of the ENaC, *vide infra*.^{71,73-77} As shown in Figure 62–5, the apical Na⁺-Cl⁻ cotransporter in the DCT is the major target for the thiazide-type diuretics (chlorthalidone, hydrochlorothiazide, bendroflumethiazide, and metolazone).^{71,78}

The thiazide-type diuretics were introduced into clinical medicine in 1957⁷⁹ and were followed by the more-potent loop diuretics (furosemide, bumetanide, and ethacrynic acid).

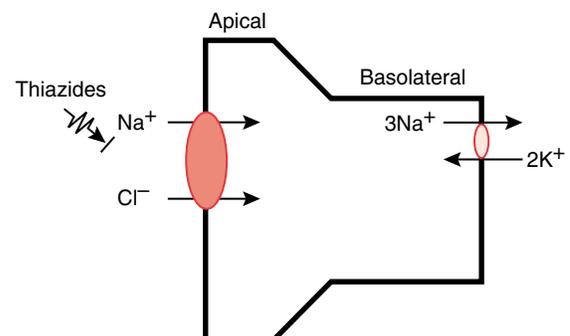

Figure 62–5 Molecular physiology of salt transport in the early distal convoluted tubule.

Several years later the first clue to the mechanism of action of thiazides was elucidated by Kunau et al.,⁸⁰ who demonstrated that thiazides inhibited Cl^- reabsorption in the distal nephron and not in the proximal tubule as was originally proposed. Then Stokes et al.⁸¹ showed for the first time that thiazides inhibited a Na^+ - Cl^- cotransporter. These authors used a urinary bladder preparation from the winter flounder.^{82,83} With this preparation, Stokes et al.⁸¹ unequivocally showed that thiazides competitively inhibited the salt reabsorption by blocking the function of the apical Na^+ - Cl^- cotransporter. A few years later, Ellison et al.,⁷¹ using in vivo microperfusion, finally defined the existence of a thiazide-sensitive Na^+ - Cl^- cotransporter as the major pathway for salt reabsorption in the DCT. It was later observed that tracer [^3H]metolazone was able to bind with high affinity to membrane preparations from rat renal cortex.^{84,85} These studies showed that both Na^+ and Cl^- needed to be present for binding of [^3H]metolazone to renal cortex. It was observed that cations stimulated the binding of tracer metolazone following a saturation curve compatible with Michaelis-Menten behavior, whereas Cl^- produced a biphasic effect: At low Cl^- concentration, the binding was stimulated, whereas at higher concentration, it was inhibited. Following these observations, it was proposed that to block the function of the cotransporter, the thiazides probably compete with Cl^- for the same binding site on the cotransporters.⁸⁵ However, careful analysis of the functional properties of the rat cotransporter has recently revealed that thiazides compete with both Na^+ and Cl^- .⁸⁶

In the DCT, salt and Ca^{2+} reabsorption rates are reciprocally related. Blocking or reducing the activity of the Na^+ - Cl^- cotransporter increases Ca^{2+} reabsorption, while increased expression or activity of the Na^+ - Cl^- cotransporter reduces Ca^{2+} reabsorption.⁸⁷ The mechanism by which thiazide diuretics affects calcium reabsorption is still unclear, but most evidence suggests that thiazide action and calcium reabsorption may be functionally linked through an indirect mechanism. Thiazides reduce NaCl entry at the apical membrane, but intracellular Na^+ is continuously pumped out of the cell by the Na^+ , K^+ -ATPase at the basolateral membrane. Thus intracellular Na^+ concentration is reduced, and as a consequence, DCT cells become hyperpolarized, increasing the electrochemical driving force for Ca^{2+} entry at the apical membrane through Ca^{2+} channels.⁸⁸ This secondary effect of thiazides on Ca^{2+} reabsorption constitutes the basis for their use in the treatment of calcium stone disease and may also explain the protective effect of thiazides in osteoporosis.^{89,90}

Molecular Biology of the Apical Na^+ - Cl^- Cotransporter

With a functional expression strategy in *Xenopus laevis* oocytes, the first electroneutral Na^+ -coupled Cl^- cotransporter to be identified at the molecular level was the thiazide-sensitive Na^+ - Cl^- cotransporter (NCC) from the winter flounder urinary bladder.⁹¹ Then, with a cRNA probe constructed from the fish cDNA, the mammalian cDNA encoding the NCC was isolated by homology.⁷⁸ The functional expression of fish and mammalian NCC in *Xenopus* oocytes gives rise to a $^{22}\text{Na}^+$ transport uptake mechanism that is Cl^- dependent and inhibitable by thiazide-type diuretics, with an inhibition profile (polythiazide > metolazone > hydrochlorothiazide > chlorothiazide) similar to the clinical potency of thiazides and to that previously shown

for inhibition of Cl^- -dependent Na^+ absorption,⁹² as well as the thiazide competition for the high-affinity [^3H]metolazone binding sites on kidney cortical membranes.⁸⁴

NCCs share a similar secondary topology with the other members of the Na^+ -coupled Cl^- cotransporter family, as deduced from the hydrophobicity analysis following the Kyte-Doolittle algorithm.⁹³ The human NCC is a glycoprotein of 1022 amino acid residues, with core molecular weight of ~120 kDa, that shows the basic structure of 12 putative transmembrane domains flanked by two hydrophilic amino- and carboxyl-terminal domains containing several putative PKC and PKA phosphorylation sites (Figure 62–6). Mutation analysis of rat NCC has shown that there are two N-linked glycosylation sites in the loop between S7 and S8 that are absolutely required for the protein to be functional.⁹⁴ The protein is extensively glycosylated, increasing its molecular weight to 163 kDa as measured by immunoblotting studies.⁹⁵

Eight members of the cation-coupled Cl^- cotransporter gene family have been identified from vertebrate sources. A phylogenetic tree depicting the relationship between members in this family is shown in Figure 62–7. Two genes encode the NKCC1 and NKCC2 Na^+ , K^+ -2 Cl^- cotransporters,^{78,96} one gene encodes NCC⁹¹ (see later), and there are four genes encoding isoforms of the K^+ - Cl^- cotransporters: Three are ubiquitously expressed (KCC1, KCC3, and KCC4),⁹⁷ and another gene exhibits brain-specific expression (KCC2).⁹⁸ In addition, one gene encodes a member of the family known as CIP (cotransporter interacting protein) for which the function is still unknown.^{99,100} As Figure 62–7 shows, two branches are clearly separated. One includes the Na^+ -coupled Cl^- cotransporters NKCC1, NKCC2, and NCC, whereas the other includes the Na^+ -independent, K^+ -coupled Cl^- cotransporters KCC1 to KCC4. Homology between the Na^+ -coupled Cl^- cotransporters and the K^+ -coupled Cl^- cotransporters is ~20%. The degree of identity between NKCC1, NKCC2, and NCC is more than 50%. The strongest homology is observed in the transmembrane domains but is also evident in the interconnecting loops as well as in the C-terminal domain.

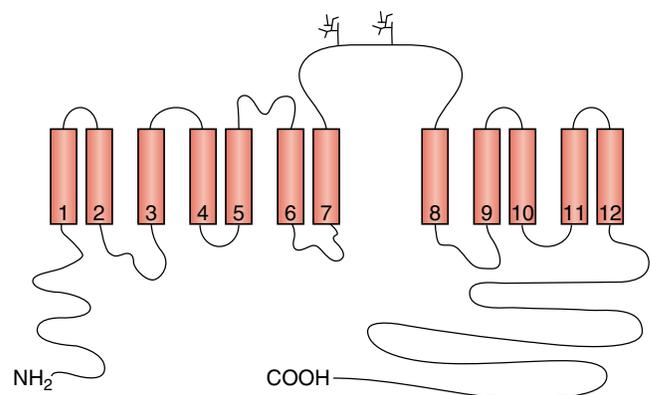

Figure 62–6 Proposed topology of the distal convoluted tubule thiazide-sensitive Na^+ - Cl^- cotransporter. The central hydrophobic domain features 12 membrane spanning domains shown by numbers. Two glycosylation sites are shown in the putative extracellular loop between membrane domains 7 and 8 as two little evergreen bushes.

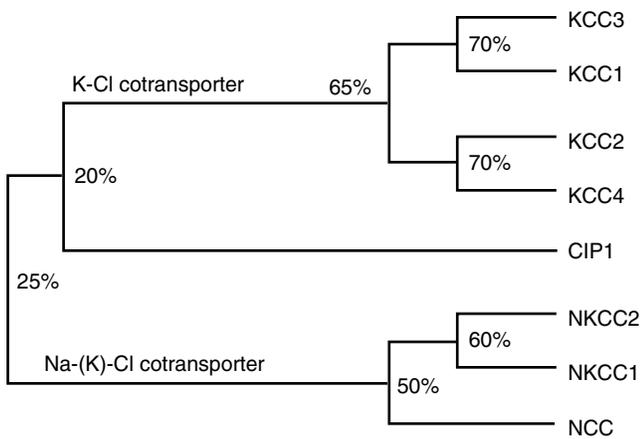

Figure 62-7 Phylogenetic tree of the electroneutral Na-coupled chloride cotransporter family SLC12.

Regulation of the Na⁺-Cl⁻ Cotransporter

With the advent of high-quality polyclonal antibodies to all the major Na⁺ transporters expressed along the renal tubule, profiling techniques have been used to investigate the pattern of Na⁺ transporter abundance changes under different physiologic and pathophysiologic circumstances (for review see references 101-103). These studies have been coupled with other approaches to show that NCC expression is highly regulated by multiple factors that are known to modulate the renal excretion of sodium and hence the arterial blood pressure. Such studies have revealed that an important regulator of NCC is the mineralocorticoid aldosterone.

Early micropuncture studies in adrenalectomized rats showed an increase in sodium tubule fluid:plasma concentration ratio in the DCT¹⁰⁴ that was decreased to control levels by aldosterone. In addition, *in vivo* micropuncture investigations have shown that aldosterone increases thiazide-sensitive salt transport in the DCT.¹⁰⁵ Aldosterone has been shown to increase [³H]metolazone binding in membrane fractions from renal cortex, a measure of NCC abundance,¹⁰⁶ and by immunoblotting with specific anti-NCC antibodies, it has been demonstrated that elevated plasma aldosterone concentration is associated with increase in the NCC abundance in renal cortex, regardless of whether plasma aldosterone is increased by aldosterone infusion⁹⁵ or dietary-sodium restriction.¹⁰⁷ The increment in NCC abundance in response to dietary-salt restriction is significantly higher than the increase observed in the subunits of the amiloride-sensitive Na⁺ channel.^{107,108} It has been shown that infusions of aldosterone in dexamethasone-replaced adrenalectomized rats clearly increase NCC abundance in renal cortex and that this increment is prevented by spironolactone.¹⁰⁹ Additionally, it has been demonstrated that the furosemide-induced increase in NCC expression can be abrogated with spironolactone.¹¹⁰ These findings suggest that aldosterone regulation of NCC protein is mediated through the classical mineralocorticoid receptor. Interestingly, however, existing evidence indicates that NCC regulation by mineralocorticoids must be indirect (i.e., unrelated to NCC gene transcription), because there has been a consistent failure to detect changes in NCC mRNA levels in response to dietary-salt restriction^{111,112} or furosemide administration.^{110,111} Indeed, a study in which NCC mRNA

and protein levels were assessed simultaneously showed that the increase in NCC protein induced by dietary NaCl restriction was not associated with detectable changes in NCC mRNA levels.¹⁰⁸

In addition to regulation by aldosterone, the abundance of NCC protein in kidney is regulated in several conditions in which aldosterone levels are not affected, indicating that NCC is a target for other hormones and regulators. NCC abundance is moderately increased by vasopressin administration (DDAVP).¹¹³ Furthermore, when the kidney undergoes escape from vasopressin-induced water retention after the development of hyponatremia, NCC abundance is more markedly increased.¹¹⁴ The authors proposed that this increase in NCC abundance in response to water retention may be associated with inappropriate secretion of antidiuretic hormone.

Despite the positive regulation by aldosterone, NCC is the only transport protein that is decreased during the aldosterone escape phenomenon,¹¹⁵ suggesting that NCC is one of the principal targets of pressure natriuresis. A similar conclusion has been drawn by Majid and Navar based on measurements of pressure natriuresis in intact dogs.¹¹⁶ NCC abundance is also increased in hyperinsulinemic conditions such as obesity,¹¹⁷ streptozotocin administration,¹¹⁸ or insulin infusions,¹¹⁹ suggesting that increased sodium reabsorption by NCC could be implicated in the development of hypertension in these conditions (see following).

NCC is positively regulated by estradiol¹²⁰ and by the acid-base status¹²¹: Metabolic acidosis induces a decrease in NCC abundance, whereas metabolic alkalosis increases it. Potassium depletion reduces expression of NCCs by a mechanism not related to aldosterone because a decrease in NCC mRNA levels is involved.¹²² Finally, NCC protein expression is up-regulated in an animal model of prenatally programmed hypertension¹²³ and down-regulated in animal models of chronic liver disease¹²⁴ and chronic renal failure,¹²⁵ suggesting that NCC is implicated in the development of hypertension and the urinary abnormalities observed in these syndromes. Therefore, regulation of NCC expression appears to be an important cog in the overall mechanism by which the kidney regulates sodium excretion.

Potential Role of NCC in Arterial Hypertension

Given the important physiologic role for the Na⁺-Cl⁻ cotransporters in the kidney, it was expected that mutations in these genes would play a role in human pathophysiology. Because of the resemblance between the inherited hypokalemic metabolic alkalosis syndromes and the clinical and metabolic picture of chronic diuretic intoxication, the NCC (gene SLC12A3) was a strong candidate gene for such a disease. More than 80 different mutations along the human SLC12A3 gene have been found to be present in patients with Gitelman's syndrome,¹²⁶⁻¹²⁸ and all Gitelman's patients that have been genotyped have mutations in the SLC12A3 gene, suggesting that no other genes are involved in Gitelman's syndrome. The complete linkage that was observed between Gitelman's syndrome and the locus for NCC, located in human chromosome 16, strongly suggested that inactivating mutations of this gene were associated with Gitelman's disease.^{126,127,129} Subsequently, a phenotype resembling Gitelman's syndrome was obtained in mice by targeted disruption of the NCC gene,¹³⁰ and

heterologous expression in *Xenopus laevis* oocytes of mouse NCC cRNA containing some of the point mutations reported in Gitelman's kindreds revealed that the resulting NCC proteins are nonfunctional.^{131,132} Thus, inactivating mutations of NCC are the cause of Gitelman's syndrome. One of the major features of this disease is the reduction in the arterial blood pressure. The study of 199 members of a single large family with Gitelman's syndrome, containing 60 subjects with both alleles normal, 113 with mutation in one allele, and 26 with mutations in both alleles, revealed that Gitelman's patients (those having both alleles mutated) develop arterial hypotension, while heterozygous subjects, those with one normal and one mutated allele, do not exhibit a significant decrease in arterial blood pressure. However, urinary $\text{Na}^+:\text{Cr}$ ratio was significantly higher in homozygous and heterozygous persons, as compared with normal subjects, indicating that a compensatory increase in dietary sodium uptake corrected arterial hypotension in heterozygous subjects.¹³³

NCC is implicated in the pathophysiology of a salt-dependent hypertension syndrome known as *pseudohypoaldosteronism type II* (PHAII) or *Gordon's syndrome*. PHAII is an autosomal-dominant disease caused by mutations in the gene encoding a particular serine/threonine kinase named WNK4.¹³⁴ PHAII is a mirror image of Gitelman's syndrome because PHAII patients develop arterial hypertension accompanied by hyperkalemic metabolic acidosis. Mayan et al.¹³⁵ have shown that the PHA syndrome is particularly sensitive to treatment with thiazide diuretics, because the reduction of mean arterial pressure in response to only 20 mg of hydrochlorothiazide in patients with PHAII is 6 to 7 times greater than in patients with essential hypertension. Thus NCC was proposed as a candidate gene for PHAII, but no linkage was observed between the presence of the disease and the NCC locus in PHAII kindreds.¹³⁶ However, it has been shown by two independent groups that one function of wild-type WNK4 is to inhibit activity of the Na-Cl cotransporter NCC via reduced cell surface expression of the cotransporter^{137,138} and that WNK4-bearing PHAII-type mutations lose the ability to inhibit NCC expression. These observations suggest that loss of WNK4 negative regulation of NCC activity is at least one of the mechanisms for increasing arterial blood pressure in PHAII patients because of an increased reabsorption of salt in the distal nephron.¹³⁹ Thus, by regulating the extracellular fluid volume, NCC is important for the regulation of arterial blood pressure and therefore is a candidate gene in the genesis of essential arterial hypertension.

Thiazide-Type Diuretics in the Treatment of Hypertension

In 1957, Frederick C. Novello and James M. Sprague synthesized chlorothiazide, the first benzothiadiazine that exhibited a strong diuretic effect and was clinically useful,⁷⁹ a major breakthrough in the treatment of hypertension. Almost 50 years after the discovery of thiazide diuretics, these compounds are still considered by many clinicians as the first-line drug in the treatment of hypertension. According to the recommendation of the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7),¹⁴⁰ thiazide diuretics should be used as the initial drug therapy for most hypertensive patients, either alone or in combination with other antihypertensive agents. Thiazide-type diuretics have been investigated in controlled

clinical trials of antihypertensive therapy. In most of these trials, including the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), thiazides have been superior to other antihypertensive drugs in preventing at least some of the cardiovascular complications of hypertension.¹⁴¹ Thus, according to JNC 7, thiazides are the recommended drug for initial therapy in most patients with stage 1 hypertension (systolic blood pressure between class 140 and 159 mm Hg and/or diastolic blood pressure between 90 and 99 mm Hg),¹⁴⁰ although the report makes clear that angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, β -blockers, or calcium channel blockers can be considered as acceptable alternatives. In addition, JNC 7 recommendations are that thiazide diuretics should also be included when combination therapy is in order. In patients with stage 2 hypertension (systolic blood pressure >160 mm Hg and/or diastolic blood pressure >100 mm Hg) a two-drug combination is recommended, usually a thiazide-type diuretic plus an ACE inhibitor, an angiotensin receptor blocker, a β -blocker, or a calcium channel blocker. Interestingly, despite the fact that JNC VI and 7 recommend thiazide-type diuretics as first-line therapy for hypertension, they appear to be underutilized.¹⁴²

AMILORIDE CONGENERS

Transport Mechanisms in the Collecting Duct

ENaCs are expressed in apical plasma membranes of principal cells in the distal nephron (Figure 62–8), extending from the late distal convoluted tubule through the inner medullary collecting duct. These channels are the major pathway that mediates reabsorptive Na^+ transport across epithelial cell layers in conjunction with a basolateral Na^+,K^+ -ATPase and are selectively inhibited by submicromolar concentrations of the diuretic amiloride. Epithelial Na^+ channels have a key role in the regulation of urinary Na^+ reabsorption, extracellular fluid volume homeostasis, and control of blood pressure and are a major site of action of key volume regulatory hormones such as aldosterone.¹⁴³

Cloning and Characteristics of ENaC

The epithelial Na^+ channel is composed of three structurally related subunits—termed α -, β -, and γ -ENaC—that share limited sequence identity.¹⁴⁴ These channels have a tetrameric

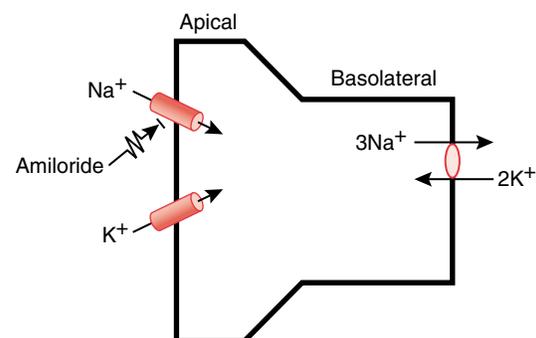

Figure 62–8 Molecular physiology of sodium reabsorption in the principal cells of the collecting duct.

structure consisting of two α -, two β -, and one γ -subunit that surround a central pore.¹⁴⁵ The α -subunits are on opposite sides of the pore, separated by β - and γ -subunits.¹⁴⁶ Figure 62–9 depicts a linear representation of the three subunits. They are polypeptides of 641 to 670 amino acid residues with molecular weight between 72 and 76 kDa. Each subunit has two membrane-spanning domains separated by a large extracellular domain and intracellular amino- and carboxyl-termini.^{147,148} The extracellular loops are highly glycosylated, increasing the molecular weight of each subunit, and possess several cysteine-rich regions that are conserved in all members of the ENaC family, suggesting that disulfide bridges among isoforms could play an important role in the tertiary structure of the protein. The channel pore is formed by the regions immediately preceding and extending through the second membrane-spanning domain. Sites that restrict K^+ permeation through the channel and sites where amiloride interacts with the channel are found within the area just preceding the second membrane-spanning domain.^{149,150}

ENaCs are members of a growing gene superfamily.¹⁵¹ Members include genes identified in *Caenorhabditis elegans* based on mutations that result in mechanosensation defects (*mecs*) or neuronal degeneration (*degs*), H^+ -gated channels (referred to as ASIC) that have a role in nociception, a peptide-gated channel cloned from the marine snail *Helix aspers*, and a family of ion channels found in the fruit fly *Drosophila melanogaster*.

Regulation of Na^+ Channels

ENaC activity is regulated by several hormones that modulate extracellular volume and blood pressure, including aldosterone, arginine vasopressin, insulin, angiotensin II (via AT_1 receptors in the collecting duct), and endothelin. ENaC activity is also regulated by a variety of factors within the urinary space. For example, serine proteases, such as prostaticin, are secreted into the tubular lumen and activate Na^+ channels, presumably by cleaving Na^+ channel subunits.^{152–154} Urinary acidification and mechanical forces, such as shear stress associated with increases in rates of tubular flow, activate ENaC.¹⁵⁵

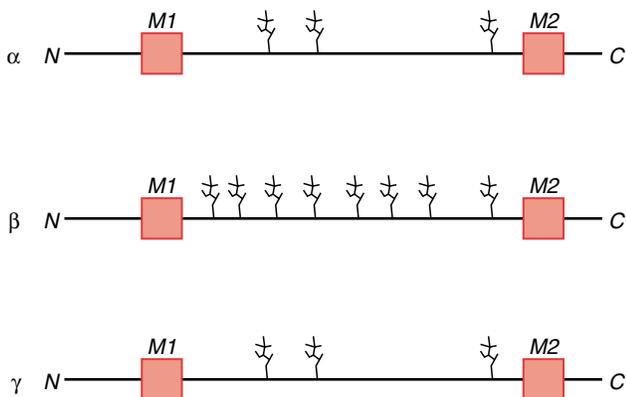

Figure 62–9 Linear representation of the proposed topology of the epithelial sodium channel α -, β -, and γ -subunits. The boxes in black marked as M1 or M2 are the transmembrane helices. The extracellular loop located between M1 and M2 contains several glycosylation sites (depicted as little evergreen bushes).

Figure 62–10 illustrates the regulation of ENaC surface expression in the apical membrane of collecting duct cells. The C-termini of ENaC subunits have a proline-rich protein interaction module, referred to as a “PY” domain. Nedd4 (neural precursor cells expressed developmentally down-regulated) is a ubiquitin ligase that contains multiple “WW” domains¹⁵⁶ that are protein interaction modules that recognize and bind PY domains. WW domains are made up of 35 to 40 amino acid residues containing two conserved tryptophan (W) residues that are spaced 20 to 22 amino acid residues apart. Nedd4 binds to ENaC β - and γ -subunits through WW-PY interactions and facilitates the transfer of ubiquitin to the ENaC subunits. Channel ubiquitination serves as a signal for internalization of channels from the plasma membrane and degradation.^{157,158} Mutations described in patients with Liddle’s syndrome result in deletions of or mutations within the PY domain that disrupt the binding of Nedd4 to ENaC and subsequent channel ubiquitination. Na^+ channels with Liddle’s syndrome mutations reside at the plasma membrane for a significantly longer time than wild-type channels, leading to enhanced Na^+ reabsorption by the collecting duct. A number of Nedd4 isoforms have been described, and the role of specific Nedd4 isoforms in the regulation of ENaC is presently being explored.

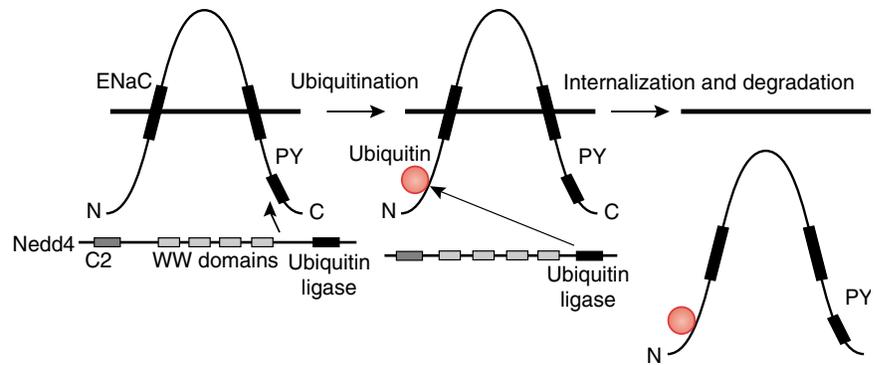

A number of studies have provided new insights regarding mechanisms by which aldosterone regulates epithelial Na^+ channels. Aldosterone increases the expression of the α -subunit of ENaC in specific renal tubular segments, as well as expression of channels at the luminal membrane.^{107,159} A growing number of aldosterone-regulated genes have been identified. The serum- and glucocorticoid-regulated kinase (sgk) is an aldosterone-induced protein that, when co-expressed with ENaC, results in an increase in surface expression of Na^+ channels.¹⁶⁰ Sgk has a PY motif and binds the protein Nedd4. Subsequent sgk-mediated phosphorylation of Nedd4 prevents the interaction of Nedd4 with ENaC and reduces Nedd4-mediated ubiquitination and internalization of ENaC.^{161,162}

Liddle’s Syndrome and Pseudohypoaldosteronism Type I

Na^+ channel gain-of-function mutations have been identified in patients with Liddle’s syndrome, a rare disorder characterized by volume expansion, hypokalemia, and hypertension. Patients with this disorder have mutations in genes encoding ENaC β - or γ -subunits that result in either truncations of the intracellular carboxyl-termini or amino acid substitutions within the PY motifs of the β - or γ -subunits.^{143,163,165} As discussed previously, these mutations are thought to disrupt the binding of Nedd4 to ENaC and prevent Nedd4-dependent inhibition of channel expression. Furthermore, certain common human epithelial Na^+ channel polymorphisms segregate with blood pressure (i.e., $\beta T594M$), suggesting that these polymorphisms are associated with altered activity of the channel.¹⁶⁶ Rare mutations of the mineralocorticoid receptor that result in receptor activation by progesterone have been associated with early-onset hypertension that is exacerbated by pregnancy.¹⁶⁷ Specific disorders of mineralocorticoid and glucocorticoid metabolism are also associated with hypertension and are reviewed in Chapter 75.

Na^+ channel loss-of-function mutations have been identified in patients with an autosomal-recessive variant of type 1

Figure 62-10 Regulation of ENaC surface expression by Nedd4. (Adapted from Snyder PM.¹⁸⁸)

pseudohypoaldosteronism, a disorder characterized by volume depletion, hypotension, and hyperkalemia.¹⁶⁸ Mutations in the mineralocorticoid receptor have been reported in patients with an autosomal-dominant variant of type 1 pseudohypoaldosteronism, a relatively mild form of pseudohypoaldosteronism that tends to remit with age.¹⁶⁹

Amiloride Congeners

Amiloride was discovered during a search for diuretics that could prevent the kaliuresis that was observed with thiazide and loop diuretics.¹⁷⁰ Amiloride induces a mild natriuresis following oral administration while exerting an antikaliuretic effect. Both the natriuresis and antikaliuretic effects are due to inhibition of the epithelial Na⁺ channel.¹⁷¹ In the late distal convoluted tubule through the cortical collecting duct, Na⁺ reabsorption via epithelial Na⁺ channels is tightly coupled to K⁺ secretion that is mediated by apical membrane K⁺ channels. Activation of Na⁺ channels enhances K⁺ secretion, whereas inhibition of Na⁺ channels is associated with an inhibition of K⁺ secretion. The major apical membrane K⁺ channel in the distal nephron is a member of the family of inwardly rectifying K⁺ channels referred to as *Kir1.1* or *ROMK*.¹⁷² Other K⁺ channels, including a large conductance Ca²⁺-activated K⁺ channel, commonly referred to as *maxi K⁺*, also participate in renal K⁺ secretion in the collecting duct.^{173,174}

Increased tubular flow rates in the collecting duct occur with administration of thiazide or loop diuretics. As mentioned previously, increased tubular flow rates in collecting ducts activate epithelial Na⁺ channels and enhance rates of Na⁺ reabsorption. Furthermore, an increase in tubular flow rates in collecting ducts activates maxi K⁺ channels. Thus the kaliuresis observed with thiazide and loop diuretics reflects both flow-dependent activation of epithelial Na⁺ channels and maxi K⁺ channels in cortical collecting ducts.

Amiloride is a substituted pyrazinolyguanidine, and it is the charged, or protonated, form of amiloride that blocks the Na⁺ channel. The pKa of amiloride is 8.8 in water, and amiloride is largely protonated in the distal nephron where urinary acidification occurs.¹⁷⁵ Other organic cations, including triamterene and trimethoprim, inhibit Na⁺ channels and function as K⁺-sparing diuretics.^{176,177} These organic cations apparently block the channel's pore, and residues that likely participate in amiloride binding have been localized to a region immediately preceding the channel's selectivity filter.¹⁷⁸ Mineralocorticoid antagonists, such as spironolactone and eplerenone, are also K⁺-sparing diuretics. Spironolactone is

often used in the clinical setting of cirrhosis and extracellular fluid volume expansion. Administration of spironolactone in the setting of severe congestive heart failure has been associated with a reduction in mortality.¹⁷⁹ However, side effects associated with administration of spironolactone, including gynecomastia, limit its clinical use. Eplerenone represents a member of a new class of selective mineralocorticoid receptor antagonists that may provide physicians with an alternative to spironolactone that is better tolerated.¹⁸⁰ A recent publication from the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) indicated that administration of eplerenone to patients following myocardial infarction complicated by heart failure was associated with a reduction in mortality and morbidity.¹⁸¹ Eplerenone was extremely well tolerated in the EPHESUS trial.

Amiloride in the Treatment of Hypertension

Diuretics are used in the treatment of hypertension and edematous states, including congestive heart failure and cirrhosis. Amiloride has been used alone as a diuretic in the treatment of these disorders, although more-potent diuretics that affect different sites in the nephron, including thiazides and loop diuretics, are more frequently used in this setting. Both thiazide and loop diuretics induce kaliuresis, and amiloride is most often administered to prevent kaliuresis, because hypokalemia may lead to further elevations in blood pressure in patients with hypertension.^{182,183} In addition, hypokalemia is also associated with insulin resistance, diabetes, arrhythmias, and sudden death.¹⁸⁴⁻¹⁸⁶ Amiloride may be used to prevent hypokalemia and hypertension associated with elevated circulating levels of glucocorticoids or mineralocorticoids and in patients with inherited disorders associated with Na⁺ channel activation such as Liddle's syndrome. Amiloride also exerts Mg²⁺-sparing effects and the combined use of amiloride and loop diuretics, such as furosemide, may prevent diuretic-induced Mg²⁺ wasting.¹⁸⁷ The major side effect associated with administration of amiloride and other K⁺-sparing diuretics is hyperkalemia. Although approximately 10% of patients receiving amiloride in the absence of a kaliuretic diuretic may develop hyperkalemia, defined as a serum K⁺ concentration of greater than 5.5 mEq/L, the incidence of hyperkalemia decreases to a few percent when amiloride is administered with a thiazide diuretic. The incidence of hyperkalemia in patients receiving K⁺-sparing diuretics increases in patients receiving β -adrenergic blockers or ACE inhibitors. In

addition, the incidence of hyperkalemia is increased in patients with renal insufficiency, diabetes mellitus, metabolic or respiratory acidosis, and in the elderly. The use of K⁺-sparing diuretics is also associated with an increase in urinary pH and decrease in serum bicarbonate concentration, which reflects a decrease in proton secretion in the distal nephron.

β -Adrenergic Blockers

William H. Frishman

The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) from the National High Blood Pressure Education Program of the National Heart Lung and Blood Institute has reiterated the recommendation of JNC III thru VI that β -adrenergic blockers are appropriate alternatives as first-line treatment for hypertension.¹ These recommendations are based on the reduction of patient morbidity and mortality when these drugs are used in large clinical trials. Although there is no consensus as to the mechanisms by which β -blocking drugs lower blood pressure (BP), it is probable that some or all of the modes of action referred to in Box 63–1 are involved.²

Thirteen orally active β -adrenergic blockers are approved in the United States for the treatment of hypertension (Table 63–1). In addition, intravenous labetalol is approved for the management of hypertensive emergencies. Oral bisoprolol in combination with a very-low-dose diuretic is available as a first-line antihypertensive treatment, the first such β -blocker combination so approved for the treatment of hypertension.³ The various β -blocking agents differ in terms of the presence or absence of intrinsic sympathomimetic activity (ISA), membrane-stabilizing activity (MSA), β_1 -selectivity, α -adrenergic blocking activity, and relative potencies and durations of action. Nevertheless, all β -blockers studied to date appear to have favorable BP-lowering effects when used in appropriate dosages.^{4,5}

PHARMACODYNAMIC PROPERTIES

Membrane-Stabilizing Activity

At concentrations well above therapeutic levels, certain β -blockers have a quinidine-like or local anesthetic membrane-stabilizing effect on the cardiac action potential. There is no evidence that MSA is responsible for any direct negative inotropic effect of the β -blockers, because drugs with and without this property can depress left ventricular function. However, MSA can manifest itself clinically with massive β -blocker intoxications.^{2,4}

β_1 -Selectivity

When used in low doses, β_1 -selective blocking agents such as acebutolol, betaxolol, bisoprolol, esmolol, atenolol, and metoprolol inhibit cardiac β_2 -receptors but have less influence on bronchial and vascular β -adrenergic receptors (β_2). In higher doses, however, β_1 -selective blocking agents also block β_2 receptors. Accordingly, β_1 -selective agents may be safer than nonselective ones in patients with obstructive pulmonary disease, because β_2 receptors remain available to mediate adrenergic bronchodilation. However, even selective β -blockers may

aggravate bronchospasm in certain patients, and so these drugs should generally not be used in patients with bronchospastic disease.^{2,4}

A second theoretical advantage is that unlike nonselective β -blockers, β_1 -selective blockers in low doses may not block the β_2 receptors that mediate dilation of arterioles. It is possible that leaving the β_2 receptors unblocked and responsive to epinephrine may be functionally important in some patients with asthma, hypoglycemia, hypertension, or peripheral vascular disease treated with β -adrenergic blocking drugs.^{2,4}

Intrinsic Sympathomimetic Activity or Partial Agonist Activity

Certain β -adrenergic receptor blockers possess partial agonist activity at β_1 -adrenergic receptor sites, β_2 -adrenergic receptor sites, or both. In a β -blocker, this property is identified as a slight cardiac stimulation, which can be blocked by propranolol. The β -blockers with this property slightly activate the β receptor in addition to preventing the access of natural or synthetic catecholamines to the receptor. In the treatment of patients with arrhythmias, angina pectoris of effort, or hypertension, drugs with mild-to-moderate partial agonist activity appear to be as efficacious as β -blockers lacking this property. It is still debated whether the presence of partial agonist activity in a β -blocker constitutes an overall advantage or disadvantage in cardiac therapy. Drugs with partial agonist activity cause less slowing of the heart rate at rest than do propranolol and metoprolol, although the increments in heart rate with exercise are similarly blunted. β -Blocking agents with nonselective partial agonist activity reduce peripheral vascular resistance and may also cause less depression or atrioventricular conduction delay compared with drugs lacking this property.^{2–6}

α -Adrenergic Activity

Carvedilol and labetalol are β -blockers with antagonistic properties at both α - and β -adrenergic receptors and direct vasodilator activity. Like other β -blockers, they are useful in the treatment of hypertension and angina pectoris. However, unlike most β -blocking drugs, the additional α -adrenergic blocking actions of carvedilol and labetalol lead to a reduction in peripheral vascular resistance that may maintain cardiac output. Whether concomitant α -adrenergic blocking activity is actually advantageous in a β -blocker remains to be determined.^{2,4}

PHARMACOKINETIC PROPERTIES

Although the β -adrenergic blocking drugs as a group have similar therapeutic effects, their pharmacokinetics are markedly different (Tables 63–2 and 63–3). Their varied aromatic ring structures lead to differences in completeness of

Box 63-1 Proposed Mechanisms to Explain the Antihypertensive Actions of β -Blockers

1. Reduction in cardiac output
2. Central nervous system effect
3. Inhibition of renin-angiotensin-aldosterone system
4. Reduction in plasma volume
5. Reduction in vasomotor tone
6. Reduction in peripheral vascular resistance
7. Improvement in vascular compliance
8. Resetting of baroreceptor levels
9. Effects on prejunctional β receptors: reduction in norepinephrine release
10. Attenuation of pressor response to catecholamines with exercise and stress

(From Frishman WH. Clinical Pharmacology of the β Adrenoceptor Blocking Drugs, 2nd ed. Norwalk, Appleton-Century-Crofts, 1984. With permission.)

gastrointestinal absorption, amount of first-pass hepatic metabolism, lipid solubility, protein binding, extent of distribution in the body, penetration into the brain, concentration in the heart, rate of hepatic biotransformation, pharmacologic activity of metabolites, and renal clearance of the drugs and their metabolites, which may influence their clinical usefulness in some patients.^{2,4,7}

The β -blockers can be divided by their pharmacokinetic properties into two broad categories: those eliminated by hepatic metabolism, which tend to have relatively short plasma half-lives, and those eliminated unchanged by the kidney, which tend to have longer half-lives. Propranolol and metoprolol are both lipid soluble, are almost completely absorbed by the small intestine, and are largely metabolized by the liver. They tend to have highly variable bioavailability

and relatively short plasma half-lives. A lack of correlation between the duration of clinical pharmacologic effect and plasma half-life may allow these drugs to be administered once or twice daily.^{2,4}

In contrast, agents such as atenolol and nadolol are more water soluble, are incompletely absorbed through the gut, and are eliminated unchanged by the kidney. They tend to have less variable bioavailability in patients with normal renal function, in addition to longer half-lives, allowing one dose a day. The longer half-lives may be useful in patients who find compliance with frequent β -blocker dosing a problem.^{2,4}

Extended-release formulations of metoprolol and propranolol are available that allow once-daily dosing of these drugs. Studies have shown that both long-acting propranolol and metoprolol provide much smoother curves of daily plasma levels than do comparable divided doses of conventional propranolol and metoprolol. In addition, a delayed-release/extended-release chronotherapeutic formulation of propranolol has become available, which is dosed at night to address circadian variations in BP in an attempt to blunt early morning elevations while providing 24-hour BP control.⁸ Early morning BP peaks have been associated with increased cardiovascular and cerebrovascular events, but the clinical significance of early morning BP blunting with delayed-release drugs has not yet been shown.⁹ Sublingual and nasal spray formulations that can provide immediate β -blockade have been tested in clinical trials.^{2,4}

Ultra-short-acting β -blockers are now available and may be useful where a short duration of action is desired (e.g., in patients with questionable congestive heart failure [CHF]). One of these compounds, esmolol, a β_1 -selective drug has been shown to be useful in the treatment of perioperative hypertension and supraventricular tachycardias. The short half-life (approximately 15 minutes) relates to the rapid metabolism of the drug by circulating and hepatic esterases. Metabolism does not seem to be altered by disease states.¹⁰

Table 63-1 Pharmacodynamic Properties of β -Adrenergic Blocking Drugs Used for Hypertension in the United States

Drug	β_1 -Blockade Potency Ratio (Propranolol = 1.0)	Relative β_1 -Selectivity	Intrinsic Sympathomimetic Activity	Membrane-Stabilizing Activity
Acebutolol	0.3	+	+	+
Atenolol	1.0	++	0	0
Betaxolol	1.0	++	0	+
Bisoprolol*	10.0	++	0	0
Carteolol	10.0	0	+	0
Carvedilol†	10.0	0	0	++
Labetalol‡	0.3	0	+?	0
Metoprolol	1.0	++	0	0
Nadolol	1.0	0	0	0
Penbutolol	1.0	0	+	0
Pindolol	6.0	0	++	+
Propranolol	1.0	0	0	++
Timolol	6.0	0	0	0

(Adapted from Frishman WH. Alpha and beta-adrenergic blocking drugs. In Frishman WH, Sonnenblick EH, Sica DA (eds). Cardiovascular Pharmacotherapeutics, 2nd ed. New York, McGraw Hill, 2003; pp 67-97.)

*Bisoprolol is also approved as a first-line antihypertensive therapy in combination with a very-low-dose diuretic.

†Carvedilol has additional α_1 -adrenergic blocking activity without peripheral β_2 -agonism.

‡Labetalol has additional α_1 -adrenergic blocking activity and direct vasodilatory activity (β_2 -agonism); it is available for use in intravenous form for hypertensive emergencies.

Table 63-2 Pharmacokinetic Properties of β-Adrenoceptor Blocking Drugs Used in Hypertension

Drug	Extent of Absorption (% of Dose)	Extent of Bioavailability (% of Dose)	Dose-Dependent Bioavailability (Major First-Pass Hepatic Metabolism)	Interpatient Variations in Plasma Levels	β-Blocking Plasma Concentrations	Protein Binding (%)	Lipid Solubility*
Acebutolol	≈90	≈40	Yes	7-fold	0.2-2.0 μg/ml	25	Low
Atenolol	≈50	≈40	No	4-fold	0.2-5.0 μg/ml	<5	Low
Betaxolol	>90	≈80	No	2-fold	0.005-0.05 μg/ml	50	Low
Bisoprolol	>90	≈88	No		0.005-0.02 μg/ml	≈30	Low
Carteolol	≈90	≈90	No	2-fold	40-160 ng/ml	20-30	Low
Carvedilol	>90	≈30	Yes	5-10-fold	10-100 ng/ml	98	Moderate
Celiprolol	≈30	≈30	No	3-fold		22-24	Low
Esmolol†	NA	NA	NA	5-fold	0.15-1.0 μg/ml	55	Low
Labetalol	>90	≈33	Yes	10-fold	0.7-3.0 μg/ml	≈50	Moderate
Metoprolol	>90	≈50	Yes	10-fold	50-100 ng/ml	12	Moderate
Metoprolol LA	>90	65-70	Yes	10-fold	35-323 ng/ml	12	Moderate
Nadolol	≈30	≈30	No	7-fold	50-100 ng/ml	≈30	Low
Nebivolol	>90	12-96	Yes	7-fold	1.5 ng/ml	98	High
Oxprenolol	≈90	19-74	Yes	5-fold	80-100 ng/ml	80	Moderate
Penbutolol	>90	≈100	No	4-fold	5-15 ng/ml	80-98	High
Pindolol	>90	≈90	No	4-fold	50-100 ng/ml	57	Moderate
Propranolol	>90	30-70	Yes	20-fold	50-100 ng/ml	93	High
Propranolol LA‡	>90	30-40	Yes	20-30-fold	20-100 ng/ml	93	High
Sotalol	≈70	≈90	No	4-fold	1-32 μg/ml	0	Low
Timolol	>90	≈75	Yes	7-fold	5-10 ng/ml	≈10	Low-Moderate

*Determined by the distribution ratio between octanol and water.

†Ultra-short-acting β-blocker available only in intravenous form.

‡Propranolol is available in both extended-release and delayed-release/extended-release formulations.

Table 63-3 Elimination Characteristics of β -Adrenoceptor Blocking Drugs Used in Hypertension

Drug	Elimination Half-Life (hours)	Total Body Clearance (ml/min)	Urinary Recovery of Unchanged Drug (% of Dose)	Total Urinary Recovery (% of Dose)	Predominant Route of Elimination	Active Metabolites	Drug Accumulation in Renal Disease
Acebutolol	3-4*	480	\approx 40	>90	RE (\approx 40% unchanged and HM)	Yes	Yes
Atenolol	6-9	130	\approx 40	>95	RE	No	Yes
Betaxolol	15	350	15	>90	HM	No	Yes
Bisoprolol	9-12	260	50	>98	RE + HM	No	Yes
Carteolol	5-6	497	40-68	90	RE	Yes	Yes
Carvedilol	7-10	600†	<2	16	HM	Yes	No
Celiprolol	5	500	\approx 90	\approx 30	RE (\approx 50% unchanged and HM)	Yes	No
Esmolol	9 min	285 ml/min/kg or 19,950 ml/min	1-2	71-88	Red blood cells	No	No
Labetalol	3-4	2700	<1	>90	HM	No	No
Metoprolol	3-4	1100	\approx 3	>95	HM	No	No
Metoprolol LA	3-4	1100	\approx 3	>95	HM	No	No
Nebivolol	8-27	—	<1	—	HM	No	Yes
Oxprenolol	2	—	\leq 3	—	HM	—	No
Penbutolol	27	350	50-70	>90	RE	No	No
Pindolol	3-4	400	\approx 40	>90	RE (\approx 40% unchanged and HM)	No	No
Propranolol	3-4	1000	<1	>90	HM	Yes	No
Propranolol LA†	10	1000	<1	>90	HM	Yes	No
Timolol	4-5	660	\approx 20	65	RE (\approx 20% unchanged and HM)	No	No

(Adapted from Frishman WH. Clinical Pharmacology of the β -Adrenoceptor Blocking Drugs, 2nd ed. Norwalk, Appleton-Century-Crofts, 1984.)

RE, renal excretion; HM, hepatic metabolism.

*Acebutolol has an active metabolite with elimination half-life of 8 to 13 hours.

†Plasma clearance.

‡Includes the extended-release and delayed-release/extended-release formulations.

EFFECTS ON BLOOD PRESSURE

β-Adrenergic blockers, alone and in combination with other antihypertensives, reduce BP in patients with combined systolic and diastolic hypertension and with isolated systolic hypertension.¹¹⁻¹⁴ Uncommonly, there is a paradoxical elevation of systolic blood pressure during β-blockade in persons with severe aortic arteriosclerosis, presumably due to the increased stroke volume caused by rate slowing in the setting of increased impedance. Escalating doses of β-blockers and combined α-β-blockers can induce salt and water retention, making diuretics a common adjunctive therapy.¹⁵ The β-blocking drugs are considered to be an alternative first-line treatment for hypertension and are also indicated for patients having concomitant angina pectoris, arrhythmias, hypertrophic cardiomyopathy, congestive cardiomyopathy, hyperdynamic circulations, essential tremor, and migraine headaches.^{2,6,15-21} Some β-adrenergic blockers are also found to reduce the risk of mortality in survivors of acute myocardial infarction (MI), with and without heart failure.^{22,23} The drugs can be used with caution in pregnancy, and appear to be especially useful in treating and preventing perioperative hypertension.^{24,25}

Most antihypertensive drugs, including β-blockers, may reduce left ventricular mass and wall thickness.^{26,27} However, in an outcome study of patients with stage 2 hypertension and ECG evidence of left ventricular hypertrophy (LVH), it was shown that losartan had a greater effect on LVH regression compared with atenolol, despite similar BP control.²⁸ Using a primary composite endpoint of death, stroke, and cardiovascular morbidity, there was a significant benefit in favor of losartan.²⁹

There is evidence that some β-adrenergic blockers (those not having partial agonist activity) may not be as effective as other antihypertensive treatments in Black patients. Similar observations have been made in older patients.³⁰ However, when combined with a diuretic, β-blockers appear to be as effective as other combination treatment regimens in both Black and elderly patients.^{2,4}

The α-β-blocker, labetalol, is the only β-blocker indicated for parenteral management of hypertensive emergencies and for treatment of intraoperative and postoperative hypertension. It can also be used in oral form to treat patients with hypertensive urgencies.^{2,4}

ADVERSE EFFECTS AND CONTRAINDICATIONS

β-Adrenergic blockers should not be used in patients with asthma, chronic obstructive pulmonary disease, unstable CHF with systolic dysfunction, heart block (greater than first degree), or sick sinus syndrome.²⁻⁶ The α-β-blocker carvedilol can be used to reduce morbidity and mortality in those patients having hypertension and stable New York Heart Association (NYHA) class II-IV heart failure who are receiving diuretics, angiotensin-converting enzyme (ACE) inhibitors, and digoxin.^{16,31,32} The β₁-selective agents bisoprolol and long-acting metoprolol used in an extended-release formulation have also been shown to reduce morbidity and mortality in patients with stable NYHA class II-III heart failure.^{33,34}

β-Blockers should be used with caution in insulin-dependent diabetes because they may worsen glucose intolerance and mask the symptoms of and prolong recovery from hypoglycemia. There is probably a shorter recovery period from hypoglycemia with β₁-selective adrenergic blockers.^{2,4} β-Blockers should not be discontinued abruptly in patients with known ischemic heart disease.²⁻⁶ In a prospective cohort study, it was found that antihypertensive therapy with β-blockers was associated with a greater incidence of type 2 diabetes than was the use of ACE inhibitors, diuretics, and calcium channel blockers.³⁵ However, this increased risk of diabetes must be weighed against the proven benefit of β-blockers in reducing the risk of cardiovascular events.³⁶ Perhaps for this reason, JNC 7 recommended β-blockers as having “compelling indications” for use in patients with diabetes in whom the leading cause of death is cardiovascular disease.

β-Blockers may increase levels of plasma triglycerides and reduce those of high-density lipoprotein cholesterol.³⁷ Despite this effect, β-blockers without ISA are the only agents conclusively shown to decrease the rate of sudden death, overall mortality, and recurrent MI in survivors of acute MI.²² β-Blockers with ISA or α-blocking activity have little or no adverse effect on plasma lipids.³⁷

Dreams, hallucinations, insomnia, and depression can occur during therapy with β-blockers.^{5,38} These symptoms provide evidence of drug entry into the central nervous system (CNS) and may be more common with the highly lipid-soluble β-blockers (propranolol, metoprolol), which presumably penetrate the CNS better. It has been claimed that β-blockers with less lipid-solubility (atenolol, nadolol) cause fewer CNS side effects.^{39,40} This claim is intriguing but its validity has not been corroborated by other extensive clinical experiences.^{41,42}

There are special considerations when β-blockers are combined with other drugs.⁴³⁻⁴⁵ Combinations of diltiazem or verapamil with β-blockers may have additional sinoatrial and atrioventricular node depressant effects, and may also promote negative inotropy.⁴³ Combinations of β-blockers and reserpine may cause marked bradycardia and syncope. Combination with phenylpropanolamine, pseudoephedrine, ephedrine, and epinephrine can cause elevations in BP due to unopposed α-receptor-induced vasoconstriction.

α -Adrenoceptor Blockers

James L. Pool

THE SYMPATHETIC NERVOUS SYSTEM IN BLOOD PRESSURE REGULATION

In the human vasculature, there are two types of adrenoceptors, alpha (α) and beta (β), which are transmembrane receptors initiating biologic signals. Since the discovery of the α - and β -adrenergic receptors (adrenoceptors) more than 50 years ago,¹ α -adrenoceptors (α AR) have been shown to participate in the physiologic regulation of vascular resistance and also play a role in hypertension² and other cardiovascular disorders such as myocardial hypertrophy.³ To understand the role of α AR and the modulation of receptor function in hypertension by pharmacologic antagonists of α AR, it is necessary to be familiar with the contributions of the sympathetic nervous system (SNS) to the development of hypertension (see Chapter 6).^{2,4-6}

Effective organ perfusion requires appropriate resistance to blood flow to maintain arterial pressure. The arterial pressure is regulated by changes in cardiac output and/or systemic vascular resistance. The dominant regulator of vascular resistance is smooth muscle tone, which helps regulate the most important determinant of resistance to flow, the cross-sectional area of a vessel. Two major neurohormonal systems—the autonomic nervous system (ANS) and the renin-angiotensin-aldosterone system (RAAS)—regulate smooth muscle tone. The peripheral ANS has three main components: (1) the SNS, which comprises the autonomic outflow from the thoracic and high lumbar segments of the spinal cord; (2) the parasympathetic nervous system (PNS), which includes the outflow from the cranial nerves and the low lumbar and sacral spinal cord; and (3) the enteric nervous system, the intrinsic neurons in the wall of the gut. In addition to the blood vessels, the urinary bladder, penis, and prostate also have smooth muscle cells that are innervated by SNS and PNS neurons to help regulate micturition, erection, and ejaculation.^{7,8} As noted later, the SNS influences on lower urinary tract function play an important role in benign prostatic hyperplasia (BPH)⁹ and lower urinary tract symptoms (LUTS),¹⁰ both common conditions among older males with hypertension.

ABNORMALITIES OF THE SYMPATHETIC NERVOUS SYSTEM IN HYPERTENSION

A number of abnormalities have been identified in high blood pressure, most notably increased SNS activity, which contributes to an increase in vasoconstriction and total peripheral vascular resistance. Studies have demonstrated in both borderline and mild hypertension an increased cardiac β -adrenergic drive with increased cardiac output and faster heart rate and an increased vascular α -adrenergic drive. A longitudinal study over 20 years showed the gradual transformation of

such patients to established hypertension with normal cardiac output and increased vascular resistance.¹¹ Mechanisms that underlie this transition from high cardiac output to high vascular resistance involve modifications of SNS receptors and a dominant role for α AR. There is functional down-regulation of β -adrenergic responsiveness in the heart¹² plus alteration of vascular anatomy and function⁴ followed by a steady increase in vascular resistance. An exaggerated response of blood vessels to adrenergic and nonadrenergic vasoconstrictors¹³ likely contributes to the steady increase in vascular resistance during this evolution of hypertension.

THE SUBTYPES OF α -ADRENOCEPTORS

Almost all vasomotor neurons are adrenergic, with the neurotransmitter norepinephrine producing vasoconstriction by acting on a specific type of transmembrane receptor on the vascular smooth muscle, the α AR. Within α AR there now identified six subtypes—which are designated α_{1A} , α_{1B} , α_{1D} , α_{2A} , α_{2B} , and α_{2C} —and one other candidate (α_{1L}), which may be a conformational state of the α_{1A} adrenoceptor.¹⁴⁻¹⁶ Table 64-1 lists further details about these six subtypes.¹⁷ Furthermore, the vascular endothelium is now known to be more than a passive anatomic barrier that contacts the blood. Instead, the endothelium is an important organ possessing at least two different α AR subtypes (α_{2A} , α_{2C}) and three β -adrenoceptor subtypes (β_1 , β_2 , and β_3), which either directly or through the release of nitric oxide actively participate in the regulation of the vascular tone. The precise roles for each of these multiple subtypes of adrenoceptors in the regulation of blood pressure are not completely defined.

MOLECULAR MECHANISM OF α_1 -ADRENOCEPTOR ACTIVATION

Stimulation of the α AR complex begins when circulating norepinephrine binds to the postsynaptic α_1 -adrenoceptor (α_1 AR), thus activating the receptor.¹⁸ As shown in detail in Figure 64-1, innervation of smooth muscle by sympathetic nerve terminals involves a tight junction (or “synapse”), so there is close proximity of neural membranes to smooth muscle cells. The synaptic gap (or “cleft”) between the neural endings and the smooth muscle cells is visible only with an electron microscope. The neural components of these synapses are described as “presynaptic”; the smooth muscle components, including the α_1 AR, are “postsynaptic.” Sympathetic nerve impulses travel down the nerve, depolarize the nerve terminal, and stimulate the release of norepinephrine into the synaptic cleft by exocytosis. Exocytosis occurs when norepinephrine-containing vesicles in the nerve terminals bind to presynaptic neural membranes; the fused vesicles then

Table 64-1 α₁-Adrenoceptor Subtypes (1995 Classification)

Native Receptors	Cloned Receptors	Cloned Receptors (Historical)	Human Chromosome Location
α _{1A}	α _{1a}	α _{1a}	C8
α _{1B}	α _{1b}	α _{1b}	C5
α _{1D}	α _{1d}	α _{1a/d} , α _{1a}	C20

open and empty their neurotransmitter (norepinephrine) into the synaptic cleft, where it is available to bind to postsynaptic adrenoceptors.

The postsynaptic α₁AR is a complex structure that spans the width of the smooth muscle cell membrane, with specific topographic features on its outer surface that “recognize” and bind the newly released norepinephrine. This α₁AR complex includes (1) the α₁AR, (2) a “transducer subunit”—the guanine nucleotide releasing protein (GNRP), (3) a “catalytic subunit”—phospholipase C (PLC), and (4) the dual “second messengers”—inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). When circulating norepinephrine binds to the transmembrane α₁AR, this “activates” the receptor and initi-

ates a cascade of events. The activated α₁AR couples with a GNRP to activate PLC, which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP₂) to generate IP₃ and DAG. Release of the newly synthesized IP₃ initiates a sharp rise in the cytoplasmic, ionized calcium (Ca²⁺) by releasing intracellular stored Ca²⁺. The large and transient increase in Ca²⁺ activates chloride channels, leading to a membrane depolarization, which opens voltage-gated Ca²⁺ channels, releasing Ca²⁺ into the cytoplasm, resulting in contraction of the smooth muscle cell. In addition, the other “second messenger,” DAG, transiently activates protein kinase C (PKC), which increases the opening probability of Ca²⁺ channels through a phosphorylation-dependent process, thus increasing cytoplasmic Ca²⁺.

α-ADRENOCEPTORS IN THE URINARY BLADDER AND LUMBOSACRAL SPINAL CORD

During the development of BPH and LUTS in males, obstruction to urine flow is attributed to two components: (1) a “static” or anatomic component (enlarged prostate gland) and (2) a “dynamic” or functional component (increased smooth muscle tone in the bladder neck, the prostate capsule, and the fibromuscular stroma of the prostate gland). Up to 40% of

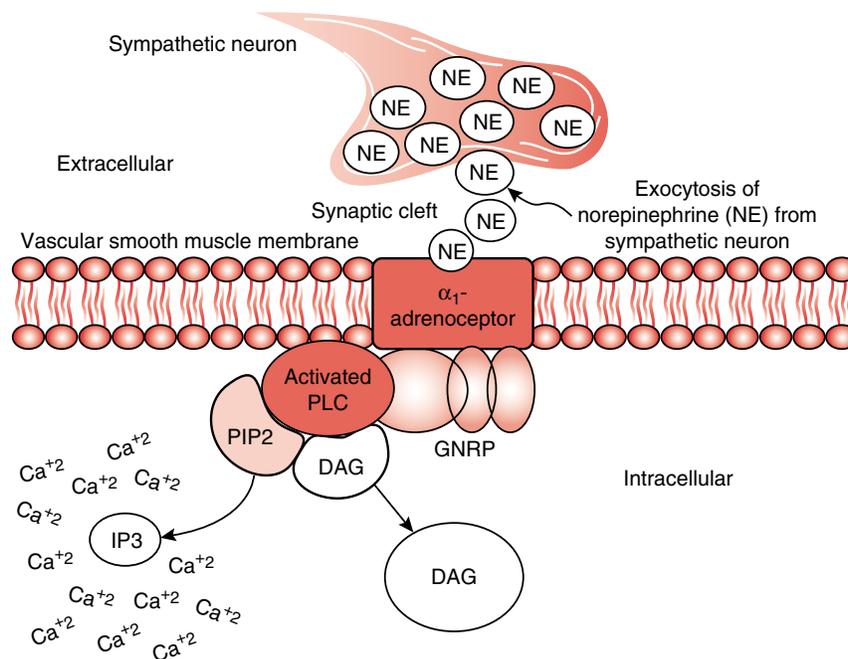

Figure 64-1 Sympathetic nerve impulses depolarize nerve terminals and stimulate the release of norepinephrine (NE) into the synaptic cleft by the process of exocytosis. NE-containing vesicles in nerve terminals bind to presynaptic neural membranes; then the fused vesicles open, emptying NE into the synaptic cleft, where it is available to bind to adrenoceptors (AR). The active α₁AR couples with a guanine nucleotide releasing protein (GNRP) (Gq/G11) to activate phospholipase C (PLC), which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP₂) to generate inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ releases intracellular stored Ca²⁺. Not shown in this figure are two additional intracellular events. The large and transient increase in Ca²⁺ activates chloride channels, leading to a membrane depolarization that opens voltage-gated Ca²⁺ channels. Also, DAG transiently activates protein kinase C (PKC), which increases the opening probability of Ca²⁺ channels through a phosphorylation-dependent process. This complex α₁AR pathway causes the physiologic action (contraction) of NE in vascular smooth muscle.

total urethral pressure is due to α -adrenergic tone, and the rest is due to static pressure from the enlarged prostate.¹⁹ Relaxation of this smooth muscle tone by α_1 AR blockers increases urinary flow and improves LUTS in patients with BPH.²⁰

Although a simplified explanation of this therapeutic effect was provided initially, the exact role of the SNS in the regulation of micturition in normal and BPH persons remains uncertain. Early findings suggest that two types of spinal α_1 AR mechanisms are involved in reflex bladder activity.⁷ Facilitatory α_1 AR in bulbospinal pathways from the brainstem to the lumbosacral spinal cord contribute to neural control of the lower urinary tract. In the urinary outflow tract, α_1 AR are located in smooth muscle cells of the neck of the urinary bladder, capsule of the prostate, and fibromuscular stroma of the prostate. Stimulation of α_1 AR in the bladder outflow tract increases resistance to urine flow. The frequency of the reflex to urinate is inhibited by afferent α_1 AR in the spinal cord. The descending limb of the micturition reflex pathway may be facilitated by α_1 AR. For control of the micturition reflex, selective α_1 adrenoceptor antagonists (α_1 ARA) are used, and it is thought that these drugs have dual sites of action, including both the central nervous system and the smooth muscle of the lower urinary tract.

SELECTIVE POSTSYNAPTIC α_1 -ADRENOCEPTOR BLOCKADE

When stimulated, α_1 AR, located postsynaptically in smooth muscle, produce vasoconstriction of the blood vessels. Sympathetic overactivity in hypertension results in an excess stimulation of postsynaptic α_1 AR. Consequently, there emerged a sound therapeutic rationale for the use of selective α_1 ARA in the treatment of hypertension. By selectively inhibiting the vascular α_1 AR and thereby inhibiting the receptor-mediated response to norepinephrine, these agents reduce blood pressure via a decrease in peripheral vascular resistance (Figure 64-2).²¹ The reduction in blood pressure is achieved with little or no change in central hemodynamic parameters such as heart rate, stroke index, or cardiac index. As shown in Figure 64-2, these favorable hemodynamic effects of selective α_1 inhibitors are evident during exercise, when cardiac performance is better preserved with α_1 -blockers than with β -blockers.

AN OVERVIEW OF α -ADRENOCEPTOR ANTAGONISTS

Nonselective α -adrenoceptor antagonists, phentolamine and phenoxybenzamine, which bind to both α_1 and α_2 receptors, were discovered first. However, three categories of α -adrenoceptor blockers have been introduced over the past four decades, including nonselective ($\alpha_1 + \alpha_2$), presynaptic α_2 , and postsynaptic α_1 ARA. Table 64-2 lists clinically available and major research drugs available in this class. Selective, postsynaptic α_1 ARA, often referred to as " α_1 -blockers" or simply " α -blockers," lower blood pressure primarily by post-synaptic α_1 AR blockade. In this respect, selective α_1 ARAs differ from nonselective α -blockers including the competitive inhibitor phentolamine and the noncompetitive inhibitor phenoxyben-

zamine.²² Importantly, stimulation of presynaptic α_2 -adrenoceptors inhibits norepinephrine release. Nonselective α -blockade prevents this inhibition and causes α_2 receptors to increase norepinephrine release, with resultant β -adrenoceptor-mediated tachycardia, enhanced renin secretion, and attenuation of postsynaptic α_1 inhibition. In fact, selective blockade of these presynaptic α_2 -adrenoceptors with a drug such as yohimbine can lead to a rise in blood pressure. As a result of these pharmacodynamic consequences of nonselective α -adrenoceptor blockade, these agents were unsuccessful in treatment of essential hypertension and symptomatic BPH.

Phentolamine, a parenteral drug, is used almost exclusively for emergent and urgent severe hypertension with excess catecholamine release (see Chapter 78). The oral, nonselective and noncompetitive α inhibitor phenoxybenzamine remains an important agent in the preoperative management of pheochromocytoma and cases of inoperable metastatic pheochromocytoma (see Chapter 76). In contrast to the nonselective drugs, the selective α_1 ARAs, which include the three major marketed antihypertensive agents doxazosin, prazosin, and terazosin (Figure 64-3), reduce vascular tone in capacitance vessels and resistance vessels to provide a balance of preload and afterload reduction, thus avoiding vasodilation (afterload reduction) without venodilation (preload reduction), which would promote an increase in cardiac output and heart rate.

A unique feature of two of the selective α_1 ARAs—labetalol and carvedilol—is blockade of β_1 - and β_2 -adrenoceptors. Labetalol is an equal molar mixture of four stereoisomers. One stereoisomer is an α_1 ARA, which is equivalent to ~10% of α -blockade with phentolamine. Another isomer is a nonselective β -adrenoceptor antagonist with partial agonist activity, and the other two isomers are inactive. The isomer that is a β -adrenoceptor antagonist was developed separately as a drug (dilevalol) but was removed from world markets because of serious hepatotoxicity. Labetalol lowers arterial pressure by reducing vascular resistance as a consequence of blockade of α_1 AR and stimulation of peripheral β_2 -adrenoceptors. In contrast, carvedilol is predominately a nonselective β -blocker and selective α_1 ARA, which is indicated for the treatment of heart failure and/or hypertension. The ratio of α_1 - to β -adrenoceptor antagonist potency for carvedilol is 1:10.

TREATMENT OF HYPERTENSION WITH α_1 -ADRENOCEPTOR ANTAGONISTS

Clinical studies have shown α_1 ARA to lower blood pressure through reduction of vascular resistance without significant effects on heart rate, cardiac output, or central hemodynamic parameters in hypertensive patients.²³ In normotensive persons who have normal sympathetic tone and peripheral vascular resistance, blood pressure effects are not clinically significant, which has contributed to their utility in the treatment of conditions other than hypertension, such as BPH and Raynaud's disease. Prazosin, terazosin, and doxazosin are effective antihypertensive agents, whether used as monotherapy or as part of a regimen of multiple antihypertensive drugs. Because of their longer duration of action, doxazosin and terazosin have generally replaced prazosin in treatment of blood pressure. Their effects are additive to those of angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor

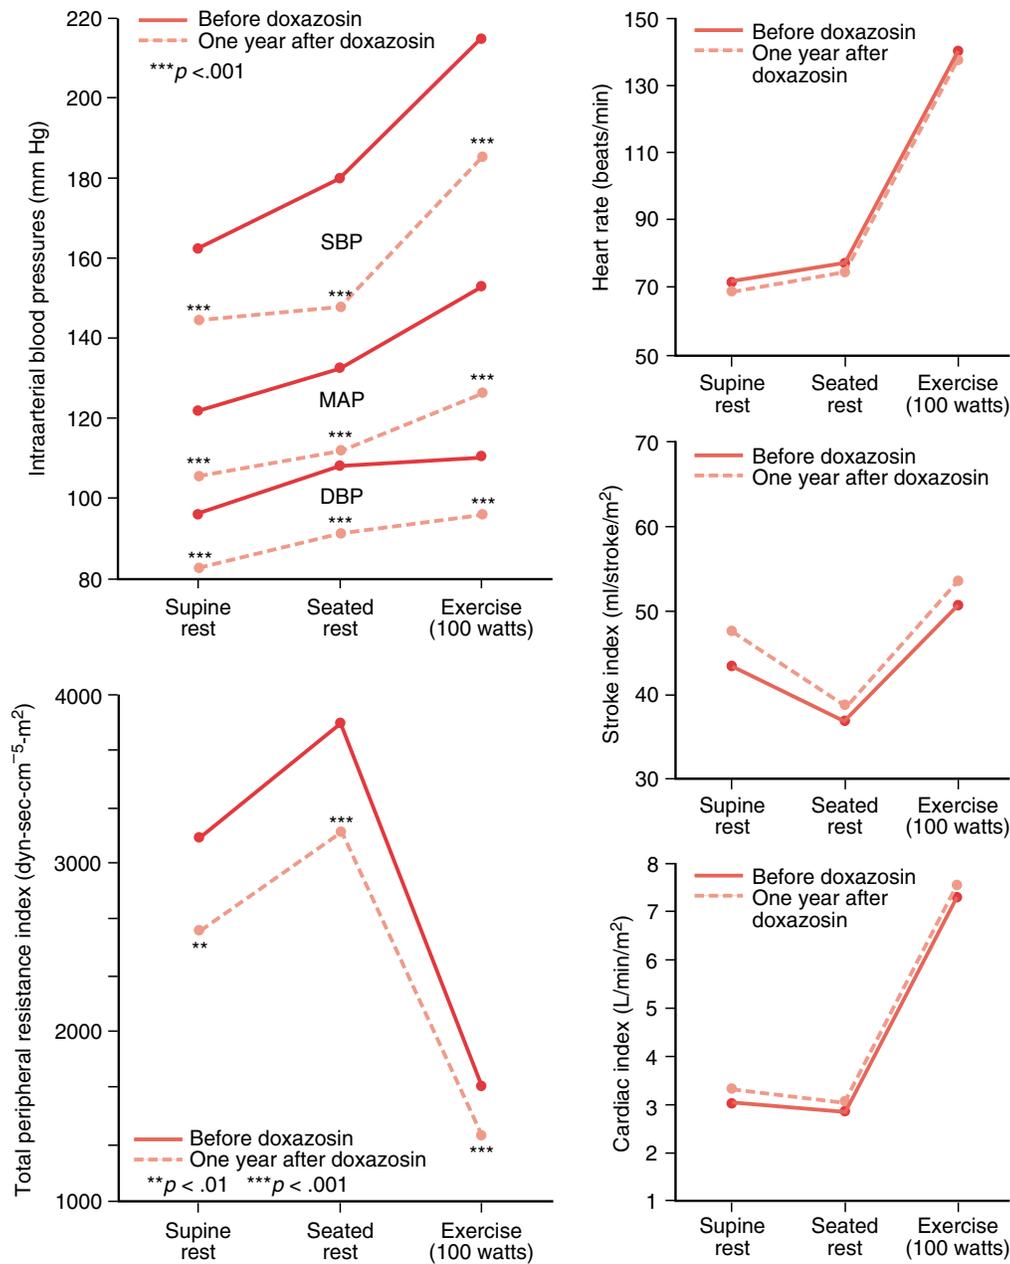

Figure 64-2 During chronic treatment of 12 patients for 1 year with doxazosin, there is a marked decrease in the total peripheral resistance index at rest and exercise, but maintenance of normal central hemodynamic parameters, including stroke index and cardiac index. (From Lund-Johansen P, Omvik P. Acute and chronic hemodynamic effects of drugs with different actions on adrenergic receptors: A comparison between alpha blockers and different types of beta blockers with and without vasodilating effect [Review]. *Cardiovasc Drug Ther* 5(3):605-615, 1991. Reprinted with permission of Kluwer Academic Publishers, Boston, MA.)

antagonists, β-blockers, calcium channel blockers, diuretics, and direct-acting vasodilators. About 50% of mild to moderate essential hypertensives treated with monotherapy in placebo-controlled trials achieved diastolic blood pressures <90 mm Hg but lesser systolic blood pressure control <140 mm Hg.²⁴ In large placebo-controlled hypertension studies, doxazosin or terazosin once daily lowered blood pressure at 24 hours by ~10/8 mm Hg as compared with placebo in the standing position and ~9/5 mm Hg in the supine position.

Age, race, and gender do not influence blood pressure response to selective α₁-blockers. In clinical practice for more than a decade, α₁-blockers have had their widest application as one component of multiple drug regimens for the treatment of moderate to severe hypertension. Although less pronounced than with potent vasodilators, monotherapy with α₁-blockers promotes sodium and water retention. Use of a diuretic prevents fluid retention and can markedly enhance the antihypertensive effect of the drugs.

INEFFECTIVE FOR TREATMENT OF HEART FAILURE

α -Blockers have not shown sustained benefits in chronic congestive heart failure (CHF). Mortality from left ventricular dysfunction is not improved by selective α_1 ARA. In the 1986 Veterans Administration Cooperative Study²⁵ on the effect of vasodilator therapy in chronic CHF, mortality in the prazosin treatment group was similar to that in the placebo group. Furthermore, chronic therapy in heart failure with α_1 -blocker (doxazosin) plus β -blocker (metoprolol) produces effects identical to those seen in patients receiving β -blocker alone.

METABOLIC EFFECTS

Selective α_1 ARA have proven beneficial effects on the lipid profiles of hypertensive patients. Several controlled studies

have demonstrated reductions in total cholesterol, low-density lipoprotein (LDL) cholesterol and triglycerides and increased levels of high-density lipoprotein (HDL) cholesterol and the ratio of HDL cholesterol:total cholesterol.²⁶ In hypertensive patients with baseline values similar to the general population, doxazosin produced small reductions in total serum cholesterol (2%-3%), LDL cholesterol (4%), and a similarly small increase in the HDL:total cholesterol ratio (4%). These modifications of the serum lipid profile are the result of several different mechanisms.²⁷ These include an increase in LDL cholesterol receptor number, a decrease in LDL cholesterol synthesis, stimulation of lipoprotein lipase activity, reduction of very-low-density lipoprotein (VLDL) cholesterol synthesis and secretion, and a reduction in the absorption of dietary cholesterol. In addition, a unique feature of the 6-hydroxy and 7-hydroxy metabolites of doxazosin is the ability to inhibit the oxidation of LDL cholesterol,²⁸ which has an important role in the initiation and progression of atherosclerosis. In hypertensives with diabetes mellitus that are treated

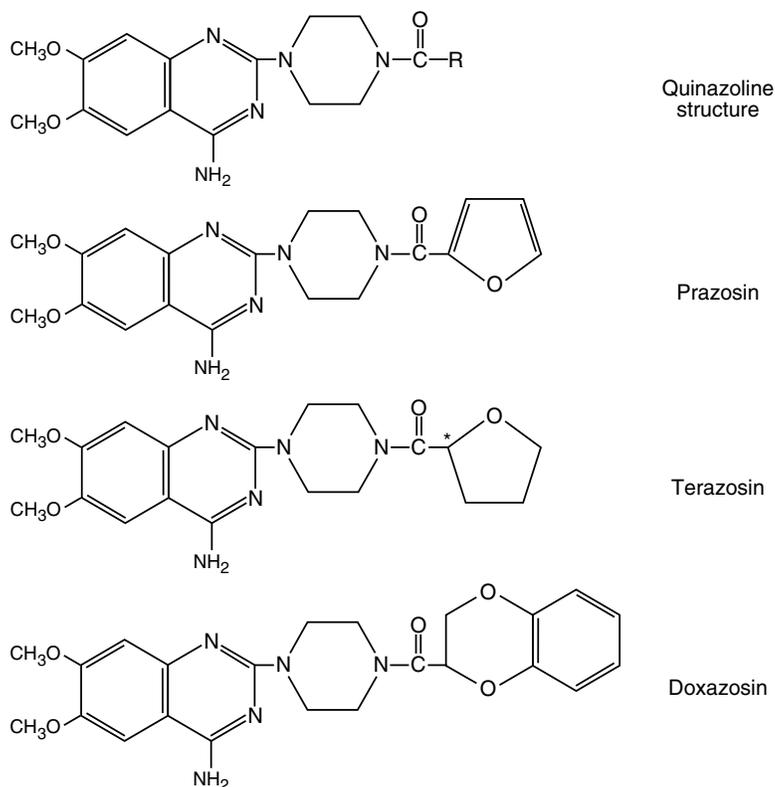

Figure 64-3 The chemical structure of quinazoline compounds is shown at the top with the three derivatives (prazosin, terazosin, and doxazosin) that are approved by the U.S. Food and Drug Administration for the treatment of hypertension and benign prostatic hyperplasia. The saturated furan configuration of terazosin provides the molecule with one optically active chemical center (*), so terazosin has two enantiomeric forms. The 6'- and 7'-hydroxy metabolites of doxazosin (not shown here) have demonstrated *in vitro* antioxidant properties.

with α_1 -blockers, improvements in insulin sensitivity and reductions in elevated serum insulin levels and fasting glucose have been demonstrated.²⁹

ADVERSE DRUG EFFECTS

Selective α_1 -antagonists are generally well-tolerated, with a few common adverse effects. In placebo-controlled trials, the symptoms that most commonly caused discontinuation of α_1 -antagonist therapy were asthenia (2%), nasal congestion (2%), and dizziness (1%).^{24,30} Generally, there is no drug dose relationship for clinical adverse effects. Dizziness secondary to α_1 -blockers is not entirely understood, because patients can experience this sensation without documented postural hypotension. However, a major precaution is the so-called “first-dose phenomenon,” which is severe, symptomatic orthostatic hypotension that usually occurs within 90 minutes after the first dose or when the dose is increased rapidly. If the patient has concomitant treatment with one or more agents (especially diuretic, β -blocker, or verapamil), additional caution with the first dose is advisable. However, syncope is uncommon, occurring in <1% of patients when an initial, small dose (1 mg or less) was taken at bedtime as monotherapy. Men should be cautioned that the combine of α_1 -blocker and sildenafil (Viagra), tadalafil (Cialis), or vardenafil (Levitra) could produce marked hypotension. Postmenopausal women with pelvic relaxation syndrome and individuals with certain types of urinary bladder dysfunction can develop urinary incontinence with α_1 -blocker-mediated relaxation of the bladder outlet.

There are no clinically important adverse effects on laboratory tests. Serum electrolytes, BUN, creatinine, glucose, and uric acid are not altered. There are no significant effects on

renal function in hypertensive patients with normal, moderate, or severe renal impairment. In placebo-controlled trials, a greater percentage of α_1 -blocker patients had small decreases in hematocrit, hemoglobin, white blood cell count, total serum protein, and albumin levels from baseline values. Except for the white blood cell count, these changes have been attributed to hemodilution secondary to mild fluid retention. The reduction of white blood cell counts remains unexplained, but individual reductions have been small, and prolonged drug treatment has not been associated with progressive white blood cell count reductions.

ALLHAT TRIAL CHANGED α_1 -BLOCKER USE

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was a large, randomized, double-blind superiority trial comparing four antihypertensive drugs—chlorthalidone, doxazosin, amlodipine, and lisinopril—with a total of 42,448 recruited patients.^{31,32} The participants were men and women aged ≥ 55 years with hypertension plus an additional risk factor for coronary heart disease. At a median follow-up of 3.3 years in 9067 patients, the doxazosin and chlorthalidone treatment groups had no difference in the primary endpoint of fatal and nonfatal myocardial infarction.³³ However, the doxazosin limb of the study was discontinued because, compared with the chlorthalidone group, there was a 25% higher incidence of significant cardiovascular disease (Figure 64-4),³⁴ which was predominately the result of twice the incidence of CHF. There was an early divergence of the Kaplan-Meier curves for CHF for doxazosin and chlorthalidone after randomization, which has raised questions about withdrawal of previous drug therapy

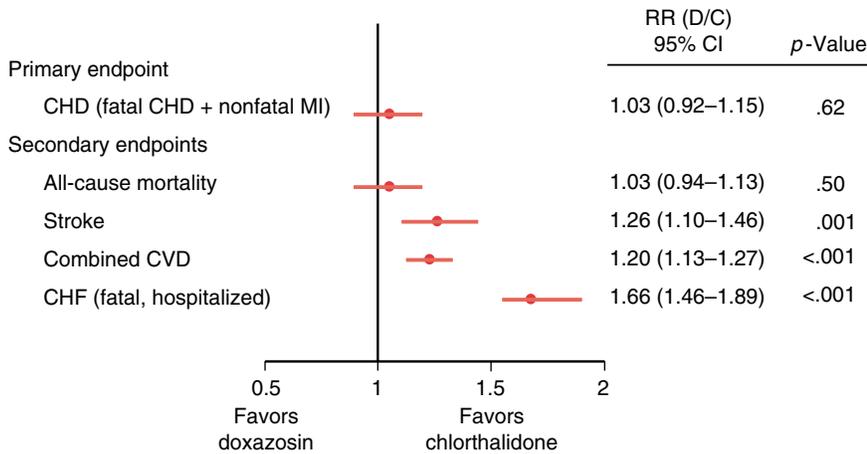

Figure 64–4 The principal outcomes of the ALLHAT Trial for the α -blocker (doxazosin) treatment arm versus diuretic (chlorthalidone) treatment arm are shown for the primary CHD endpoint and the four major secondary endpoints.³⁴ Abbreviations: RR, risk ratio; D/C, doxazosin compared with chlorthalidone; CI, confidence interval.

(i.e., diuretics, ACE inhibitors, or β -blockers) among patients at risk for CHF. ALLHAT has raised a number of questions that cannot be answered because there was no placebo control and systolic blood pressure control was not equal in the doxazosin and chlorthalidone groups. As shown in Figure 64–5, systolic blood pressure throughout the ALLHAT Trial was 2 to 3 mm Hg higher in the doxazosin treatment arm. Nevertheless, this information on the outcomes of long-term antihypertensive treatment with α_1 ARA has led to α_1 ARA not being recommended as a first-line treatment for hypertension in several countries. However, ALLHAT was not designed to investigate the use of α_1 ARA for (1) younger hypertensive subjects or hypertensives with a lesser CHD risk factor profile, (2) diuretic-based combination therapy for the treatment of hypertension, (3) combined treatment of hypertension and BPH, or (4) treatment of normotensive patients with BPH, where α_1 ARAs remain the best monotherapy for the control of symptoms.

In spring 2000, as a result of early, unfavorable results from ALLHAT, α -blockers were no longer recommended as first-

line treatment for hypertension in high-risk patients. Stafford et al.³⁵ tracked trends in α -blocker prescriptions filled by community pharmacies and reports of α -blocker use in patient encounters with office-based physicians from 1996 to 2002. The authors used U.S. data from two sources: (1) α -blocker prescription orders reported in the National Prescription Audit—a random, computerized sample of about 20,000 of 29,000 pharmacies—and (2) office-based physician α -blocker prescribing patterns reported in the National Disease and Therapeutic Index, a random sample of about 3500 physician offices. The researchers found that there had been steady increases in new α -blocker prescriptions, dispensed prescriptions, and physician prescribing from 1996 through 1999. There was a moderate reversal in these trends following the early termination and subsequent publications of ALLHAT in early 2000. Between 1999 and 2002, new annual α -blocker prescription orders declined by 26%, from 5.15 million to 3.79 million, dispensed prescriptions by 22%, from 17.2 million to 13.4 million, and physician-reported drug use by 54%, from 2.26 million to 1.03 million.

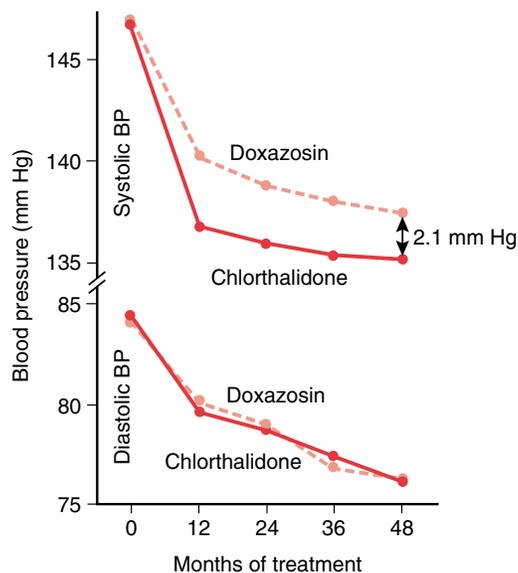

Figure 64–5 Mean systolic and diastolic blood pressures (BPs) in the ALLHAT Trial are shown at baseline and four annual visits. Diastolic BPs are controlled equally, but there are consistently 2 to 3 mm Hg higher systolic BPs in the doxazosin group at all treatment visits.³⁴

α -BLOCKERS EXPAND MANAGEMENT OF BENIGN PROSTATIC HYPERPLASIA

For men older than the age of 60 years, LUTS associated with BPH and obstruction occur in up to 70%.³⁶ Before effective medical management, men with bothersome LUTS were observed for variable lengths of time until they were considered suitable candidates for transurethral prostatectomy (TURP). In the early 1970s, α -blockers emerged as an effective treatment option for LUTS secondary to BPH to relieve bothersome symptoms.²⁰ Medical therapy evolved into the major clinical option in the management of BPH, including men with mild to severe LUTS. Before α -blockers, there was no suitable treatment option for mild LUTS. There was a dramatic increase in prescriptions for medical therapies and a decline in the use of TURP. Today, medical therapy is the dominant form of treatment for BPH.

The lack of specificity and side effects of nonselective α -blockers limited their use in LUTS patients. Although developed for the treatment of essential hypertension, selective α_1 -blockers contributed largely to the growth of medical therapy for BPH. In 1987, terazosin was approved in the United States for treatment of hypertension; in 1994, it was

approved for treatment of LUTS, followed by approval of doxazosin for both indications. Finasteride, the 5- α -reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone, was the first drug approved by the FDA in 1992 to treat BPH. However, α -blockers became the predominant medical therapy because of excellent efficacy in relieving LUTS. Generally, 59% to 86% of men using α -blockers will see a decrease in symptoms.³⁶ Symptoms generally improve in 2 to 3 weeks. Terazosin and doxazosin typically improve urinary flow rate by 2 to 2.5 ml/sec. Tamsulosin introduced the concept of uroselectivity. Targeting the α_{1a} - and α_{1b} -adrenoceptors in the bladder neck and prostate, tamsulosin achieves a greater effect on the prostate and a similar degree of improvement in both urine flow rates and symptoms with fewer cardiovascular side effects as compared with nonselective agents. Tamsulosin has become the most widely used α_1 -blocker for BPH in the United States; it eliminates the need for titration and has fewer side effects. However, the incidence of retrograde ejaculation with higher doses of tamsulosin approaches 20%.

The Veterans Affairs (VA) Cooperative BPH Study³⁷ in 1996 was the first large-scale study (n = 1229) to compare an α -blocker (terazosin), a 5- α -reductase inhibitor (finasteride), and the combination of these two agents for the improvement of LUTS and urine flow rate in BPH. This 1-year VA trial showed that terazosin achieved greater improvement in symptoms and flow rate as compared with finasteride, which was similar to placebo. The combination of terazosin and finasteride was not better than α -blocker alone. The 4-year Proscar (finasteride) Long-Term Efficacy and Safety Study (PLESS)³⁸ with 3040 men reported the impact of finasteride alone as compared with placebo on disease progression defined as acute urinary retention (AUR) and BPH surgery. Finasteride reduced the incidence of AUR by 57% and surgery for BPH by 55% as compared with placebo, which established a role for finasteride in long-term management of BPH. Men with moderate to severe symptoms and an enlarged prostate respond best to finasteride therapy. Men with little or no enlargement of the prostate are less likely to experience improvement in symptoms or reduction in events with finasteride. The size of the prostate does not predict improvements in LUTS symptoms during α -blocker therapy.

In 2003, the Medical Therapy of Prostatic Symptoms (MTOPS) Trial³⁹ with 3047 men, which lasted 4.5 years, established a role for combination drug therapy with α -blocker and finasteride. The “overall risk of clinical progression”—defined as an increase from baseline of ≥ 4 points in the American Urological Association (AUA) symptom score, acute urinary retention, urinary incontinence, renal insufficiency, or recurrent urinary tract infections—was significantly reduced by doxazosin by 39%, by finasteride by 34%, and by a combination of doxazosin and finasteride by 66% as compared with placebo. Long-term combination therapy with doxazosin and finasteride was safe and reduced the risk of overall clinical progression of BPH more than did treatment with either drug alone. Combination therapy and finasteride alone reduced the long-term risk of AUR and the need for invasive BPH therapy. The principal effect of doxazosin on progression was prevention of a 4-point rise in AUA symptom score.

These long-term, large clinical trials of medical therapy for BPH have clarified treatment options. α -Blockers offer the best monotherapy for symptom relief of LUTS. The available

selective α -blockers have similar effects on symptoms and flow rate. Finasteride prevents disease progression, whether defined by symptoms, AUR, or surgery. Finally, combination therapy with an α -blocker plus finasteride is the most-effective treatment for BPH symptoms and disease progression, and the ideal candidates for combination therapy have moderate or severe symptoms and prostate enlargement.

Angiotensin-Converting Enzyme Inhibitors

Domenic A. Sica, Todd W. B. Gehr

INTRODUCTION

In the management of hypertension and cardiovascular disease, multiple treatment strategies have come and gone over the last four decades. The *stepped care* approach was popular for some time. The diuretic-based stepped care approach to hypertension therapy is supported by sound outcomes data from numerous randomized, controlled trials.¹ However, adopting a *stepped care* approach to the treatment of hypertension neglects the diverse *individualized* pathophysiology of this condition. Its advocates value the clarity of standardization of hypertension treatment, while others are displeased with its inflexible nature.

The concept of individualized *therapy* has gradually evolved, particularly in the context of the recent treatment experience with angiotensin-converting enzyme (ACE) inhibitors. Over the past two decades, the renin-angiotensin-aldosterone (RAA) axis has been increasingly viewed as wielding an important influence on hypertension and target organ disease and thus has emerged as an attractive target for pharmacologic intervention. Of drugs known to interrupt the RAA axis, the treatment experience is greatest for ACE inhibitors.²

The ACE inhibitor class has expanded to include 10 ACE agents available in the United States and many more worldwide. In addition to their vasodepressor properties, ACE inhibitors effectively slow the progression of renal, cardiac, and/or vascular disease.^{2,3} Thus it was a logical step in their development to seek additional indications for treatment of congestive heart failure (CHF), postmyocardial infarction (post-MI), and diabetic nephropathy (Tables 65–1 and 65–2).^{2,3} A therapeutic indication has also been granted for the ACE inhibitor ramipril for the treatment of the high-risk cardiac patient without discernable left ventricular dysfunction.⁴

This chapter broadly discusses the pharmacokinetics, pharmacodynamics, response, and outcomes data for ACE inhibitors. The reader is directed to sources that provide more-comprehensive discussion of particular themes that cannot be discussed because of space constraints, such as the properties and function of ACE (Chapter 9) and outcome trials of ACE inhibitors (Chapter 35).

PHARMACOLOGY

The first orally active ACE inhibitor was the sulfhydryl-containing compound captopril, which was introduced in 1981. Subsequently, the more long-acting compound enalapril maleate, a prodrug requiring *in vivo* hepatic and intestinal wall esterolysis to yield the active diacid inhibitor enalaprilat, and lisinopril became available. All orally administered ACE inhibitors are prodrugs with the exception of

lisinopril and captopril.⁵ It was originally thought that formation of the active diacid metabolites of ACE inhibitors, such as enalapril, would be inhibited in the presence of hepatic impairment, as in advanced CHF. This slowdown in metabolism proved to be inconsequential, however.⁶

ACE inhibitors are structurally heterogeneous. The binding ligand for ACE separates these drugs into three groups: sulfhydryl-, phosphinyl-, and carboxyl-containing moieties. The purported pharmacologic advantages of sulfhydryl-containing ACE inhibitors, such as captopril, are to date clinically unproved, but the sulfhydryl group found on captopril is widely viewed as the source of the more-frequent skin rashes—usually maculopapular in type—and the dysgeusia seen with this compound.⁷ The suggestion that the phosphinyl group, found on fosinopril, might favorably alter its penetration into the myocardium and thereby improve myocardial inotropic and lusitropic responses is likewise unproved.⁸

ACE inhibitors can be further distinguished by differences in rate and extent of absorption, plasma protein binding, systemic half-life, and mode of systemic disposition, but they behave quite similarly in how they lower blood pressure (BP) (Table 65–3).^{3,5,9,10} Beyond the issue of dosing frequency, these pharmacologic differences are seldom of sufficient consequence to govern selection of an agent.^{3,10} Two pharmacologic considerations for the ACE inhibitors, route of systemic elimination and tissue-binding, have recently generated considerable discussion and merit additional comment.^{11,12}

Route of Elimination

In the presence of chronic kidney disease (CKD), the ACE inhibitors ramipril, enalapril, fosinopril, trandolapril, and benazepril do not accumulate with repetitive dosing, suggesting that these prodrugs either undergo biliary clearance directly or that their conversion to an active diacid form is independent of renal function.^{13–15} Each of these prodrug ACE inhibitors is marginally active, so the absence of accumulation in CKD should not be viewed as evidence of a clinically relevant dual route of elimination for these drugs. ACE inhibitor accumulation in CKD is most germane for the diacid metabolites (typically the active form) of these compounds. The diacid metabolites of fosinopril and trandolapril, fosinoprilat and trandolaprilat, are the only ones that undergo dual renal and hepatic elimination.^{14,15} The systemic clearance of all other ACE inhibitors is largely renal, declining early in the course of CKD and occurring as a function of varying degrees of filtration and tubular secretion.¹¹ ACE inhibitor accumulation has yet to be associated with known side effects, such as cough or angioneurotic edema. However, elevations in ACE inhibitor concentrations can be accompanied by significantly reduced BP and its organ-directed sequelae.¹⁶

Table 65-1 FDA-Approved Indications for ACE Inhibitors

Drug	HTN	CHF	Diabetic Nephropathy	High-Risk Patients Without Left Ventricular Dysfunction
Captopril	•	• (post-MI)*	•	
Benazepril	•			
Enalapril	•	•†		
Fosinopril	•	•		
Lisinopril	•	• (post-MI)*		
Moexipril	•			
Perindopril	•			
Quinapril	•	•		
Ramipril	•	• (post-MI)		•
Trandolapril	•	• (post-MI)		

*Captopril and lisinopril are indicated for CHF treatment both postmyocardial infarction and as adjunctive therapy in general heart failure therapy.

†Enalapril is indicated for asymptomatic, left ventricular dysfunction.

ACE, angiotensin-converting enzyme; HTN, hypertension; CHF, congestive heart failure; MI, myocardial infarction.

Table 65-2 ACE Inhibitors: Dosage Strengths and Treatment Guidelines

Drug	Trade Name	Usual Total Dose and/or Range—Hypertension (Frequency day)	Usual Total Dose and/or Range—Heart Failure (Frequency day)	Comment	Fixed-Dose Combination*
Benazepril	Lotensin	20-40 (1)	Not FDA approved for heart failure		Lotensin HCT
Captopril	Capoten	12.5-100 (2-3)	18.75-150 (3)	Generically available	Capozide†
Enalapril	Vasotec	5-40 (1-2)	5-40 (2)	Available generically and intravenously	Vaseretic
Fosinopril	Monopril	10-40 (1)	10-40 (1)	Renal and hepatic elimination	Monopril-HCT
Lisinopril	Prinivil, Zestril	2.5-40 (1)	5-20 (1)	Generically available	Prinizide, Zestoretic
Moexipril	Univasc	7.5-30 (1)	Not FDA approved for heart failure		Uniretic
Perindopril	Aceon	2-16 (1)	Not FDA approved for heart failure		
Quinapril	Accupril	5-80 (1)	10-40 (1-2)		Accuretic
Ramipril	Altace	2.5-20 (1)	10 (2)	Indicated in high-risk vascular patients	
Trandolapril	Mavik	1-8 (1)	1-4 (1)	Renal and hepatic elimination	Tarka

*Fixed-dose combinations in this class typically contain a thiazide-like diuretic.

†Capozide is indicated for first-step treatment of hypertension.

Table 65-3 Predominant Hemodynamic Effects of ACE Inhibitors

Hemodynamic Parameter	Effect	Clinical Significance
CARDIOVASCULAR		
Total peripheral resistance	Decreased	These parameters contribute to a general decrease in systemic blood pressure
Mean arterial pressure	Decreased	
Cardiac output	Increased or no change	
Stroke volume	Increased	
Preload and afterload	Decreased	
Pulmonary artery pressure	Decreased	
Right atrial pressure	Decreased	
Diastolic dysfunction	Improved	
RENAL		
Renal blood flow	Usually increased	Contributes to the renoprotective effect of these agents
Glomerular filtration rate	Variable, usually unchanged but may ↓ in renal failure	
Efferent arteriolar resistance	Decreased	
Filtration fraction	Decreased	
PERIPHERAL NERVOUS SYSTEM		
Biosynthesis of noradrenaline	Decreased	Enhances blood pressure lowering effect and resets baroreceptor function
Reuptake of adrenaline	Inhibited	
Circulating catecholamines	Decreased	

Tissue Binding

The physicochemical differences among ACE inhibitors, including binding affinity, potency, lipophilicity, and depot effect, allow for the arbitrary classification of ACE inhibitors according to affinity for tissue-ACE.^{12,17,18} The extent to which tissue ACE is blocked by an ACE inhibitor is a function of both the inhibitor’s intrinsic binding affinity and the free inhibitor concentration found within that tissue. The tissue-based free inhibitor concentration is in a continuous state of flux and at any one time is determined by the sum of ACE inhibitor delivered to tissues and residual ACE inhibitor released from tissues for reentry into the bloodstream. The quantity of ACE inhibitor conveyed to tissues is determined by several pharmacologic variables including dose frequency/amount, absolute bioavailability, plasma half-life, and tissue penetration. When blood levels of an ACE inhibitor are high—typically in the first third to half of the dosing interval—tissue retention per se of an ACE inhibitor is not needed for an enduring level of ACE inhibition. However, as ACE inhibitor blood levels fall during the second half of the dosing interval, two factors—inhibitor binding affinity and tissue retention—take on added importance if functional ACE inhibition is to be maintained.

The question arises as to whether the degree of tissue ACE inhibition may extend to efficacy differences between the various ACE inhibitors. In this regard, there appears to be little difference among the various ACE inhibitors in their capacity to reduce BP. When relative drug-to-drug BP responses differ among ACE inhibitors, it is generally the result of dissimilar half-lives of the compounds under study.

An additional consideration is whether ACE inhibitors with high tissue affinity differ in their ability to provide BP-independent target organ protection, as has been theorized for ramipril in the Heart Outcomes Prevention Evaluation (HOPE).¹⁹ In this regard, endothelial function has been observed to improve more regularly with the higher tissue-

ACE affinity compounds, such as quinapril and ramipril. If improvement in endothelial function is accepted as a surrogate for protection from target organ events, then relevant differences may exist among ACE inhibitors.

However, there have been no direct head-to-head outcomes trials comparing ACE inhibitors with different tissue affinity. Results of the limited head-to-head comparisons available do not convincingly support the claim of overall superiority for lipophilic ACE inhibitors.^{20,21}

APPLICATION OF PHARMACOLOGIC DIFFERENCES

Because there is little that truly separates one long-acting ACE inhibitor from another in the treatment of hypertension, cost has assumed increased importance.²² For pricing to be key in the selection of an ACE inhibitor is not unreasonable if the drug were being used only for the control of BP. ACE inhibitors, however, are also extensively used for their cardiorenal outcomes benefits, and only a limited number of ACE inhibitors have been studied in this context. The term *class effect* has entered into the discussion of both of these aspects of ACE inhibitor use but is relevant to one and not the other.

Class effect is a phrase often invoked to legitimize substitution of one ACE inhibitor for another that has been specifically studied in a disease state, such as CHF or diabetic nephropathy.^{19,23-25} The concept of *class effect* is well suited for application to the BP effects of ACE inhibitors, where scant difference exists among the numerous agents in the class. The concept of *class effect*, already vague in its definition, becomes even more ambiguous when “true” dose equivalence for a non-BP endpoint, such as rate of progression to end-stage renal disease (ESRD) or survival in the setting of CHF, is being determined for the various ACE inhibitors. Determining ACE inhibitor dose equivalence from outcomes

trials is confounded by differing dose frequency, titration requirements, and level of renal function in individual studies.²⁶⁻³¹ The latter is particularly relevant to the elderly, because senescence-related changes in renal function extend the functional half-life of ACE inhibitors (renally cleared) and make it nearly impossible to determine “true” dose equivalence between various drugs in the class. In interpreting the results of outcome studies with ACE inhibitors, it is prudent to assume that the benefits derive from the compound being tested, for the outcome being studied, at the per protocol dose and frequency of dosing. However, despite these caveats about the difficulty in establishing dose equivalence, the clinician can estimate equivalent doses among the various ACE inhibitors if ACE inhibitor substitution is planned.

MECHANISM OF ACTION AND HEMODYNAMIC EFFECTS

The site of ACE inhibitor activity (within the RAA axis) can be pinpointed at the pluripotent ACE, an enzyme known to catalyze the conversion of angiotensin I to angiotensin II, as well as to facilitate the degradation of bradykinin to assorted peptides.^{17,32} However, ACE inhibition, as a means to reduce angiotensin II levels has inherent limitations.¹⁷ ACE inhibition fails to suppress production of angiotensin II by alternative enzymatic pathways—such as chymase and other tissue-based proteases.^{17,33} These alternative pathways represent the principal mode of angiotensin II generation in several tissues, including the myocardium and the vasculature of humans.^{34,35} With long-term administration of an ACE inhibitor, these alternative pathways become involved in a sequence of events culminating in a return of angiotensin-II concentrations to pretherapy levels (“angiotensin II escape”).

Substrate for these alternative pathways is obtained from the increase in angiotensin I levels arising from a disinhibition of renin secretion by ACE inhibition-induced reductions in circulating angiotensin II.^{35,36} Because ACE inhibitors reduce angiotensin II levels for only a limited period of time (weeks) during chronic administration, other mechanisms must account for their persistent BP-lowering effect.^{36,37} One possibility is that increased concentrations of the vasodilator bradykinin enhance the release of nitric oxide (NO), stimulate the production of endothelium-derived hyperpolarizing factor, and accentuate the release of prostacyclin (PGI₂).^{38,39} Moreover, ACE is also responsible for the degradation of angiotensin-(1-7), an angiotensin peptide with the capacity to counterbalance a number of the pleiotropic (renal and vascular) effects of angiotensin II (see Chapter 10).³⁹ The contribution of angiotensin “fragments” (many of which are physiologically active) and prostaglandins/NO to the antihypertensive effect of ACE inhibitors is still debated.^{39,40}

Conversely, nonsteroidal antiinflammatory drugs (NSAIDs) and selective cyclooxygenase inhibitors (COXIBs), such as celecoxib and rofecoxib, attenuate the BP-lowering effect of a number of antihypertensive drugs including ACE inhibitors.^{41,42} This occurs more commonly in salt-sensitive hypertensives, as in many elderly patients.⁴² A question that remains unresolved is the degree to which aspirin (acetylsalicylic acid [ASA]) administration interferes with the anti-

hypertensive and/or cardioprotective effects of an ACE inhibitor.⁴³⁻⁴⁵ Low-dose ASA (100 mg/day or less) appears to minimally affect the BP reduction seen with ACE inhibition.^{43,44} For example, in the Hypertension Optimal Treatment (HOT) study, long-term, low-dose ASA did not interfere with the BP-lowering effect of antihypertensive combinations, which in many cases included ACE inhibitors.⁴⁴ However, higher doses, generally above 236 mg/day, can blunt the antihypertensive response to an ACE inhibitor and possibly neutralize the clinical benefits of ACE inhibitors in patients with heart failure.⁴⁵

A reduction in both central and peripheral sympathetic nervous system (SNS) activity accounts for a portion of the antihypertensive effect of an ACE inhibitor (Table 65-3).^{46,47} ACE inhibitors preserve circulatory reflexes and baroreceptor function; thus they do not reflexly increase heart rate when BP is reduced.⁴⁸ The latter property accounts for the low incidence of postural hypotension with ACE inhibitors and provides an important safety benefit in elderly persons, who as a group are typically predisposed to orthostatic hypotension.⁴⁹ ACE inhibitors also improve endothelial function, facilitate vascular remodeling, and favorably modify the viscoelastic properties of structurally abnormal blood vessels (see Chapters 14 and 15).^{50,51} These vascular effects are the likely explanation for the incremental reduction in BP with the long-term use of ACE inhibitors.

BLOOD PRESSURE-LOWERING EFFECT

All ACE inhibitors available in the United States are FDA-approved for the treatment of hypertension (see Table 65-2). Based on outcome data, the Seventh Report of the Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7); the World Health Organization/International Society of Hypertension; and European Society of Hypertension/European Society of Cardiology now recognize ACE inhibitors as an option for first-line therapy in patients with essential hypertension, especially in those with a high coronary disease risk profile, diabetes with renal disease/proteinuria, CHF, and/or post MI.^{1,52-55}

The enthusiasm for the use of ACE inhibitors extends beyond the issue of effectiveness, because they are comparably efficacious as (and no better than) most other drug classes, including diuretics, β -blockers, and calcium channel blockers. Response rates with ACE inhibitors range from 40% to 70% in stage 1 or 2 hypertension, with salt intake and race serving as important variables in determining the response.⁵⁶ In interpreting clinical trial results with ACE inhibitors, a distinction should be made between the mean reduction in BP (which is typically highly significant) and the percentage of individuals who are poor, average, and excellent responders (which may vary considerably among studies).

There are few predictors of the vasodepressor response to ACE inhibitors. Although ACE gene polymorphism (and specific genotypes), among other genetic determinants, have been suggested to predict the antihypertensive response to an ACE inhibitor, findings have been sufficiently inconsistent to warrant a wait-and-see attitude for genotyping.⁵⁷ There has also been a limited predictive relationship between the pretreatment and/or posttreatment PRA value (used as a marker of RAA axis activity)

and the fall in BP with an ACE inhibitor. However, when hypertension is marked by significant elevation of PRA (activation of the RAA axis), as in renal artery stenosis, the response to an ACE inhibitor can be profound.⁵⁸

Certain patient groups, including low-renin, salt-sensitive, volume-expanded individuals such as the diabetic and African American hypertensives, are generally less responsive to ACE inhibitor monotherapy. However, the BP response to an ACE inhibitor can be highly variable in African American and diabetic patients, with some individuals in these groups experiencing significant falls in BP. The low-renin state characteristic of the elderly hypertensive differs from other low-renin forms of hypertension in that it reflects the consequences of senescence-related changes in the RAA axis and not volume expansion.⁵⁹ The elderly generally respond well to ACE inhibitors in conventional doses,⁶⁰ although senescence-related renal failure, which slows the elimination of most ACE inhibitors, complicates interpretation of dose-specific treatment successes.

Results from a number of head-to-head trials support the comparable antihypertensive efficacy and tolerability of the various ACE inhibitors if comparable doses of the individual ACE inhibitors are given (see Table 65–2). However, there are differences among the ACE inhibitors, as to the time to onset and/or duration of effect, which may relate to the absorption and tissue distribution characteristics of a compound.

Enalaprilat is the lone ACE inhibitor available in an intravenous form; however, multiple choices exist for the orally available ACE inhibitors.³ ACE inhibitors labeled as “once-daily” vary in their ability to reduce BP for a full 24 hours, as defined by a trough:peak ratio >50%.⁶¹ Consequently, in deciding on the dosing frequency for ACE inhibitors, one should bear in mind that response patterns to these drugs are highly individualized, with many patients requiring a second daily dose to maintain effect. However, in the elderly, senescence-related changes in renal function (and reduced renal clearance of the compound) and/or giving a high dose may obviate a second ACE inhibitor dose during the 24-hour treatment period.⁶²

A frequent question asked is what steps to take when an ACE inhibitor fails to normalize BP. This question is best answered in the context of the magnitude of the response. If there is a minimal BP-reducing effect, then a switch to an alternative drug class is justified unless continuation of an ACE inhibitor is indicated on the basis of a high cardiac and/or renal risk profile. However, ACE inhibitor nonresponders fairly regularly “respond” on addition of a diuretic or a calcium channel blocker, so very few patients should have an ACE inhibitor discontinued simply based on a failure to “respond” to monotherapy.

If the BP response to an ACE inhibitor is modest, one can increase the daily dose (possibly by reverting to twice-daily administration), understanding that the dose-response curve for ACE inhibitors, like many antihypertensive agents, is fairly steep at the beginning doses and flattens thereafter.^{63–64} Increasing the dose of an ACE inhibitor does not generally change the peak effect; rather, it extends the duration of response. In fact, several of the shorter-acting ACE inhibitors, such as enalapril, can behave as once-a-day medications if high-enough daily doses are given to prolong the duration of effect. A final consideration with ACE inhibitor therapy is that of an incremental benefit (over several weeks) on BP relating

to factors such as vascular remodeling and/or improvement in endothelial function.⁵¹

ACE INHIBITORS IN COMBINATION WITH OTHER AGENTS

The BP-lowering effect of an ACE inhibitor is improved with the simultaneous administration of a diuretic, particularly in salt-sensitive forms of hypertension.⁶⁵ This pattern of response has encouraged the development of fixed-dose combination products, composed of an ACE inhibitor and varying doses (as low as 12.5 mg) of a thiazide-type diuretic.^{65,66} The rationale for combining these two drug classes arises from the observation that diuretic-related sodium depletion activates the RAA axis, causing BP to shift to an angiotensin II–dependent mode, a circumstance most responsive to the BP-reducing effect of an ACE inhibitor.

β -Blockers have also been administered in conjunction with ACE inhibitors, an approach that was possible per protocol in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).⁵³ The β -blocker atenolol was the most commonly added second medication in ALLHAT. A potential physiologic basis for this combination is that β -blockade blunts the reactive rise in PRA that goes along with ACE inhibitor therapy; alternatively, this combination can be considered for use in the setting of coronary artery disease, with any BP gain being a secondary consideration.⁶⁷ When a meaningful reduction in BP follows from the addition of a β -blocker to an ACE inhibitor, it is often accompanied by a reduction in pulse rate. Alternatively, adding a peripheral α -antagonist, such as doxazosin, to an ACE inhibitor can further reduce BP, albeit without a clear mechanistic basis.⁶⁸

The BP-lowering effect of an ACE inhibitor is enhanced with the addition of a CCB, either dihydropyridine or non-dihydropyridine, and this has been the basis for several fixed-dose combination products.^{69–71} Adding an ACE inhibitor to a CCB is also helpful in attenuating the peripheral edema commonly seen with CCB therapy.⁷² In addition, preliminary evidence supports use of CCB-therapy in attenuating the reduction in glomerular filtration rate (GFR) that can accompany ACE inhibitor treatment.⁷³ This is of particular relevance to the elderly, since one reason for underuse of ACE inhibitors in older persons is fear of inducing a decline in renal function superimposed on preexisting renal dysfunction. This CCB-ACE inhibitor hemodynamic interaction at a renal level may occasionally result in false-positive captopril renography studies.

The efficacy of both ACE inhibitors and angiotensin-receptor blockers (ARBs) as antihypertensive agents is well established. This has fueled the belief that in combination, these two drug classes may provide an incremental benefit in both BP reduction and target organ protection. However, there is insufficient evidence to support a general recommendation for the combination of these two drug classes in BP management.^{74,75}

Studies have established the utility of ACE inhibitors in the management of hypertensive patients otherwise unresponsive to multiple drug combinations, such as a diuretic together with minoxidil, a CCB and/or a peripheral α -blocker.⁷⁶ If an acute reduction in BP is needed, oral or sublingual captopril—with an onset of action as soon as 15 minutes after administration—can be administered. An additional

option for the management of hypertensive emergencies is intravenous enalaprilat, with a dose of 0.625 mg representing a maximal effective dose (higher doses may only extend the duration of action).⁷⁷ ACE inhibitors should be administered cautiously in patients suspected of marked activation of the RAA axis (e.g., prior treatment with diuretics and/or immediately post-MI). In such persons, sudden and extreme falls in BP—so-called first dose hypotension—have been observed.⁷⁸

ACE INHIBITORS IN HYPERTENSION ASSOCIATED WITH OTHER DISORDERS

ACE inhibitors effectively regress left ventricular hypertrophy (LVH).⁷⁹ This is an important property of ACE inhibitors, given that LVH portends a significant future risk of sudden death or MI.⁸⁰ ACE inhibitors can be safely utilized in patients with coronary artery disease (CAD) and are indicated for secondary prevention after acute MI.^{2,3} The ACE inhibitor perindopril has been shown to reduce cardiovascular risk in a low-risk population with stable CAD and no apparent heart failure.⁸¹ Although they are not proven coronary vasodilators, ACE inhibitors improve hemodynamic factors such that myocardial oxygen consumption is reduced with no worsening of angina and possibly some attendant reductions in ischemia (Table 65–3). For example, ACE inhibitors do not reflexively increase myocardial sympathetic tone in hypertensive patients with angina, as can take place with other antihypertensives.^{82,83}

ACE inhibitors are useful in the treatment of both isolated systolic hypertension and systolic-predominant forms of hypertension, in part because of their capacity to improve artery compliance.^{51,84} They are also of value in the treatment of patients with cerebrovascular disease, because they preserve cerebral autoregulation in the face of reduced BP, a property of particular relevance to the elderly hypertensive.⁸⁵ ACE inhibitors dilate both small and large arteries and can be used safely in patients with peripheral arterial disease (PAD). They may favorably modify the pattern and/or the course of intermittent claudication.⁸⁶ Of the 9297 patients in the HOPE study, 4051 had PAD—defined by a history of PAD, claudication, or an ankle-brachial index <0.90. These patients had a reduction in the primary endpoint similar to those without PAD, indicating that ACE inhibition lowers the risk of fatal and nonfatal ischemic events in PAD patients.⁸⁷

ACE inhibitors are preferred agents in the hypertensive diabetic patient for both BP reduction and organ protection, a use presumably independent of BP lowering.⁸⁸ It is often necessary to coadminister a diuretic, because the BP-lowering effect of ACE inhibitor monotherapy is modest in the low-renin, volume-expanded form of hypertension characteristic of the diabetic. A final consideration in the hypertensive diabetic relates to the effect of ACE inhibitors on lipid parameters and/or insulin resistance. Although an unambiguous effect on serum lipids and/or insulin resistance has yet to be demonstrated for ACE inhibitors,⁸⁹ both the CAPtopril Prevention Project (CAPPP) and HOPE studies showed that the ACE inhibitors captopril and ramipril, respectively, decreased the incidence of new-onset type 2 diabetes mellitus.^{90,91}

TARGET ORGAN EFFECTS AND RECENT CLINICAL TRIALS

Renal

JNC 7 recommends the use of ACE inhibitors in patients with hypertension and CKD to both control hypertension and slow the rate of progression of renal failure.^{1,54} However, the renoprotective features of ACE inhibitors should never substitute for tight BP control, which is of paramount importance in the management of the hypertensive CKD patient. In this regard, JNC 7 suggests a goal BP of <130/80 mm Hg in albuminuric patients (>300 mg/day) with or without CKD.⁵⁴ In hypertensive CKD patients, ACE inhibitor monotherapy (without related diuretic administration) rarely yields a brisk BP-lowering response—because of the volume dependency of this form of hypertension. For example, in the African American Study of Kidney Disease (AASK), hypertensive African American CKD patients treated with ramipril and randomized to a mean arterial BP of 102 to 107 mm Hg required three additional medications on average to achieve this goal BP range.⁹²

Both macroproteinuria and microalbuminuria have emerged as strong markers for the rate of CKD progression.⁹³ In particular, microalbuminuria foreshadows the progression of diabetic nephropathy and should be routinely measured in all diabetics.⁹³ The choice of risk terms (macroproteinuria or microalbuminuria) is by no means absolute in that the partition values for urine albumin:creatinine ratio, used to identify microalbuminuria, are without a specific threshold value.⁹⁴ Proteinuria also serves as an independent risk factor for fatal and nonfatal cardiovascular events.^{94,95} Screening for microalbuminuria is recommended in all diabetics and increasingly in others perceived to be at high risk for renal or cardiovascular disease.^{96,97} It is now recommended that proteinuria be therapeutically targeted when present in either diabetic or non-diabetic renal disease.^{98,99} ACE inhibitors and ARBs effectively reduce protein excretion and thereby are important tools in the treatment of microalbuminuria or macroalbuminuria with or without concomitant hypertension.^{99,100}

ACE inhibitors have renoprotective effects in various settings, including established type 1 insulin-dependent diabetic nephropathy,²⁴ type 2 non-insulin-dependent diabetic nephropathy,^{101,102} normotensive type 1 diabetic patients with microalbuminuria,¹⁰³ and an assortment of nondiabetic renal diseases.^{98,104–106} In some diabetic patients, ACE inhibitor therapy has resulted in the remission of nephrotic range proteinuria and long-term stabilization of renal function.^{107,108}

However, aggressive BP control (<130/80 mm Hg) in elderly patients with type 2 diabetes and preserved renal function has been shown to stabilize renal function regardless of whether the initial therapy was with an ACE inhibitor or a calcium channel blocker.^{109,110} ACE inhibitor therapy is also beneficial in nondiabetic renal diseases. In AASK, ramipril was more effective than amlodipine in limiting the decline in GFR in patients with hypertensive nephrosclerosis and a urinary protein:creatinine ratio >0.22.¹⁰⁶ Moreover, a meta-analysis of ACE inhibitor use in nondiabetic renal disease concluded that ACE inhibitors conferred renal benefit in nondiabetic patients with >0.5 g/day of proteinuria.¹¹¹ In many of the studies making up this meta-analysis, the target BP was <140/90 mm Hg, which is important in that the renoprotective effects of ACE inhibitors (compared with other

antihypertensive agents) may not be as conspicuous at lower BP values.

However, positive renal outcomes with ACE inhibitors in nephropathic states are not guaranteed. In the Ramipril Efficacy in Nephropathy (REIN) study, patients with proteinuric chronic nephropathies were assigned randomly to treatment with the ACE inhibitor ramipril or placebo plus conventional antihypertensive therapy. ACE inhibitors significantly reduced the rate of proteinuria, the decline in GFR, and the risk of ESRD in patients with >3 g/day of proteinuria; however, during the study period, those with proteinuria less than 2 g/24 hours, type 2 diabetes, or polycystic kidney disease did not benefit to an appreciable extent from ACE inhibitor therapy.¹¹²

ACE inhibitor regimens shown to slow the rate of CKD progression include captopril 25 mg three times per day, enalapril 5 to 10 mg/day, benazepril 10 mg/day, and ramipril 2.5 to 5 mg/day.³ Each of these compounds is renally cleared; thus it can be presumed that reduced renal clearance under the circumstances of CKD extended their pharmacologic effect.¹¹³ Whereas it is accepted that the beneficial effects of ACE inhibition are greatest when urinary protein excretion is excessive (> 3 g/24 hours),¹¹⁴ the ACE inhibitor dose providing optimal renoprotection is still debated. For example, low-dose ramipril (1.25 mg/day) had no effect on cardiovascular and renal outcomes of patients with type 2 diabetes and albuminuria, despite a slight decrease in BP and urinary albumin,¹¹⁶ whereas in the HOPE trial, ramipril given at a high-end dose (titrated to 10 mg/day) prevented or delayed the progression of microalbuminuria.¹¹⁵ Dose titration of an ACE inhibitor should be viewed in the context of the therapeutic endpoint, because reduction in protein excretion, lipid parameters, and BP exhibit differing dose responses to up-titration of an ACE inhibitor.^{117,118} For example, in chronic proteinuric nondiabetic nephropathies, up-titration of the ACE inhibitor lisinopril to maximum tolerated doses improves hypertriglyceridemia and hypercholesterolemia (through increases in serum albumin/total protein concentration and thereby oncotic pressure by a direct, dose-dependent effect). These lipid benefits occur with upward dose titration even though the majority of the BP-lowering effect is realized with low-end doses of lisinopril (Figure 65–1).¹¹⁸

ACE inhibitor treatment offers a variety of potentially beneficial renal effects involving hemodynamic, cellular, and lipid-related pathways. However, the positive hemodynamic effects of ACE inhibition can sometimes be misconstrued to represent a “nephrotoxic” process. ACE inhibitors transiently reduce GFR in tandem with reductions in glomerular capillary pressures.^{119,120} Such falls in GFR are typically inconsequential, generally of the order of 10% to 15% and usually reversible, and in point of fact, predictive of renal protection in the long term.¹²⁰ The elderly are more prone to frequent reductions in GFR with ACE inhibitors, at least in part because of their more-extensive microvascular and macrovascular renal disease (see *Side Effects of ACE Inhibitors*).¹²¹ A question commonly put forward, particularly in the elderly, is whether a specific level of renal function exists at which an ACE inhibitor should not be started. There is not a specific level of renal function that prohibits the start of an ACE inhibitor unless clinically important hyperkalemia is anticipated.

Four factors can be viewed as possible modifiers of the renal effects of ACE inhibition. First, a low-sodium intake enhances both the antiproteinuric and antihypertensive response to ACE

Diverse effects of increasing lisinopril doses on lipid abnormalities in chronic nephropathies. *Circulation* 107:586-592, 2003.¹¹⁸

inhibition.^{122,123} Second, short-term studies indicate that dietary protein restriction adds to the ACE inhibitor effect on protein excretion in nephrotic patients, implying that the combination of ACE inhibition and dietary-protein restriction could prove more effective than ACE inhibition alone in slowing the progression of CKD.¹²⁴ A third factor is nocturnal resistance to the antiproteinuric effect of ACE inhibition despite 24-hour persistence of the BP effect.¹²⁵ Finally, inherited variations in the activity of ACE exist because of two common polymorphisms of the ACE gene (I [insertion] and D [deletion]), giving rise to three potential genotypes II, ID, and DD. The DD genotype is associated with higher circulating ACE levels and an increased pressor response to infused angiotensin I as compared with the II genotype, with the ID genotype displaying intermediate characteristics.¹²⁶

The observation that DD patients were at increased risk for MI and ischemic cardiomyopathy was the first indication that the inherited variation in ACE activity might be of clinical significance.¹²⁷ One observational study has shown that renal function declines more precipitously in diabetic CKD patients with the DD genotype, and when such patients are given ACE inhibitors, they do not show significant reductions in either protein excretion or the rate of CKD progression.¹²⁸ Although a promising concept, pharmacogenetic studies to date do not provide a definitive answer as to whether the antiproteinuric effect of ACE inhibition (or renal failure progression rate) is adversely affected (or bettered) by a specific ACE genotype.¹²⁹

Cardiac

ACE inhibitor therapy provides positive outcome benefits in a number of cardiac scenarios, including CHF,^{23,28,130} post-MI,¹³¹⁻¹³⁴ and the hypertensive patient with a high definable

cardiac risk.^{19,52,53,81} This benefit exists both in normotensive¹⁹ and hypertensive^{19,52,53} individuals and in those with varying risk profiles.^{19,52,53,81} This beneficial effect has been observed with several ACE inhibitors, suggesting that a class effect may be present for the positive cardiac outcome benefits of these compounds.^{19,52,53,81} Placebo-controlled and open-label trials suggest that ACE inhibitors improve CHF symptomatology and more importantly, reduce the risk of death and hospitalization from CHF.^{23,28,130} These positive outcome results have established ACE inhibitors as first-line therapy in the treatment of CHF.^{135,136} ACE inhibitors decrease angiotensin II production (at least in the short term)^{34,35} and thereby readjust the neurohumoral imbalance of CHF.^{137,138} Low doses of ACE inhibitors are sufficient to improve exercise tolerance and CHF symptoms^{27,30} and arrest the weight loss otherwise seen with progressive CHF.¹³⁹ However, improvement in CHF mortality requires high-dose ACE inhibitor therapy.^{28,31}

The treatment of CHF should include sequential titration of ACE inhibitors to doses proven to favorably affect mortality in randomized clinical trials. The ability to reach these doses in the CHF patient oftentimes proves challenging, because systemic hypotension and/or a decline in GFR often arise with high-dose ACE inhibitor therapy.^{140,142} Thus, reaching full ACE inhibitor doses calls for a well-developed understanding of the relationship between volume status, BP, and the sought-after ACE inhibitor dose.^{140,141}

Several ACE inhibitors—including captopril, fosinopril, lisinopril, quinapril, ramipril, and trandolapril—now can claim positive outcomes data in various types of CHF.^{130,131} Despite these compelling outcomes data, physician prescribing practice has lagged behind. Only a modest fraction (50%-75%) of CHF patients eligible for ACE inhibitor therapy actually receive the therapy.^{143,144} Moreover, the ACE inhibitor doses commonly used in real-world practice on average are less than one half the targeted dose proven effective in randomized, controlled trials.^{143,144} Factors predicting the use and optimal dosing of ACE inhibitors include the treatment setting (prior hospitalization and/or specialty clinic follow-up), the prescribing physician (cardiology specialty vs. family practitioner/general internist), the patient status (increased severity of symptoms, male, younger), and the drug (lower frequency of administration).¹⁴³ Underdosing of ACE inhibitors has a negative economic impact in CHF because it is associated with more frequent CHF hospitalizations.¹⁴⁵

Enalapril, captopril, lisinopril, and trandolapril have been shown to significantly reduce morbidity and mortality over a wide range of ventricular dysfunction in the post-MI patient.^{131,133,134} In a hemodynamically stable patient (systolic BP >100 mm Hg) following an MI, an oral ACE inhibitor should be initiated (generally within the first 24 hours of the event), particularly if the MI is accompanied by depressed left ventricular function.¹⁴⁶ The hemodynamic effects and overall benefit of ACE inhibition are gained early after an MI, with the 30-day survival increasing by 40% in the first day, 45% in days 2 to 7, and approximately 15% thereafter.¹⁴⁷ Recent trends show a promising increase in ACE inhibitor prescriptions for patients discharged following an acute MI.¹³²

Captopril, lisinopril, ramipril, and trandolapril are approved for specific post-MI left ventricular dysfunction, and enalapril is indicated for use in asymptomatic left ventricular dysfunction (see Table 65-1).³ The consistency of these findings suggests a class effect for this facet of ACE

inhibitor use.¹³⁴ There are too few data to conclude that there are clinically significant differences among the ACE inhibitors in the post-MI setting, given both the lack of head-to-head trials and the variability of study circumstances for particular ACE inhibitors.^{133,134}

Several trials have assessed the utility of ACE inhibitors in modifying cardiac endpoints.^{19,52,53,81} These trials have compared ACE inhibitor therapy to either placebo^{19,81} or an active comparator such as a thiazide diuretic.^{52,53} A number of these trials have been interpreted as showing that ACE inhibitors have particular advantages in reducing cardiovascular disease outcomes. However, available data demonstrate insignificant differences in total major cardiovascular events between regimens based on ACE inhibitors, calcium antagonists, and diuretics or β -blockers, taken in the context of ACE inhibitor-based regimens reducing BP less.¹⁴⁸ Ethnic background of the study participants may also be an important determinant of the efficiency of ACE inhibitors in outcome trials. For example, the ALLHAT trial⁵³ showed a smaller reduction of total major cardiovascular events with the ACE inhibitor lisinopril than with the diuretic chlorthalidone, in large part because of the large proportion of African American patients in the study and the much smaller reduction in BP achieved with lisinopril in that subgroup.

Stroke

Given the significant public health impact of stroke and the identification of both nonmodifiable (age, gender, race/ethnicity) and modifiable (BP, diabetes, lipid profile, and lifestyle) risk factors, early prevention strategies are increasingly being put into practice. When a patient suffers a stroke, the focus of care becomes the prevention of secondary events. This can be accomplished with antiplatelet and lipid-lowering, as well as BP-reduction, strategies. Despite the clear risk reduction with effective realization of these preventative strategies, new approaches are needed. One such “new” approach is to determine whether the stroke benefit gained from BP reduction is unique to the agent employed—such as an ACE inhibitor or an ARB—or a simple consequence of upgrading the hemodynamic profile.¹⁴⁹⁻¹⁵¹ The data supporting ACE inhibitors in reducing stroke rate have been mixed.^{150,152} In the ALLHAT study, stroke incidence was 15% greater with the ACE inhibitor lisinopril (primarily in African Americans) than with the thiazide-type diuretic chlorthalidone.⁵³ In part, this was related to the less-effective BP reduction in the lisinopril group than in the chlorthalidone group. Similar negative data for ACE inhibitors and stroke arose from the Perindopril Protection Against Recurrent Stroke Study (PROGRESS) of the ACE inhibitor perindopril in the context of secondary stroke prevention.¹⁴⁹ In this study, 6105 hypertensive and non-hypertensive patients who had sustained a stroke without a major disability within the past 5 years were randomized to a 4-mg dose of perindopril with or without a 2.5-mg dose of indapamide (diuretic therapy was at the discretion of the treating physician). BP was reduced by an average of 9/4 mm Hg in the active treatment group, resulting in a 28% reduction in risk of major stroke in all participants. This reduction of risk extended to all forms of stroke (major disabling, hemorrhagic, ischemic, or unknown) to patients with and without hypertension and with and without diabetes. The most beneficial effect was seen in the group receiving perindopril and indapamide,

in which BP decreased by 12/5 mm Hg. Surprisingly, patients who received perindopril monotherapy had no reduction in cerebrovascular morbidity and mortality despite a significant 5/3–mm Hg fall in BP.¹⁴⁹ The PROGRESS data are important because it has been debated whether the long-term lowering of BP in patients who have sustained a prior cerebrovascular event reduces recurrent stroke rate comparably with the benefit observed for primary stroke prevention with BP reduction.

The HOPE trial results with the ACE inhibitor ramipril showed that the benefits of lowering BP on the risk of stroke are not confined to patients with hypertension. Compared with placebo, ramipril reduced the risk of any stroke by 32% and that of fatal stroke by 61%. Benefits were consistent across baseline BPs, concomitant drug use, and subgroups defined by the presence or absence of previous stroke, peripheral arterial disease, diabetes, or hypertension.¹⁵³ Based on the HOPE study, the American Heart Association guidelines for the primary prevention of stroke recommend ramipril to prevent stroke in high-risk patients and in patients with diabetes and hypertension.¹⁵⁴

SIDE EFFECTS OF ACE INHIBITORS

A syndrome of “functional renal insufficiency” has been observed as a class effect with ACE inhibitors.¹⁵⁵ This phenomenon was initially reported in patients with renal artery stenosis and a solitary kidney or bilateral renal artery stenosis. Predisposing conditions include dehydration, CHF, NSAID use, and/or either microvascular or macrovascular renal disease.^{142,156} The mechanism common to these conditions is a fall in afferent arteriolar flow. When this occurs, glomerular filtration temporarily declines. In response to this reduction in glomerular filtration, local production of angiotensin II

increases. In concert with this increase in angiotensin II, the efferent or postglomerular arteriole constricts, reestablishing hydrostatic pressures in the more proximal glomerular capillary bed.

The abrupt removal of angiotensin II, as occurs with an ACE inhibitor (or an ARB), will acutely dilate the efferent arteriole in tandem with a reduction in systemic BP. In combination, these hemodynamic changes drop glomerular hydrostatic pressure such that glomerular filtration plummets. This type of “functional renal insufficiency” is best treated by discontinuation of the responsible agent, careful volume expansion (if intravascular volume contraction is a contributing factor), and, if warranted on clinical grounds, evaluation for the presence of renal artery stenosis (Figure 65–2).¹⁴⁰

Hyperkalemia is an additional ACE inhibitor–associated side effect.¹⁵⁷ ACE inhibitor–related hyperkalemia occurs infrequently unless a specific predisposition to hyperkalemia exists, such as diabetes or CHF with renal failure (receiving potassium-sparing diuretics or potassium supplements).^{158,159} Conversely, ACE inhibitors reduce the potassium loss that ordinarily accompanies diuretic therapy.

A dry, irritating, nonproductive cough is a common complication of ACE inhibitor treatment, with an incidence of up to 44%.¹⁶⁰ Cough is a class effect of ACE inhibitors and has been attributed to an increase in bradykinin and/or other vasoactive peptides such as substance P, which may play a second messenger role in setting off the cough reflex. Although numerous therapies have been tried, few have had any lasting success in eliminating ACE inhibitor–induced cough. The sensible clinical approach for suspected ACE inhibitor–related cough is to reassess the patient several weeks after drug discontinuation. Disappearance of the cough can then be taken as proof of an ACE inhibitor cause.

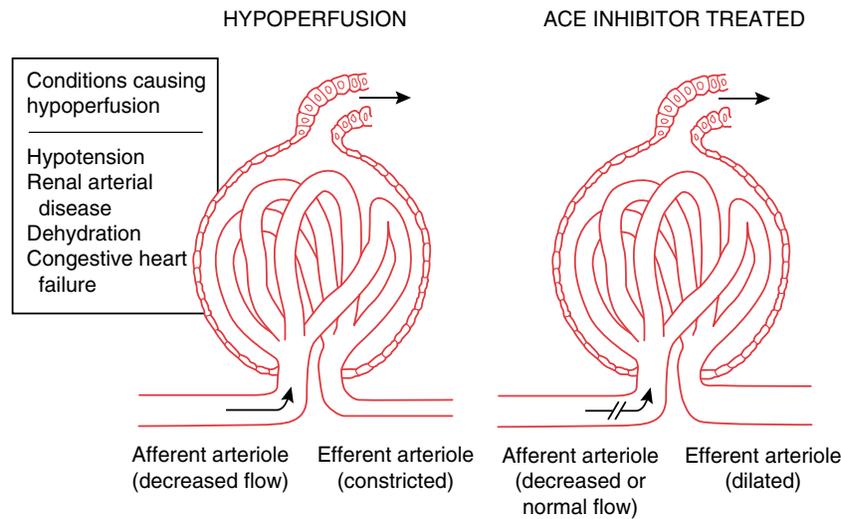

Figure 65–2 Schematic illustration of settings wherein ACE inhibitor therapy may worsen renal function. Conditions causing renal hypoperfusion include systemic hypotension, high-grade renal artery stenosis, extracellular fluid volume contraction (simplified as “dehydration” in the figure), administration of vasoconstrictor agents (NSAIDs or cyclosporine, not shown), and CHF. These conditions typically increase renin secretion and angiotensin II production. Angiotensin II constricts the efferent arteriole to a greater extent than the afferent arteriole, such that glomerular hydrostatic pressure and GFR can be maintained despite hypoperfusion. When these conditions occur in ACE inhibitor–treated patients, angiotensin II formation and effect are diminished, and GFR may decrease. (Adapted with permission from *Circulation* 104:1985–1991, 2001.¹⁴⁰)

Nonspecific side effects of ACE inhibitors are generally uncommon with the exception of taste disturbances, leukopenia, skin rash, and dysgeusia, which are largely seen in captopril-treated patients.¹⁶¹ ACE inhibitor use has not been associated with headache. In fact, ACE inhibitors have been used for migraine prophylaxis, and they have been proven effective in reducing the risk of nitrate-induced headache.¹⁶² Angioneurotic edema is a potentially life-threatening complication of ACE inhibitors that is more common in Blacks.¹⁶³ Angioedema of the intestine (more common in women) can also occur with ACE inhibitor therapy, with a typical presentation of abdominal pain/diarrhea with or without facial and/or oropharyngeal swelling (Figure 65–3).¹⁶⁴ However, the use of ACE inhibitors is not associated with a significantly increased risk of acute pancreatitis.¹⁶⁵ A final side effect of ACE inhibitors is anemia. ACE inhibitors suppress the production of erythropoietin in a dose-dependent manner, which presents a particular problem when they are administered in the presence of renal failure.¹⁶⁶ Alternatively, this aspect of ACE inhibitor effect can be used therapeutically in posttransplant erythrocytosis and high-altitude polycythemia.^{167,168}

SUMMARY

ACE inhibitors are used commonly to reduce BP or to provide cardioprotection and/or renoprotection. They provide the greatest target organ protection in patients with CHF, proteinuric renal disease, or post-MI. Dosing guidelines exist for each of these scenarios, although such guidelines may not be followed as closely in clinical practice as is advised. ACE

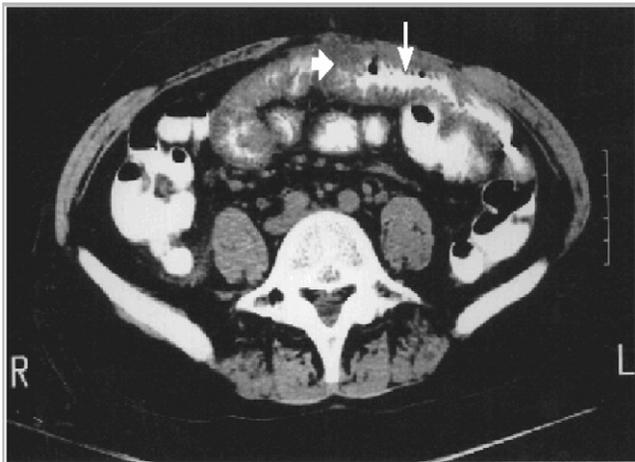

Figure 65–3 Abdominal computed tomography was performed in a 58-year-old woman with acute abdominal pain, nausea, vomiting, and abdominal distention. The patient had had recurrent swelling of the tongue and pharynx during therapy with lisinopril, but the medication had been continued. On the scan, the mucosa of a loop of small intestine is markedly thickened, and the irregularities within the wall are most consistent with the presence of edema (thick arrow). The valvulae conniventes are prominent and widened (thin arrow), resulting in a severely narrowed lumen. All of the patient's symptoms resolved within 24 hours after the discontinuation of lisinopril. Adapted with permission from *N Engl J Med* 334:1641, 1996.¹⁶⁴

inhibitor–related side effects are generally easily recognized and, other than functional renal insufficiency, do not occur more commonly other than in the elderly.

Calcium Antagonists

L. Michael Prisant

Calcium antagonists are commonly used antihypertensive drugs among prescribing physicians.¹⁻⁴ In the Cardiovascular Health Study, there was an increase in the use of calcium antagonists from 14% in 1990 to 36% in 1999 among 5775 participants aged 65 years or older (Figure 66-1).⁴ The growth of calcium antagonist use has been attributed to increased drug advertising.⁵ Their use has not been influenced by the academic controversy involving alleged excess cardiovascular events, gastrointestinal bleeding, and cancer.⁶⁻¹² There has been a decline in their use among patients with coronary disease, decreasing from a peak of 57% in 1994 to 43% in 1999 ($p < 0.001$).⁴ It remains to be seen whether the report of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) will influence treatment decisions regarding calcium antagonist use.¹³

PHARMACOLOGY OF CALCIUM ANTAGONISTS

Calcium antagonists are more heterogeneous than other classes of antihypertensive drugs (e.g., angiotensin receptor blockers). They are divided into the phenylalkylamine (verapamil); benzothiazepine (diltiazem); and 1,4-dihydropyridine (nifedipine-like) classes.¹⁴ Others prefer simply to divide the calcium antagonists into dihydropyridines (vasodilating) and nondihydropyridines (myocardial active) to emphasize their relative vascular to cardiac selectivity. The dihydropyridines may be further subdivided based on their tissue selectivity (Figure 66-2). Tissue selectivity refers to the ratio calculated as a 50% inhibition of vascular constriction versus inhibition of the contractility of isolated myocardium.¹⁵ The higher the ratio, the more selective the calcium antagonist is for vascular tissue and the lower the potential for producing a negative inotropic effect. All dihydropyridines other than nifedipine, lacidipine, and lercanidipine have been referred to as second-generation dihydropyridines.^{14,16} The third-generation dihydropyridines lercanidipine and lacidipine are hydrophobic, membrane soluble, and have a long duration of action.¹⁷

All calcium antagonists bind to the α_{1c} -subunit of the voltage-dependent L-type calcium channel, although the actual binding sites differ among the three groups.¹⁸ By inhibiting the influx of calcium from outside the cell to inside the cell through the voltage-dependent L-type channel, actin and myosin do not interact and vasodilation occurs. Mibefradil (Posicor), which was withdrawn from the market because of drug-drug interactions, blocked both the low-voltage T and the high-voltage L channels.^{14,19} L-type channels are located on cardiac muscle, arteries, and veins, as well as leukocytes, platelets, brain, retina, salivary glands, gastric mucosa, pancreas, adrenal glands, pituitary gland, and other smooth muscle (bronchial, gastrointestinal, genitourinary, and uterine).¹⁸ This explains some side effects and the diverse application of calcium antagonists to sys-

temic hypertension, angina pectoris, supraventricular arrhythmias, subarachnoid hemorrhage, myocardial infarction, Raynaud's disease, esophageal spasm, primary pulmonary hypertension, and migraine headaches.²⁰ In addition to the smooth muscle relaxation, there are other effects of calcium antagonists that potentially lower blood pressure, including acute and repetitive natriuresis,^{21,22} inhibition of aldosterone release,²³ inhibition of growth and proliferation of vascular smooth muscle cells and fibroblasts,²⁴ and interference with α_2 -adrenoreceptor- and angiotensin-mediated vasoconstriction.^{25,26} Antiatherogenic properties have been documented in animal models (Figure 66-3),^{27,28} but results of studies of the vascular effects of calcium antagonists in humans have been mixed.²⁹⁻³³

Division of calcium antagonists into dihydropyridines and nondihydropyridines differentiates their effects on myocardial contractility, cardiac conduction, and glomerular hemodynamics. Verapamil and diltiazem depress the sinoatrial (SA) node slightly, decrease conduction through the atrioventricular (AV) node, and reduce myocardial contractility. Unlike the dihydropyridines, there is less vasodilation and related vascular side effects.³⁴ The dihydropyridines increase or fail to reduce intraglomerular pressure, completely abolish renal autoregulation, and increase proteinuria and glomerulosclerosis.

There are differences in time to peak concentration and elimination half-life among calcium antagonists (Table 66-1). All except amlodipine, lacidipine, and lercanidipine are short-acting in their native form and require novel drug delivery systems to prolong their duration of action.³⁵⁻³⁷ The short plasma half-life of lercanidipine is misleading given its long duration of action.¹⁷ The explanation for the discrepancy is that the molecule is attached to the arterial wall and not circulating in plasma. Several calcium antagonists (Covera-HS, Verelan-PM, Cardizem LA) have been designed as chronotherapeutic formulations.³⁸⁻⁴¹ Because cardiovascular events are more likely to occur in the early morning hours, the delivery system was created to deliver peak plasma levels in the early morning hours when taken at bedtime. Intravenous diltiazem, nicardipine, and verapamil are available.

PHARMACOKINETICS

After oral dosing, all three classes of calcium antagonist undergo first-pass metabolism by intestinal enterocytes and the liver.⁴² Bioavailability is 20% for verapamil, 45% for diltiazem, and 45% to 75% for nifedipine. Amlodipine has a relatively high bioavailability as compared with all other calcium antagonists.⁴³ All calcium antagonists are highly bound to plasma proteins.

More than 90% of verapamil is absorbed; bioavailability is reduced because of extensive first-pass metabolism⁴⁴ but increases with repetitive dosing. Verapamil is a substrate for

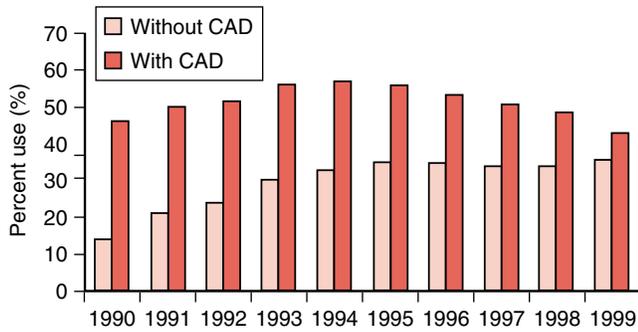

Figure 66-1 Percent use of calcium antagonist use from 1990-1999. The Cardiovascular Health Study ($n = 5775$). (Data from Psaty BM, Manolio TA, Smith NL, et al. Time trends in high blood pressure control and the use of antihypertensive medications in older adults: The Cardiovascular Health Study. *Arch Intern Med* 162:2325-2332, 2002.)

cytochrome P450 CYP3A and P-glycoprotein. *N*-dealkylation and *O*-demethylation are the primary metabolic pathways for verapamil. There are 12 metabolites, but norverapamil has 20% of the pharmacologic activity of verapamil. Urinary excretion accounts for 70% of the drug elimination. Clearance is decreased in cirrhosis, in the elderly, and in women.^{45,46} Caution has been sounded for the use of sustained-release verapamil in patients with chronic kidney disease.⁴⁷

More than 90% of diltiazem is absorbed after oral administration. Bioavailability is reduced because of extensive first-pass metabolism.⁴⁸ Diltiazem is a substrate for cytochrome P450 CYP3A and P-glycoprotein. *O*-deacetylation and *N*-demethylation followed by *O*-demethylation are the primary metabolic pathways for diltiazem. Deacetyldiltiazem accounts for 15% to 35% of diltiazem levels and has at most 50% of the pharmaco-

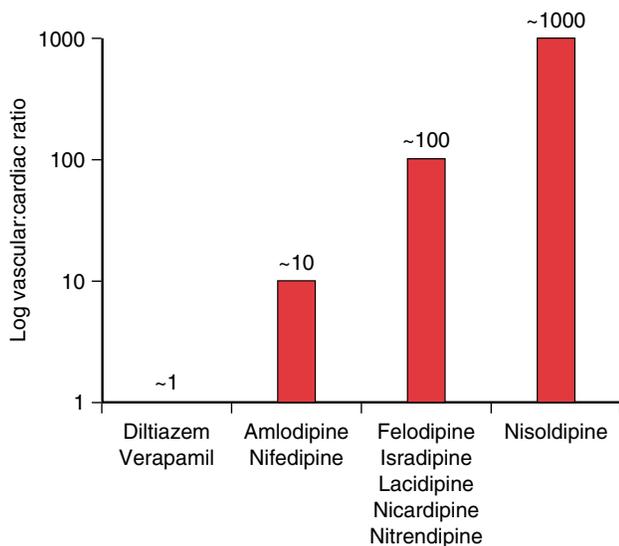

Figure 66-2 Relative vascular-cardiac selectivity of calcium antagonists. (Derived from Godfraind T, Salomone S, Dessy C, et al. Selectivity scale of calcium antagonists in the human cardiovascular system based on in vitro studies. *J Cardiovasc Pharmacol* 20(Suppl 5):S34-S41, 1992.)

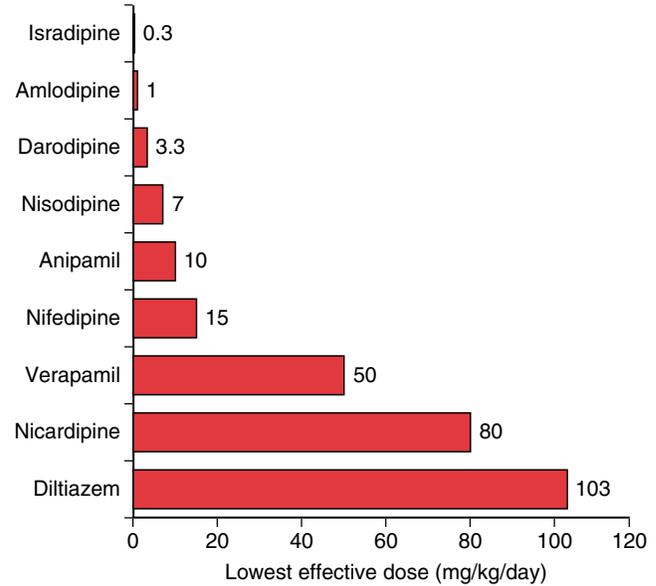

Figure 66-3 Lowest effective dose of oral administration of a calcium antagonist to reduce aortic cholesterol accumulation in lipid-fed rabbits. (Derived from Weinstein DB, Heider JG. Antiatherogenic properties of calcium antagonists. *State of the art. Am J Med* 86:27-32, 1989; and Nayler WG. Vascular injury: Mechanisms and manifestations. *Am J Med* 90:8S-13S, 1991.)

logic effect of the parent compound. Clearance is decreased in elderly patients.⁴⁸

Almost 95% of nifedipine is absorbed after oral administration.⁴⁹ About 30% to 40% of the drug is eliminated with first-pass metabolism. Oxidation results in three inactive metabolites that are predominately excreted in the urine. Unlike other calcium antagonists, amlodipine does not undergo extensive first-pass metabolism.

DRUG DELIVERY SYSTEMS

Drug delivery systems for calcium antagonists are intended to prolong the intrinsic duration of action of the drug, to decrease dosing frequency and reduce side effects (Table 66-2). Disadvantages for these drug delivery systems include postponed achievement of pharmacodynamic effect on initiation of therapy, the potential for sustained toxicity, decreased absorption with rapid gastrointestinal tract motility, and adverse reactions caused by the delivery system. Care must be taken when switching from a drug of one delivery system to another by titrating the drug dose.

Plendil, Adalat CC, and Sular use the coat core system, which is a hydrophilic gel surrounding active drug (Figure 66-4). The drug diffuses across the hydrophilic gel matrix coat as it travels throughout the gastrointestinal tract, and the matrix eventually erodes. Crushing or dividing the tablet exposes the patient to the active drug acutely, resulting in flushing, hypotension, and tachycardia.

The osmotic pump or Gastrointestinal Therapeutic System (GITS) provides zero-order drug delivery and is used with Procardia XL, Dynacirc CR, and Covera HS (Figure 66-5).^{50,51}

Table 66-1 Comparative Pharmacokinetics of Calcium Antagonists

Drug	Absorption	Bioavailability	Protein Binding	Time to Peak (hours)	Elimination Half-life (hours)
Diltiazem CD	95%	40%	70-80%	10-14	5-8
Amlodipine	>90%	60-65%	95%	6-12	35-45
Felodipine ER	>99%	20%	99%	2.5-5	10-17
Isradipine CR	90-95%	15-24%	95%	7-18	8
Lercanidipine	44%	10-12%	98%	2-3	8-10
Nicardipine SR	>90%	35%	>90%	1-4	8.6
Nifedipine CC	>90%	84-89%	92-98%	2.5-12	7
Nisoldipine CC	>80%	5%	>99%	6-12	7-12
Verapamil SR	>90%	20-35%	>90%	5.2-7.7	4.5-12

CC, coat core; CD, controlled delivery; CR, controlled release; ER, extended release; SR, sustained release.

The osmotic pump contains two compartments, a polymeric push compartment and an osmotic drug core; the entire tablet is surrounded by a cellulosic membrane, which is permeable to water but not to the drug or the osmotic excipients.⁵² There is a laser-drilled opening on the drug side of the tablet to allow dispensing of the drug as the polymeric push compartment swells. Covera HS has two laser drill holes for drug release and a special delay coat to time the release of verapamil in the hours prior to awakening. The osmotic pump is very hard, which increases the possibility for chipping teeth, obstructing the gastrointestinal tract where there is a stricture, and the theoretical possibility of eroding through diverticula.⁵³

Cardizem SR, Cardizem CD, Cardizem LA, Tiazac, Verelan, Verelan PM, and Cardene SR use encapsulated beads.³⁷ Cardene SR is a mixture of 25% immediate-release powder and 75% slow-release beads.⁵⁴ Cardizem CD consists of two populations of beads: (1) 40% with a thin copolymer coat for the initial 12 hours and (2) 60% with a thicker copolymer coat for the next 12 hours.⁵⁵ Tiazac consists of coated beads with a monolayer microporous semipermeable polymer, which controls the rate of drug diffusion in the gastrointestinal tract. Cardizem LA differs from Tiazac in the amount of coating

applied to the beads. It is dosed at bedtime and formulated to reach peak plasma levels between 6 A.M. and 12 noon. Verelan is a multiparticulate bead system (Spheroidal Oral Drug Absorption System, SODAS) that consists of 1-mm inert beads surrounded by rate-controlling polymers that allow release of verapamil without regard to pH (Figure 66-6). Similar to Verelan, Verelan PM uses water-soluble and water-insoluble polymers to delay release of verapamil for 4 to 5 hours.⁵⁶

Isoptin SR and Calan SR consist of a mixture of verapamil combined with polysaccharide sodium alginate, which absorbs water and becomes gelatinous in the gastrointestinal tract. Verapamil is released via diffusion through the matrix, and surface erosion of the tablet. Unlike Verelan, this formulation must be taken with food to avoid doubling the peak plasma levels.

Dilacor XR uses the completely biodegradable Geomatrix tablets, which consist of two slow hydrating barriers sandwiching a hydrophilic matrix core (Figure 66-7).⁵⁷ Diltiazem diffuses at a constant rate across the unprotected sides of the active layer as the volume of the dry tablet increases from 0.19 to 2.21 ml with complete hydration. Each tablet contains 60 mg of diltiazem; thus three tablets are encapsulated for the 180-mg dose.

Table 66-2 Novel Drug Delivery Systems for Calcium Antagonists

Generic Name	Brand Name	Dosing Interval	Delivery System
Diltiazem	Cardizem SR	2X/day	Coated beads (Multiple)
	Cardizem CD	1X/day	Coated beads (2 Populations)
	Cardizem LA	1X/day HS	Coated beads (Multiple)
	Tiazac	1X/day	Coated beads (Multiple)
	Dilacor	1X/day	Geomatrix
Felodipine	Plendil	1X/day	Coat core
Isradipine	DynaCirc CR	1X/day	Osmotic pump
Nicardipine	Cardene SR	2X/day	Coated beads and powder
Nifedipine	Procardia XL	1X/day	Osmotic pump
	Adalat CC	1X/day	Coat core
Nisoldipine	Sular	1X/day	Coat core
Verapamil	Calan SR	1-2X/day	Sodium alginate matrix
	Isoptin SR	1-2X/day	Sodium alginate matrix
	Verelan	1X/day	Coated beads (multiple)
	Covera HS	1X/day HS	Osmotic pump with delay coat
	Verelan PM	1X/day HS	Multiple beads with delay coat

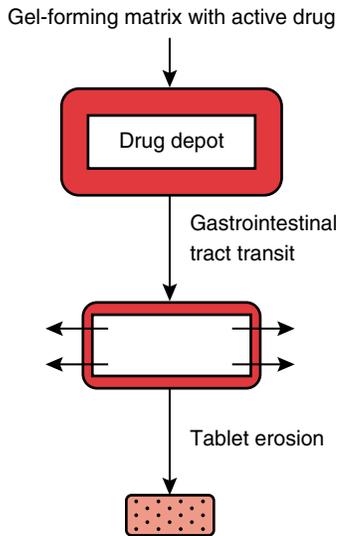

Figure 66-4 Coat Core Delivery System. This delivery system is used with nifedipine, nisoldipine, and felodipine.

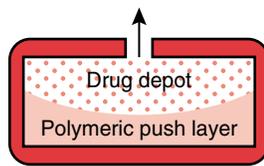

Figure 66-5 Osmotic Pump Delivery System. This delivery system is used with nifedipine, isradipine, and verapamil.

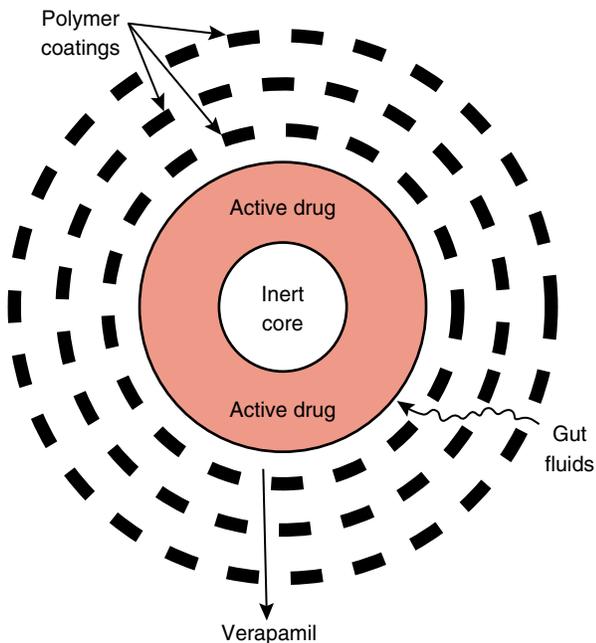

Figure 66-6 Spheroidal Oral Drug Absorption System. Bead delivery systems are used with verapamil, diltiazem, and nifedipine.

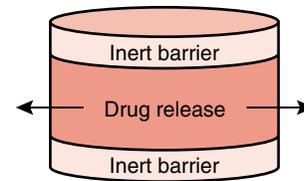

Figure 66-7 Geomatrix Delivery System. This delivery system is used with diltiazem.

DRUG INTERACTIONS

Table 66-3 lists common pharmacokinetic drug-drug interactions. Grapefruit juice inhibits cytochrome P450 CYP3A on enterocytes⁵⁸ and increases the bioavailability of felodipine by 200%, of nisoldipine by 150%, and of amlodipine or nifedipine by 20% to 30%. Increases in verapamil levels following grapefruit juice have been reported.⁵⁹ Lithium neurotoxicity occurs with verapamil use.⁶⁰

There are several important pharmacodynamic interactions between calcium antagonists and other drug classes. Drugs that slow the heart rate or conduction or reduce contractility can magnify those effects in combination with verapamil or diltiazem. These includes β -blockers, α_2 -stimulants, digitalis, amiodarone, flecainide, and disopyramide.

SIDE EFFECTS

Short-acting dihydropyridines are associated with flushing, tachycardia, angina, dizziness, and headache caused by vasodilation. Long-acting dihydropyridines avoid these side effects but are associated with dose-dependent peripheral edema (Figure 66-8).⁵¹ The peripheral edema is caused by a mismatch between arteriolar and venular dilation favoring fluid extravasation.^{61,62} This side effect occurs less commonly with the nondihydropyridine calcium antagonists. The peripheral edema is not associated with weight gain and therefore is not responsive to diuretics. There appears to be a lower rate of peripheral edema among the third-generation dihydropyridines. In a multicenter double-blind, parallel trial of 828 elderly hypertensives treated with lacidipine 2 to 4 mg/day, lercanidipine 10 to 20 mg/day, or amlodipine 5 to 10 mg/day, the rate of edema was 4.3%, 9.3%, or 19% ($p < .0001$), respectively.⁶³ The prevalence of peripheral edema is reduced when a converting enzyme inhibitor is combined with a dihydropyridine. In an 8-week, double-blind, parallel group trial of 563 hypertensives, the rate of peripheral edema was 4.9% for amlodipine 5 mg, 23.6% for amlodipine 10 mg, 2.2% for amlodipine 5 mg/benazepril 10 mg, and 1.5% for amlodipine 5 mg/benazepril 20 mg ($p < .001$).⁶⁴

Gingival overgrowth (Figure 66-9) occurs with calcium antagonists, cyclosporin, and phenytoin.⁶⁵ The prevalence is higher with nifedipine (38%) than with diltiazem (21%) or verapamil (19%) or in control patients (4%).⁶⁶ Attention to plaque control is important. Rarely, gingivectomy is needed.

Figure 66-10 shows common side effects seen with diltiazem in a randomized controlled trial.⁵⁵ Sinus bradycardia and peripheral edema were seen with the higher doses of diltiazem. Occasionally headache, dizziness, asthenia, fatigue, rash, and

first-degree AV block were also reported. Figure 66-11 emphasizes that constipation occurs as a dose-dependent side effect of verapamil.⁶⁷ Dizziness, headache, and nausea also occur. Rarely, hepatotoxicity, complete heart block, or skin eruptions can occur. Calcium antagonists, including diltiazem and verapamil, should be avoided in patients with heart failure (systolic dysfunction), because they are associated with heart failure exacerbations.^{68,69}

CALCIUM ANTAGONISTS AS ANTIHYPERTENSIVES

Table 66-4 lists the calcium antagonists marketed in the United States and their indications according to the Food and Drug Administration. Not listed are nimodipine, which is used for subarachnoid hemorrhage, and bepridil, an antianginal drug that is rarely used.

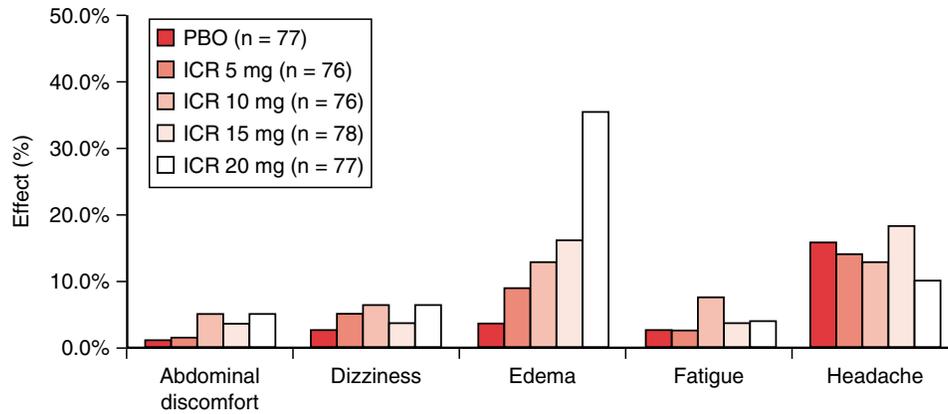

Figure 67-8 Side effects of the dihydropyridine isradipine controlled-release. This was a randomized, double-blind, placebo-controlled, multicenter 9-week study. The only side effect that was dose-related was edema. PBO, placebo; ICR, isradipine controlled-release. (Derived from data of Chrysant SG, Cohen M. Sustained blood pressure control with controlled-release isradipine (isradipine-CR). *J Clin Pharmacol* 35:239-243, 1995.)

EFFICACY

Calcium antagonists are as effective as other antihypertensive agents in lowering blood pressure. Two studies directly compared multiple classes of antihypertensive medications in terms of efficacy and side effects. The Treatment of Mild Hypertension Study was a randomized, double-blind, placebo-controlled trial of 902 men and women 45 to 69 years of age with a diastolic blood pressure less than 100 mm Hg.⁷⁰ All participants were advised to reduce sodium and alcohol intake, lose weight, and increase physical exercise. They were randomized to placebo, chlorthalidone 15 mg/day, acebutolol 400 mg/day, doxazosin 2 mg/day, amlodipine 5 mg/day, or enalapril 5 mg/day. If the blood pressure exceeded a prespecified threshold, then enalapril 2.5 to 5 mg/day could be added to the diuretic group or chlorthalidone 15 to 30 mg/day could be added to all other groups. As shown in Figure 66-12, amlodipine was as effective as the representative of any other antihypertensive drug class at the dose of drug used and tended to be more effective than the angiotensin-converting enzyme inhibitor. The greatest decline in left ventricular mass was seen in the

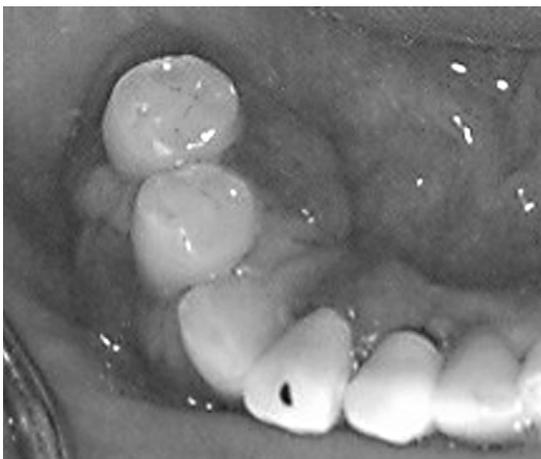

Figure 66-9 Gingival growth caused by a calcium antagonist.

chlorthalidone group, as determined by serial echocardiograms (Figure 66-13).⁷¹ The mean reduction in left ventricular mass of 25 g was nearly identical in all groups (including acebutolol, doxazosin, and enalapril, not shown), except chlorthalidone (34 g, $p = .03$ vs. placebo). Erectile dysfunction was significantly more common with chlorthalidone (Figure 66-14).⁷² At 24 months, the incidence of erectile dysfunction was greatest with chlorthalidone as compared with placebo ($p = .025$). At 48 months there was no difference among the groups. The average decrease in low-density lipoprotein cholesterol was greater with doxazosin than amlodipine (-11.3 mg/dl vs. -5.1 mg/dl, $p < .01$), and the decline in triglycerides was greater with amlodipine than acebutolol (-18.4 mg/dl vs. -6.4 mg/dl, $p < .01$). Amlodipine did not change glucose, potassium, uric acid, or creatinine. The starting dose of amlodipine (81.6%) and acebutolol (77.0%) was more likely to be maintained than placebo (54.6%, $p < .01$).⁷⁰

The only other trial that compared six classes of antihypertensive drugs against placebo is a Veterans Affairs Cooperative Study, a randomized, double-blind study that involved 1292 men with untreated diastolic blood pressure between 95 to 109 mm Hg.⁷³⁻⁷⁵ The following drugs were titrated over a period of 4 to 8 weeks: hydrochlorothiazide 12.5 to 50 mg/day, atenolol 25 to 100 mg/day, clonidine 0.1 to 0.3 mg twice daily, captopril 12.5 to 50 mg twice daily, prazosin 2 to 10 mg twice daily, diltiazem sustained-release 60 to 180 mg twice daily, or placebo. Treatment was deemed successful if the diastolic blood pressure was less than 90 mm Hg after the titration period and at 1 year of treatment (Figure 66-15). Diltiazem was significantly better than captopril, prazosin or placebo ($p < .05$).⁷⁵ Diltiazem (21.6%) was less likely to fail to achieve the titration goal of a diastolic blood pressure less than 90 mm Hg as compared with atenolol (29.4%), clonidine (30.7%), prazosin (34.2%), hydrochlorothiazide (38.1%), or placebo (61%).⁷³ Among younger and older African Americans, diltiazem achieved the highest treatment success rate after 1 year. Figure 66-16 shows the change in left ventricular mass from baseline in subjects whose pretreatment mass was greater than 350 g.⁷⁶ At 8 weeks, diltiazem and prazosin significantly reduced left ventricular mass ($p < .01$) to the greatest extent. However, after 1 year, hydrochlorothiazide ($p < .001$), captopril ($p < .01$), and atenolol ($p < .05$) were most effective.

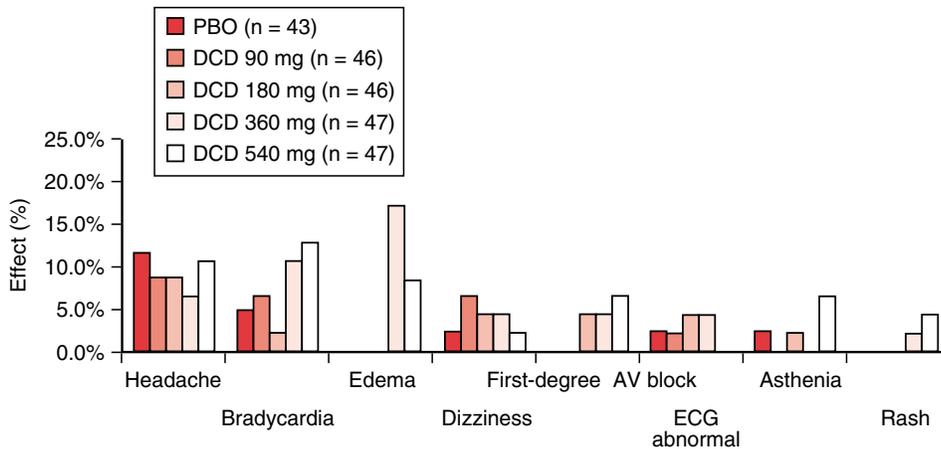

Figure 66-10 Side effects of diltiazem-controlled delivery. This was a multicenter, randomized, double-blind, placebo-controlled parallel design trial with a 4- to 6-week placebo baseline and 4-week treatment period. Sinus bradycardia and edema were treatment-related adverse events. (Derived from data of Felicetta JV, Serfer HM, Cutler NR, et al. A dose-response trial of once-daily diltiazem. *Am Heart J* 123:1022-1026, 1992.)

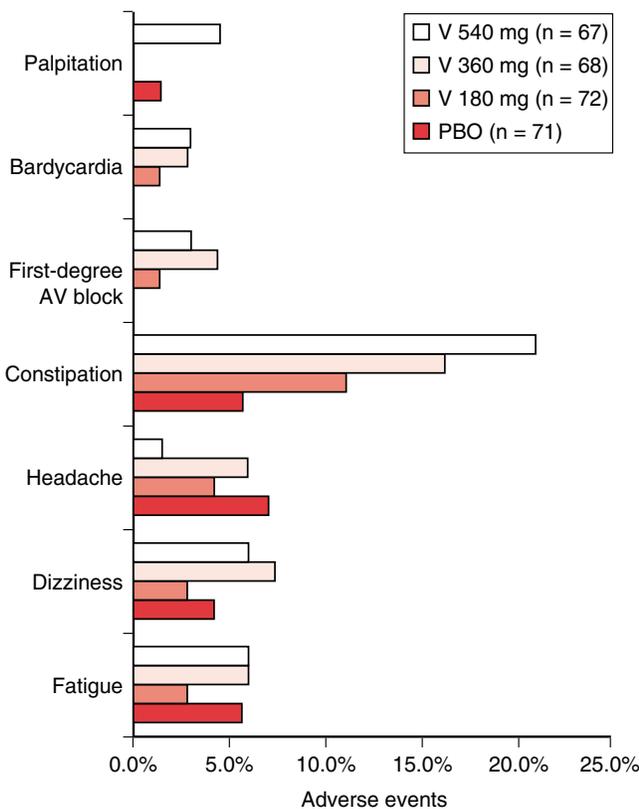

Figure 66-11 Side effects of verapamil chronotherapeutic extended-release. This was a double-blind placebo-controlled parallel-group trial with fixed-dose treatment for 4 weeks. Constipation is a dose-related adverse event. PBO, placebo; V, Verapamil. (Derived from data of Cutler NR, Anders RJ, Jhee SS, et al. Placebo-controlled evaluation of three doses of a controlled-onset extended-release formulation of verapamil in the treatment of stable angina pectoris. *Am J Cardiol* 75:1102-1106, 1995.)

DEMOGRAPHICS

Calcium antagonists are believed to be more effective in elderly and Black patients. Pharmacokinetic studies using verapamil, diltiazem, and amlodipine document a lower clearance and prolonged elimination half-life, as well as greater declines in blood pressure in elderly patients than in younger patients.^{45,48,77}

In a double-blind, positively controlled, forced-dose titration study comparing atenolol, captopril, and verapamil sustained release as single agents in the treatment of 394 Black patients with a diastolic blood pressure 95 to 114 mm Hg, verapamil was most effective in controlling blood pressure.⁷⁸ Another study showed a slower clearance of nifedipine in Black subjects (8.9 ± 0.7 ml/min/kg) as compared with white subjects (11.6 ± 0.8 ml/min/kg; $p = .00004$).⁷⁹ Figure 66-17 shows that in the Veterans Affairs Cooperative Study, diltiazem achieved the highest treatment success rate after 1 year among younger and older African Americans.

Although gender has not generally been viewed as an important factor in the response of antihypertensive agents, data suggest that oral verapamil is not cleared as well and plasma concentrations are higher among women.^{46,80} These pharmacokinetic data translate well into differences in blood pressure response, as documented by a meta-analysis of three randomized, double-blind, placebo-controlled trials of controlled-onset, extended-release verapamil.⁸¹ When using ambulatory blood pressure, the change in blood pressure was $-15.1/-10.4$ mm Hg for women as compared with $-10.0/-8.2$ mm Hg for men ($p < .001$ for systolic and $p = .003$ for diastolic pressure).

SODIUM INTAKE AND NONSTEROIDAL ANTIINFLAMMATORY DRUGS

The calcium antagonists differ from the angiotension-converting enzyme inhibitors in that their blood pressure-lowering effect is not augmented by sodium restriction. In one small study, the change in blood pressure in response to verapamil 120 mg dosed three times daily on a low-sodium (9 mEq) diet was $-18/11$ mm Hg and on a high sodium (212 mEq) diet $-19/-14$ mm Hg.⁸² Another double-blind study randomized 397 salt-sensitive hypertensive

patients to isradipine 2.5 to 20 mg twice daily, enalapril 2.5 to 20 mg twice daily, or placebo to evaluate modulation of blood responses.⁸³ This study observed that the decline in blood pressure was greater for isradipine on a high- versus low-sodium ($-14.9/-10.1$ mm Hg vs. $-7.6/-4.8$ mm Hg) diet, whereas enalapril had a similar effect on both diets.

Nonsteroidal antiinflammatory agents attenuate the anti-hypertensive effects most classes of blood pressure-lowering drugs, probably because of inhibition of renal prostaglandin production.⁸⁴⁻⁸⁷ However, calcium antagonists appear to be resistant to this effect. In a randomized, double-blind, study of

162 hypertensive patients treated with sustained-release verapamil hydrochloride 240 to 480 mg/day, participants were randomized to ibuprofen, naproxen, or placebo for 3 weeks.⁸⁸ There were no significant differences in sitting, standing, or supine blood pressure with ibuprofen 400 mg dosed three times daily or naproxen 500 mg dosed twice daily as compared with placebo despite increased weight with both nonsteroidal antiinflammatory drugs (Figure 66-18). In another study, 100 patients were treated with nifedipine 30 mg three times daily and then randomized to 375 mg of naproxen twice daily or placebo for 4 weeks. Although weight increased by about

Figure 66-12 Average Blood Pressure Change from Baseline at 48 Months: The Treatment of Mild Hypertension Study. For systolic or diastolic blood pressure, acebutolol, amlodipine, chlorthalidone, and doxazosin lowered blood pressure more than placebo ($p < .01$). (Data derived from Neaton JD, Grimm RH Jr., Prineas RJ, et al. Treatment of Mild Hypertension Study. Final results. Treatment of Mild Hypertension Study Research Group. JAMA 270:713-724, 1993.)

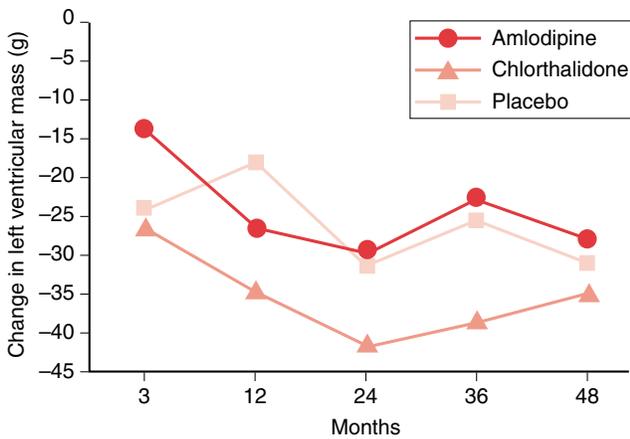

Figure 66-13 Change in Echocardiographic Left Ventricular Mass: Treatment of Mild Hypertension Study. The mean change in left ventricular mass of 25 g was nearly identical in all groups (including acebutolol, doxazosin, and enalapril not shown), except chlorthalidone (34 g, $p = .03$ versus placebo). (Derived from data of Liebson PR, Grandits GA, Dianzumba S, et al. Comparison of five antihypertensive monotherapies and placebo for change in left ventricular mass in patients receiving nutritional-hygienic therapy in the Treatment of Mild Hypertension Study (TOMHS). *Circulation* 91:698-706, 1995.)

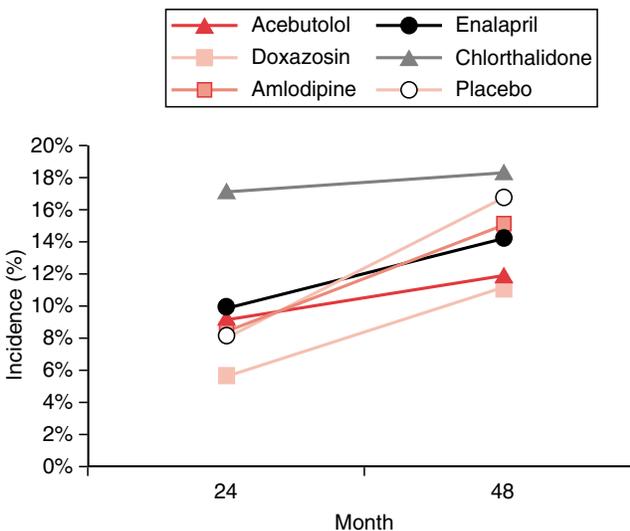

Figure 66-14 Incidence of Erectile Dysfunction: The Treatment of Mild Hypertension Study. At 24 months, the incidence of erectile dysfunction was greatest with chlorthalidone as compared with placebo ($p = .025$). At 48 months, there was no difference among the groups. (Derived from data of Grimm RH Jr., Grandits GA, Prineas RJ, et al. Long-term effects on sexual function of five antihypertensive drugs and nutritional hygienic treatment in hypertensive men and women. *Treatment of Mild Hypertension Study (TOMHS)*. *Hypertension* 29:8-14, 1997.)

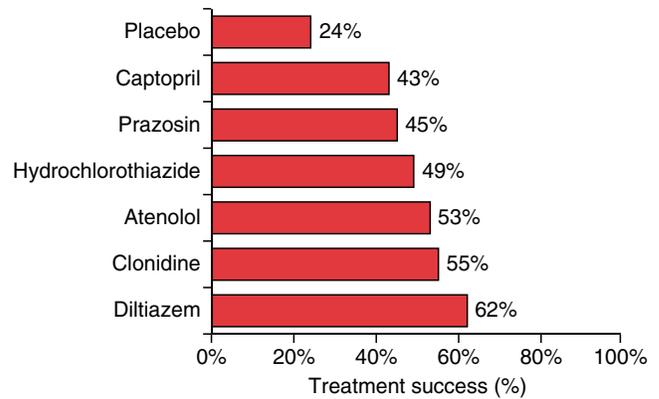

Figure 66-15 Comparison of Six Antihypertensive Drugs—Treatment Success: Veterans Administration Cooperative Study. Treatment success is determined by a diastolic blood pressure less than 90 mm Hg after 1 year of treatment. Diltiazem was significantly better than captopril, prazosin, or placebo ($p < .05$). (Derived from data of Materson BJ, Reda DJ, Cushman WC. Department of Veterans Affairs Single-Drug Therapy of Hypertension Study. Revised figures and new data. Department of Veterans Affairs Cooperative Study Group on Antihypertensive Agents. *Am J Hypertens* 8:189-192, 1995.)

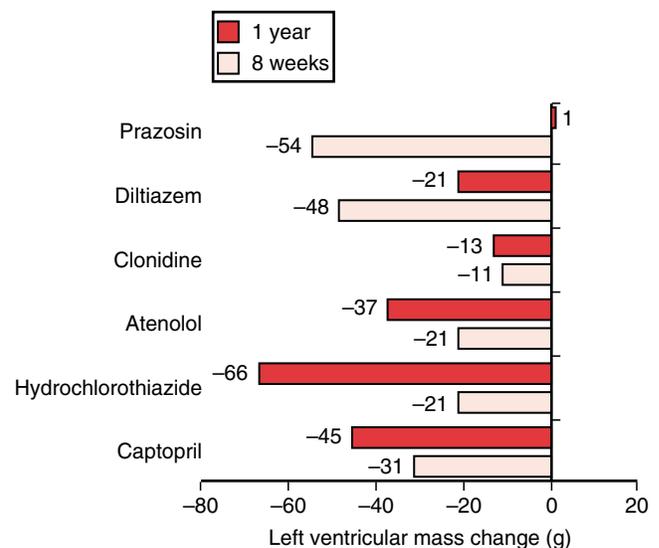

Figure 66-16 Regression of Left Ventricular Mass with Monotherapy: Veterans Affairs Cooperative Study. The change in left ventricular mass from baseline is shown in subjects whose pretreatment mass was greater than 350 g. At 8 weeks diltiazem and prazosin significantly reduced left ventricular mass ($p < .01$). However, after 1 year hydrochlorothiazide ($p < .001$), captopril ($p < .01$), and atenolol ($p < .05$) were most effective. (Derived from data of Gottdiener JS, Reda DJ, Massie BM, et al. Effect of single-drug therapy on reduction of left ventricular mass in mild to moderate hypertension: Comparison of six antihypertensive agents. The Department of Veterans Affairs Cooperative Study Group on Antihypertensive Agents. *Circulation* 95:2007-2014, 1997.)

daily to pindolol, a β -blocker with intrinsic sympathomimetic activity, reduced supine blood pressure by $-18/-15$ mm Hg ($p < .001$) after 4 weeks.¹⁰⁰ In a randomized, double-blind, crossover study with 4-week treatment phases, 15 patients received diltiazem 120 mg twice daily, atenolol once daily, both drugs, or placebo.¹⁰¹ Compared with placebo, either monotherapy reduced blood pressure by $-8/-9$ mm Hg; the combination reduced blood pressure by $-16/-13$ mm Hg and was superior to monotherapy ($p < .05$). The average PR interval 2 hours after drug dosing was 0.164 second for placebo, 0.175 second for diltiazem, 0.174 second for atenolol, and 0.184 second for the combination. Other studies have combined verapamil and propranolol.¹⁰² Combining verapamil or diltiazem with a β -blocker increases the risk of sinus bradycardia or arrest, junctional escape rhythm, AV conduction block, and heart failure.

Combining an α_1 -blocker with a calcium antagonist may be synergistic.¹⁰³ In a randomized, double-blind, crossover study, each of 75 patients received amlodipine 10 mg, doxazosin 4 mg, and the combination of amlodipine 5 mg and doxazosin 2 mg daily for 6 weeks after a 2-week washout period.¹⁰⁴ The change from baseline was $-29/-10$ mm Hg for amlodipine monotherapy, $-28/-8$ mm Hg for doxazosin monotherapy, and $-41/-15$ mm Hg for the half-strength combination. The mechanism for the hypotensive response is unclear. One study observed an increase in bioavailability of terazosin when added to verapamil.¹⁰⁵ The use of this combination requires great care in slowly titrating the dose of the α_1 -blocker. The patient should be told that his or her prescription must be refilled promptly without any lapse to avoid severe orthostatic hypotension and syncope.

Whether combining calcium antagonists and diuretics has an advantageous effect on blood pressure control is controversial.¹⁰⁶⁻¹⁰⁸ It has been suggested that the sequence of drug administration may be important. Addition of isradipine to hydrochlorothiazide-treated patients has been shown to be as efficacious as adding propranolol,¹⁰⁹ and factorial design trials with verapamil and diltiazem have shown an additive antihypertensive effect.^{110,111}

The combination of a dihydropyridine to a nondihydropyridine produces additive antihypertensive effects.¹¹²⁻¹¹⁴ One study reported a decrease in blood pressure when either diltiazem sustained-release or verapamil sustained-release was added to nifedipine sustained-release.¹¹⁵ However, diltiazem more effectively lowered blood pressure than did verapamil. This is because nifedipine levels were higher when the drug was combined with diltiazem (1430 ng•h/ml) than when it was combined with verapamil (1134 ng•h/ml, $p = .026$) as compared with baseline nifedipine levels (957 ng•h/ml). The combination of verapamil and nifedipine was associated with more side effects than the combination of diltiazem and nifedipine.¹¹⁵

MAJOR CLINICAL TRIALS

Calcium antagonists are effective antihypertensive and antianginal agents. Major prospective clinical trials support their role for treating hypertension without worsening overall mortality. ALLHAT documents that the long-acting calcium antagonist amlodipine does not increase cardiovascular or all-cause mortality as compared with chlorthalidone.¹³ This review will consider only hypertension trials (Table 66–5).

TRIALS OF CAROTID INTIMA-MEDIA PROGRESSION

The Multicenter Isradipine Diuretic Atherosclerosis Study (MIDAS) randomized 883 hypertensive patients to short-acting isradipine or hydrochlorothiazide to assess the rate of progression of carotid thickening over 3 years.³¹ Enalapril 2.5 to 10 mg twice daily could be added to attain a diastolic blood pressure goal below 90 mm Hg. Systolic blood pressure was reduced more with the diuretic. There was no difference in the rate of progression of carotid thickening. Although there were more hospitalizations for unstable angina with isradipine treatment, there was no difference in all-cause mortality ($p = .81$) or any major vascular event ($p = .07$).

The Verapamil in Hypertension and Atherosclerosis Study (VHAS) randomized 498 patients to either sustained-release verapamil or chlorthalidone over 4 years to assess the impact on carotid intimal-medial thickness at six sites.³² Captopril 25 to 50 mg could be added if blood pressure remained uncontrolled. For the first 6 months, the study was double-blind and afterward was open-label. Blood pressure control was similar with both drugs. The number of fatal and nonfatal cardiovascular events was similar in the two groups. There was significantly greater plaque regression in the group treated with verapamil as compared with chlorthalidone ($p < .02$). Furthermore, fatal and nonfatal cardiovascular events occurred in 19 of 224 verapamil-treated and 35 of 232 chlorthalidone-treated patients.

A substudy of the International Nifedipine GITS Study: Intervention as a Goal in Hypertension Treatment (INSIGHT) examined progression of intima-media carotid thickening in 439 patients treated with nifedipine GITS or amiloride with hydrochlorothiazide over 48 months.¹¹⁶ Atenolol 25 to 50 mg or enalapril 5 to 10 mg could be added if blood pressure was not controlled. There was no difference in blood pressure control, but more progression in carotid thickening was observed with the diuretic than with the calcium antagonist.

The European Lacidipine Study on Atherosclerosis (ELSA) studied 2334 patients randomized to either lacidipine or atenolol to assess the effect on carotid intima-media thickness at four sites over 4 years.¹¹⁷ A diuretic could be added if blood pressure was not controlled. Clinic blood pressure measurements were similar between the two groups; however, 24-hour blood pressure was lower with atenolol than lacidipine. Despite this difference, there was less progression of intima-media thickness with lacidipine than with atenolol. However, there was no difference in the number cardiovascular events between treatments.

TRIALS OF RENAL PROTECTION

Small short-term studies show proteinuria reduction with diltiazem and verapamil in hypertensive diabetic patients.^{93,118} Many trials with dihydropyridine calcium antagonists do not show similar protection. The Microalbuminuria Reduction with Valsartan Study (MARVAL) reported a greater reduction in urinary albumin excretion rate among diabetics with microalbuminuria treated with valsartan versus amlodipine.¹¹⁹ The African American Study of Kidney Disease and Hypertension (AASK) randomized 1094 nondiabetic Black

Table 66-5 Clinical Trials of Hypertension with Calcium Antagonists

Trial	n	Design	Intervention	Duration	Primary Outcome	Results
AASK	1094	R, DB	Amlodipine 5-10 mg vs. ramipril 2.5-10 mg vs. metoprolol 50-200 mg	3 yr	Rate of change of glomerular filtration rate (amlodipine arm terminated by data safety and monitoring committee)	Ramipril was superior to amlodipine for proteinuria more than 300 mg/day; no difference in deaths
ABCD	470	R, DB	Nisoldipine 20-60 mg vs. enalapril 10-40 mg ± metoprolol ± HCTZ*	5 yr	Relative effects of moderate and intensive blood pressure control on the change in creatinine clearance; one secondary outcome included cardiac morbidity and mortality	No difference in primary endpoint, but more fatal and nonfatal myocardial infarctions with nisoldipine, but no difference in cardiovascular death or total mortality
ALLHAT	33,357	R, DB	Chlorthalidone 12.5-50 mg, amlodipine 2.5-10 mg, lisinopril 10-40 mg, doxazosin 2-8 mg ± reserpine 0.5-0.2 mg, clonidine 0.2-0.6 mg, hydralazine 50-200 mg	4.9 yr	Fatal coronary heart disease or nonfatal myocardial infarction	No difference in primary endpoint or total mortality, but more heart failure with amlodipine compared to diuretic ± atenolol 25-100 mg
CONVINCE	16,476	R, DB	Verapamil-COER 180-360 mg vs. HCTZ 12.5-25 mg or atenolol 50-100 mg ± ACE inhibitor or HCTZ	3 yr	Nonfatal myocardial infarction or stroke or death from cardiovascular disease (terminated prematurely by sponsor)	No difference in the combined endpoint, but fewer myocardial infarctions and more strokes with calcium antagonist; no difference in all-cause mortality
ELSA	2334	R, DB	Lacidipine 4-6 mg vs. atenolol 50-100 mg	4 yr	Rate of progression of mean maximum intima media thickness in 6 carotid focal points over 3 years	Less progression with lacidipine than atenolol; no difference in cardiovascular events
FACET	380	R, SB	Fosinopril 20 mg vs amlodipine 10 mg (or both if blood pressure not controlled)	2.8 yr	Treatment-related difference in serum lipids and diabetes control Cardiovascular events were a secondary outcome	No difference in the primary endpoint, but there were fewer major vascular events in the fosinopril and combination group than the amlodipine group
HOT	18,790	PROBE	Felodipine 5-10 mg ± β-blocker or ACE* inhibitor ± diuretic	3.8 yr	Major cardiovascular events and target diastolic blood pressure ≤80, ≤85, and ≤90 mm Hg	Fewer cardiovascular events in patients with diabetes mellitus (n = 1501), but not in the overall cohort
IDNT	1715	R, DB	Irbesartan 300 mg vs. amlodipine 10 mg vs. placebo	2.6 yr	Doubling of serum creatinine, onset of end-stage renal disease, or all-cause mortality	Irbesartan superior to placebo and amlodipine for composite endpoint; no difference in cardiovascular events
INSIGHT	6321	R, DB	Nifedipine GITS* 30-60 mg vs. amloride 2.5-5 mg with HCTZ 25-50 mg ± atenolol 50-100 mg or enalapril 5-10 mg	4 yr	Cardiovascular death, heart failure, myocardial infarction, and stroke	No difference in primary endpoint, but more fatal myocardial infarctions and nonfatal heart failure in nifedipine GITS group; no difference in overall mortality

	439	R, DB	As above	4 yr	Rate of progression of mean maximum intima-media thickness of the carotid	Less progression with nifedipine than the diuretic
INVEST	22,576	PROBE	Verapamil SR 240-360 mg \pm trandolapril 2-4 mg \pm HCTZ 25 mg vs. atenolol 50-100 mg \pm HCTZ 25-50 mg \pm trandolapril 2-4 mg	2.7 yr	All-cause mortality, nonfatal myocardial infarction, and nonfatal strokes	No difference in primary outcome; lower rate of diabetes in calcium channel blocker arm
MARVAL	332	R, DB	Valsartan 80-160 mg vs. amlodipine 5-10 mg \pm bendrofluazide \pm doxazosin	24 wk	Urinary albumin excretion rate from baseline	Valsartan was more effective than amlodipine
MIDAS	883	R, DB	Isradipine 2.5-5 mg vs. hydrochlorothiazide 12.5-25 mg \pm enalapril	3 yr	Rate of progression of mean maximum intima-media thickness in 12 carotid focal points over 3 years	No difference in the rate of progression between the isradipine and the diuretic; no difference in mortality, but more admissions for angina
NICS-EH	414	R, DB	Nicardipine 40 mg vs. trichlormethiazide 2 mg	5 yr	Cardiovascular complications	No difference in rate of complications
NORDIL	10,881	PROBE	Diltiazem 180-360 mg vs. diuretic and/or β -blocker \pm ACE inhibitor \pm α_1 -blocker	5 yr	Cardiovascular death or nonfatal stroke or myocardial infarction	No difference in primary endpoint, but fewer strokes in diltiazem group
SHELL	1882	PROBE	Lacidipine 4-6 mg vs. chlorthalidone 12.5-25 mg \pm fosinopril 10 mg	32 mo	Composite endpoint of sudden death, fatal or nonfatal myocardial infarction, stroke, heart failure, myocardial revascularization, carotid endarterectomy	No difference in the composite or individual cardiovascular or cerebrovascular endpoints; no difference in total mortality
STONE	1632	A, DB	Nifedipine 10-60 mg vs. placebo \pm captopril 25-50 mg \pm HCTZ 25 mg	30 mo	Stroke, heart failure, myocardial infarction, severe arrhythmia, sudden death	Fewer strokes and severe arrhythmias, but no difference total mortality, cardiovascular deaths, or sudden deaths
STOP-2	6614	PROBE	Diuretics \pm β -blockers vs. ACE inhibitors \pm HCTZ vs calcium antagonists \pm β -blocker		Cardiovascular mortality	ACE inhibitors or calcium antagonists were not better than diuretics and β -blockers; there were fewer myocardial infarctions and heart failure with ACE inhibitors compared with calcium antagonists; no difference in total mortality among three groups
SYST-CHINA	2394	A, DB	Nitrendipine 10-40 mg vs. placebo \pm captopril 12.5-50 mg \pm HCTZ 12.5-50 mg	2 yr	Fatal and nonfatal stroke	Active treatment reduced strokes and total mortality

(Continued)

Table 66-5 Clinical Trials of Hypertension with Calcium Antagonists—cont'd

Trial	n	Design	Intervention	Duration	Primary Outcome	Results
SYSTEMUR	4695	R, DB	Nitrendipine 10-40 mg vs. placebo ± enalapril 5-20 mg ± HCTZ 12.5-25 mg	2 yr	Stroke	Active treatment reduced nonfatal strokes, nonfatal cardiac endpoints, but not total mortality, myocardial infarction or heart failure
VALUE	15,245	R, DB	Valsartan 80-160 mg vs. amlodipine 5-10 mg ± HCTZ 12.5-25 mg	4.2 yr	Time to first cardiac event (sudden death and fatal or nonfatal myocardial, infarction, heart failure, revascularization)	No difference in primary endpoint or total mortality; few myocardial infarctions with amlodipine; less new-onset diabetes with valsartan
VHAS	498	R, SB†	Verapamil SR 240 mg vs. chlorthalidone 25 mg	4 yr	Slope of change of mean maximal thickness from 6 carotid sites over 4 years	Rate of progression greater with diuretic More cardiovascular events with diuretic

*R, Randomized; A, Alternate allocation; DB, double blind; SB, single blind; PROBE, prospective, randomized, open-label, blinded endpoint; HCTZ, hydrochlorothiazide; ACE, angiotensin-converting enzyme; GITS, gastrointestinal therapeutic system; COER, controlled-onset extended-release.

†For first 3 months, trial was double-blind, then open-labeled.

patients with hypertensive renal insufficiency (20–65 ml/min/1.73 m²) to amlodipine, ramipril, or metoprolol extended-release.¹²⁰ This randomized, double-blind trial also included two levels of blood pressure control. The average number of additional drugs needed to control blood pressure was 2.75. The amlodipine arm was terminated early because of greater (50%) worsening of glomerular filtration rate ($p = .03$) and more end-stage renal disease ($p = .01$) as compared with the ramipril arm. Proteinuria also increased with amlodipine. There was no difference in overall mortality.

The Irbesartan Diabetic Nephropathy Trial studied 1715 hypertensive diabetic patients with protein excretion ≥ 900 mg/24 hour and serum creatinine 1 to 3 mg/dl.¹²¹ Treatment was randomized to irbesartan, amlodipine, or placebo, but 3.0 to 3.3 drugs were needed to achieve the target blood pressure of 135/85 mm Hg or less. The rate of doubling of serum creatinine was 39% lower with irbesartan as compared with amlodipine ($p < .001$), and the rate of end-stage renal disease was 24% lower with irbesartan ($p = .06$). There was no difference in total mortality. The number of cardiovascular events was similar among all three groups (irbesartan, 29.7%; amlodipine, 28.3%; and placebo, 32.5%).¹²² However, there were fewer myocardial infarctions with amlodipine as compared with placebo (4.7% vs. 8.1%, $p = .021$) and more cases of heart failure with amlodipine as compared with irbesartan (16.7% vs. 10.4%, $p = .007$). There were no differences among the three groups with respect to cerebrovascular events, although a protective trend was seen in amlodipine-treated patients.

These trials suggest that amlodipine is not protective against hypertensive or diabetic end-stage renal stage disease as compared with ramipril or irbesartan. However, in ALLHAT (see later), the decline in glomerular filtration rate (Figure 66–20) over 4 years was -2.9 ml/min/1.73 m² for amlodipine ($p < .001$ vs. diuretic), -7.6 ml/min/1.73 m² for chlorthalidone, and -7.0 ml/min/1.73 m² for lisinopril ($p = .03$ vs. diuretic).¹³ Also, INSIGHT reported less impaired renal function with nifedipine GITS versus hydrochlorothiazide combined with amiloride.¹²³ These observations merit prospective studies in hypertensive patients that have no evidence of renal insufficiency at baseline. Also, studies that com-

bine a converting enzyme inhibitor with a dihydropyridine have shown reductions in urinary albumin excretion comparable with those seen with a converting enzyme inhibitor alone.¹²⁴ Thus, studies are needed that look at the impact of various combinations on diuretic outcomes.

TRIALS IN ISOLATED SYSTOLIC HYPERTENSION

The Systolic Hypertension in Europe (Syst-Eur) trial was a randomized, double-blind, placebo-controlled study in patients 60 years and older.¹²⁵ Participants received placebo or nitrendipine with enalapril and hydrochlorothiazide if needed to achieve blood pressure control. Combination drug therapy was frequently needed to lower the systolic blood pressure to less than 150 mm Hg. The study was stopped prematurely after 2 to 2.5 years because of a 42% reduction in fatal and nonfatal stroke for active as compared with placebo treatment. For fatal and nonfatal myocardial infarctions, however, there was only a nonsignificant 30% reduction in events ($p = .12$). Although not significant individually, when myocardial infarction and heart failure events were combined, there was a reduction in nonfatal cardiac endpoints ($p = .03$).

The role of a calcium antagonist in preventing vascular dementia in older patients was evaluated in Syst-Eur.^{126,127} When the Mini-Mental Status Examination and computed tomography of the brain were used as diagnostic criteria, active treatment reduced the rate of dementia from 7.4 to 3.3 cases per 1000 patient years ($p < .001$).¹²⁷ Because no other class of antihypertensive drug has documented this finding, the results should be replicated prospectively.

The Systolic Hypertension in China (Syst-China) trial treated 2394 elderly hypertensive patients with placebo or nitrendipine alone or in combination with captopril, hydrochlorothiazide, or both.¹²⁸ Treatment assignment was by alternate allocation rather than randomization. The average entry blood pressure was 171/86 mm Hg. With treatment, the blood pressure declined by 11/2 mm Hg in the placebo group and 20/5 mm Hg in the nitrendipine group. Total mortality and stroke were significantly lower with active treatment, but there was no difference between groups. There was no decline in myocardial infarction, heart failure, or sudden death.

ASSESSMENT OF CHRONOTHERAPEUTICS

The Controlled Onset Verapamil Investigation of Cardiovascular Endpoints (CONVINCE) trial tested whether a chronotherapeutic medication timed to deliver verapamil from 6 A.M. to noon is equivalent to traditional antihypertensive therapy in preventing cardiovascular events.^{129–131} A group of 16,602 high-risk subjects 55 years or older with stages 1 to 3 hypertension were randomized to a chronotherapeutic preparation of verapamil or traditional antihypertensive drugs (diuretic or β -blocker). Additional drugs, including diuretics and converting enzyme inhibitors, could be added to achieve blood pressure control. The sponsor terminated the trial prematurely. There was no difference in the combined endpoint of fatal and nonfatal myocardial infarction and stroke at that point, but because of the limited statistical power of the prematurely terminated

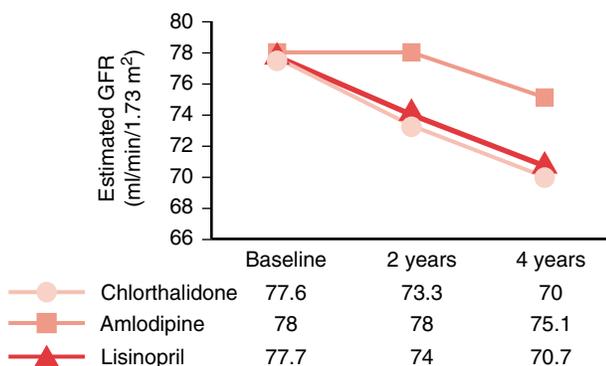

Figure 66–20 Change in glomerular filtration rate (GFR) over 4 years. (Graph derived from Major outcomes in high-risk hypertensive patients randomized to angiotensin-converting enzyme inhibitor or calcium channel blocker vs diuretic: The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT). JAMA 288:2981-2997, 2002.)

trial, it was not possible to demonstrate equivalence of the treatments. The authors concluded that, considered in the context of other trials of calcium antagonists, their data indicate that the effectiveness of calcium antagonist therapy in reducing cardiovascular outcomes is similar to but not better than traditional diuretic or β -blocker treatment.¹³¹

TRIALS OF DIABETIC PATIENTS

The Appropriate Blood Pressure Control in Diabetes (ABCD) trial was a prospective, double-blind, randomized study that examined blood pressure control in 950 patients with type 2 diabetes mellitus with a diastolic blood pressure 80 mm Hg or higher.¹³² The cohort in this single-center study was stratified into a normotensive ($n = 480$) and a hypertensive group ($n = 470$). The hypertensive group was further stratified into treatment goals of 80 to 89 mm Hg and 75 mm Hg.¹³³ Patients could receive nisoldipine 10 to 60 mg/day or enalapril 5 to 40 mg/day. If titration failed to achieve the target blood pressure, then open-labeled hydrochlorothiazide and metoprolol could be added, as well as other nonstudy medications. The primary endpoint was the effect of blood pressure control on 24-hour creatinine clearance. The secondary endpoints included the incidence of cardiovascular events. There was no difference in blood pressure control between the enalapril and nisoldipine groups, but fewer patients in the calcium antagonist group received a β -blocker ($p = .035$) or a diuretic ($p = .02$). There were more fatal and nonfatal myocardial infarctions in the nisoldipine group as compared with the enalapril group (22 vs. 5, $p = .001$). This was subsequently revised in a follow-up publication to 27 versus 9 ($p = .029$), reducing the adjusted risk ratio from 7 to 4.2.¹³⁴ This article supported the posthoc analysis of the MIDAS trial, suggesting that isradipine was associated with more cardiovascular events in the presence of elevated glycosylated hemoglobin.⁹

The Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial (FACET) compared the effectiveness of amlodipine 10 mg daily with fosinopril 20 mg daily on lipid and diabetes control in a population of 380 hypertensive diabetics.¹³⁵ If blood pressure was not controlled in this open-label study, then the opposite drug was added. Although there was no difference in the endpoint of glucose or lipid control, there were more cardiovascular events in the amlodipine monotherapy group ($n = 141$) than in the fosinopril monotherapy group ($n = 131$; 27 vs. 10 events ($p = .008$)). However, there were even fewer events in the combination group ($n = 108$; 4 events, $p = .001$).

MISCELLANEOUS TRIALS OF BLOOD PRESSURE CONTROL

The Shanghai Trial of Nifedipine in the Elderly (STONE) was a single-blind trial that used alternate treatment allocation.¹³⁶ After a 4-week placebo period, 1632 patients received nifedipine 10 to 30 mg twice daily or placebo. Captopril, dihydrochlorothiazide, or both could be added to either treatment arm to attain blood pressure treatment goals. The average decline in blood pressure was $-22/-12$ mm Hg for nifedipine and $-12/-8$ mm Hg for placebo ($p \leq .0001$ for both systolic and diastolic blood pressure). There were more strokes and

arrhythmias in the placebo group, but there was no difference in cardiovascular or total mortality.

The Hypertension Optimal Treatment (HOT) Study examined the effects of three levels of diastolic blood pressure control on cardiovascular events among 18,790 study participants with a PROBE design.¹³⁷ This international trial enrolled hypertensive patients 50 to 80 years of age with a diastolic blood pressure between 100 and 115 mm Hg. The targets for blood pressure control were ≤ 90 , ≤ 85 , or ≤ 80 mm Hg. Treatment to achieve each level of blood pressure control included stepwise increments of felodipine; a converting enzyme inhibitor, β -blocker, or both; and hydrochlorothiazide. The primary aim was to assess the relationship between major cardiovascular events (cardiovascular death nonfatal myocardial infarction, and nonfatal stroke) and the target blood pressures. The achieved blood pressures were 144/85, 141/83, and 140/81 mm Hg. There was no significant reduction in major cardiovascular events with the lower blood pressures; however, the trend for all myocardial infarction was significant ($p = .05$). Among the 1501 diabetic subjects in HOT, there was a significant reduction in cardiovascular events ($p = .005$) and cardiovascular mortality ($p = .045$) but no reduction in stroke, myocardial infarction, and total mortality.

TRIALS OF DRUG COMPARISONS

INSIGHT was a prospective, randomized, double-blind trial of 6321 patients with a blood pressure 150/95 mm Hg or higher or systolic blood pressure 160 mm Hg or higher.¹²³ Participants were randomized to nifedipine GITS 30 to 60 mg or hydrochlorothiazide 25 to 50 mg with amiloride 2.5 to 5 mg daily. If blood pressure was not lowered by 20/10 mm Hg or was greater than 140/90 mm Hg, then atenolol 25 to 50 mg or enalapril 5 to 10 mg daily could be added. The primary composite endpoint was cardiovascular death, myocardial infarction, stroke, and heart failure. There was no difference in the primary endpoint but there were more cases of fatal myocardial infarction (.05% vs. .02%, $p = .017$) and nonfatal heart failure (.08% vs. .03%, $p = .028$) among patients assigned to the calcium antagonist as compared with conventional therapy. There was no difference in all-cause mortality. New-onset diabetes occurred more commonly in the diuretic group (5.6% vs. 4.3%, $p = .02$). In the diabetic cohort ($n = 1302$), there was a 24% reduction in the composite of all-cause mortality death from vascular cause and death from nonvascular cause in the nifedipine group ($p = .03$).¹³⁸

The Swedish Trial in Old Patients with Hypertension-2 (STOP-2) study used the prospective, randomized, open-labeled, blinded endpoint (PROBE) design to compare the effects of calcium antagonists to conventional drugs or converting enzyme inhibition in 6614 elderly hypertensive subjects aged 70 to 84 years. If either component of the blood pressure was 180/105 mm Hg or greater, patients were randomly assigned to one of three arms: conventional drugs (atenolol 50 mg, metoprolol 100 mg, pindolol 5 mg, or hydrochlorothiazide 25 mg plus amiloride 2.5 mg daily), calcium antagonists felodipine 2.5 mg or isradipine 2.5 mg daily, or converting enzyme inhibitors (enalapril 10 mg or lisinopril 10 mg daily).¹³⁹ The actual drug choice within the assigned group was not randomized. If blood pressure was not

controlled to less than 160/95 mm Hg on hydrochlorothiazide or a β -blocker, the alternative drug was added; for the converting enzyme inhibitor, a diuretic was added, and for the calcium antagonists, a β -blocker was added. There was no difference in the primary endpoint, cardiovascular mortality, according to treatment. However, the converting enzyme inhibitors were associated with a 23% lower rate of myocardial infarction (12.8% vs. 16.7%, $p = .018$) and 22% lower rate of heart failure (13.9% vs. 17.5%, $p = .025$) as compared with the calcium antagonists.

The National Intervention Cooperative Study in Elderly Hypertensives Study Group (NICS-EH) compared the outcomes of a diuretic versus calcium antagonist treatment in preventing cardiovascular events in elderly hypertensive patients in Japan.¹⁴⁰ After a 4-week placebo period, either sustained-release nifedipine 20 to 40 mg or trichlormethiazide 2 to 4 mg daily was given to 414 participants 60 years or older with a systolic blood pressure 160 to 220 mm Hg and a diastolic blood pressure less than 115 mm Hg. Medication was administered by using the double-dummy technique. After 5 years, blood pressure control was similar. There was no difference in the rate of cardiovascular endpoints in the two groups.

The Nordic Diltiazem (NORDIL) study studied 10,881 patients between 50 to 74 years with a diastolic blood pressure 100 mm Hg or higher by using a PROBE design.¹⁴¹ Patients were titrated with diltiazem or conventional antihypertensive drugs (diuretics, β -blockers, or both) to achieve a diastolic blood pressure less than 90 mm Hg. A converting enzyme inhibitor or α_1 -blocker could be added to either therapy. The combined primary endpoint was any cardiovascular death and nonfatal myocardial infarction or stroke. There was no difference in the primary endpoint, but there were 20% fewer strokes with diltiazem (6.4% vs. 7.9%, $p = .04$) than with conventional therapy.

ALLHAT was a randomized, double-blind trial of 42,466 high-risk hypertensive patients 55 years or older comparing the effects of treatment with chlorthalidone 12.5 to 25 mg ($n = 15,255$) to amlodipine 2.5 to 10 mg ($n = 9048$), lisinopril 10 to 40 mg ($n = 9054$), and doxazosin 1 to 8 mg daily ($n = 9061$) on the primary combined endpoint of fatal coronary heart disease and nonfatal myocardial infarction.¹³ The primary hypothesis of ALLHAT was that representatives of the newer classes of antihypertensive drugs would be superior to the diuretic in endpoint reduction. If blood pressure was not controlled, atenolol 25 to 100 mg daily, clonidine 0.1 to 0.3 mg twice daily, or reserpine 0.05 to 0.2 mg daily could be titrated. Hydralazine 25 to 100 mg twice daily could be added for additional blood pressure control. The doxazosin arm was stopped early because of higher rates of stroke and heart failure and futility of finding significant advantage over the diuretic with respect to the primary endpoint.¹⁴² However, blood pressure was not as well controlled with doxazosin as with the diuretic. Comparing chlorthalidone and amlodipine, there was no difference for the primary combined outcome, combined coronary heart disease events, or end-stage renal disease. Participants randomized to amlodipine had the lowest all-cause mortality and stroke rates. Rates of cancer and gastrointestinal bleeding were not increased with the calcium antagonist, nor were there increases in hospitalized or treated angina. Only heart failure occurred with a 38% higher incidence ($p < .001$). The rate of heart failure increased very early in the trial. Critics of ALLHAT have suggested that much of the investigator diag-

nosed heart failure in the trial was due to misdiagnosis or secondary to withdrawal of prior diuretics and to unmasking of heart failure.¹⁴³ Subsequent publications have validated the diagnosis, at least for hospitalized and fatal cases.^{144,145} As previously stated, ALLHAT has disproved many of the criticisms previously directed against calcium channel blockers.

The Systolic Hypertension in the Elderly: Lacidipine Long-term (SHELL) study was designed to compare a diuretic with lacidipine on cardiovascular outcome in elderly patients with isolated systolic hypertension, defined as a systolic blood pressure 160 mm Hg or higher and a diastolic blood pressure 95 mm Hg or less.¹⁴⁶ A composite of cardiovascular and cerebrovascular events was the primary outcome. The study used a PROBE design; however, 12 sites followed a double-blind design for the first year. Patients ($n = 1882$) were randomly assigned to chlorthalidone 12.5 mg or lacidipine 4 mg dosed once daily after a 2-week washout period. If there was not a reduction in systolic blood pressure 20 mm Hg or greater and systolic blood pressure exceeded 160 mm Hg after 4 weeks, chlorthalidone was titrated to 25 mg or lacidipine to 6 mg daily. If blood pressure control was still not achieved after 1 month, then the dose of the assigned drug was reduced to the starting dose and fosinopril 10 mg once daily was added. The planned sample size of 4800 patients was not achieved. Baseline blood pressure was 178/87 mm Hg. After 32 months, blood pressure was reduced by 36/8 mm Hg in chlorthalidone-treated patients and 35/8 mm Hg in the lacidipine-treated patients. Low-dose monotherapy was taken by 72% of lacidipine-treated and 47% of diuretic-treated patients. The overall incidence of the primary endpoints was 9.3% with no difference according to treatment. There was no significant difference for individual cardiovascular events. Total mortality, a secondary endpoint, was comparable.

The International Verapamil SR/Trandolapril Study (INVEST) enrolled 22,576 hypertensive patients with known coronary artery disease and used a PROBE design.¹⁴⁷ Patients were randomized to sustained-release verapamil 240 mg once daily or atenolol 50 mg once daily.¹⁴⁷ Drugs were titrated to a blood pressure goal of 140/90 mm Hg or 130/85 mm Hg for patients with diabetes mellitus or chronic renal insufficiency. Verapamil was titrated from 240 to 360 mg and trandolapril from 2 to 4 mg with hydrochlorothiazide 25 mg added, if necessary. Atenolol was titrated from 50 to 100 mg and hydrochlorothiazide 25 to 50 mg with trandolapril 2 to 4 mg added if needed. Diastolic and systolic blood pressure was controlled in 91% and 64% of study participants, respectively. The average decline in blood pressure at 24 months was $-18.7/-10$ mm Hg and $-19.0/-10.2$ mm Hg in the calcium antagonist and β -blocker arms, respectively. Greater than 48% of subjects required three or more drugs. The composite primary endpoint was nonfatal myocardial infarction, nonfatal stroke, and total mortality. Blood pressure control was similar over the 4 years of the study. There was no difference between groups for the composite primary endpoint or the individual components, but new-onset diabetes was more common in the β -blocker arm than the calcium antagonist arm (8.2% vs. 7.0%).

The Valsartan Antihypertensive Long-term Use Evaluation (VALUE) trial compared the efficacy of valsartan and amlodipine for reducing first cardiac events.¹⁴⁸ The double-blind trial enrolled 15,245 hypertensive patients. Valsartan 80 to 160 mg or amlodipine 5 to 10 mg was titrated with hydrochlorothiazide 12.5 to 25 mg and other nonstudy

medications to achieve a blood pressure less than 140/90 mm Hg. The mean follow-up was 4.2 years. The average reduction in blood pressure was 15.2/8.2 mm Hg and 17.3/9.9 mm Hg for valsartan- and amlodipine-assigned patients, respectively ($p < .0001$). The greatest decline in blood pressure was observed during the first 3 months with amlodipine. There was no difference in overall cardiac morbidity, cardiac mortality, or total mortality. There were fewer myocardial infarctions recorded with amlodipine (4.1%) compared with valsartan (4.8%, $p = .02$). New onset diabetes was reduced by 23% ($p < .0001$) with valsartan. Although there was no overall difference in the primary composite endpoint, there was a benefit favoring amlodipine during the first 3 months, which paralleled the greatest difference between treatment regimens. An exploratory analysis was undertaken using serial median matching to compare similar patients based on demographics and level of systolic blood pressure.¹⁴⁹ Using this technique, there was no difference in the composite endpoint, stroke, death, or myocardial infarction; however, heart failure was 19% less among valsartan-treated patients.

TRIAL IN PROGRESS

Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT)

ASCOT is a 2x2-factorial designed trial of 19,342 hypertensive patients with three additional cardiovascular risk factors randomized to receive the calcium antagonist amlodipine 5 to 10 mg with the converting enzyme inhibitor perindopril 4 to 8 mg, if needed or the β -blocker atenolol 50 to 100 mg with bendroflumethiazide 1.25 to 2.5 mg and potassium supplements, if necessary.¹⁵⁰ Doxazosin GITS 4 to 8 mg can be added to either arm if blood pressure is not controlled. The 10,305 participants with nonfasting total cholesterol concentrations ≤ 6.5 mmol/L (≤ 207 mg/dl) were randomly assigned to atorvastatin 10 mg or placebo. The primary endpoint of ASCOT is combined fatal coronary heart disease and nonfatal myocardial infarction. The lipid arm (ASCOT-LLA) has been terminated for benefit.¹⁵¹

SUMMARY

Calcium channel blockers will continue to be used by physicians because they are effective in lowering blood pressure. The ALLHAT study has proven their safety in hypertensive patients. There was no increased risk of myocardial infarction, cancer, or overall mortality as compared with chlorthalidone. Care must be taken in using these medications in patients with systolic heart failure or advanced renal insufficiency and patients receiving multiple medications.

Angiotensin II Receptor Antagonists

Michael C. Ruddy, John B. Kostis

INTRODUCTION

The main components of the renin-angiotensin system were characterized by the mid-1950s. Leonard Skeggs and his group in Cleveland had used hog renal renin and equine plasma renin substrate to show that there are two forms of the peptide product.¹ The biologically inactive decapeptide angiotensin I was found to be quickly transformed in plasma by a chloride-dependent “converting enzyme” to the vasopressor octapeptide angiotensin II.² The same laboratory also determined the nature of the renin substrate molecule from which angiotensin is generated, as well as the function of converting enzyme. They found three important biochemical properties of the converting enzyme: its anion dependence, its metalloprotein nature, and its ability to catalyze the hydrolytic cleavage of a dipeptide from the carboxyl terminus of its decapeptide substrate. By 1956, these investigators had documented the precise amino acid sequence of angiotensin I and II.³

Skeggs suggested three possible avenues of therapeutic effect on the renin-angiotensin system. The first possibility, that of direct inhibition of the action of renin on its substrate, remains to this day under study with several renin inhibitors currently undergoing investigation (see Chapter 72). A second proposal was to prevent the formation of the octapeptide hypertensin II (angiotensin II) from its decapeptide precursor by inhibition of the converting enzyme. This strategy has since been extraordinarily successful through the development of orally active angiotensin-converting enzyme (ACE) inhibitors (see Chapters 9 and 65).

A third suggestion was to prevent the vasoconstrictive action of angiotensin II on smooth muscle with inhibitory compounds based on the structure of angiotensin II.⁴ Since the mid-1990s, this latter approach has developed into a mainstay of therapy for an increasing number of patients with hypertensive circulatory and renal disorders. This chapter outlines the increasingly important products of Skeggs’s amazingly prescient hypotheses.

ANGIOTENSIN SYSTEM

Pathways for Angiotensin Generation

All of the known biologic actions of the renin-angiotensin system are mediated by the angiotensin series of peptides. Of these, the octapeptide angiotensin II has the broadest range of activity and the greatest potency in circulatory regulation. Most angiotensin II is formed in two steps through the sequential catalytic action of renin and ACE on the substrate angiotensinogen. In addition, some angiotensin II is formed in cardiac and renal tissue through the action of other proteolytic enzymes, such as chymase and cathepsin on the decapeptide angiotensin I.⁵

Actions of Angiotensin II

A primary function of the renin-angiotensin system is to maintain perfusion when the circulation is threatened by volume depletion or hypotensive stress.⁶ In this respect, acute effects of angiotensin II production include vasoconstriction, increased aldosterone secretion with retention of salt, increased thirst and release of antidiuretic hormone, and amplification of sympathetic nervous system activity.^{7,8}

Blood Vessels

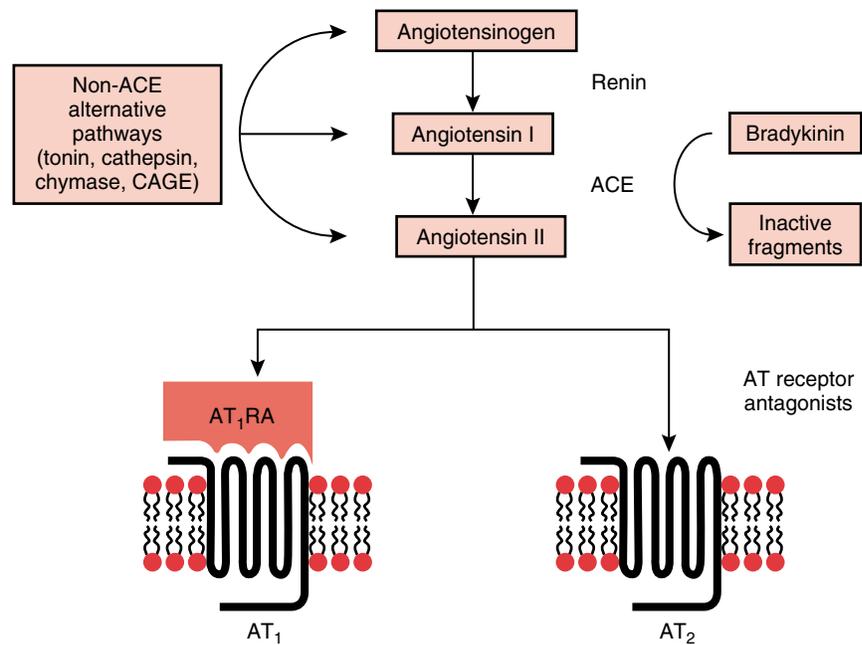

Angiotensin II acts as a potent constrictor of precapillary arterioles and, to a lesser extent, postcapillary venules.⁹ The direct action at the vascular smooth muscle site appears to account for most of the increase in peripheral resistance. The vasoconstrictor effect of angiotensin II is mediated primarily through direct binding to angiotensin II type 1 (AT₁) receptors on vascular smooth muscle.¹⁰ However, in certain vascular beds, such as those perfusing skeletal muscle of the extremities of humans, it has been demonstrated that α -adrenergic antagonists can appreciably attenuate the vasoconstrictor effect of infused angiotensin II.¹¹ This finding is consistent with an important role for sympathetic augmentation of the vascular action of angiotensin II. The vasoconstrictor effect of angiotensin II is greatest in the splanchnic, renal, and cutaneous vascular beds and is less in vessels of the brain, lung, heart (coronary), and skeletal muscle. In the latter regions, blood flow may actually increase during low-dose infusions of angiotensin II due to the stronger effect of elevated systemic blood pressure opposing the relatively weak vasoconstrictor response in these areas.¹²

Adrenal Cortex

The angiotensin system has an important role in the regulation of plasma volume through the actions of angiotensin II on the adrenal gland and the kidney. Angiotensin II is the primary secretagogue for the synthesis and release of aldosterone by cells of the adrenal cortical zona glomerulosa. The cells of the zona glomerulosa have a high density of AT₁ receptors.¹³ Adrenal secretion of aldosterone can be elicited by concentrations of angiotensin II that are well below the threshold of a systemic pressor response.¹³ Aldosterone acts on the distal tubule and collecting duct of the kidney to promote reabsorption of sodium in exchange for secretion of potassium and hydrogen ions. The effect of increasing aldosterone levels is preservation of or expansion of total body sodium and plasma volume.

Aldosterone has important profibrotic and hypertrophic effects in the cardiovascular system (see Chapters 12 and 70).¹⁴ These include direct prosynthetic effects on collagen 1A1, 1A2, and 3A1, and indirect effects via transforming growth factor- β_1 (TGF- β_1).¹⁵ Aldosterone has also been shown

Figure 67-1 The renin-angiotensin system cascade. ACE, angiotensin-converting enzyme; CAGE, chymostatin-sensitive angiotensin II-generating enzyme; AT₁, angiotensin II. (From Johnston CI, Risvanis J. Preclinical pharmacology of angiotensin II receptor antagonists: Update and outstanding issues. *Am J Hypertens* 10:306S-310S, 1997.)

to up-regulate the expression of AT₁ receptors, suggesting positive feedback between the actions of angiotensin II and aldosterone.¹⁶

Kidney

The rate-limiting step for the production of intrarenal angiotensin II appears to be mostly dependent on renin secreted by the cells of the juxtaglomerular apparatus.¹⁷ The final catalytic step in the formation of renal interstitial angiotensin II from its precursor molecule, angiotensin I, appears to be predominantly via non-ACE pathways.¹⁸ The kidney appears to be especially sensitive to the actions of angiotensin II. Most of the intrarenal effects of angiotensin II can be observed experimentally at circulating levels 10 to 100 times lower than required for its extrarenal actions.¹⁹

Angiotensin II receptors are found in the efferent and afferent glomerular arterioles, the juxtaglomerular cells, glomerular mesangial cells and podocytes, the basolateral and apical surfaces of proximal and distal tubular cells, the macula densa, the collecting duct, and medullary interstitium.²⁰ Effects of angiotensin II have been observed in each of the major cellular elements of the kidney, including cells of the microvasculature, the mesangium, the tubular epithelium, and the interstitium.

Autoregulation of glomerular filtration rate in response to variations in renal perfusion pressure is mediated predominantly, although not exclusively, through angiotensin II.²¹ At the level of the preglomerular and postglomerular arterioles, angiotensin II acts as a vasoconstrictor. The glomerular efferent arterioles are highly sensitive to even low concentrations of this peptide.²² The glomerular afferent arterioles are less sensitive to the constrictor effects of angiotensin II, perhaps due to differential production of vasodilator prostaglandins and nitric oxide by these vessels.²³ Also, angiotensin II produces a direct contractile response of the glomerular mesangial cells, which tends to decrease the effective surface area available for glomerular filtration.²⁴ Modest increases in tissue or circulating angiotensin II levels act to increase glomerular

hydrostatic pressure and filtration rate by the dual additive effects of raised systemic perfusion pressure together with heightened resistance of the postglomerular outflow. At higher levels of angiotensin II, the less sensitive preglomerular afferent arterioles constrict, impeding glomerular perfusion. Thus, reduced glomerular perfusion combined with the direct contractile action of angiotensin II on the glomerular mesangium may result in significant impairment of renal blood flow and glomerular filtration rate. AT₁ receptors on the cell surface of the juxtaglomerular apparatus mediate an inhibitory signal for renin release by these cells, thereby providing a key element in the rapid servocontrol of local and systemic production of angiotensin II.

Angiotensin II, through activation of cytokines, such as TGF- β , promotes mesangial cell proliferation and extracellular matrix deposition.²⁵ Glomerular hypertension and angiotensin II have also been shown to increase the rate of glomerular podocyte loss.²⁶ In aging and in several disease states, these local actions of angiotensin II are likely to contribute importantly to glomerulosclerosis and progressive decline of filtration rate.

The proximal tubular epithelial cells express a high density of AT₁ receptors on both the basolateral and luminal membranes.²⁷ The density of receptors decreases from the most proximal to distal portions of this segment.²⁸ Low to moderate concentrations of angiotensin II promote tubular reabsorption of filtered sodium and water.²⁹ This is mediated primarily through stimulation of the epithelial apical sodium-proton pump.³⁰ Also, glomerular autoregulation leads to increased filtration fraction and concomitant elevation of peritubular capillary and interstitial oncotic pressure. The latter serves to amplify the more direct, receptor-mediated actions of angiotensin II on tubular sodium and fluid reabsorption. Thus, angiotensin II within the usual physiologic range serves to preserve or enhance net renal sodium retention by at least three mechanisms: (1) direct receptor-mediated actions along the proximal tubule, (2) indirect alterations of peritubular Starling forces, and (3) indirectly through stimulation of

adrenal aldosterone release and augmentation of basolateral Na,K-ATPase along the distal tubular epithelium and collecting duct.

Nervous System

The effects of angiotensin II on the nervous system are complex (see Chapter 6). The earliest described action was the central pressor effect. It has been demonstrated that infusion of angiotensin II into the isolated cerebral circulation of dogs was associated with a rise in systemic blood pressure even though the angiotensin has no access to the systemic blood vessels.³¹ Blockade of peripheral α -adrenergic receptors inhibited this central action of angiotensin II, indicating that sympathetic tone plays an important role.³² Ablation of the area postrema inhibits the effects of centrally administered angiotensin II, indicating that this area mediates angiotensin II induced stimulation of sympathetic outflow.³³

It has also been demonstrated that angiotensin II enhances the activity of peripheral noradrenergic nerve terminals. Angiotensin II stimulates the release of and inhibits the reuptake of norepinephrine at peripheral sympathetic nerve endings.⁷

Both intravenous and centrally administered angiotensin II has been shown to provoke water intake and salt appetite and also stimulate secretion of vasopressin and adrenocorticotrophic hormone.³⁴ These central actions of angiotensin II are thought to provide short and intermediate-term defense for extracellular fluid volume in the hypovolemic or hypotensive state. Although angiotensin II does not cross the blood-brain barrier, there is evidence that its central actions may be mediated through the subfornical organ.³⁵ Finally, it has been found that neurons at various locations in the central nervous system are capable of synthesizing angiotensin II, presumably for local release as a neuromodulator.

Structural Effects of Angiotensin II

Suppressor amounts of angiotensin II, when administered over days to weeks, can produce hypertrophy of the myocardium and vascular smooth muscle.³⁶ These actions can be attenuated or prevented altogether with ACE inhibitors and angiotensin receptor antagonists. In vascular smooth muscle cell cultures, angiotensin II has been shown to enhance production of extracellular matrix proteins, such as type V collagen and fibronectin.³⁷ Angiotensin II can also act as a mitogen by promoting a proliferative response in fibroblasts, adrenal cortical cells, and vascular smooth muscle cells.³⁸ The growth promoting effects of low levels of angiotensin II occur despite down-regulation of the AT₁ receptors.

Distribution of Angiotensin Receptors

Angiotensin II, like other peptidic hormones, elicits its cellular actions by first binding to highly specific receptors located on the cell membrane. In humans, two angiotensin II receptor subtypes have been identified. The AT₁ and AT₂ receptor subtypes have been cloned and characterized as members of the superfamily of seven-transmembrane-spanning G-protein-coupled receptors (see Chapter 11).³⁹ The AT₁ receptor appears to mediate most of the known actions of the angiotensins.

Table 67-1 Actions of Angiotensin II

Tissue	Action
Vasculature	Vasoconstriction Promotes smooth muscle hypertrophy
Adrenal cortex	Stimulates synthesis and secretion of aldosterone
Adrenal medulla	Increases release of epinephrine
Kidney	Vasoconstriction of the efferent and afferent arterioles Inhibition of renin release by the juxtaglomerular apparatus Stimulation of sodium reabsorption in the proximal tubule Promotion of mesangial growth and matrix deposition
Heart	Stimulation of myocardial hypertrophy and collagen synthesis
Brain	Stimulation of thirst and release of vasopressin Increase in central sympathetic outflow
Peripheral sympathetic nerve terminals	Presynaptic augmentation of norepinephrine release

AT₁ receptors have been demonstrated in a large number of tissues, including vascular smooth muscle, adrenal zona glomerulosa, mesangial and tubular epithelial cells of the kidney, myocardium, neuronal tissue, and choroid plexus.⁴⁰ The AT₂ receptor subtype has been found in abundance in fetal mesenchymal cells, brain tissue, adrenal medulla, and uterus.⁴⁰ The physiologic functions and intracellular signaling mechanisms of the AT₂ receptor protein remain incompletely understood. There is evidence that the AT₂ receptor subtype can mediate antiproliferative and apoptotic effects of angiotensin II.⁴¹

With the exception of the adrenal glomerulosa, prolonged exposure of target organs to angiotensin II reduces responsiveness, an effect that has been shown to be associated with internalization and phosphorylation of the AT₁ receptor.⁴² Comparisons among different cell types reveal that receptor density and magnitude of response to angiotensin II are not always related. For example, vascular smooth muscle cells have a much lower density of AT₁ receptors than cells of the adrenal glomerulosa yet have a more rapid and dramatic response to angiotensin II.⁴³

DEVELOPMENT OF ANGIOTENSIN II ANTAGONISTS

Peptide Analogs of Angiotensin II

Detailed analyses of the structural requirements of angiotensin for binding to its receptors and studies of many analogs of angiotensin II eventually led to the development of saralasin, a potent angiotensin II receptor blocker (ARB).⁴⁴ Saralasin is an octapeptide, which differs in structure from angiotensin II at the first (sarcosine) and eighth (alanine)

amino acid positions. Sarcosine is a nonmammalian amino acid, which, when located at the N-terminal of angiotensin II, was found to slow the degradation of the molecule. Saralasin was shown to lower blood pressure and aldosterone levels in humans in proportion to the circulating levels of angiotensin II.⁴⁵ Due to its peptide nature, saralasin required intravenous administration, was expensive to manufacture, and had a short half-life. Initially, saralasin was approved only as a diagnostic probe for renin-dependent forms of hypertension.⁴⁶ Because this agent also possessed weak agonist action, it occasionally produced a significant pressor effect in patients with low renin forms of hypertension.⁴⁷ The inconvenience and expense of administration, coupled with the unpredictability of response, markedly limited the application of saralasin in the clinical mainstream. Following the development and approval of the orally active converting enzyme inhibitors in the early 1980s, saralasin was withdrawn from the market.

Medicinal Chemistry of Nonpeptide Angiotensin II Receptor Antagonists

For several decades investigators struggled to identify potent orally active ARBs. An important breakthrough occurred in 1982, when Furakawa et al. of the laboratories of Takeda Ltd. in Japan identified and patented several 1-benzylimidazole 5 acetic acid derivatives that had specific angiotensin II receptor binding activity.⁴⁸ However, these initial compounds possessed only weak antihypertensive effects.⁴⁹ Investigators at the Dupont Merck Pharmaceutical Company postulated that the imidazole compounds and angiotensin II bound to the same receptor site, but the test molecules needed enlargement to better mimic angiotensin II at its points of attachment to the

receptor. The molecular model employed by these investigators suggested that there was overlap between the imidazole groups with histidine at the 6-position of angiotensin II.⁵⁰ The lipophilic *N*-butyl group at the 2-position was pointed at the leucine at the 5-position of the octapeptide. It was posited that the benzyl group of the Takeda compound extended in the direction of the N-terminal of angiotensin II. Elongation of the compound by building the molecule toward the tyrosine site at the 4-position of angiotensin II might increase potency.⁵⁰

Addition of a carboxylic moiety at the para position of the benzene ring improved receptor binding 10-fold and lowered blood pressure when administered intravenously to renal hypertensive rats. By enlarging the molecule with placement of a second acidic phenyl group linked by a single carbon atom to the first aromatic ring, binding affinity increased another 10-fold, and oral bioavailability was markedly enhanced.⁵¹ A significant and final improvement in bioavailability and receptor binding was obtained when the carboxylic moiety located on the second phenyl group was replaced by a tetrazole at the ortho position.

BIPHENYL TETRAZOLE DERIVATIVES

Losartan is chemically described as 2-butyl-4-chloro-1-[*p*-(*o*-1*H*-tetrazole-5-ylphenyl)-benzyl] imidazole-5-methanol monopotassium salt and was the first approved nonpeptide orally active antihypertensive agent with specific binding to the AT₁ receptor subtype.⁵² Maximum pharmacologic action requires the oxidation of the 5-hydroxymethyl group on the imidazole ring to form EXP3174, the carboxylic acid metabolite of losartan.⁵³

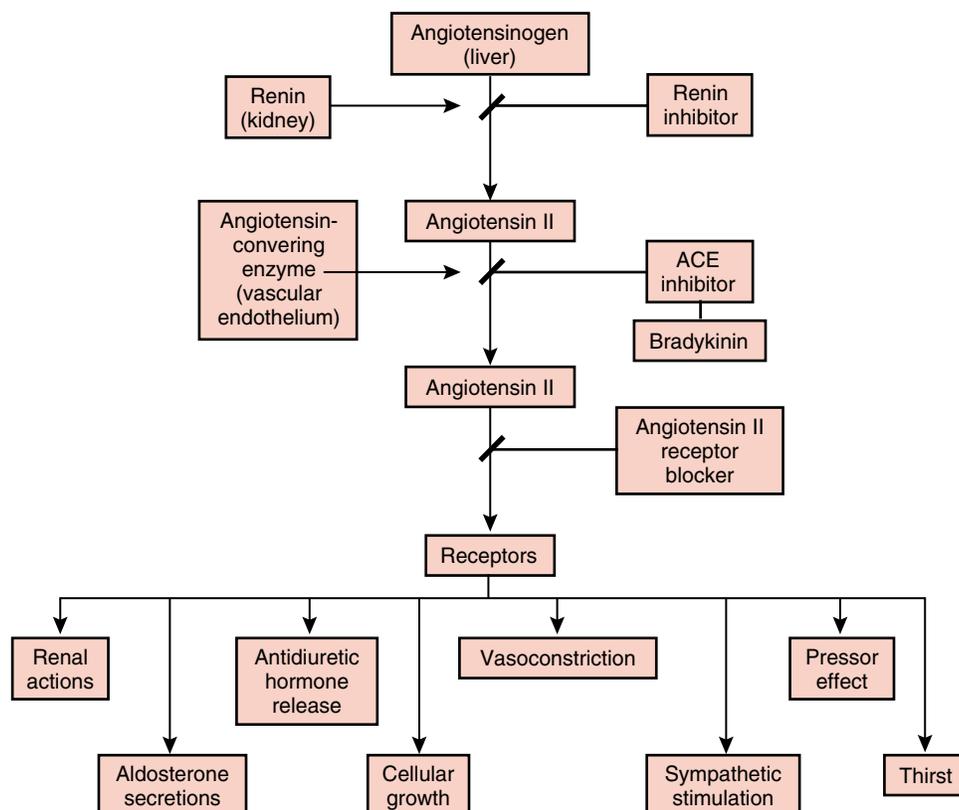

Figure 67-2 Approaches to regulating the renin-angiotensin system. (From Gibbons G. The pathophysiology of hypertension: The importance of angiotensin II in cardiovascular remodeling. *Am J Hypertens* 11:177S-181S, 1998.)

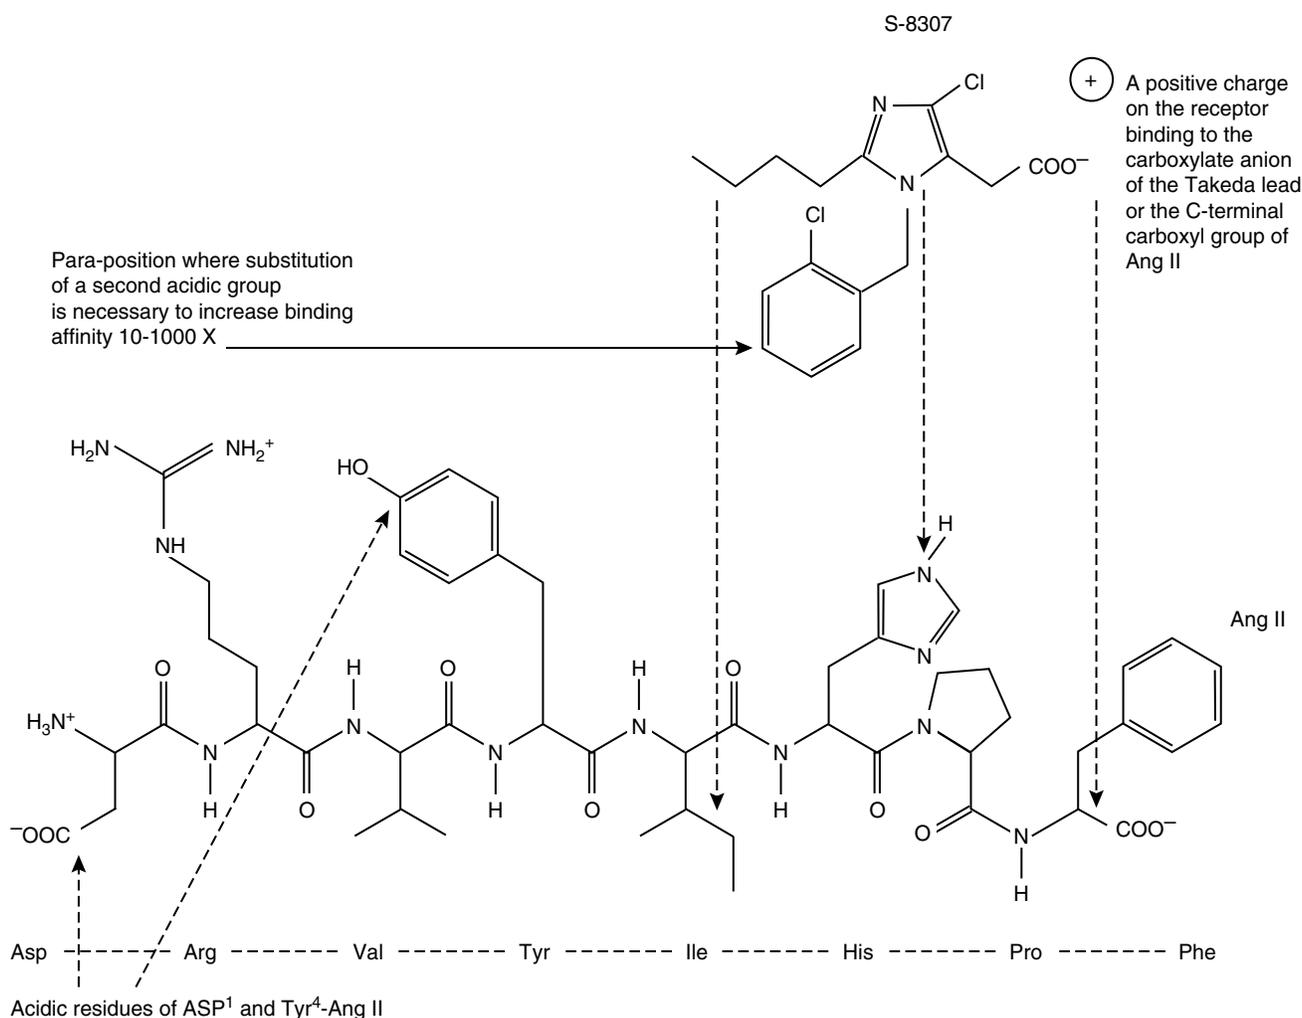

Figure 67-3 Hypothetical structure relations of angiotensin II and the orally active angiotensin II receptor antagonists. (From Timmerman PB, Duncia JV, Carini D, et al. Discovery of losartan, the first angiotensin II receptor antagonist. *J Hum Hypertens* 9:S3-S18, 1995.)

The second AT₁ subtype ARB to gain approval for clinical use is valsartan. Investigators at Ciba (Novartis) in Switzerland employed a strategy to open up the imidazole ring and replace it with the acylated amino acid valine.⁵⁴ The acidic biphenyl tetrazole substituent is preserved. The carboxyl moiety of the valine serves to preserve oral bioavailability with high affinity receptor binding. Thus, valsartan is, like EXP3174 (the active metabolite of losartan), a diacid. Unlike losartan, valsartan does not require metabolic oxidation to achieve maximum pharmacologic effect.⁵⁵

Irbesartan is chemically described as 2-butyl-(1*H*-tetrazol-5-yl) [1,1'-biphenyl]-4-yl [methyl]-1,3-diazepino [4,4] non-1-en. This compound was discovered by Sanofi Recherche of France and has been jointly developed with Bristol-Myers Squibb in the United States. The French investigators incorporated an imidazolinone moiety in place of the imidazole heterocyclic ring. A carbonyl group functions as the hydrogen bond acceptor in place of the 5-hydroxymethyl group of losartan and the valine carboxylic acid group of valsartan.⁵⁶ This agent possesses a high affinity and specificity for AT₁ receptors. Irbesartan does not require biotransformation to achieve its effects.⁵⁷

Another successful approach has been to develop fused-ring imidazoles. Candesartan cilexetil is an ester carbonate benzimidazole prodrug that has been designed by Takeda Ltd. and jointly developed with Astra-Zeneca.⁵⁸ This agent is rapidly metabolized to CV-11974, a highly potent AT₁ receptor antagonist. The latter compound bears a C7 carboxyl group that is positioned in a fashion similar to the imidazole carboxyl moiety of EXP3174, the active metabolite of losartan.⁵⁹

NONBIPHENYL TETRAZOLE DERIVATIVES

The Boehringer Ingelheim/Thomae research team has followed a similar fused-ring approach but substituted a second phenylimidazole moiety at the 6-position of the primary heterocycle.⁶⁰ This compound, telmisartan, incorporates a carboxylic acid as the biphenyl acidic group that achieves greater receptor antagonism than does the tetrazole analog.⁶¹

Investigators at SmithKline Beecham devised an alternative model for the superimposition of the Takeda benzylimidazole antagonists with angiotensin II. As with the Dupont model,

the 2-chlorobenzyl substituent of the Takeda lead was proposed to be spatially equivalent to the Tyr-4 position of angiotensin II, and the aliphatic butyl group pointed toward the Ile-5. However, the equivalence between the imidazole of the Takeda lead and the His-6 of angiotensin II was not assumed. Instead, the imidazole was thought to function as a scaffold for positioning of substituent groups toward the receptor.⁶² This led to a different but also successful approach through refining the presentation of the carboxylic acid and greater filling of the binding pocket for the Phe-8 side chain of angiotensin II. Chain extension at the imidazole-5-position via a *trans*-5-acrylic acid group yielded the final product, eprosartan, which is 40,000-fold more potent than the original Takeda lead.⁶³

EFFECTS OF ANGIOTENSIN ANTAGONISTS

Hemodynamic Effects

Angiotensin II antagonists reduce peripheral resistance and systemic arterial pressure in hypertensive animals.⁶⁴ The depressor effect is more potent and more consistent in renin-angiotensin dependent models, such as the 2-kidney 1-clip or angiotensin-infusion forms of hypertension.^{65,66} Volume expansion or bilateral nephrectomy appears to attenuate or abolish the antihypertensive effect of the ARBs.⁶⁷ In euvoletic normotensive animals and humans, angiotensin II antagonists have little effect. In the majority of hypertensive humans these agents produce a significant reductions in peripheral resistance and blood pressure.^{68,69}

Lowering of peripheral resistance is most likely due to several factors, especially direct binding to and antagonism of vascular angiotensin II receptor sites and reversal of the vasoconstrictive action normally mediated by angiotensin II.⁶⁷ Augmentation of this effect may occur through binding and blockade of angiotensin II receptors on sympathetic nerve terminals with consequent attenuation of sympathetically mediated vasoconstriction.⁷⁰ ARBs have also been demonstrated to enhance nitric oxide-mediated vascular endothelial function.⁷¹ In normotensives ARB-induced declines in arterial compliance and blood pressure have been found to correlate with pretreatment plasma renin activity.⁷²

Cardiac Effects

Despite the angiotensin antagonist-induced decline in peripheral resistance, heart rate is little affected in euvoletic hypertensive animals and humans during ARB treatment. This neutral effect on heart rate in the setting of lowered peripheral resistance may be due to antagonism of angiotensin II receptors at peripheral sympathetic sites, as well as through centrally mediated actions of these agents.⁷³

Based on several converging lines of evidence, it has been predicted that AT₁ antagonists would have an especially beneficial effect on cardiac and vascular hypertrophy. Plasma angiotensin II levels tend to increase during therapy with these agents, most likely as a result of AT₁ receptor-mediated disinhibition of renin release by cells of the renal juxtaglomerular apparatus.⁷⁴ Also, it has been found that the cardiac chymase-angiotensin system provides an alternate path

for angiotensin II formation that is independent of converting enzyme.⁷⁵ Moreover, there is evidence that the AT₂ receptor subtype can mediate an antiproliferative effect on vascular cells.⁷⁶ Thus, administration of a selective AT₁ antagonist would not only attenuate growth promoting effects mediated by the AT₁ receptor but also, as angiotensin II levels rise, may enhance the antiproliferative effect mediated by the unblocked AT₂ receptor subtype.⁷⁶

There is evidence that ARBs prevent angiotensin II mediated cardiac growth and remodeling.^{78,79} These effects may prove to be of importance in the prevention or treatment of ischemic or hypertensive cardiomyopathies. In experimental models of coronary ischemia, losartan appears to have beneficial effects on survival and on myocardial growth and remodeling.^{79,80}

ARBs may also benefit the heart by decreasing collagen deposition and cardiac fibrosis, by blocking angiotensin II effects directly or aldosterone effects indirectly.⁸¹ ARBs may prevent the development of atrial fibrillation by attenuation of structural remodeling of the atrial myocardium.⁸²

There is experimental evidence that ARBs may improve coronary reserve in hypertensive animals concomitant with a reduction in cardiac mass.^{83,84} Alterations in coronary blood flow are a function of coronary vasomotor tone, diastolic perfusion pressure, and left ventricular end-diastolic pressure, all of which may be affected by ARBs.^{85,86} Thus, in the clinical setting, the effects of ARBs on coronary flow are expected to vary.

Renal Effects

Through binding to AT₁ receptor sites, the ARBs inhibit the intrarenal actions of angiotensin II. In healthy persons on a low-salt diet, an orally administered ARB was found to produce a prompt dose-related increase in renal plasma flow and a slightly delayed, but more prolonged, increase in plasma renin activity.⁸⁷ In patients with essential hypertension, ARBs generally have no discernible effect on glomerular filtration rate as assessed by creatinine clearance.⁸⁸ Renal blood flow is usually unaffected by ARBs in the euvoletic animal or human.⁸⁹

The overall effect of angiotensin II blockade on renal hemodynamics depends on the nature and degree of local and systemic counteracting responses. For example, in healthy men on a very-low-salt diet, it has been found that renal blood flow increases with an ARB administration to an extent that equals or exceeds that following ACE inhibitor infusion.⁹⁰ On the other hand, compensatory activation of the sympathetic nervous system may occur in response to a pronounced fall in systemic blood pressure and, in turn, result in net renal vasoconstriction and a decline in renal function.⁹¹ In the clinical setting of salt or volume depletion ARBs may also produce a decline in glomerular filtration rate, perhaps by interference with glomerular blood flow autoregulation.⁹²

In experimental models of unilateral renal artery stenosis, ARBs consistently produce a decline in glomerular filtration rate in the affected kidney.⁹³ Reported effects on glomerular filtration and renal blood flow in the contralateral kidney have been variable.⁹⁴ In patients with renal impairment and renovascular occlusive disease, reversible increases in serum creatinine have been reported with ARB treatment.^{92,95}

ARBs produce a modest natriuretic action through blockade of proximal tubular AT₁ receptor sites that mediate sodium reabsorption.⁹² This effect is most evident in the volume depleted state, in which the renin activation and the influence

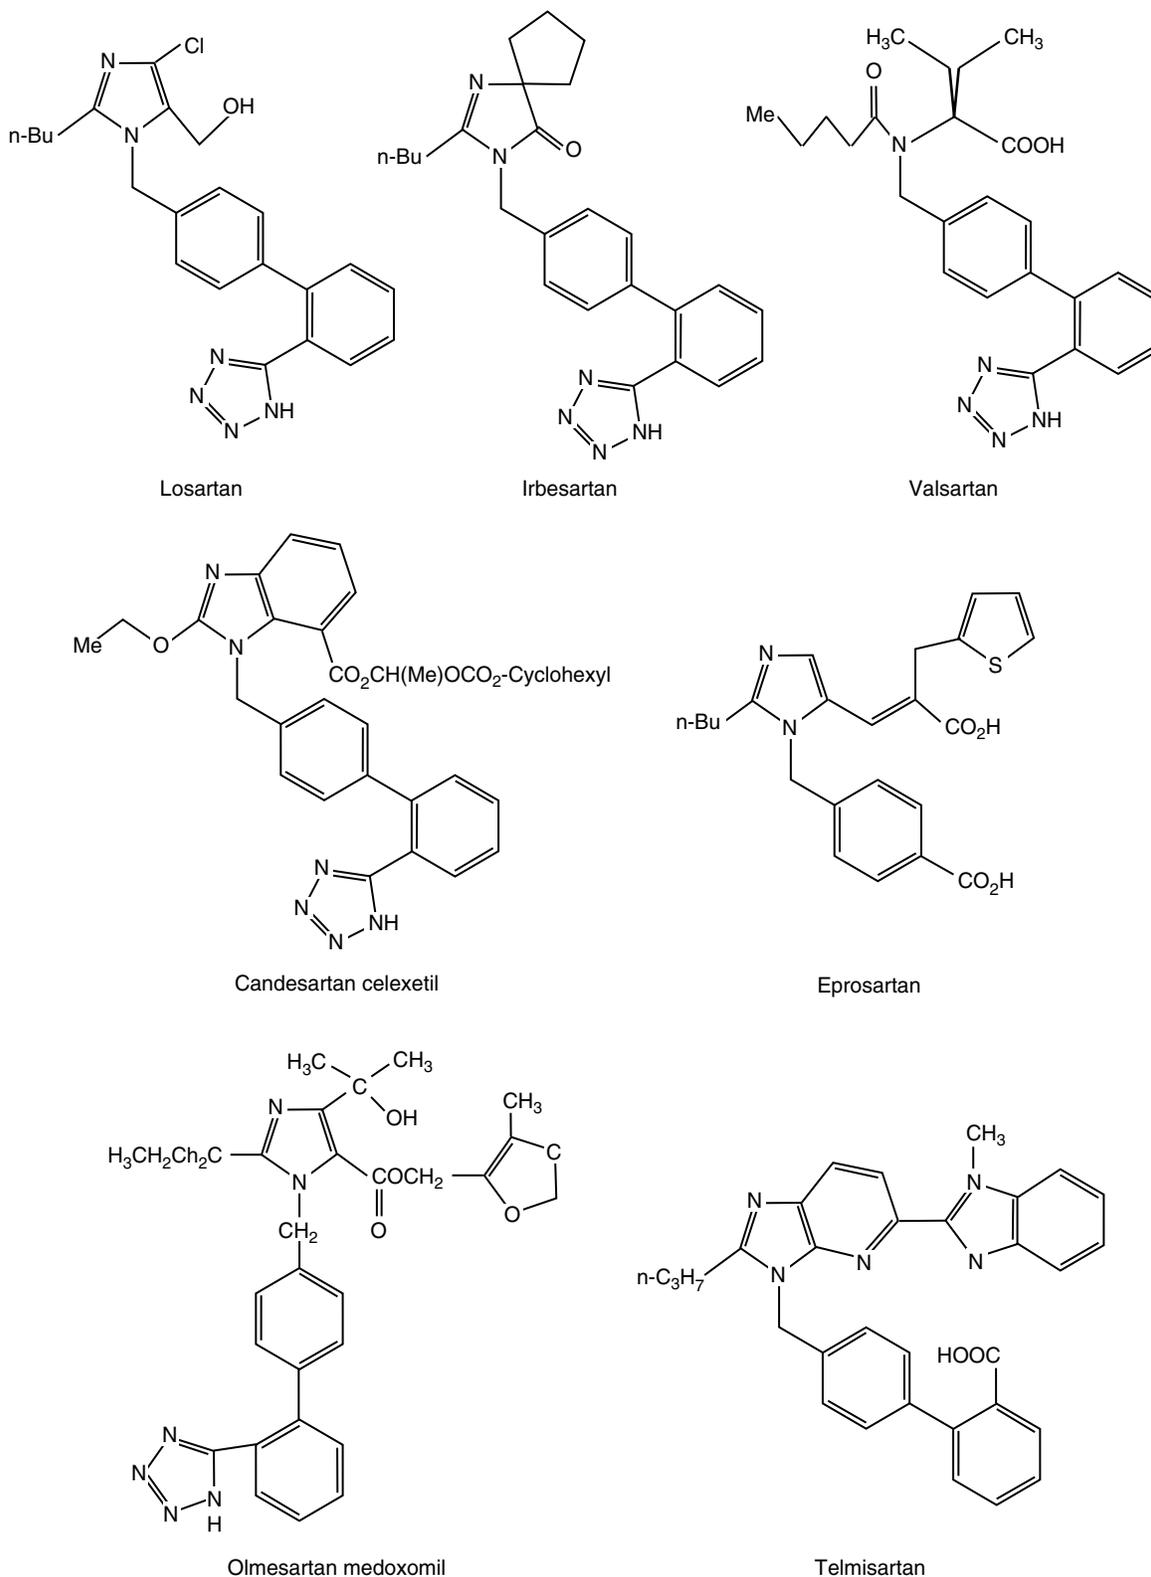

Figure 67-4 Chemical structures of the angiotensin II receptor antagonists.

of the renin-angiotensin system are greatest.^{92,96} An additional natriuretic action occurs through inhibition of aldosterone synthesis and release by the adrenal zona glomerulosa cells.^{97,98} Reduced aldosterone-mediated distal tubular sodium reabsorption may contribute to the diuretic effect of the ARBs.

Administration of ARBs to animals with several forms of experimental renal impairment produced a decline of proteinuria in association with attenuated glomerular hydrostatic pressure. Moreover, because angiotensin II has the potential for growth promoting effects at the mesangial tissue

level, it has been speculated that angiotensin II receptor blockade may exert additional effects on glomerular filtration at the basement membrane filtration barrier site.⁹⁹ In hypertensive patients with proteinuric renal disorders, administration of losartan was associated with a decrease in urinary protein, an increase in effective renal blood flow and stable glomerular filtration rate.¹⁰⁰ A number of clinical studies have found that the administration of ARBs to patients with diabetic and nondiabetic renal disorders is associated with a reduction in proteinuria. The degree and time course of the antiproteinuric response to these agents vary considerably and appear to differ from that of the anti-hypertensive effect. The peak of the ARB-antiproteinuric dose-response curve has yet to be reported.

Among the ARBs, losartan appears to have the unique property of exerting a modest uricosuric effect.¹⁰¹ The effect is dose dependent and has been documented in normotensive and hypertensive individuals with and without renal impairment. It does not appear to be dependent on the activity of the renin-angiotensin system and is not affected by changes in salt intake. Infusion of the active metabolite of losartan, EXP3174 has no effect on uric acid excretion, indicating that the effect is specific to the parent drug losartan.¹⁰¹ The mechanism is not known but may be related to renal tubular anion load competing with urate at the tubular transport sites.

Nervous System

Angiotensin II antagonism appears to inhibit peripheral sympathetic activity via blockade of presynaptic AT₁ receptors that normally amplify release of neurotransmitters.¹⁰² There is also evidence that these agents, when administered intracerebrally to experimental animals, inhibit centrally mediated sympathetic nervous outflow at the level of the paraventricular nucleus.¹⁰³ Drinking behavior and release of vasopressin are also suppressed following central administration of these agents.¹⁰⁴

Behavior, Affect, and Cognition

In experimental animals ARBs have been shown to improve cognitive function and anxiety-associated deficits.¹⁰⁵ In humans, a randomized trial comparing amlodipine with losartan showed that the ARB treated group had higher mean scores on the Psychological Well-Being Index after 12 weeks of double-blind therapy, despite equivalent blood pressure lowering.¹⁰⁶

Blockade of the brain AT₁ receptors has been shown in animals to reduce the sympathoadrenal and hormonal responses to stress and prevent stress-induced gastric injury.¹⁰⁷ It has been suggested but not yet proven that there may be a role for ARBs in the treatment of stress-related disorders and in the preservation of cognition.^{107,108}

The Study on Cognition and Prognosis in the Elderly (SCOPE) was designed to assess the relative effects of candesartan versus placebo on cardiovascular outcomes and cognition scores in 4500 elderly hypertensive patients. The primary endpoint of combined cardiovascular mortality, non-fatal stroke and myocardial infarction was slightly, but not significantly, reduced in the ARB group. Cognitive function was equally well preserved in both treatment groups.¹⁰⁹

Box 67-1 Hemodynamic and Neurohumoral Effects of AT₁ Receptor Antagonists

- Arterial vasodilation
- Decrease in peripheral resistance
- Reduction of serum aldosterone levels
- Increase in plasma renin activity
- Increase in plasma angiotensin II
- Inhibition of peripheral sympathetic activity
- Decreased glomerular filtration rate in volume depletion states
- Increased glomerular filtration fraction in volume depletion states

CLINICAL PHARMACOLOGY

The angiotensin AT₁ receptor antagonists appear to occupy space among the seven transmembrane helices of the receptor protein. Interaction with amino acid residues in these regions of the receptor molecule prevents the binding of angiotensin II to the receptor.¹¹⁰ All currently available ARBs have been shown to attenuate the circulatory, renal, endocrine, and neurohumoral actions normally mediated by angiotensin II. Unlike the earlier nonselective peptide antagonist, saralasin, these agents are devoid of partial agonist effect. The ARBs have been shown to cause a twofold to threefold rise in plasma renin activity and a consequent rise in angiotensin II concentration.¹¹¹

At this time seven ARBs have U.S. Food and Drug Administration (FDA) approval for the treatment of hypertension. Losartan and irbesartan have also gained approval for use in diabetic nephropathy. Ongoing and completed clinical trials are evaluating various ARBs for treatment of additional hypertension-related circulatory disorders.

It is important to note that ARBs and ACE inhibitors are contraindicated during pregnancy. Several dozen cases of fetal and neonatal morbidity and death have been reported in conjunction with ACE inhibitor administration in the second or third trimester of pregnancy.¹¹² Fetal abnormalities have included renal failure, oligohydramnios, limb and craniofacial deformities, and hypoplastic lung development.

The ARBs differ from each other in their oral bioavailability, rate of absorption, tissue distribution, metabolism, and rate of elimination. Several of these agents act as prodrugs with conversion to more biologically active metabolites.

Losartan Potassium

Losartan potassium is the first orally active ARB approved for clinical use.¹¹³ It is chemically described as 2-butyl-4-chloro-1[p-(o-1H-tetrazol-5-ylphenyl)-benzyl]imidazol-5-methanol monopotassium salt. The potassium salt of losartan is well absorbed orally with a systemic bioavailability of approximately 33%.¹¹⁴⁻¹¹⁶ It is rapidly absorbed with peak plasma levels achieved in about 1 hour. Losartan has a relatively short terminal half-life of 1.5 to 2.5 hours.¹¹⁷ Losartan undergoes substantial first pass metabolism by the cytochrome P450 enzymes 2C9 and 3A4.^{118,119} The methyl hydroxyl group of losartan located on the imidazole ring undergoes biooxidation

to the carboxylated form of the compound, EXP3174.¹¹⁸ Approximately 50% of orally administered losartan is converted to the active metabolite. EXP3174, with potency 15 to 30 times greater than that of losartan, is responsible for most of the angiotensin receptor antagonism.¹¹⁷

The more active metabolite reaches peak concentration in 3 to 4 hours and has a longer terminal half-life of 6 to 9 hours.¹¹⁷ Food intake slows absorption of losartan and delays the time to peak concentration (C_{max}) but has little effect on the total area under the curve (AUC) of either losartan or its principal metabolite.¹²⁰

Losartan is a competitive antagonist of angiotensin II in that it causes a rightward shift of the concentration-contractile curve without depression of the maximum pressor response to the octapeptide. In contrast, EXP3174 is a noncompetitive, so-called insurmountable antagonist in that it produces a nonparallel right shift in the concentration-contractile curve and reduces the maximum response to angiotensin II. The mechanism for the noncompetitive nature of drug-receptor interaction is not yet known. However, it seems likely that tight receptor binding by the active metabolite contributes to the prolonged biologic activity of orally administered losartan.

In the plasma, losartan and its metabolites are highly protein bound (98.7%–99.8%) in a nonsaturable mode. These compounds have been shown to penetrate the blood-brain barrier poorly, if at all. Biliary excretion plays a major role in the elimination of losartan and its metabolites.¹²⁰ A lower starting dose is recommended for patients with hepatic dysfunction. Somewhat less than one third of the absorbed drug and its metabolites are cleared by renal filtration.¹²⁰ Dose adjustment is not necessary in patients with renal impairment, including dialysis patients, unless they are volume depleted or have occlusive renovascular disease.¹²¹ Neither losartan nor EXP3174 can be removed by hemodialysis.¹¹⁹

Losartan administration does not affect the pharmacokinetics of warfarin or digoxin.^{122,123} Coadministration of losartan with cimetidine led to about a 20% increase in the AUC of losartan but not its more potent metabolite.¹¹⁹ Phenobarbital administration led to a reduction of about 20% in the AUC of both losartan and its carboxylated metabolite.¹¹⁹ These interactions are not considered to be clinically significant.

In healthy volunteers, administration of fluconazole, an inhibitor of the cytochrome P450 isoenzyme CYP2C9 but not itraconazole, an inhibitor of CYP3A4, was found to inhibit the formation of the active metabolite EXP-3174.¹²⁴ This implies that CYP2C9 is a major enzyme for the conversion of losartan to its more active metabolite. It is possible that concomitant use of other agents known to inhibit one of these oxidative enzymes may significantly attenuate the therapeutic effect of losartan.

Losartan is approved by the U.S. FDA for the treatment of hypertension and diabetic nephropathy. It is available in 25- and 50-mg tablets. The usual starting dose is 50 mg once daily and the highest recommended dose is 100 mg/day. For patients with intravascular depletion or on diuretic therapy, the 25-mg dose may be safer.

Valsartan

Valsartan acts as a competitive antagonist for the AT_1 receptor of angiotensin II and is chemically described as *N*-(1-oxopentyl)-*N*[[2'-(1*H*-tetrazol-5-yl)[1,1'-biphenyl]-4-

yl]methyl]-*L*-valine.⁵⁵ Unlike losartan, valsartan is not a pro-drug, and its activity is independent of hepatic metabolism.¹²⁵ Oral bioavailability for the capsule formulation of valsartan is approximately 25% (range 10%–35%).¹²⁶ The time to peak concentration in the plasma is 2 to 4 hours. Food intake decreases AUC by approximately 40% and peak plasma concentrations by about 50%.¹²⁷ Like losartan, valsartan is highly bound to serum proteins (95%), primarily albumin.¹²⁸ The volume of distribution of this compound is only 17 L, indicating that tissue distribution is not very extensive. For most patients the onset of the antihypertensive effect is about 2 hours, with the maximum reduction of blood pressure achieved in about 6 hours.^{125,127}

Elimination of valsartan is mainly (80%) in the unchanged form through the gastrointestinal tract.¹²⁶ Approximately 9% of the dose is metabolized to valeryl 4-hydroxy valsartan. This process does not appear to be cytochrome P450 dependent. Orally administered valsartan shows a biexponential decay curve with an elimination half-life of about 6 hours. The antihypertensive action of valsartan persists for 24 hours following oral administration. Valsartan does not appear to accumulate in plasma following repeated administration. However, patients with hepatic or biliary tract impairment have an increase in the AUC, indicating a slower plasma clearance rate.¹²⁹

The pharmacokinetics of valsartan do not appear to be appreciably affected by renal impairment. However, as with all agents that affect the renin-angiotensin system, the presence of renal insufficiency warrants careful monitoring of the patients' hemodynamic, renal, and electrolyte status.

Coadministration of valsartan with amlodipine, atenolol, cimetidine, digoxin, furosemide, glibenclamide, hydrochlorothiazide, indomethacin, or warfarin has failed to show any clinically significant pharmacokinetic interactions.¹²⁷ Valsartan, like other ARBs and ACE inhibitors, is contraindicated in pregnancy. The extent to which it is excreted in human milk is not yet known. Dose adjustment does not appear to be necessary for the elderly, although careful clinical monitoring is prudent in this group.¹³⁰

Valsartan is approved for the treatment of hypertension in the United States and other countries. It is available in capsule form as the 80- and 160-mg dose formulations. It is recommended to initiate valsartan therapy with 80 mg once daily. The dosage of valsartan may be increased as needed up to a total daily dose of 320 mg. It is prudent to reevaluate patients within 1 month following such a dose adjustment.

Irbesartan

Irbesartan is chemically described as 2-butyl-3-[[2(1*H*-tetrazo 5yl) [1,1' biphenyl 4yl] methyl]-1,3 diazaspino [4,4] non-1 en-4-olone. This compound has an imidazolinone ring in which a carbonyl group functions as the hydrogen bond acceptor in place of the C-5 hydroxymethyl group of losartan.⁵⁶ Irbesartan has been shown to be an insurmountable noncompetitive antagonist of the AT_1 receptor (Figure 67–5).^{57,131} Irbesartan does not require biotransformation for its pharmacologic action.¹³²

Oral bioavailability of Irbesartan is relatively high at 60% to 80% and is not affected by food intake.¹³³ Peak plasma concentrations occur 1.5 to 2 hours following oral administration. Irbesartan is less protein bound than other ARBs and has a plasma half-life of approximately 11 to 15 hours.¹³³

Irbesartan is metabolized by oxidation and glucuronide conjugation. Oxidation is mediated primarily through the 2C9 isoenzyme. Metabolism by 3A4 was found to be negligible.¹³² Irbesartan had no effect on the function of other cytochrome P450 oxidative isoenzymes, such as 1A1, 1A2, 2A6, 2B6, and 2E1.¹¹² Irbesartan has no demonstrated effects on the pharmacokinetics or pharmacodynamics of nifedipine, hydrochlorothiazide, warfarin, and digoxin.¹³²

Irbesartan is eliminated from the body primarily through biliary excretion (75%) and to a lesser extent through the kidneys.¹³⁴ Drug accumulation does not appear to occur in the setting of hepatic or renal insufficiency, and dose adjustment is not required for these conditions.¹³² Irbesartan is not dialyzable. In the elderly, C_{max} and AUC are increased by 20% to 50% and elimination half-life unchanged. Dose adjustment of irbesartan has not been found to be necessary in the elderly or for gender or race.^{112,132,134}

Irbesartan is approved for use in the treatment of high blood pressure and diabetic nephropathy. It is available in tablets containing 75, 150, and 300 mg. The usual starting dose is 150 mg once daily.¹¹² However, for patients receiving a diuretic or otherwise volume depleted it may be prudent to begin with a lower initial dose, such as 75 mg/day.

Candesartan Cilexetil

Candesartan, 2-ethoxy-1-[[2'-(1H-tetrazol-5-yl)biphenyl-4-yl]methyl]-1H-benzimidazole-7-carboxylic acid, is a potent ARB.¹³⁵ This structure is a biphenyl imidazole derivative that, like losartan, has a tetrazolyl moiety, a lipophilic side chain, and a carboxyl group. To overcome poor oral absorption, the cilexetil ester prodrug form was synthesized. Candesartan cilexetil has been found to be rapidly and completely converted by hydrolytic cleavage to the active compound, candesartan, during gastrointestinal absorption.

Candesartan has been shown to have a high degree of AT_1 receptor affinity and to dissociate slowly from its binding sites.¹³⁵ In the presence of angiotensin II, candesartan acts as an insurmountable antagonist for the AT_1 receptor. The effects of candesartan at the receptor level have been observed at low doses and found to be of long duration.¹³⁶

The maximal serum concentration of candesartan is reached at approximately 4 hours after oral dosing with a terminal half-life of about 9 hours.¹³⁷

The AUC of candesartan has been found to be linear throughout the dose range of 2 to 16 mg. In elderly healthy volunteers, steady-state concentrations of candesartan are approximately 30% to 50% higher than in younger subjects.¹³⁷ Oral bioavailability does not appear to be affected by food intake.¹³⁸ Most of the drug is excreted in the urine as candesartan with a smaller fraction as an inactive metabolite.¹³⁹ Excretion through the biliary tract accounts for less than 40% of total drug elimination.

The pharmacokinetic profile of candesartan has been shown to not be altered in patients with mild to moderate hepatic dysfunction.¹⁴⁰ In patients with renal impairment, the AUC, C_{max} , and terminal half-life were significantly greater than in healthy subjects. It may be prudent to employ lower starting doses in patients with severe renal dysfunction. The drug is not dialyzable.¹⁴⁰

Coadministration of candesartan cilexetil with hydrochlorothiazide has caused a small but significant decrease in the AUC

of the latter agent and a slightly higher bioavailability and C_{max} for candesartan itself.¹⁴¹ Candesartan produces a small decrease in warfarin trough concentration but does not affect prothrombin time. No significant interactions have been found when candesartan cilexetil was coadministered with nifedipine, glibenclamide, digoxin, or estrogen-containing oral contraceptives.¹⁴¹

Candesartan cilexetil is approved in the United States and in other countries for the treatment of hypertension. It is available as 4-, 8-, 16-, and 32-mg tablets.

Eprosartan

Eprosartan is a nonphenyl, nontetrazole ARB with a high degree of affinity for AT_1 receptor sites.¹⁴² This compound is chemically described as (E)- α -[[2-butyl-1-[(4-carboxyphenyl)methyl]-1H-imidazol-5-yl]methylene]-2-thiophenepropanoic acid. Eprosartan has incomplete oral absorption, with an oral bioavailability of 13% to 15%.¹⁴³ Maximum plasma concentrations of the drug are reached in 1 to 3 hours. Food intake appears to have unpredictable effects on C_{max} and time to C_{max} .¹⁴⁴ The bioavailability of eprosartan has been shown to increase with age.¹⁴⁴

Approximately 90% of orally administered eprosartan is found in the feces and the remainder found in the urine.¹⁴⁵ Of the excreted drug only 20% undergoes metabolism to its glucuronide form.¹⁴⁵ Both renal insufficiency and hepatic impairment have been found to delay the elimination of eprosartan. Eprosartan is not metabolized by the cytochrome P450 system and has not been shown to have significant drug interactions with glyburide and digoxin.¹⁴⁶ Eprosartan, like most of the current ARBs, is highly protein bound in plasma (98%) but does not appear to affect the anticoagulant activity of warfarin.¹⁴⁶

Eprosartan has been approved for use in the United States and in other countries in the treatment of high blood pressure. It is available in 200-, 300-, and 400-mg tablets for once-daily administration.

Telmisartan

Telmisartan, 4'-[(1,4'-dimethyl-2'-propyl[2,6'-bi-1H-benzimidazol]-1'-yl)methyl]-[1,1'-biphenyl]-2-carboxylic acid, is an orally active ARB with competitive affinity for the AT_1 receptor subtype.¹⁴⁷ Approximately one half of an orally administered dose is absorbed.¹⁴⁸ Oral bioavailability is somewhat dose-dependent. Peak plasma concentrations of telmisartan are reached relatively rapidly, within 0.5 to 1.0 hours following oral ingestion. Food intake reduces the AUC by 6% to 20%. Unlike losartan and candesartan, telmisartan is not a prodrug. Approximately 87% of an orally administered dose is eventually excreted unchanged through the biliary tract. A very small proportion of telmisartan undergoes metabolism to the glucuronide form. The cytochrome P450 isoenzymes are not involved in the metabolism of telmisartan.

Telmisartan is highly protein bound in plasma (>99.5%) and has a very large volume of distribution of approximately 500 L, indicating additional tissue binding. The terminal elimination half-life is approximately 24 hours.¹⁴⁷ Due to its biliary route of elimination, telmisartan should be used with caution in patients with hepatic insufficiency. Telmisartan and digoxin coadministration has been shown to be associated with significant increases in levels of the later agent. It is recommend-

ed that digoxin levels be monitored when initiating, adjusting and discontinuing telmisartan to avoid possible over-digitalization. Telmisartan does not appear to affect the anticoagulant effect of warfarin.

The antihypertensive effect of telmisartan has been found to be greater in hypertensive patients with higher plasma renin activity.¹⁴⁹ In the United States and in other countries telmisartan is approved for the treatment of hypertension. It is available in the United States as 40- and 80-mg tablets for once-daily administration. The recommended starting-dose for telmisartan is 40 mg once daily.

Olmesartan Medoxomil

Olmesartan medoxomil is chemically described as 2,3-dihydroxy-2-butenyl 4-(1-hydroxy-1-methylethyl)-2-propyl-1-[p-(*o*-1 *H*-tetrazol-5-ylphenyl)benzyl]imidazole-5-carboxylate, cyclic 2,3-carbonate. It is an orally active AT₁ receptor antagonist that is rapidly and completely deesterified in vivo in the intestinal wall to the active diacid metabolite, olmesartan.¹⁵⁰ It is selective for the AT₁ receptor without partial agonist activity and, as expected, suppresses the pressor response to angiotensin II in rats. Olmesartan has higher affinity for the AT₁ receptor than losartan in that 50% inhibition of angiotensin II binding to the AT₁ receptor of bovine adrenocortical cells was 7.7 nanomolar, approximately 8% of the concentration of losartan needed to achieve the same degree of binding inhibition. It lowers SBP and DBP and increases renin and angiotensin II concentrations in humans.

After oral administration, olmesartan medoxomil is rapidly absorbed and deesterified during absorption to the pharmacologically active compound olmesartan with peak plasma concentrations between 1 and 3 hours and an elimination half-life of 12 to 18 hours.¹⁵¹ The absolute bioavailability of olmesartan medoxomil after oral administration is 26% to 28.6%. Steady-state plasma concentrations are reached within the first few daily doses, and accumulation is not noted on long-term dosing. The volume distribution after intravenous administration is 15 to 25 L. Olmesartan is not metabolized, and 35% to 50% of the systemically available active compound is excreted unchanged in the urine and the remainder in the bile. Olmesartan medoxomil has minimal or no inhibitory activity on human cytochrome P450. Coadministration of olmesartan medoxomil with digoxin or warfarin did not result in clinically significant steady-state pharmacokinetic interaction.¹⁵¹

Data from seven randomized, multicenter, double-blind, placebo-controlled Phase II and III trials with similar designs, eligibility criteria, and efficacy endpoints were pooled in a single integrated analysis of efficacy for olmesartan medoxomil (2.5–80 mg/day) (*n* = 2693).¹⁵² Reductions in cuff seated systolic blood pressure (SeSBP) and seated diastolic blood pressure (SeDBP) (SeSBP by 15.1 and 17.6 mm Hg and SeDBP by 12.2 and 13.1 mm Hg for the 20- to 40-mg dose), as well as in 24-hour ambulatory blood pressure were observed. Placebo-corrected trough/peak ratios were 64% to 79% for DBP and 52% to 72% for SBP, indicating a more than appropriate diurnal profile for once-daily dosing.¹⁵² Minor changes in heart rate were observed (−0.5 to −1.1 beats/min compared with −0.3 beats/min with placebo). In both older and younger individuals, the only adverse experience reported more frequently in the olmesartan medoxomil treated subjects compared with placebo-treated subjects was dizziness, usually mild.

The ARBs olmesartan medoxomil, losartan potassium, valsartan, and irbesartan were compared in a 588 patient multicenter randomized double-blind trial with once-a-day therapy with the recommended starting doses.¹⁵³ Sitting DBP reduction at 24 hours postdosing, the primary efficacy variable, was 11.5 mm Hg with olmesartan medoxomil 20 mg, 8.2 mm Hg with losartan potassium 50 mg, 7.9 mm Hg with valsartan 80 mg, and 9.9 mm Hg with irbesartan 150 mg. The more pronounced reduction with olmesartan medoxomil with respect to the other three agents was statistically significant. In addition, the reduction in mean 24-hour DBP on ambulatory blood pressure monitoring was significantly larger with olmesartan medoxomil (8.5 mm Hg) than with losartan potassium (6.2 mm Hg) and valsartan (5.6 mm Hg) but not significantly different from irbesartan (7.4 mm Hg). Systolic blood pressure trough/peak ratio was highest for olmesartan medoxomil (0.69), lowest for valsartan (0.55), and intermediate for losartan potassium and irbesartan (0.64 and 0.62, respectively). Adverse event rates were comparable among the four treatment groups.

As with other ARBs, the antihypertensive effect of olmesartan medoxomil is enhanced with the addition of low-dose hydrochlorothiazide.¹⁵⁴

Safety and Adverse Effects of the Angiotensin II Receptor Antagonists

ARBs are generally very well tolerated. With two important exceptions, these agents have a side effect profile that is similar to that of the ACE inhibitors. Like the ACE inhibitors, ARBs may produce excessive and too rapid fall of blood pressure in the volume depleted or otherwise highly renin-dependent forms of hypertension. In patients with renal impairment there is an increased risk of hyperkalemia due to inhibition of aldosterone release. As with ACE inhibitors, patients with bilateral renovascular and renal parenchymal disease who are treated with ARBs are at increased risk of deterioration of renal function, which is usually but not always reversible.

ARBs do not appear to have adverse effects on glucose or lipid metabolism. Losartan is unique among this class in its uricosuric effect.

Of special note is that the incidence of cough with ARBs is similar to that of placebo.^{155–157} The incidence of angioedema appears to be very low, although cases have been reported.^{158,159} Indeed, among the currently available antihypertensive drug classes, ARBs appear to have the lowest incidence of adverse effects.^{160,161}

CLINICAL USES OF THE ANGIOTENSIN II RECEPTOR ANTAGONISTS

Hypertension

All of the currently approved ARBs have been demonstrated in randomized, placebo-controlled clinical trials to lower blood pressure in hypertensive individuals. Approximately 50% to 60% of hypertensive patients have a clinically significant response to these agents.^{69,162} This is comparable to monotherapy with diuretics, β-blockers, ACE inhibitors, and calcium antagonists.^{163,164}

The antihypertensive efficacy of the ARBs seems to depend at least partially on the activity of the renin-angiotensin system.⁷² Approximately 80% of patients demonstrate a significant blood pressure lowering response when losartan is combined with a thiazide diuretic.¹⁵⁴ The antihypertensive response can be abolished in experimental animals following nephrectomy and is attenuated in humans following volume expansion.¹⁶⁵ The full therapeutic profile of the ARBs has yet to be completely elucidated. The effects of age, race, and concomitant medical conditions on the antihypertensive efficacy of these agents await further clarification.

Several studies have compared the relative efficacy among the currently available ARBs. In general, the observed differences have been modest. In one double-blind, parallel group study of 8 weeks' duration, candesartan cilexetil 8 mg/day was found to produce an antihypertensive effect equal to

that of losartan 50 mg/day.¹⁶⁶ The 16-mg dose of candesartan cilexetil was found to be more effective than losartan 50 mg administered once daily. However, the use of microcrystalline cellulose back-filled gelatin capsules in the losartan group has been debated.^{167,168} In a double-masked, elective dose titration study of 8 weeks' duration, irbesartan 150 to 300 mg once daily was found to produce a greater decline in trough seated diastolic BP than did losartan 50 to 100 mg/day.¹⁶⁹ Also, a smaller proportion of patients taking the starting dose of irbesartan (53%) as compared with the losartan group (61%) required up-titration at 4 weeks to reach the goal DBP of 90 mm Hg. Adding hydrochlorothiazide to both study drugs produced further reductions in blood pressure, with the greater effect seen in the irbesartan group compared with the losartan group.¹⁶⁹ The incidence of adverse effects in patients receiving either candesartan cilexetil or irbesartan was similar to that experienced by the patients receiving losartan.^{166,169}

It has been suggested that the highly insurmountable receptor antagonists may have a greater amplitude and duration of action.¹⁷⁰ As outlined earlier, the recommended daily starting dose of olmesartan 20 mg has been observed to have a somewhat greater effect on DBP than losartan 50 mg, valsartan 80 mg, or irbesartan 150 mg.¹⁵³ A meta-analysis of 43 controlled trials involving the use of losartan, valsartan, irbesartan, and candesartan concluded that within the ARB class of antihypertensive drugs, there is comparable antihypertensive efficacy and a flat-dose response.¹⁷¹ All of the agents studied showed substantial augmentation of the antihypertensive effect with the addition of thiazide diuretics.

ARBs in Cardiac Disease

Angiotensin II exerts many actions on the heart and the coronary circulation. In the vasculature, angiotensin II causes vasoconstriction, as well as smooth muscle cell hypertrophy, and enhances norepinephrine release further potentiating vasoconstriction. Angiotensin II also causes increased contractility and facilitates the development of left ventricular hypertrophy. Angiotensin II effects on plasminogen

Box 67-2 Antihypertensive Mechanisms of the Angiotensin II Receptor Antagonists

Vascular actions

- Direct blockade of angiotensin II-mediated vasoconstriction
- Reversal of vascular hypertrophy
- Augmentation of nitric oxide-mediated endothelial function

Renal actions

- Augmentation of renal blood flow
- Direct and indirect enhancement of proximal tubular natriuresis
- Inhibition of aldosterone release and distal tubular sodium

Reabsorption

Central and sympathetic nervous system actions

- Attenuation of presynaptic norepinephrine release
- Inhibition of central all-mediated sympathetic outflow
- Inhibition of all-mediated thirst and vasopressin release

activator inhibitor I, smooth muscle proliferation, and extracellular matrix formation may enhance the development of atherosclerosis.

The rationale for the use of ARBs in heart failure is based on several factors.¹⁷² Because these agents reduce peripheral resistance, it has been posited that concomitant reduction in cardiac impedance would promote cardiac emptying with less left ventricular wall stress. Also, blockade of the direct hypertrophic action of angiotensin II on the myocardium by the ARBs might augment the benefit. Furthermore, there is evidence that some intracardiac angiotensin II is formed via a non-ACE-dependent mechanism. The latter effect might be expected to provide an advantage over ACE inhibitor therapy for treatment of heart failure.

In young healthy adults, plasma angiotensin II, lean body mass, and systemic blood pressure are related to left ventricular mass.¹⁷³ Moreover, in patients with heart failure, those who are on ACE inhibitor therapy have been shown to have higher plasma angiotensin II levels than controls, a finding consistent with non-ACE-mediated angiotensin II production in patients with failing hearts.¹⁷⁴

In a study of the acute effects of ARBs in patients with heart failure, ARB treatment has been found to improve hemodynamic indices, such as blood pressure, pulmonary wedge pressure, systemic vascular resistance, and cardiac output.¹⁷⁵ In patients with ischemic or idiopathic dilated cardiomyopathy, exercise VO_2 and exercise tolerance were found to increase during treatment with both the ACE inhibitor enalapril and the ARB losartan.¹⁷⁶ In contrast to enalapril, the effect of losartan was not antagonized by aspirin.¹⁷⁶ In an earlier study, oral administration of losartan to patients with symptomatic heart failure resulted in beneficial hemodynamic effects with short-term administration and more enhanced benefits after 12 weeks of therapy.¹⁷⁷

The ELITE (Evaluation of Losartan in the Elderly) study was designed to determine whether the ARB, losartan, offered advantages over the ACE inhibitor captopril in older patients with heart failure.¹⁷⁸ The primary endpoint of the study was persistent increase in serum creatinine equal to or greater than 0.3 mg/dl on therapy. The secondary endpoint was death or hospital admission for heart failure. In this randomized, double-blind study of 722 patients with heart failure and ejection fraction equal to or lower than 40%, losartan was titrated to 50 mg once a day and captopril was titrated to 50 mg three times a day for 48 weeks. The occurrence of the primary endpoint (persistent increase in serum creatinine) was the same in the two groups. For the secondary endpoints, the losartan treatment group had a 46% lower risk of death, 64% reduction in sudden death, and a 26% reduction in total hospitalization rate compared with the captopril treated group. Improvement in symptoms was similar for the two groups, as was the rate of hospitalization for progressive heart failure. Fewer losartan patients than captopril patients discontinued therapy because of adverse experiences (12.2% vs. 20.8%). It remains unclear why the relative beneficial effect of losartan was so dramatic for sudden death and less so for symptoms of and hospitalization rates for heart failure. This unexpected lowering in mortality with losartan compared to captopril may have been due to better suppression of the effects of angiotensin II, the absence of bradykinin effects during losartan therapy, or to the better compliance of patients on losartan.

To confirm this, ELITE II was carried out in a larger number of patients (3152) with similar characteristics and with a protocol similar to ELITE. All cause mortality was slightly but not significantly higher for losartan (11.7%) compared with 10.4% for captopril.¹⁷⁹ Losartan was again somewhat better tolerated than captopril. In another study, where the effects of losartan and enalapril were compared in patients with moderate or severe chronic heart failure, no significant differences between the groups in terms of exercise capacity or neurohormonal activation (plasma levels of N-terminal atrial natriuretic factor and norepinephrine) were observed.¹⁸⁰

In patients with symptomatic heart failure receiving maximally prescribed or tolerated ACE inhibitors, the effects of add-on therapy with ARBs have been studied.¹⁸¹ The combination was found to be safe and to lead to a further decrease in cardiac afterload. It has been hypothesized that the combination will produce a greater suppression of angiotensin II effects by blocking both ACE and non-ACE-dependent pathways. At the same time the potentially beneficial effects of ACE inhibition in preventing bradykinin degradation should be maintained.

In the Val-Heft (Valsartan Heart Failure Trial), valsartan 160 mg twice daily was compared with placebo in patients with heart failure treated with digitalis, diuretics, and ACE inhibitors in the majority and β -blockers in some.^{182,183} The combined endpoint of worsening heart failure, resuscitated cardiac arrest, or mortality occurred 13% less frequently in the valsartan group, primarily because of a decrease in heart failure hospitalizations. Significant improvements in heart failure symptoms, ejection fraction, and quality-of-life indices were observed. The beneficial effect of valsartan on patients who were not on background ACE inhibitor therapy was marked.

The effects of ARBs in patients with left ventricular hypertrophy have also been studied. Findings from experimental and clinical studies suggest that the pharmacodynamic profile of the antihypertensive agent plays a role in addition to that of blood pressure lowering in decreasing left ventricular mass. Losartan has been found to decrease cardiac mass and improve coronary flow reserve in spontaneously hypertensive rats and to decrease left ventricular hypertrophy due to volume overload induced by aortic insufficiency in Wistar rats.^{184,185}

In a 10-month study of 89 hypertensive patients, losartan given as monotherapy or in association with hydrochlorothiazide produced not only a significant reduction in blood pressure but also a decrease in left ventricular mass studied by echocardiography.¹⁸⁶ The Losartan Intervention for Endpoint Reduction in Hypertension study (LIFE) was designed to compare the effects of losartan with the β -blocker atenolol in a double-blind, parallel design on more than 9000 patients with electrocardiographic evidence of left ventricular hypertrophy.¹⁸⁷ The primary endpoint of cardiovascular morbidity and mortality (i.e., stroke, myocardial, infarction, and cardiovascular death) occurred significantly less frequently in the losartan group. Also, new-onset diabetes was less common with losartan than with the β -blocker.¹⁸⁸

The CHARM clinical trial (Candesartan in Heart failure Assessment of Reduction in Mortality and Morbidity) compared candesartan titrated to 32 mg once daily to placebo in three distinct populations: (1) patients with left ventricular ejection fraction less than or equal to 40% who were not receiving ACE inhibitors (CHARM-Alternative Trial, 2028 patients), (2) patients with left ventricular ejection fraction

less than or equal to 40% who were receiving ACE inhibitors (CHARM-Added Trial, 2548 patients), and (3) patients with left ventricular ejection fraction higher than 40% (CHARM-Preserved Trial, 3023 patients). Overall, when all three studies were analyzed together, candesartan was generally well tolerated and significantly reduced cardiovascular deaths and hospital admissions for heart failure.¹⁸⁹⁻¹⁹²

The OPTIMAAL (Optimal Trial in Myocardial Infarction with the Angiotensin II Antagonist Losartan) compared losartan, target dose 50 mg daily, to captopril 50 mg three times daily in 4577 patients with acute myocardial infarction.¹⁹³ At an average follow-up 2.7 years, mortality was 17% in the losartan group and 16% in the captopril group ($p = .07$). In the VALIANT study of 14,703 patients, with myocardial infarction complicated by left ventricular systolic dysfunction, heart failure, or both, valsartan treatment was equivalent to captopril for the composite endpoint of fatal and nonfatal cardiovascular events.¹⁹⁴ Of note is that the combination of valsartan and captopril increased the rate of adverse events without improving survival.

Taken together, these trials indicate that ARBs confer benefits similar to ACE inhibitors in patients with coronary heart disease, left ventricular hypertrophy, and heart failure. The combination of ARBs with ACE inhibitors may convey additional benefits, especially in preventing hospitalization for heart failure.

Renal Disease

ARBs, like the ACE inhibitors, have multiple hemodynamic and nonhemodynamic actions that contribute to renoprotection. The ELITE trial was among the first clinical trials to assess the relative effects of ARB therapy on renal function. The study found that in humans with heart failure, long-term therapy with losartan has a comparable effect with that of captopril on renal function, as assessed by serum creatinine levels.¹⁷⁸

In nonhemodynamically mediated experimental renal disease, the evidence is less consistent. For example, experimental puromycin nephrosis does not appear to be affected by the administration of ARBs.¹⁹⁵ In passive Heymann nephritis, a rat model of membranous nephropathy with proteinuria, angiotensin blockade had virtually no effect on urinary albumin excretion, as opposed to a markedly beneficial effect observed with enalapril.¹⁹⁶ However, in a model of antithymocyte serum-induced mesangioproliferative glomerulonephritis, angiotensin II blockade was found to be attenuate histopathologic changes and reduce renal TGF- β mRNA.¹⁹⁷

Several randomized clinical trials have recently demonstrated the renal protective effect of angiotensin II receptor blockade in proteinuric diabetics. The Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) study and the Irbesartan Diabetic Nephropathy Trial (IDNT) were similarly designed comparisons of the long-term effects of ARB therapy with conventional antihypertensive therapy on the composite primary endpoint of doubling of serum creatinine, occurrence of end-stage renal failure, or death.^{198,199} Both of the ARB-treated groups showed a significant reduction in composite risk of 16% to 20%. The relative risk reductions experienced by the ARB groups in both studies were also significant for the renal-

specific outcomes of doubling of serum creatinine (33% for IDNT and 25% for RENAAL) and end-stage renal disease (28% for IDNT and 25% for RENAAL). Losartan and irbesartan have been approved for use in diabetic nephropathy.

In most cases diabetic proteinuria (urinary albumin excretion >300 mg/24 hour) is preceded by microalbuminuria (urinary albumin excretion 30-300 mg/24 hour). Furthermore, microalbuminuria is a strong predictor of all-cause mortality and cardiovascular mortality in type 2 diabetes. Although the mechanism underlying the association between microalbuminuria and mortality is not well understood, the presence of microalbuminuria may reflect a generalized defect in vascular permeability leading to atherogenesis. Therapy with ARBs is associated with a reduction of microalbuminuria and a slowing of progression to macroalbuminuria.²⁰⁰⁻²⁰² In humans with nondiabetic renal disease and proteinuria, therapy with ARBs has been found to significantly reduce protein excretion in a dose-dependent manner comparable with that of ACE inhibitors.²⁰³⁻²⁰⁶

Rationale for the Use of ARBs in Combination with ACE Inhibitors

ACE inhibitors and ARBs have been found to slow the progression of renal impairment in experimental animals and in humans with diabetic and nondiabetic chronic kidney disease.²⁰⁷ Both classes of antihypertensive agent inhibit the vasoconstrictive effects of angiotensin II at the efferent arteriole, by either reducing the concentration of angiotensin II (ACE inhibitors) or by blocking its receptor site (ARBs). ARBs and ACE inhibitors have both been observed to exert nonhemodynamic actions as well. Treatment with ACE inhibitors also increases the level of bradykinin and other small peptides that are normally degraded by ACE. There is evidence that this action may contribute to the renoprotective effect of the ACE inhibitors, a property not shared with the ARBs. On the other hand, renal production of angiotensin II is not completely

Box 67-3 Clinical Effects of Angiotensin II Receptor Antagonists Results from Randomized Clinical Trials

- Uncomplicated hypertension
 - Decreased blood pressure
- Hypertension with left ventricular hypertrophy
 - Decreased mortality
 - Decreased incidence of new-onset diabetes
- Chronic heart failure
 - Improved hemodynamic profile
 - Improved exercise tolerance
 - Decreased hospitalization rate
 - Decreased cardiovascular mortality rate
- Acute myocardial infarction with and without left ventricular dysfunction
 - Beneficial effect on cardiovascular mortality similar to that of the ACE inhibitors
- Proteinuric chronic kidney disease
 - Decreased proteinuria
- Hypertension with type 2 diabetes and proteinuria
 - Preservation of renal function

blocked by ACE inhibition due to the presence of chymase and other non-ACE peptidases. Furthermore, the currently available ARBs are selective for the AT₁ receptor subtype, leaving the AT₂ receptors available to the effects of higher levels of angiotensin II. The AT₂ receptors have been shown to mediate production of nitric oxide and attenuate cell proliferation in a number of organs, including the kidney.^{208,209} Thus, it seems apparent that ACE inhibitors and ARBs have both overlapping and complementary mechanisms of action.

Several reports have shown that the combination of ACE inhibitor with ARB therapy is associated with a greater antiproteinuric effect than with either agent alone.^{210,211} In the recent COOPERATE trial carried out in Japan, 263 patients with nondiabetic proteinuric renal disease were randomized to receive either losartan 100 mg/dl, the ACE inhibitor trandolapril 3 mg/day, or combination therapy at the same doses.²¹² During a 3-year follow-up, the ACE inhibitor-ARB combination group achieved a highly significant 49% to 50% relative risk reduction for reaching the combined renal endpoint of doubling of serum creatinine or end-stage renal failure. Many of the patients in the COOPERATE trial had IgA nephropathy, a less common cause of renal failure in North America. Whether the findings of COOPERATE hold promise for the treatment of other forms of glomerular and nonglomerular renal disease remains to be determined.

SUMMARY

The ARBs are effective antihypertensive agents in a broad range of patients and appear to have a lower incidence of adverse effects than other currently available drugs. As a class, these ARBs have a high degree of specificity for the AT₁ receptor subtype and also have become valuable pharmacologic probes for studying the role of the renin-angiotensin system in a number of circulatory and renal disorders.

Seven ARBs have gained U.S. FDA approval for the treatment of hypertension and several for the treatment of diabetic renal disease.²¹³ The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) has recognized that hypertension often exists with other serious conditions for which, based on clinical trials data, there are “compelling” indications for use of a particular drug or class of drugs, including the ARBs.²¹⁴ Such high-risk conditions for which ARBs are indicated include congestive heart failure, chronic kidney disease, and diabetes mellitus. Absence of a positive “compelling” indication for any disorder does not exclude the potential efficacy of ARBs or any other drug class for that disorder, if clinical trials data are lacking or are inconclusive.

Studies are underway to assess whether ARB therapy is equally or more effective than other agents in decreasing cardiovascular morbidity and mortality in hypertensives with comorbidities, such as diabetes, smoking, hyperlipidemia, obesity, left ventricular hypertrophy, renal disease, and proteinuria.^{215,216} Promising results from a number of clinical trials suggest that ARBs may confer important benefit for patients with other serious conditions, such as chronic coronary artery disease, acute coronary syndromes, and nondiabetic chronic kidney disease, as well as for primary and secondary prevention of cerebrovascular events.¹⁶⁵

Direct-Acting Smooth Muscle Vasodilators and Adrenergic Inhibitors

Edward D. Frohlich

Since the early 1970s, antihypertensive drug therapy has made a tremendous impact on morbidity and mortality from cardiovascular diseases. Nevertheless, despite the introduction of newer modalities of treatment and the claims of adverse effects related to the adrenergic inhibitors and the direct-acting smooth muscle vasodilators, improvement in cardiovascular outcomes seems to have stalled. End-stage renal disease (ESRD) and congestive heart failure, both related to hypertension, continue to increase unabated.

Whereas use of many of the agents discussed in this chapter has drastically decreased in the United States in favor of newer agents with different mechanisms of action, the older agents continue to be used broadly elsewhere around the world. No doubt this is related to availability of generic formulations of these agents and their lower cost. Moreover, one subclass of the adrenergic inhibitors, the α -adrenergic receptor blockers, continue to be employed widely for the treatment of benign prostatic hyperplasia (BPH).

Among the more-potent antihypertensive drugs are those that inhibit sympathetic activity. This inhibition may be achieved at practically any anatomic level of adrenergic function. However, for these compounds to maintain their effectiveness over time, for the most part, they must be used in conjunction with diuretics. The following discussion reviews these adrenergic agents, describing their mechanisms of action, hemodynamic effects, clinical uses, and adverse effects.

Every direct-acting smooth muscle vasodilator and adrenergic inhibitor except the β -adrenergic receptor blockers and, perhaps, the α -adrenergic blockers, will induce compensatory sodium and water retention and extracellular fluid volume expansion following reduction of arterial pressure.¹⁻³ The clinician must therefore recognize the need for concomitant diuretic therapy. The type of diuretic is relatively unimportant: Drastic dietary-sodium restriction, a thiazide diuretic, or a loop diuretic can be employed. However, because it is most important to minimize potassium wastage and maintain persistent and steady contraction of the intravascular volume, a thiazide is generally the best choice for patients with relatively normal renal function because it has a longer duration of action than the loop diuretic. The diuretic enhances the antihypertensive action of the adrenergic inhibitor by maintaining the contraction of the extracellular and intravascular compartments characteristic of most hypertensive diseases.

ADRENERGIC INHIBITORS

Stress and anxiety can alter cardiovascular function, producing transient increases in heart rate and arterial blood pressure. However, these stimuli are generally not sufficient to cause hypertension, which requires persistent increased tension or tone of the arteriolar vascular smooth muscle for its

maintenance. Confusion in terminology can confound any discussion of agents that inhibit neural function. The present discussion does not concern itself with agents that sedate, tranquilize, or minimize psychic stress through higher centers.

Central adrenergic efferent impulses pass through major cardiovascular centers in the hypothalamic, medullary, and other subcortical areas to the spinal cord to synapse with second neurons located in sympathetic ganglia at the thoracolumbar level of the spinal column. These more distal neurons are stimulated at the ganglion level by the release of acetylcholine from the terminals of the central neurons, thereby propagating the peripheral outflow of adrenergic impulses. Neural impulses, passing distally via the adrenergic neurons, reach the heart or blood vessels, where they release norepinephrine from nerve terminals. Norepinephrine stimulates the effector organ—heart, venule, or arteriole—by attachment to specific binding sites identified as either α - or β -adrenergic receptors.

Norepinephrine and other neurohumoral mediators, including epinephrine and dopamine, are synthesized in the adrenal gland and adrenergic neurons, but norepinephrine is the major neurotransmitter that is released from postganglionic nerve terminals. Norepinephrine synthesis begins with the essential amino acid L-tyrosine by hydroxylation with tyrosine hydroxylase to form L-hydroxyphenylalanine and then L-hydroxyphenylethylamine (dopamine). Dopamine β -hydroxylase and phenylethanolamine-*N*-methyltransferase continue the biosynthesis of the catecholamines to form L-norepinephrine and L-epinephrine, respectively. Norepinephrine is the major neurotransmitter and is most responsible for adrenergic receptor stimulation. Norepinephrine is found in the axon sheath and stored in the nerve terminals in vesicles that release it on nerve stimulation.

Norepinephrine is metabolized within the nerve terminal, by monoamine oxidase (MAO) in the mitochondria via a deamination process to form, initially, dihydroxymandelic acid and later, vanillylmandelic acid. In contrast, the norepinephrine that finds its way extraneuronally is metabolized by the enzyme catechol O-methyltransferase to form 3-methoxy,4-hydroxymandelic acid or vanillylmandelic acid. These metabolic products can be measured in the laboratory as metanephrines and normetanephrines or vanillylmandelic acid, respectively. Consideration of these metabolic processes is important in the interpretation of laboratory tests utilized in the diagnosis of pheochromocytoma, particularly in the identification of therapeutic agents that may be responsible for false-positive or false-negative test results.

With the arrival of the adrenergic impulse at the postganglionic nerve terminal, there is release of free norepinephrine. The neurotransmitter may bind to myocardial and/or vascular smooth muscle receptor sites, producing the adrenergic cardiovascular response. It may also be taken up by the nerve

terminal (so-called reuptake) for conservation and release at a later time or may be acted on by the extraneuronal enzymatic system to form the metabolites or to circulate freely within the vascular system. The normal circulating levels of epinephrine and norepinephrine are less than 100 pg/ml and less than 500 pg/ml, respectively; the daily urinary excretion rates of catecholamines and metabolites are shown in Table 68-1.

With the binding of norepinephrine at the effector receptor site, several possible processes may occur. Stimulation of the β -adrenergic receptor will produce vasoconstriction of the arteriole and venule. Stimulation of the α -adrenergic receptor will promote peripheral vasodilation and increased heart rate, myocardial contractility, and myocardial metabolism.

There are many loci at which antihypertensive agents may inhibit the adrenergic nerve stimulus, including afferent sensory pathways from the heart, vessels, and mechanoreceptors; centrally at the ganglion level; or at the nerve terminal. Certain antihypertensive agents may also inhibit norepinephrine biosynthesis or block its action at the adrenergic receptor. The following discussion concerns the specifics of each class of adrenergic inhibitors.

Ganglion Blocking Drugs

Mechanism of Action

When the adrenergic preganglionic impulse arrives at the ganglion, acetylcholine is released from the nerve terminals, crosses the synaptic gap, and stimulates the postganglionic axons. The physiochemical action on the axon membrane is complex, but in simplest terms, involves the alteration of axon permeability. Thus, when acetylcholine attaches to receptor sites on the axon membrane, transmembrane ion flux is permitted, by which potassium ions move extracellularly and sodium ions intracellularly. When this depolarization process reaches an optimal rate, transmission of the neural impulse down the postganglionic neuron continues.⁴

One of the first major classes of antihypertensive drugs was the ganglion blockers.⁵ These agents act by occupying receptor sites on the postganglionic axon to stabilize the membrane against acetylcholine stimulation; they have no effect on preganglionic neuronal acetylcholine release, cholinesterase activity, postganglionic neuronal catecholamine release, or

vascular smooth muscle contractility.^{4,6} Tetraethylammonium chloride was the first agent used; later, other compounds were synthesized, including hexamethonium chloride, pentolinium tartrate, mecamlamine hydrochloride, pempidine hydrochloride, and chlorisondamine chloride. In a controlled, prospective, double-blind study involving three of the more commonly used ganglion-blocking drugs (at the time of their popular use), when equivalent doses of these agents were employed, all three agents were equally efficacious in reducing arterial pressure.⁷

Because interference with transmission of the autonomic impulse at the ganglion level impairs adrenergic and parasympathetic impulse transmission, clinical use of ganglion blockers was associated with severe side effects of unwanted parasympathetic inhibition. With the advent of more-specific adrenergic-blocking drugs, such as guanethidine sulfate and methyldopa, the ganglion-blocking drugs were less frequently used, until at present they are mostly of academic interest.

The exception is trimethaphan camsylate, which is still useful as an antihypertensive agent because of its intravenous formulation and mode of action. Trimethaphan is infused by slow intravenous drip (1 mg in a 1-L solution with the addition of one or two additional 1000-mg ampules, if necessary).⁸ Reduction of arterial pressure is immediate, and careful monitoring of pressure is essential. When the infusion is discontinued, return of arterial pressure to preinfusion levels is prompt. Therefore, when administering this agent to the severely hypertensive patient, the physician must initiate long-acting antihypertensive therapy before discontinuing the infusion. Furthermore, as with any adrenergic inhibitor, volume contraction is associated with augmented hypotensive responses, and norepinephrine administration is associated with an enhanced pressor response. This phenomenon of denervation supersensitivity is extremely important in patients treated with sympatholytic agents.⁹

Hemodynamic Effects

Adrenergic transmission to the heart and vessels is impaired by ganglion-blocking drugs, and reduced heart rate, myocardial contractility, and total peripheral resistance result. The fall in arterial pressure and vascular resistance is not as great in the supine as in the upright position because the adrenergic venomotor effect is enhanced by the gravitational effect of pooling of blood when the patient is upright. As a result of a reduction in venomotor tone, the patient treated with ganglion-blocking drugs or any other sympatholytic therapy will pool blood in the capacitance vessels of the dependent areas of the body. As a result, venous return to the heart is reduced in proportion to the degree of adrenergic inhibition and the degree of upright posture. This effect explains the phenomenon of orthostatic hypotension that, if carried to the extreme, can be associated with syncope.¹⁰ Thus the orthostatic fall in cardiac output is not primarily the result of direct adrenergic inhibition of myocardial function but of reduced venous return. Because the orthostatic effect on arterial pressure is so important with sympatholytic therapy, the knowledgeable physician should measure blood pressure in the supine or sitting, as well as in the standing, position. The orthostatic hypotension should be considered an effect of treatment rather than a side effect. To enhance the antihyper-

Table 68-1 24-Hour Urinary Excretion Rate of Catecholamines and Metabolites

CATECHOLAMINES

HVA, homovanillic acid; VMA, vanillylmandelic acid.

tensive effect of sympatholytic agents in the supine position, it is necessary to reduce intravascular (and extracellular fluid) volume and prevent reexpansion of blood volume.^{2,3,11} Furthermore, to artificially produce this orthostatic response, elevation of the head of the bed is a worthwhile maneuver. Because cardiac output is reduced with ganglion-blocking therapy, there is at least a proportionate reduction of renal blood flow, which may be associated with a reduced creatinine clearance.^{12,13} Cerebral¹⁴ and splanchnic¹⁵ blood flows are also reduced.

Side Effects

It is often stated that with prolonged hypotensive therapy with trimethaphan (48 to 72 hours), the patient often becomes refractory (or tachyphylactic) to the treatment.¹⁴ Although this may occur, expansion of intravascular volume is a more likely explanation, and better control of pressure may be achieved with introduction of a diuretic or more vigorous use of diuretics already prescribed.^{1,2} Moreover, contraction of intravascular volume produces exaggerated hypotension and adrenergic stimulation (e.g., with norepinephrine). Because parasympathetic inhibition also results from ganglion blockade, tonic activity to the gastrointestinal tract will occur, and the physician is cautioned to consider development of a paralytic ileus or acute urinary retention as possible side effects. Thus, abdominal pain with reduced bowel sounds, constipation, or reduced urinary output during ganglion-blocking therapy in a patient with aortic dissection may not reflect extension of the dissecting aneurysm into the mesenteric or renal arteries but instead may be a side effect of the medication.

Clinical Uses

Although several other potent and rapidly acting parenteral antihypertensive agents are available, there is still a role for trimethaphan in the treatment of hypertensive emergencies. Thus, in producing controlled hypotension during surgery, in arteriography, or in acute aortic dissection, trimethaphan-induced hypotension may be more manageable than hypotension induced by an agent with a more-prolonged action. Under these circumstances, ganglion blockade will not be associated with the secondary reflective stimulation of the heart that is found with other vasodilator therapy.

Postganglionic Adrenergic Inhibitors

When acetylcholine stimulates the postganglionic axon at the ganglion level, the impulse is propagated distally and culminates in the release of norepinephrine at the nerve terminal with stimulation of adrenergic receptors on the vascular smooth muscle membrane. This impulse can be interfered with pharmacologically by a variety of mechanisms, including depletion of neurohumoral stores at the nerve terminal, prevention of norepinephrine reuptake by the nerve terminal, inhibition of catecholamine biosynthesis, therapeutic introduction of false neurohumoral transmitters that bind to the adrenergic receptors on vascular smooth muscle, or blockade of the latter receptors. The following discussion concerns sympathetic blocking drugs that act through one or a combination of these mechanisms.

Rauwolfia Alkaloids

These agents, including reserpine and more than 20 related compounds, were initially introduced for the treatment of hypertension in the early 1950s. They deplete the myocardium, blood vessels, adrenergic nerve terminals, adrenal medulla, and brain of catecholamines and serotonin.^{16,17} By depleting the nerve terminal of norepinephrine stores and inhibiting norepinephrine reuptake, adrenergic transmission is altered so that vascular resistance falls. With prolonged treatment, the persistent arterial hypotension is associated with slight decreases in renal blood flow and glomerular filtration rate. This may be related to the reduction in cardiac output or a venodilator effect similar to that of ganglion-blocking drugs.^{17,18} Although arterial dilation with increased blood flow has been considered greatest in the skin, other vascular beds are also involved (e.g., nasal stuffiness, a frequent complaint, is ameliorated by nasally administered vasoconstrictors).^{19,20}

Side Effects

Because the inhibitory effect of the rauwolfia alkaloids is selective for adrenergic function, parasympathetic activity remains unopposed. Thus, bradycardia, prolonged atrioventricular conduction, nasal dilation and stuffiness, increased gastric acid secretion with possible secondary peptic ulceration, and frequency of bowel movements are adverse effects of these drugs.²⁰ These effects may be counteracted by parasympathetic inhibitors or by intranasally administered vasoconstrictors. However, prolonged use of those latter agents may produce a chemical rhinitis. As a result of depletion of brain catecholamines and serotonin, there may be behavioral alterations and subtle or overt depression, sometimes leading to suicide.²¹

Clinical Uses

Reserpine and similar alkaloids are efficacious in reducing arterial pressure to normal levels when used with diuretics and/or hydralazine.^{22,23} When reserpine is used in doses of 0.10 to 0.50 mg/day (or with whole-root preparations, 50-100 mg), it synergizes the antihypertensive action of these two agents. Reserpine and other sympatholytic agents have been useful in treating hypertensive emergencies and the cardiovascular manifestations of thyrotoxicosis without altering thyroid function.^{24,25}

Guanethidine and Bretylium

These agents interfere with adrenergic neurotransmission at the postganglionic nerve terminals. Like reserpine, these compounds deplete nerve terminals, blood vessels, and myocardium of catecholamine stores. However, unlike reserpine, they have little effect on catecholamine stores in the adrenal gland and brain. Furthermore, even though they fail to deplete normal adrenal medullary catecholamines, they can release these substances from a pheochromocytoma, producing an alarming and dramatic hypertensive crisis. With catecholamine depletion and impairment of chemical neurotransmission, denervation supersensitivity of effector cells is achieved.^{26,27}

Hemodynamic Effects

After injection of guanethidine or bretylium, there is a transitory pressor phase associated with an increased heart rate and cardiac output related to catecholamine release.

A prolonged period of cardiac, vascular, and nerve terminal catecholamine depletion follows, associated with progressive reductions in systemic and pulmonary arterial pressure. The arterial pressure reduction, brought about through an interference in chemical neurotransmission, can be explained by a reduction in vascular resistance. This hypotension is not as great in the supine position as in the upright posture or with agents that simultaneously contract or prevent reexpansion of plasma volume.¹⁻³ Because of the coincidental inhibition of venous tone,¹⁹ venous return to the heart is reduced by peripheral pooling of blood in dependent areas of the body with upright posture. As a result, cardiac output falls and enhances the hypotensive action of guanethidine by this effect (not a side effect) of orthostatic hypotension.^{28,29} Associated with the resulting fall in cardiac output, there is a proportionate reduction in organ blood flows.²⁹⁻³² The renal and splanchnic areas may receive a smaller proportion of the total cardiac output, but glomerular filtration rate and renal function appear to return toward normal with time.³⁰⁻³³ With reduced skeletal muscle blood flow and adrenergic innervation to skeletal muscle, resting muscle weakness may result that can be exacerbated by diuretic treatment.^{34,35} This muscle weakness may be aggravated still further during or immediately after exercise when, because of arteriolar dilation, increased muscle flow, and passively increased peripheral pooling of blood, cardiac output becomes so reduced that the patient becomes symptomatic.³⁶

Side Effects

Many of the side effects of guanethidine (orthostatic hypotension, exercise hypotension, bradycardia, increased gastric secretion) result from unopposed parasympathetic activity and impaired adrenergic function. Similarly, diarrhea, retrograde ejaculation, and fluid retention may also be explained by reduced adrenergic transmission. Many of these side effects may be counteracted by reduced guanethidine dosage, addition of parasympatholytic agents, or addition of a diuretic.³⁷ Because guanethidine acts by entering the nerve terminal and interfering with neurohumoral transmission, any agent that prevents this will block the action of guanethidine. This is the means by which the tricyclic antidepressants—imipramine, desipramine, and protriptyline compounds—act.^{38,39} Therefore guanethidine, guanadrel, and bretylium should not be prescribed for any patient receiving these psychoactive agents (and the converse also obtains).

Clinical Uses

Because of the prolonged action of guanethidine, it need be prescribed only once daily (25-150 mg). Moreover, because sympathetic inhibition is usually maximal with bedrest, there is little to be gained by prescribing it in divided doses. Furthermore, because fluid retention and expanded intravascular and extracellular fluid volumes are most pronounced with potent adrenolytic agents, a diuretic is indicated for use with guanethidine with the caveat that patients should be observed carefully for hypokalemia and impaired renal excretory function. This phenomenon of fluid reexpansion explains most of the refractoriness to guanethidine and other sympatholytic therapy, since impairment in drug absorption over time seems unlikely.³⁷ Moreover, when a diuretic is added to guanethidine, care should be exercised to determine development of symptomatic orthostatic hypotension.

Methyldopa, Clonidine, Guanabenz, and Guanfacine

The mechanisms of the antihypertensive effects of these adrenergic inhibitors are different from those of the foregoing agents. Originally, the antihypertensive action of methyldopa was believed to be exerted through tissue depletion of biogenic amines via inhibition of dopa decarboxylase.⁴⁰ However, although methyldopa does inhibit dopa decarboxylase, that mechanism contributes minimally to its blood pressure-lowering effect. Instead, methyldopa lowers blood pressure by being converted to α -methyl-norepinephrine, a metabolite that displaces norepinephrine from the α -adrenergic receptor site, thereby preventing the neurotransmitter from producing vascular smooth muscle stimulation (e.g., the concept of false neurotransmission). Even more importantly, this metabolite of methyldopa, as well as clonidine and the other agents in this group stimulates adrenergic receptors in central vasomotor centers (e.g., nucleus tractus solitarius), thereby inhibiting sympathetic outflow from the brain.⁴¹⁻⁴⁷

Hemodynamic Effects

Shortly after their administration (by mouth or by injection), these agents cause a progressive decrease in arterial pressure and heart rate that is associated with a reduction in cardiac output or total peripheral resistance, or both.^{37,48} With time, the reduction in cardiac output becomes less apparent, and the renal blood flow is maintained.⁴⁹

Clinical Uses

Methyldopa has been useful in all types and degrees of severity of hypertension. It is effective in reducing supine pressure without associated orthostatic hypotension in doses from 250 mg to 2.0 g daily. This antihypertensive effect may diminish if methyldopa is used as monotherapy; its effectiveness can be restored and enhanced with a diuretic. Similar indications apply to clonidine and the other centrally active α -adrenergic receptor blockers. Another use for clonidine is in the diagnosis of pheochromocytoma. When 0.1 mg of clonidine is administered hourly for three doses, the plasma norepinephrine levels fall in patients with essential hypertension but remain elevated in those with pheochromocytoma.⁵⁰ Furthermore, clonidine can be administered via transdermal patches.

Side Effects

As with any antihypertensive agent that inhibits sympathetic nervous system activity, most anticipated side effects (postural hypotension, weakness, fluid expansion, gastrointestinal symptoms) may be related to its adrenolytic action or the resultant overriding of parasympathetic function, or both. Additional side effects characteristic of methyldopa, including somnolence and depressive reactions, may be related to its action on biogenic amine stores in the brain.³⁷ Methyldopa also may produce a flulike syndrome characterized primarily by a fever as high as 41°C (105°F)⁵¹; when therapy is discontinued, the fever disappears. This problem may be related to hepatocellular damage without jaundice or development of a positive direct Coombs' test that, rarely, may be associated with hemolytic anemia.^{37,52} In general, therapy may be maintained with methyldopa in the presence of a positive direct Coombs' test; however, if anemia occurs, the therapy should be discontinued.⁵³ Other side effects attributable to agents of this class include dry mouth, somnolence, and depression.⁵⁴

Sudden withdrawal of clonidine therapy has been associated with severe rebound hypertension. This can be treated with intravenous α -adrenergic blockers.⁵⁵

Monoamine Oxidase Inhibitors

Although still prescribed by some physicians as antihypertensive agents, their inclusion in this discussion is merited only because of their potentially dangerous side effects. The first therapeutic use of MAOs was administration of iproniazid for tuberculosis. It was soon learned that these compounds had mood-elevating effects⁵⁶ and ameliorated chest pain of coronary arterial insufficiency.⁵⁴ At present, their major role is in the treatment of mental depression,⁵⁴ but one compound, pargyline hydrochloride, was introduced primarily as an antihypertensive agent.³⁷ MAOs may actually aggravate hypertension by inhibiting norepinephrine metabolism.⁵⁴ Because MAO is inhibited in the postganglionic nerve terminal, several weakly pressor amines (e.g., dopamine, octopamine) accumulate at this site. These substances are believed to act as false neurohumoral transmitters, tending to elevate blood pressure.⁵⁷

Hemodynamic Effects

Only a relatively few hypertensive patients have been studied, and the results have not been striking. One report claimed marked reduction in arterial pressure and vascular resistance and a moderate impairment in glomerular filtration.⁵⁸

Side Effects

The major side effects are centrally mediated mental/emotional reactions including euphoria, insomnia, and acute psychoses. In addition, hepatocellular necrosis, blood dyscrasias, and symptoms of adrenergic inhibition occur.³⁷ Most important is the severe acute hypertensive crisis that has been observed repeatedly following the ingestion of certain foods containing tyramine (e.g., aged cheeses, beer, sherry, Chianti wine, and herring) while the patient is receiving MAOs (e.g., pargyline hydrochloride, tranylcypromine sulfate, phenelzine sulfate, nialamide, iproniazid).⁵⁹⁻⁶¹

Clinical Uses

Because of the potentially severe hypertensive crises that may be associated with these antihypertensive drugs, they should be considered primarily of academic interest in the treatment of hypertension.³⁷

Veratrum Alkaloids

These compounds are of importance because of their availability, potent antihypertensive efficacy, and unusual mode of action. They alter the responsiveness of the vagal afferent nerve fibers in the coronary sinus, left ventricle, and carotid sinus so that any pressure stimulus will result in increased nerve traffic. This stimulus is interpreted in the medullary vasomotor centers as reflecting a higher pressure than actually exists as a result of an induced delay in the vagal repolarization process.^{62,63}

Hemodynamic Effects

As a result of this altered afferent input to the central vasomotor centers, there is a reflexive fall in systolic and diastolic pressure and heart rate; the latter response may be abolished

by atropine sulfate. Because adrenergic function is not blocked, only reset at a different pressure level, the usual postural and adrenergic reflexive responses are not altered. The result is a significant fall in total peripheral resistance with little change in cardiac output despite the rather marked bradycardia. Cerebral and renal blood flow and glomerular filtration rate remain normal unless the hypotensive response is excessive.⁶³

Side Effects

Because of the narrow therapeutic index, the effective control of arterial pressure by the veratrum alkaloids is not infrequently associated with side effects, including nausea, vomiting, excessive salivation and diaphoresis, blurred vision, and mental confusion. These effects have been reduced slightly by combined use with other antihypertensives.

Clinical Uses

Clinical use of the veratrum alkaloids has been restricted severely by their side effects. A parenteral agent (cryptenamine tannate [Unitensin], 1.0 mg) has been useful in the treatment of certain hypertensive emergencies, including eclampsia.

α -Adrenergic Receptor Blocking Agents

Members of the class of α -adrenergic blocking agents including doxazosin, prazosin, and terazosin block adrenergic type 1 receptors localized on the vascular smooth muscle cell membrane so that the release of norepinephrine from the postganglionic nerve ending is inhibited in its action at the end-organ receptor. Consequently, peripheral adrenergic activity is diminished.

Hemodynamic Effects

As a result of the foregoing action, vascular smooth muscle tone in the arteriolar wall and total peripheral resistance is decreased. Initially, there may be a reflex increase in cardiac stimulation; but within a short period of time, the increase in heart rate is less. For this reason, the postural hypotension observed after the initial dosing of these compounds becomes less obvious with continuous drug use. As with all other agents described previously that inhibit adrenergic activity or reduce vascular smooth muscle tone by direct relaxation of the arteriolar myocyte, intravascular (plasma) volume expands. The net effect may be a lesser control of arterial pressure associated with some intravascular volume expansion with peripheral edema. The drug-induced hypotension can be restored with the addition of a diuretic.

Clinical Uses

Of the adrenergic inhibitors discussed in this chapter, the α -adrenergic blocking agents are the most commonly prescribed and yet are among the most controversial. Many of the early national consensus reports and guidelines did not recommend these agents for the initial treatment of patients with hypertension. In more recent reports they were included, but in the Joint National Committee's most recent report (JNC 7), α -adrenergic blocking drugs were excluded from initial therapeutic recommendations based on results of the large Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).⁶⁴ In ALLHAT, one of the agents in this class was found to be associated with a

higher prevalence of cardiac failure (CHF) as compared with the diuretic chlorthalidone. While these agents may not be among the more important for therapy of most patients with hypertension, there still is a very definite place for them.

The α receptor inhibitors have been of greatest value in elderly men with hypertension who also have benign prostatic hyperplasia (BPH) or in normotensive elderly men with BPH. These agents are also useful for patients who have had adverse effects (bronchospasm, negative chronotropic and inotropic cardiac effects, greater than second-degree heart block, bronchoconstriction, depression, cold-induced peripheral vasoconstriction) from a β -adrenergic blocker or other adrenergic inhibitors. The α receptor inhibitors are also of value in patients with metabolic abnormalities associated with other antihypertensive agents, because they produce no metabolic alterations.

Side Effects

As a result of the hemodynamic actions of the α -blockers, postural hypotension is not infrequent, and as a result, measurement of blood pressures should be obtained in the erect posture as well as the sitting or standing positions. When postural hypotension is documented (or even suspected by clinical symptoms), it is wise to advise these patients to assume the upright position cautiously—particularly when awakening during the night because of nocturia. The second most important side effect, as suggested previously, is apparent fluid retention. In reality, this is not true fluid retention but (as stated previously) edema associated with restoration of intravascular (plasma) volume as a result of reexpanded volume in consequence to reduced capillary hydrostatic pressure.

CHF has been identified as a major consequence of α receptor inhibition, particularly in elderly patients. This concept has been advocated in reports of increased CHF from the ALLHAT study.⁶⁴ The criteria for CHF in patients receiving doxazosin were not detailed in that report, but it was explicitly stated that the patients receiving this agent had greater risk of CHF and stroke than in those patients receiving chlorthalidone.⁶⁴ In subsequent reports, “symptomatic heart failure” was defined “as clear-cut signs or symptoms of left or right ventricular dysfunction that cannot be attributed to other causes. A patient had to have at least one symptom (paroxysmal nocturnal dyspnea, dyspnea at rest, New York Heart Association class II dyspnea, other symptoms [on less-than-ordinary exertion], or orthopnea) and one sign (rales, ankle edema, tachycardia, cardiomegaly or characteristic pulmonary pattern on chest radiography, S3 gallop, or jugular venous distension).”^{65,66} Thus, because of the apparent fluid retention that results from the intrinsic hemodynamic effects of doxazosin and other α -adrenergic blockers, the elderly hypertensive patients randomized to doxazosin in ALLHAT very well may have demonstrated some degree of dyspnea, weight gain, peripheral edema, some evidence of cardiac enlargement, and expanded intravascular volume—even if true CHF did not supervene. These patients (by study design) could not receive a diuretic to reverse the edema. Nevertheless, when prescribing an α -adrenergic inhibitor to an elderly high-risk patient, care must be exercised to follow-up not only for signs of postural hypotension but also for potential intravascular volume expansion manifested by edema and dyspnea to prevent the development of CHF.

DIRECT-ACTING VASCULAR SMOOTH MUSCLE RELAXANTS

With the introduction of β -adrenergic blocking therapy, a resurgence in interest in direct-acting smooth muscle vasodilating drugs for hypertension occurred. These agents have also been used with varying success in patients with cardiac failure. Hydralazine and minoxidil act by decreasing arteriolar resistance. With the fall in total peripheral resistance and arterial pressure, a reflex stimulation of the heart occurs so that tachycardia and palpitations frequently result unless these cardiac reflexive responses are offset by an adrenergic inhibitor (e.g., a β -adrenergic receptor blocking drug). These agents should not be administered to patients with hypertension who have myocardial infarction, angina pectoris, or aortic dissection because the reflexive cardiac effects will aggravate these underlying cardiac conditions. Other side effects include headaches and nasal stuffiness—attributable to the local vasodilation—and fluid retention and edema (i.e., pseudotolerance), which occurs more frequently with minoxidil.

A unique side effect of hydralazine is precipitation of a lupus erythematosus–like syndrome, which occurs more frequently in patients who are receiving more than 400 mg/day of hydralazine. A common side effect from minoxidil is hirsutism, which is particularly bothersome to women. When hydralazine is administered by injection (10–15 mg intravenously), a prompt reduction in pressure occurs.

Another parenteral vasodilator, diazoxide, is a nonnatriuretic thiazide congener that must be injected rapidly (in single-bolus doses of 300 mg or in successive pulsed-bolus divided doses) to prevent binding to circulating albumin. Diazoxide should not be administered to the patient with hypertension who has cardiac failure, angina pectoris, myocardial infarction, or an active aortic dissection. However, it has been useful for the patient with hypertensive encephalopathy, intracranial hemorrhage, and severe malignant or accelerated hypertension (without cardiac failure) in whom rapid and immediate reduction in arterial pressure is mandatory.

Endothelin Antagonists

Ernesto L. Schiffrin

ROLE OF ENDOTHELINS IN EXPERIMENTAL HYPERTENSION

The endothelins (ET), potent 21-amino acid vasoconstrictor peptides produced in many different tissues, particularly in the endothelium of blood vessels, have already been described in Chapter 17. ET-1 is the main endothelin secreted by the endothelium, and acts in a paracrine or autocrine fashion on adjacent cells (endothelial or smooth muscle). ET-1 may act on ET_A and ET_B smooth muscle receptors to induce contraction, proliferation, and cell hypertrophy and on endothelial ET_B receptors to induce release of nitric oxide (NO) and prostacyclin to elicit vasorelaxation. It is not known whether the vasoconstrictor or the vasorelaxant action of endothelins is their most important physiologic function, and this probably varies from one vascular bed to another. In the coronary circulation, the virtual absence of endothelial ET_B receptors¹ results in endothelins behaving as coronary vasoconstrictors. In other vascular beds it is possible that ET-1 acts on smooth muscle cells as a paracrine constrictor and growth promoter only when it is overexpressed in endothelial cells under pathologic conditions.

In the heart, ET-1 is produced by various cell types, including endothelial cells, smooth muscle cells, fibroblasts, and cardiomyocytes. Up-regulation of the ET-1 gene may occur in these cells in response to angiotensin II, wall stretch, and ischemia. The ET_A subtype is the predominant receptor present in cardiomyocytes, whereas a mixed population of ET_A and ET_B receptors is found in cardiac fibroblasts.² Endothelins stimulate expression of fetal genes, protein synthesis, and growth in cardiomyocytes.

In relation to the kidney, the expression of endothelins, the presence of ET_A and ET_B receptors and the vasoconstrictor and salt-retaining effects of these peptides have already been described in detail in Chapter 17.

Antagonists that are highly selective for the ET_A or for the ET_B receptor have been developed, have agents that have high affinity for both ET_A and ET_B receptors, the so-called balanced or nonselective ET_A/ET_B receptor antagonists (Table 69-1). It is unclear as yet whether the balanced or nonselective antagonists act through blockade of both receptor subtypes, or by predominantly blocking endothelin actions mediated via the ET_A receptor. Although some of these agents can be administered only intravenously (e.g., TAK-044, BQ-123, BQ-610, FR139317, IPI-725, BQ-788, RES-701-1), others are orally active and have at some point undergone clinical development for primary pulmonary hypertension, heart failure, subarachnoid hemorrhage, and have been considered potentially for systemic hypertension. The availability of subtype-selective and nonselective antagonists of endothelin receptors has allowed the dissection of the physiologic and pathophysiologic roles of endothelins mediated through these receptor subtypes in both experimental animals and humans.

Activation of the endothelin system has been demonstrated in salt-dependent models of hypertension, such as the deoxycorticosterone (DOCA)-salt hypertensive rat and the DOCA-salt-treated spontaneously hypertensive rat (SHR). These models overexpress ET-1 in the vascular endothelium,^{3,4} and respond with blood pressure (BP) lowering to endothelin antagonism with bosentan, an ET_A/ET_B endothelin antagonist.⁵ In contrast, the endothelin system appears not to be activated in SHR.³ When the activity of the vascular endothelin system is enhanced, growth is accentuated in resistance arteries, and administration of endothelin antagonists lowers BP and induces regression of hypertrophic arterial remodeling.^{5,6} Endothelin effects in the kidney of some of these hypertensive models may contribute to water and sodium retention, renal vasoconstriction and hypertension, and eventually, renal failure.⁷ In rats infused with angiotensin II (Ang II), a known stimulant of ET-1 expression, endothelin antagonists lowered BP and reduced cardiac and small artery hypertrophic remodeling.⁸ Thus the endothelin system seems to be activated more often in low-renin, salt-sensitive, and severe forms of hypertension, but may be also stimulated by exogenous Ang II, and therefore presumably under certain conditions by endogenous Ang II. Cyclosporine-induced hypertension may also exhibit an endothelin-dependent component, and bosentan lowers BP in this model in rats and primates.⁹ Endothelin may also play a role in hypertensive models with hyperinsulinemia and insulin resistance, in which chronic administration of bosentan reduces BP.¹⁰

In all these salt-sensitive, severe, or exogenous Ang II-infused models of hypertension in which ET-1 expression has been shown to be enhanced, severe hypertrophy of small arteries is often a characteristic feature.¹¹ In those models in which overexpression of ET-1 occurs, bosentan or other endothelin antagonists reduced BP and hypertrophic remodeling of small arteries and protected the kidney.¹² In some experimental models of hypertension enhanced expression of ET-1 may be local rather than generalized, and the endothelium of coronary arteries appears to be particularly vulnerable in this regard.¹³ Enhanced production of ET-1, without compensatory vasodilation because of absence of endothelial ET_B receptors,¹ could result in vasoconstriction of the coronary circulation and a significant role of endothelin in myocardial ischemia in hypertension. In the absence of endothelin tissue overexpression, the endothelin system may still play a role, if not in BP elevation, in perivascular fibrosis of the heart and in deterioration of renal function, as shown by the response to chronic bosentan treatment in SHR.¹⁴ Cardiac endothelin expression increases in animal models of cardiac hypertrophy, and chronic administration of either selective ET_A or mixed antagonists may reduce the development of left ventricular hypertrophy (LVH). Norepinephrine administered for 7 days increased expression of ET-1 in the heart in rats, mainly in cardiomyocytes and endothelial cells, and bosentan administration has blunted

manifestations of cardiac hypertrophy.¹⁵ The endothelin system is activated in heart failure in rats, and infusion of the ET_A antagonist BQ-123 for a short period of time decreased the rate and force of contraction of the heart, indicating an inotropic action of the activated endothelin system in this model.¹⁶ Prolonged infusion of BQ-123 significantly reduced mortality in the same rat model of heart failure.¹⁷ Deterioration of cardiac function mediated by pathophysiologic activation of the cardiac endothelin system, as well as endothelin-dependent vasoconstriction and increased afterload in advanced heart failure, may therefore respond favorably to ET receptor antagonism, as has been demonstrated in humans.¹⁸

PATHOPHYSIOLOGY OF THE CARDIOVASCULAR ENDOTHELIN SYSTEM IN HUMANS AND INVESTIGATIONAL USE OF ENDOTHELIN

Plasma endothelin levels are usually normal in human hypertension, although in some severely hypertensive patients, elevated endothelin immunoreactivity may be found in plasma.¹¹ The acute intravenous administration of the mixed ET_A/ET_B endothelin receptor antagonist TAK-044 induced an increase in forearm blood flow and lowered BP slightly in healthy subjects.¹⁹ This suggests that endothelin-dependent vascular tone may be present in normotensive humans. Enhanced plasma endothelin responses to mental stress have been reported in normotensive offspring of hypertensive parents,²⁰ which could indicate a genetically determined endothelial dysfunction preceding the development of hypertension. In patients with moderate to severe hypertension, the expression of preproET-1 mRNA in the endothelium of small arteries obtained from gluteal subcutaneous biopsies was significantly greater than in normotensive subjects or patients with mild hypertension.²¹ This is in agreement with the report of increased ET-1 production by the endothelium of small arteries in experimental models with severe hypertension.

Enhanced production of ET-1 could play a role in small artery hypertrophic remodeling in patients with moderate to severe hypertension in addition to contributing to elevation of BP. In African Americans, in whom hypertension is often severe and salt-sensitive, activation of the endothelin system has been

described.²² Other studies suggest that in Blacks, activation of the endothelin system is mainly associated with the more severe forms of hypertension.²³ It has also been shown that endothelin levels in plasma are associated with salt sensitivity in human subjects. In these subjects, abnormalities in the relation of endothelin, renin, and the sympathetic nervous system as measured by plasma catecholamines have been documented, which could contribute to activation of the endothelin system in response to a salt load. Other forms of hypertension in which endothelins may play a role are those associated with chronic renal failure, erythropoietin, and cyclosporine administration, pheochromocytoma, and pregnancy.¹¹

The definitive place of endothelins in the pathophysiology of hypertension is still unclear, and its place in the therapeutic armamentarium awaits clinical trials with the different endothelin antagonists currently developed or in development. Bosentan given to patients with mild hypertension over a period of 4 weeks at a dose of 0.5 g once or twice daily was equally effective as 20 mg of enalapril daily, and well tolerated.²⁴ In the same study, a blunting of reflex neurohormonal vasoconstrictor activation was reported following administration of bosentan.²⁵ However, elevation of liver enzymes reported with the use of large doses of bosentan has stopped the development of this agent for a chronic condition such as systemic hypertension, which is associated with long life and for which many effective treatments are available. Bosentan has been approved for use in pulmonary hypertension, a rapidly fatal condition for which few other therapeutic alternatives exist.^{26,27} The ET_A-selective endothelin antagonist LU135252 (darusentan) has been shown to lower BP in hypertensive subjects with few if any adverse effects.²⁸ Interestingly, headache was present more often in normal controls than in hypertensive persons with darusentan. This may depend on activation of NO synthase and production of NO in response to stimulation of unblocked ET_B receptors. Because there is impairment of endothelial function in hypertensive subjects, fewer nitroglycerin-like effects are expected in hypertensive (for the reasons mentioned just previously) than in normotensive subjects. However, it does not seem that endothelin antagonists will be developed in the near future for the treatment of systemic hypertension.

SUMMARY

We believe based on the data summarized in this chapter that it is likely that ET-1 is mainly involved in BP elevation and vascular hypertrophy in moderate to severe hypertension, and particularly in salt-sensitive forms and perhaps in special populations.²³ Worsening endothelial damage in hypertension may activate expression of endothelin in vessels and in the heart. Endothelin activation may be initially beneficial because (1) the vessel wall is thickened and wall stress is reduced, and (2) there are positive inotropic effects on the heart. However, progression of these changes may eventually result in pathophysiologically significant deleterious effects on the cardiovascular system. Endothelin antagonists may prove useful at this point, particularly in moderate to severe hypertension and in certain subsets of patients such as salt-sensitive hypertensives or African Americans. Endothelin antagonists may also prove to be useful in prevention of progression of nephroangiosclerosis and renal failure in hypertension,

protection from ischemic heart disease and stroke,²⁹ as well as treatment of heart failure.¹⁸ Endothelin antagonists may function in these conditions as disease-modifying agents, perhaps more than as BP-lowering agents.

Bosentan has been approved for the treatment of primary pulmonary hypertension,^{26,27} a rapidly fatal disease for which few therapeutic alternatives are available and in which activation of the endothelin system has been well documented. In acute and chronic heart failure, in which there was great hope for successful utilization of endothelin antagonists based on studies in experimental animals, results of clinical trials have been disappointing.³⁰ However, new studies with different agents are currently being performed that may offer greater hope for the use of these agents in heart failure.

Whether balanced ET_A/ET_B antagonists, selective ET_A antagonists or endothelin converting enzyme inhibitors³¹ will prove to be the preferred agents is as yet unclear. Further clinical evaluation of these drugs will allow us to learn more about their therapeutic utility and about the pathophysiologic implication of the endothelin system in human disease, as well as its role in the short- and long-term regulation of cardiovascular function.

Mineralocorticoid Receptor Antagonists

Ellen G. McMahon

Over the last several decades, the widespread use of new therapeutic agents to treat hypertension, dyslipidemia, and heart disease has reduced the morbidity and mortality associated with cardiovascular diseases. However, the incidence of end-stage renal disease and congestive heart failure continues to rise despite improvements in control of blood pressure and lipids.^{1,2} This is most likely due to the fact that, despite the availability of a vast array of agents to lower blood pressure, only 31% of treated patients reach target blood pressures.³ Typically, patients with uncontrolled hypertension have markedly elevated systolic blood pressure, diabetes, or evidence of target organ damage (left ventricular hypertrophy [LVH] or microalbuminuria). The annual risk of life-threatening cardiovascular events is estimated to be 2% to 3% per annum in these difficult to control patients.⁴ Thus the number of cardiovascular events that might be prevented with improved blood pressure control in these patients is correspondingly large.

For many years, activation of the renin-angiotensin-aldosterone system (RAAS) has been associated with unsatisfactory outcomes in patients with heart failure and hypertension. In severe heart failure patients, plasma aldosterone levels are positively correlated with mortality and, in hypertensive patients, there is a positive correlation between LVH and plasma aldosterone.^{5,6} An inverse correlation that was independent of blood pressure or age has been reported between plasma aldosterone levels and arterial compliance in a population of essential hypertensives.⁷ Patients with primary aldosteronism have increased incidence and severity of cardiovascular complications compared to essential hypertensives with similar blood pressure elevation.^{8,9} Thus, several studies have demonstrated that aldosterone correlates with the severity of target organ damage and is likely an independent risk factor for cardiovascular events.

Upstream blockers of the RAAS (angiotensin-converting enzyme [ACE] inhibitors and the angiotensin receptor blockers [ARBs]) have been available for many years. Why, then, is aldosterone blockade needed, since upstream blockers of this pathway should negate all of the negative effects of aldosterone by inhibiting aldosterone production? The answer lies in a phenomenon known as “aldosterone rebound,” which occurs during chronic treatment with ACE is such that aldosterone levels rise over time despite maximal blockade at proximal sites in the pathway. Aldosterone rebound has been reported in patients treated with ACE inhibitors and ARBs for hypertension, heart failure, and diabetic nephropathy.¹⁰⁻¹² In the Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) Pilot Study, in which heart failure patients were administered enalapril and the ARB candesartan, either alone or in combination for a period of 43 weeks, aldosterone levels return to pretreatment values with prolonged therapy even in patients treated with both enalapril and candesartan.¹³

Aldosterone rebound is expected because we know that there are multiple modulators of aldosterone secretion, in addition to angiotensin II (Ang II). Potassium, adrenocorticotrophic hormone, the neurotransmitters norepinephrine and serotonin, endothelin and nitric oxide are all known modulators of aldosterone secretion, independent of Ang II.¹⁴ Thus, it is not surprising that aldosterone rebound occurs with blockade of the Ang II pathway. Patients treated with upstream RAAS blockers remain unprotected from the deleterious effects of aldosterone.

ALDOSTERONE AND CARDIOVASCULAR INJURY

The classical mineralocorticoid effect of aldosterone on transporting epithelium in the kidney has long been thought to be the predominant cardiovascular effect of the hormone. However, there is now compelling evidence that aldosterone mediates significant cardiovascular effects via the actions on mineralocorticoid receptors outside the kidney, namely in the brain, heart, and blood vessels.¹⁵ Moreover, the enzymes responsible for aldosterone biosynthesis are present outside of the adrenal gland in the same tissues.¹⁶⁻²⁰ It is now postulated that many of the effects of aldosterone on the cardiovascular system are mediated through activation of nonepithelial mineralocorticoid receptors in these tissues (Figure 70-1).

Brilla and Weber were the first to suggest that aldosterone may play a deleterious role via its action on mineralocorticoid receptors in nonepithelial tissues. These investigators identified a link between activation of the RAAS and the development of myocardial fibrosis in both left and right ventricles, using experimental models of hypertension.²¹ Subsequent studies have confirmed and extended these original observations using the *N* ω -nitro-L-arginine methyl ester (L-NAME/Ang II/salt, Ang II/salt, deoxycorticosterone (DOCA)/salt, and aldosterone/salt models of hypertension.²²⁻²⁵ It is clear from these studies that elevated levels of aldosterone correlate strongly with the development of ventricular fibrosis. However, work from Rocha et al.²⁵ suggests that the primary damaging effect of aldosterone may be the induction of vascular inflammation and injury of the small arteries and arterioles in target organ tissues, preceding a reactive and reparative fibrotic process.

Aldosterone has also been implicated as a mediator of the aortic collagen accumulation that often occurs during the development of hypertension in animal models. Lacolley et al.²⁶ have demonstrated that mineralocorticoid receptor blockade in aldosterone/salt hypertensive rats prevents increased arterial stiffness and pulse pressure increases, even at doses that do not significantly reduce blood pressure. Similar reductions in aortic collagen accumulation with mineralocorticoid receptor antagonism were reported in the spontaneously hypertensive rat (SHR).²⁷ These animal studies are supported by clinical evidence

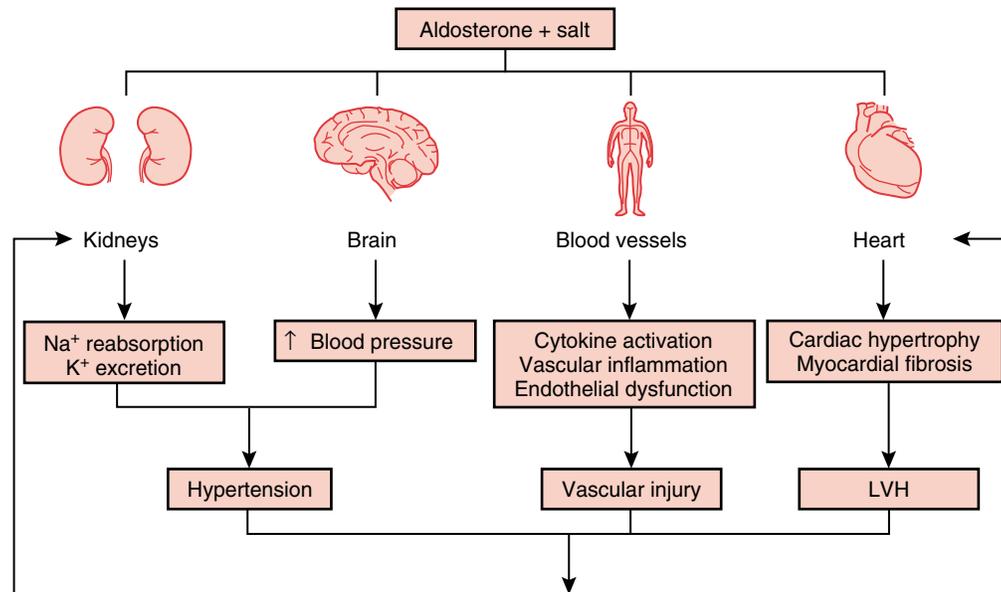

Figure 70-1 Deleterious effects of aldosterone in the presence of high salt intake leading to cardiovascular disease. (With permission from McMahon EG. Eplerenone, a new selective aldosterone blocker. *Curr Pharm Des* 9(13):1065-1075, 2003.)

of an inverse relationship between plasma levels of aldosterone and large artery compliance in hypertensive patients.²⁸

Aldosterone also appears to disrupt fibrinolytic balance. Brown et al. have demonstrated that aldosterone up-regulates plasminogen activator inhibitor type-1 (PAI-1), the major physiologic inhibitor of plasminogen activation.²⁹ Up-regulation of PAI-1 may shift thrombotic/thrombolytic balance to favor clot formation. Aldosterone may also be a mediator of endothelial dysfunction because blockade of aldosterone in patients with congestive heart failure improves endothelial function and increases nitric oxide bioactivity.³⁰ Aldosterone blockade improves endothelial dysfunction in animal models of heart failure and hypertension.^{31,32}

Aldosterone produces proarrhythmic effects in cardiomyocytes in that exposure of adult rabbit cardiomyocytes to aldosterone produced inhibitory effects on $\text{Na}^+\text{-K}^+$ pump activity.³³ In rabbits, elevated aldosterone levels induce a decrease in cardiac sarcolemmal $\text{Na}^+\text{-K}^+\text{-ATPase}$, which is blocked by mineralocorticoid receptor antagonism and thought to be due to direct activation of cardiomyocyte mineralocorticoid receptors (MR) by aldosterone.³⁴ Inhibition of $\text{Na}^+\text{-K}^+\text{-ATPase}$ is also associated with the activation of key growth-related genes in cardiomyocytes and thus, this direct effect of aldosterone on cardiomyocytes may contribute to LVH in hypertension and heart failure.³⁵

Nonepithelial effects of aldosterone have also been demonstrated in the brain. Gomez-Sanchez et al. have shown that intracerebroventricular administration of aldosterone in rats, at doses too low to have effects when administered systemically, slowly induces hypertension over a period of several weeks.³⁶ In Dahl inbred salt-sensitive rats on a high-salt diet, blood pressure rises slowly over time, despite suppression of the RAAS with high salt intake. When these animals are administered either a mineralocorticoid receptor antagonist (RU28318) or high levels of corticosterone (the physiologic glucocorticoid in the rat into the brain), the rise in blood pressure is attenuated.³⁷ Mineralocorticoid receptors have been identified in human

brain, but it is not known whether activation of these receptors by aldosterone contributes to hypertension in humans.

Nongenomic Effects of Aldosterone

On binding MR, aldosterone initiates a transcriptional response that culminates in cellular and physiologic events. Nongenomic effects of aldosterone in vascular tissues that do not require gene transcription have also been described.³⁸ These effects occur within minutes of aldosterone exposure and are typically unresponsive to the nonselective aldosterone receptor antagonist, spironolactone.³⁹ The vascular effect of eplerenone, a selective mineralocorticoid receptor antagonist,⁴⁰ on aldosterone-stimulated nongenomic activation of the $\text{Na}^+\text{-K}^+\text{-ATPase}$, was evaluated using rat aorta and rat mesenteric arteries. Aldosterone inhibited $\text{Na}^+\text{-K}^+\text{-ATPase}$ (as measured by ouabain-sensitive ^{86}Rb uptake) in rat aortic rings 20 to 25 minutes after exposure to aldosterone and eplerenone prevented this rapid effect of aldosterone on $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity.⁴¹ Inhibition of gene transcription with actinomycin D and of protein synthesis with cycloheximide had no effect on the short-term aldosterone inhibition of the $\text{Na}^+\text{-K}^+$ pump, indicating that the rapid effects are mediated via MR but involve nongenomic mechanisms. These observations suggest that aldosterone is directly involved in cellular ionic homeostasis in rat arteries and provide evidence that eplerenone is able to antagonize nongenomic aldosterone effects in vascular tissues. However, the contribution of nongenomic effects to the detrimental action of aldosterone on the cardiovascular system remains controversial.⁴²⁻⁴⁴

Spironolactone and Eplerenone

Simpson and Tait initially isolated aldosterone in 1953. It was some years before an aldosterone antagonist was developed and made available for the treatment of hypertension. Scientists at Searle Laboratories in Skokie, IL, synthesized

spironolactone in 1958 and reported on the aldosterone-blocking and oral activity of this agent in 1959.⁴⁵ Spironolactone was approved in 1962 as a potassium-sparing diuretic for the management of primary aldosteronism, edematous conditions, essential hypertension, and hypokalemia. When used for prolonged periods of time at high doses, spironolactone use is associated with endocrine side effects, such as loss of libido, menstrual irregularities, gynecomastia, and impotence.⁴⁶ These side effects are due to the affinity of spironolactone for androgen and progesterone receptors.

Eplerenone (Inspra) was synthesized by J. Grob of Ciba-Geigy back in the mid-1980s as a more selective mineralocorticoid receptor antagonist.⁴⁷ Eplerenone was approved in the United States for use in hypertension in 2002. In 2003, eplerenone was approved to improve survival in postmyocardial infarction patients with left ventricular (LV) systolic dysfunction and clinical evidence of congestive heart failure. As shown in Figure 70–1, the critical feature of the eplerenone molecule conferring enhanced selectivity is the presence of the 9,11-epoxide group in the lactone ring. Eplerenone is the first mineralocorticoid antagonist that acts at the MR to prevent its activation by aldosterone in a highly selective manner. Unlike previous aldosterone blockers (spironolactone), eplerenone possesses very low activity at the human androgen, progesterone, and glucocorticoid receptors (hAR, hPR and hGR, respectively).⁴⁸

The activity of eplerenone at human steroid receptors was measured *in vitro* using recombinant human steroid receptors. These assays measure the ability of a compound to stimulate receptor transcriptional transactivation function and/or to antagonize a full agonist transcriptional response at steroid receptors. Eplerenone antagonized hMR transcriptional activation by aldosterone in a concentration-dependent manner with a calculated IC_{50} of 0.081 μ M (Table 70–1). The potency of eplerenone at other steroid receptors was significantly reduced, with no activity measured at progesterone and glucocorticoid receptors, even when eplerenone was tested at concentrations up to 100 μ M. At human androgen receptors, eplerenone blocking activity was measurable but was only one-sixtieth of the blocking activity measured at the MR. In contrast, the earlier MR antagonist spironolactone demonstrated significant activity at all human steroid receptors tested. In particular, spironolactone possesses significant blocking

activity at the androgen receptor; the IC_{50} for androgen blockade with spironolactone is one-sixth the activity at the mineralocorticoid receptor. In addition, the spironolactone molecule is a reasonably potent agonist at progesterone receptors. These new data using human steroid receptor preparations confirm earlier studies using steroid receptor preparations from animal tissues⁴⁷ and demonstrate that eplerenone is a significantly more selective aldosterone receptor antagonist compared with spironolactone.⁴⁸

The improved selectivity of eplerenone was confirmed in clinical studies, which demonstrated that eplerenone provides continuous blockade of aldosterone for at least 1 year without tolerability issues.⁴⁹

In addition to improved steroid receptor selectivity, the pharmacokinetic properties of eplerenone in humans are different from those of spironolactone. Although both spironolactone and eplerenone are rapidly cleared from plasma, several long-lived active metabolites are produced from spironolactone that contribute to its pharmacologic activity in humans.⁵⁰ Canrenone and 6- β -OH-7- α -thiomethylspiro lactone (TMS) are the major circulating metabolites in human plasma, and both demonstrate binding to MRs and antimineralocorticoid activity in animals. Both of these active metabolites have long half-lives—16.5 and 13.8 hours mean post-steady-state half-lives, respectively, for canrenone and TMS in normal, healthy volunteers dosed with spironolactone at 100 mg/day each day for 15 days.⁵⁰ In contrast, the two major metabolites of eplerenone in humans, 6- β -OH eplerenone and the open lactone ring form of eplerenone are both inactive when tested using human mineralocorticoid receptors.⁵¹

Spironolactone has a very high degree of first-pass metabolism in humans, with metabolites that undergo a high degree of enterohepatic cycling.⁵² Spironolactone is also an inducer of hepatic microsomal drug metabolizing enzymes in humans.⁵⁰ In patients with congestive heart failure, the log-linear phase half-life of canrenone was substantially prolonged compared with the half-life in healthy subjects.⁵³ In contrast, eplerenone does not undergo extensive first-pass metabolism and is not an inducer of cytochrome P450 isoforms in humans.⁵¹

It is well documented that upstream blockers of the RAAS stimulate renin release and elevate angiotensin II levels due to disruption of the short feedback loop, whereby angiotensin II

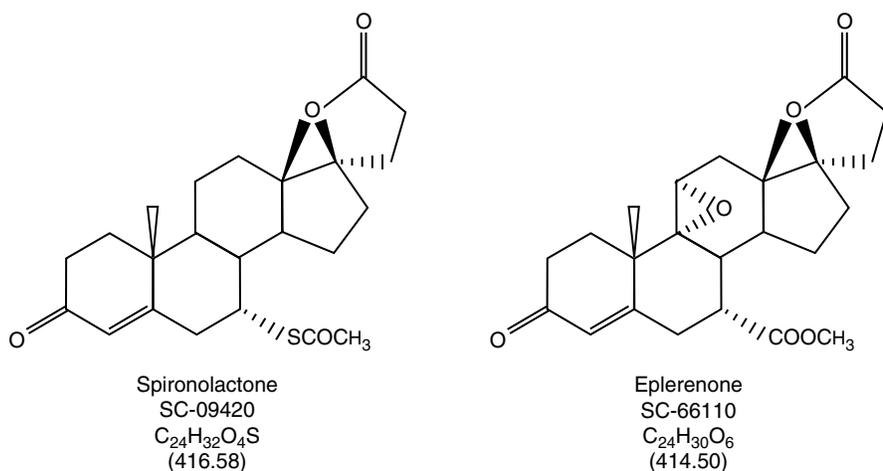

Figure 70–2 Chemical structures of spironolactone and eplerenone, the two mineralocorticoid receptor antagonists currently available in the United States. (With permission from Garthwaite SM, McMahan EG. The evolution of aldosterone antagonists. *Mol Cell Endocrinol* 217:27-31, 2004.)

Table 70-1 Comparison of Spironolactone and Eplerenone Selectivity at Human Steroid Receptors

	Eplerenone (uM)	Spironolactone (uM)
MR (IC₅₀)	0.081	0.002
AR (IC₅₀)	4.827	0.013
GR (IC₅₀)	>100	2.899
PR (EC₅₀) (agonist)	>100	2.619

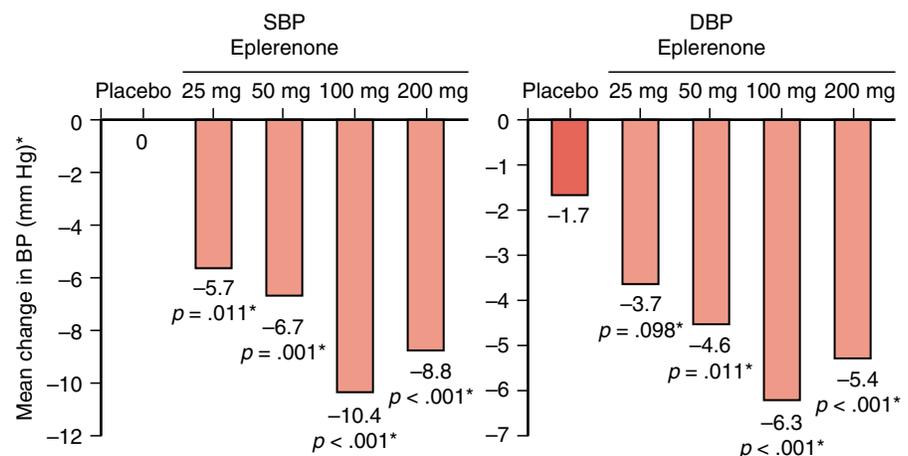

IC₅₀, the concentration of antagonist required to inhibit by 50% activation by 0.5 nM aldosterone for MR, mineralocorticoid receptor, 10 nM dihydrotestosterone for AR, androgen receptor and 5 nM dexamethasone for GR, glucocorticoid receptor. EC₅₀, the concentration of ligand to achieve 50% activation of the PR, progesterone receptor compared with the full agonist progesterone (50 nM). (With permission from Garthwaite SM, McMahon EG. The evolution of aldosterone antagonists. *Mol Cell Endocrinol* 217:27-31, 2004.)

inhibits renin release.⁵⁴ In a similar manner, blockade of aldosterone action at MR in the distal nephron by eplerenone or spironolactone stimulates renin release and increases aldosterone levels via disruption of the long feedback loop. Thus a predicted pharmacodynamic response to mineralocorticoid blockade with spironolactone or eplerenone is a rise in plasma renin and aldosterone levels.⁵⁵ The rise in aldosterone levels in response to chronic MR blockade does not produce detrimental effects because the MR is not available for activation by aldosterone. Rather, the elevation in serum aldosterone in response to MR blockade with spironolactone or eplerenone is a useful biomarker of efficacious MR blockade in vivo. It is important to note that neither spironolactone or eplerenone, at clinically relevant concentrations, inhibits the key enzymes in the biosynthetic pathway for aldosterone production.⁴⁷

Blood Pressure-Lowering Activity of Eplerenone in Humans

The blood pressure-lowering activity of eplerenone was assessed in mild-to-moderate hypertensives in a double-blind, randomized, placebo-controlled trial of 8 weeks' duration.⁵⁵

Figure 70-3 Mean changes from baseline in seated blood pressure after 12 weeks of therapy with eplerenone (25-200 mg once daily) and placebo in essential hypertensive patients. Baseline seated systolic blood pressure (SBP) averaged 151-155 mm Hg, and seated diastolic blood pressure (DBP) averaged 100-101 mm Hg. (Redrawn from White WB, Carr AA, Krause S, et al. Assessment of the novel selective aldosterone blocker eplerenone using ambulatory and clinical blood pressure in patients with systemic hypertension. *Am J Cardiol* 92:38-42, 2003.)

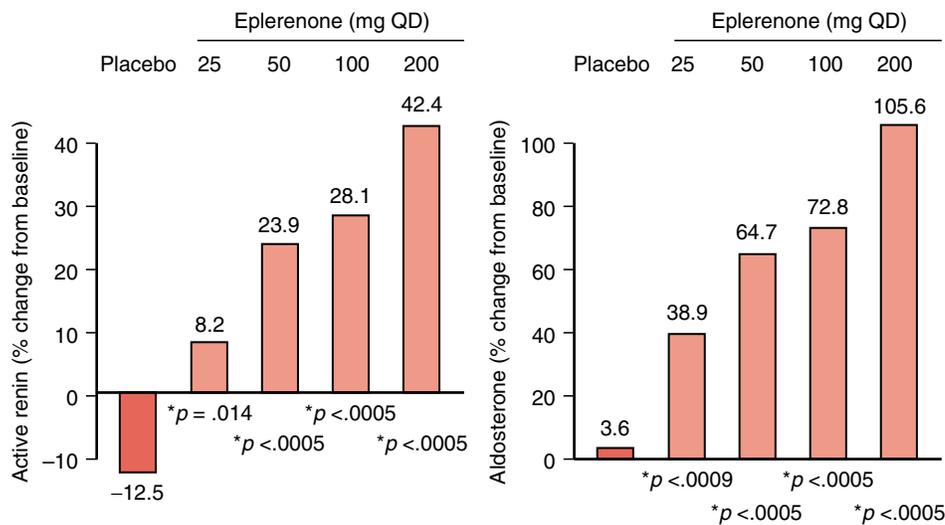

*p-Value vs. placebo based on ANCOVA using baseline as covariate and treatment and center as factors.

Blood pressure lowering with eplerenone (50, 100, and 400 mg once daily or 25, 50, or 200 mg twice daily) was compared with the response achieved with spironolactone administered at 50 mg twice daily or placebo. Seated and standing systolic and diastolic blood pressure reductions were significantly greater at all eplerenone doses compared with placebo ($p < .05$). The blood pressure lowering with eplerenone was dose dependent, and no consistent, clinically significant differences in lowering of blood pressure were observed when comparing once-daily with twice-daily dosing. Blood pressure lowering with eplerenone at 100 mg (50 mg twice daily or 100 mg once daily) was approximately 50% to 75% of that achieved with spironolactone, consistent with the greater potency of spironolactone for binding to the MR.

A more thorough dose-response study was conducted with once-daily dosing of eplerenone in a double-blind, placebo-controlled, parallel-arm, fixed-dose study in essential hypertensive patients studied for 12 weeks.⁵⁶ After single-blind placebo treatment for 3 to 4 weeks to obtain baseline measurements, patients were randomized to receive placebo or eplerenone at 25, 50, 100, or 200 mg once daily. As shown in Figure 70-3, after 12 weeks of treatment, reductions in clinic blood pressures showed a significant dose response in which 25 mg of eplerenone achieved statistical significance compared with placebo for systolic blood pressure. Maximum reductions in blood pressure were achieved with the 100-mg dose, and eplerenone was well tolerated in this 400+ patient study, with no difference in adverse event profiles in the eplerenone-treated groups compared with placebo.⁵⁶

As expected, eplerenone treatment produced dose-dependent elevations in both active renin and aldosterone levels in plasma, consistent with disruption of the normal feedback loop by downstream effectors of the pathway (Figure 70-4). It is important to note that these measurements of renin and aldosterone were obtained 24 hours after the last dose of eplerenone. Therefore, the pharmacodynamic effect of eplerenone persists for 24 hours, even though the terminal plasma half-life of the molecule is only 4 to 6 hours. This dissociation between plasma half-life and the pharmacodynamic effect of eplerenone is expected based on the mechanism of action of the compound. The MR is a cytosolic protein, which binds aldosterone and translocates into the nucleus. In the nucleus, the

*p-Value vs. placebo based on ANCOVA using baseline as covariate and treatment and center as factors.

Figure 70-4 Changes from baseline in active plasma renin and serum aldosterone in essential hypertensive patients after 12 weeks of eplerenone treatment (25-200 mg once daily) and placebo. (Redrawn with permission from White WB, Carr AA, Krause S, et al. Assessment of the novel selective aldosterone blocker eplerenone using ambulatory and clinical blood pressure in patients with systemic hypertension. *Am J Cardiol* 92:38-42, 2003.)

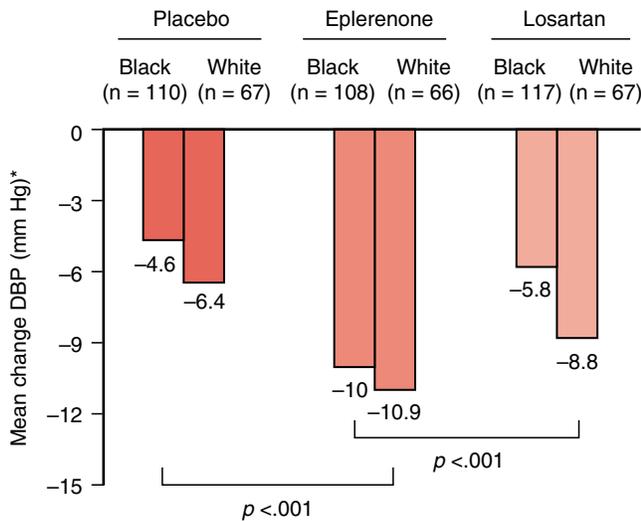

hormone-receptor complex functions as a transcription factor, whereby it binds to DNA, activating gene transcription and new protein synthesis. Therefore, the physiologic effects of aldosterone, like all steroid hormones, take hours to develop, and the response persists long after aldosterone has been cleared from plasma.⁵⁷ Likewise, blockade of this response by eplerenone can persist long after eplerenone has disappeared from the plasma. Thus, the prolonged biologic effect of eplerenone is due to this molecular mechanism of action.

The majority of patients with hypertension require two or more antihypertensive medications to achieve blood pressure treatment goals.⁵⁸ Because ACE inhibitors and ARBs often do not adequately suppress aldosterone, it was of interest to determine the efficacy and tolerability of eplerenone in patients not adequately controlled on these agents.⁵⁹ Hypertensive patients whose blood pressure was not controlled despite ACE inhibitor and ARB use, were randomized in a double-blinded fashion to receive either placebo once daily or eplerenone (50 mg once daily, increasing to 100 mg, if needed) for a period of 8 weeks. Mean seated diastolic blood pressure was significantly reduced (-12.7 ± 0.81 mm Hg) at 8 weeks in patients receiving ARB/eplerenone compared with those on ARB/placebo (-9.3 ± 0.83 mm Hg), as was systolic blood pressure (-16.0 ± 1.37 vs. -9.2 ± 1.41 mm Hg). For the ACE inhibitor-treated patients, systolic blood pressure was reduced significantly by the addition of eplerenone (-13.4 ± 1.35 vs. -7.5 ± 1.31 mm Hg), although diastolic blood pressure was not (-9.9 ± 0.88 vs. -8.0 ± 0.86 mm Hg). Thus selective aldosterone blockade with eplerenone may be useful as add-on therapy in hypertensive patients who are not adequately controlled on an ACE inhibitor or an ARB alone.

It is well known that hypertension and its complications disproportionately affect African Americans compared with whites.⁶⁰ Mortality risk from hypertensive heart disease and renal disease is twofold higher in African Americans compared with whites.⁶¹ In addition, African-American hyperten-

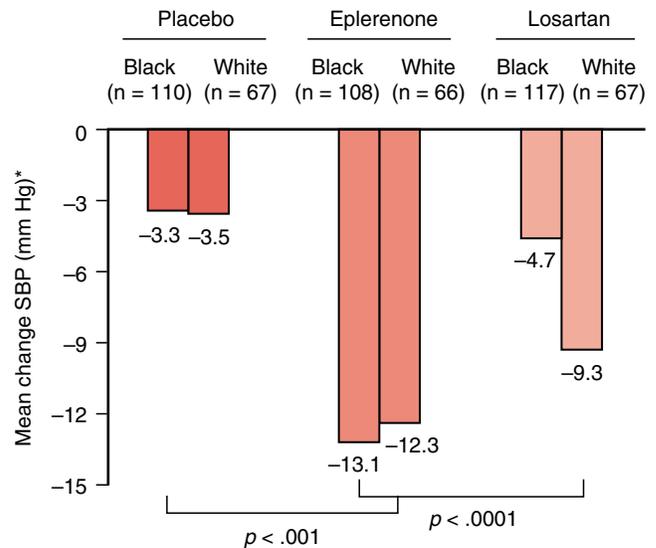

sives are more likely to have low renin levels and therefore are less responsive to monotherapy with blockers of the renin-angiotensin system.⁶² A recent study compared the efficacy of eplerenone treatment versus losartan in hypertensive Black patients (study population included Blacks living in South Africa as well as Black African Americans). The effects of these two agents were also compared in white patients.⁶³ In a randomized, double-blind, placebo- and active-controlled, placebo run-in, parallel-group design, patients with mild-to-moderate hypertension were randomized to placebo, eplerenone (starting at 50 mg once daily up to 200 mg once daily), or losartan (starting at 50 mg once daily up to 100 mg once a day, the maximal recommended dose) to achieve a blood pressure of less than 140/90 mm Hg. Duration of treatment was 16 weeks. Eplerenone was more efficacious at lowering both diastolic (Figure 70-5) and systolic blood pressure (Figure 70-6) in Black hypertensives compared with losartan and placebo. In white patients, losartan and eplerenone were equally efficacious at lowering both systolic and diastolic blood pressure. The incidence of adverse events was similar in the three treatment groups (placebo, losartan, and eplerenone), and no clinically relevant differences in laboratory values were observed, with small increases in serum potassium concentrations within the normal range noted with eplerenone treatment.

Isolated systolic hypertension, primarily in the elderly, is another difficult-to-treat form of hypertension that is increasing in prevalence because the elderly (>60 years of age) are the most rapidly growing segment of our population. Improved treatment of systolic hypertension is an important goal because systolic blood pressure is a stronger predictor of cardiovascular risk than elevated diastolic blood pressure.⁶⁴ The effects of eplerenone and amlodipine on isolated systolic hypertension in the elderly have been compared to assess the usefulness of aldosterone blockade with eplerenone in older patients.⁶⁵ Eplerenone was highly effective at lowering systolic

*Adjusted to treatment, center, and baseline value.

Figure 70-5 Mean changes in diastolic blood pressure (DBP) for placebo-, eplerenone-, and losartan-treated patients with essential hypertension after 16 weeks of therapy. Treatment was initiated with daily doses of eplerenone 50 mg, losartan 50 mg, or matching placebo. If DBP was ≥ 90 mm Hg or if systolic blood pressure was ≥ 140 mm Hg at weeks 4, 8, or 12, the dose was increased to 100 mg/day of losartan and eplerenone. If blood pressure remained above 140/90 mm Hg, the dose was increased to eplerenone 200 mg/day or continued at losartan 100 mg/day, the maximal recommended dose. (Redrawn with permission from Flack JM, Oparil S, Pratt JH, et al. Efficacy and tolerability of eplerenone and losartan in hypertensive black and white patients. *J Am Coll Cardiol* 41:1148-1155, 2003.)

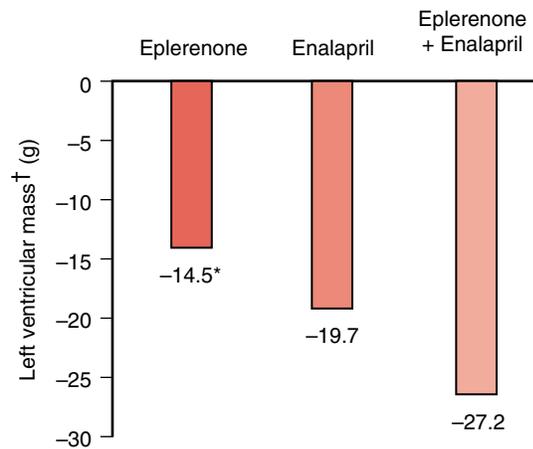

*Adjusted to treatment, center, and baseline value.

Figure 70-6 Mean changes in systolic blood pressure (SBP) for placebo-, eplerenone-, and losartan-treated patients with essential hypertension after 16 weeks of therapy. Treatment was initiated with daily doses of eplerenone 50 mg, losartan 50 mg, or matching placebo. If diastolic blood pressure was ≥ 90 mm Hg or if SBP was ≥ 140 mm Hg at weeks 4, 8, or 12, the dose was increased to 100 mg/day of losartan and eplerenone. If blood pressure remained above 140/90 mm Hg, the dose was increased to eplerenone 200 mg/day or continued at losartan 100 mg/day, the maximal recommended dose. (Redrawn with permission from Flack JM, Oparil S, Pratt JH, et al. Efficacy and tolerability of eplerenone and losartan in hypertensive black and white patients. *J Am Coll Cardiol* 41:1148-1155, 2003.)

blood pressure in this group of patients. After 24 weeks of treatment in patients with a baseline blood pressure of 168/86 mm Hg, eplerenone lowered systolic blood pressure by 20.5 ± 1.1 mm Hg compared with 20.1 ± 1.1 mm Hg with amlodipine. Diastolic blood pressure was slightly lower with amlodipine (-6.9 ± 0.7 mm Hg) compared with eplerenone (-4.5 ± 0.7 mm Hg [$p = .014$]). The effects of eplerenone and amlodipine treatment on arterial pulse wave velocity were assessed in a subset of patients in the study. Interestingly, reductions in baseline carotid-femoral and carotid-radial pulse wave velocity were significant in the eplerenone and amlodipine groups, and both compounds lowered pulse wave velocity similarly. This suggests that both compounds are effective in improving vascular compliance or reducing vessel wall stiffness. Both amlodipine and eplerenone had good tolerability and safety profiles in this older-patient population.

LVH is associated with a markedly increased risk of cardiovascular events in essential hypertensive patients, independent of blood pressure.⁶⁶ In essential hypertensive patients, LV mass index correlated strongly with serum aldosterone levels even after adjustments for blood pressure.⁶ These data suggest that aldosterone blockade in hypertension may lead to regression of LVH. A 9-month double-blind, randomized study was performed to determine whether aldosterone blockade with

eplerenone, alone or in combination with an ACE inhibitor, could lead to regression of LVH in essential hypertensive patients.⁶⁷ Patients with LVH were randomly assigned to receive eplerenone (200 mg once daily), enalapril (40 mg once daily), or eplerenone (200 mg once daily) with enalapril (10 mg once daily). Changes in LV mass were measured using magnetic resonance imaging (MRI). Eight weeks into the study, hydrochlorothiazide or amlodipine could be added, if diastolic blood pressure remained above 90 mm Hg. As shown in Figure 70-7, eplerenone and enalapril monotherapies significantly reduced LV mass, and the combination resulted in a reduction in LV mass that was greater than the effect of eplerenone-alone and numerically not statistically greater than the enalapril alone response. LVH regression achieved with aldosterone blockade was additive to that seen with ACE inhibition alone. Reductions in diastolic blood pressure were similar in the three treatment groups, as were reductions in systolic blood pressure, although the fall in systolic pressure was somewhat greater in the enalapril/eplerenone group compared to the eplerenone-alone group (Figure 70-8). When the relationship between changes in LV mass and changes in blood pressure was examined, blood pressure reduction alone did not account for the LVH regression. This conclusion is similar to those reached by investigators in the LIFE study

†Adjusted to treatment, center, and baseline value.

**p*-Value eplerenone vs. eplerenone + enalapril: *p* = .007

Figure 70-7 Adjusted mean change in LV mass from baseline as measured by cardiac MRI after 9 months of treatment in hypertensive patients with LVH treated with eplerenone, enalapril, or the combination of enalapril and eplerenone. LVH was diagnosed by either ECG or echocardiogram. After withdrawal of antihypertensive medications, patients took placebo for a 14-day, single-blind, run-in period. Patients were then randomly assigned to receive once-daily eplerenone (200 mg), enalapril (40 mg), or eplerenone (200 mg) with enalapril (10 mg). These doses were reached after a 4-week forced titration schedule. If blood pressure was not controlled (diastolic blood pressure ≥ 90 mm Hg or systolic blood pressure > 180 mm Hg at week 8), patients received open-label hydrochlorothiazide 12.5-25 mg and/or amlodipine 10 mg. (Redrawn with permission from Pitt B, Reichek N, Willenbrock R, et al. Effects of eplerenone, enalapril, and eplerenone/enalapril in patients with essential hypertension and left ventricular hypertrophy. The 4E-left ventricular hypertrophy study. *Circulation* 108: 1831-1838, 2003.)

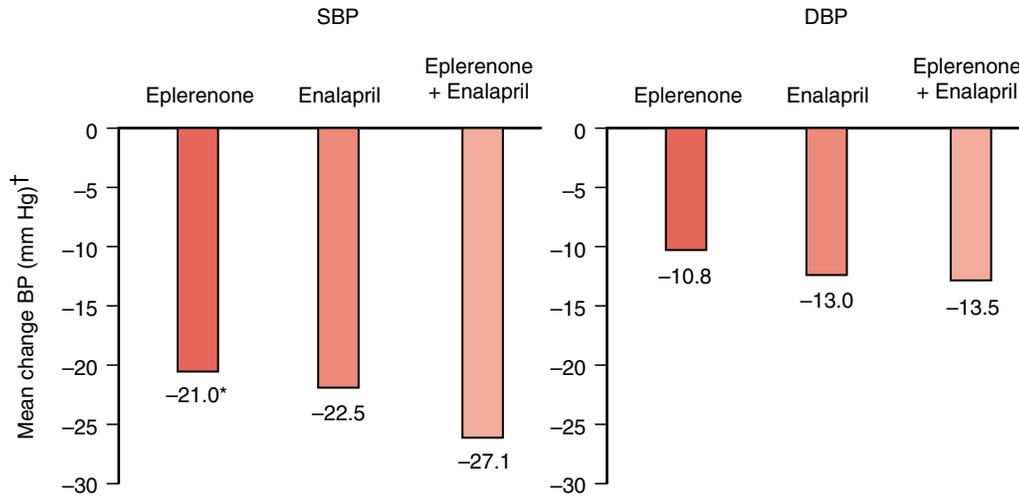

(Losartan Intervention For Endpoint Reduction), in which LV mass reduction was independent of blood pressure reduction.⁶⁸ Additional studies are required to understand the optimal dose-response relationship of eplerenone with an ACE inhibitor in this patient population and to establish that the combination of ACE inhibitor and eplerenone reduces morbidity and mortality in patients with essential hypertension and LVH.

Numerous preclinical studies support the notion that aldosterone blockade is renal protective in hypertensive animal models, independent of blood pressure lowering.⁶⁹ Rocha et al. demonstrated that removal of aldosterone, either by adrenalectomy or through administration of the selective aldosterone receptor antagonist eplerenone, markedly reduced renal damage, independent of blood pressure reduction, in the L-NAME/Ang II/salt-hypertensive rat model.²² In this study, adrenalectomy or eplerenone treatment prevented the development of proteinuria in (L-NAME/Ang II/salt-treated rats, and the add back of aldosterone to the adrenalectomized rats restored the proteinuria associated with L-NAME/Ang II/salt treatment. These studies suggest that aldosterone, rather than

Ang II, may be the important mediator of renal damage in hypertensive models produced via activation of the RAAS.

A clinical study has been conducted to determine whether aldosterone blockade with eplerenone is as effective as enalapril in reducing microalbuminuria in type 2 diabetic hypertensive patients and whether the combination may be more effective than either monotherapy.⁷⁰ Type 2 diabetic patients with mild-to-moderate hypertension and microalbuminuria (urinary albumin/creatinine ratio [UACR] ≥ 100 mg/g) were randomly assigned to receive initially once-daily treatment with eplerenone 50 mg, enalapril 10 mg, or the combination of both. Study medications were force-titrated up at week 2 and week 4, regardless of blood pressure level, to the maximum doses (200 mg of eplerenone, 40 mg of enalapril, or eplerenone 200 mg/enalapril 10 mg). At week 8 or later, if blood pressure remained uncontrolled (≥ 90 mm Hg), hydrochlorothiazide (12.5-25 mg) could be added, if needed. Treatment effects on UACR and blood pressure are shown in Table 70-2. Eplerenone reduced proteinuria significantly (by 62%) after 6 months of treatment, compared with 45% in the enalapril group and 74% in the eplerenone/enalapril group (*p* < .001 vs. baseline for all treatments). Interestingly, the combination of eplerenone/enalapril reduced proteinuria to a greater extent than either monotherapy, suggesting that the renoprotective effects of aldosterone blockade are additive to the ACE inhibitor effects. Blood pressure reductions were similar in all treatment groups except that diastolic blood pressure was reduced more in the eplerenone/enalapril combination group compared with the eplerenone monotherapy group (-16.2 ± 0.86 vs. -13.2 ± 0.84 mm Hg; *p* = .015). Systolic blood pressure was reduced similarly in all three groups, suggesting that the antiproteinuric effects of these treatments are somewhat independent of blood pressure lowering. Elevated serum potassium was noted because maximal doses of eplerenone and enalapril were used, but potassium elevations were comparable with what has been reported with ACE inhibitors in similar patient populations.^{71,72} However, additional studies are required to explore the dose range of eplerenone and enalapril that would mitigate the risk of elevated potassium but still preserve the renoprotective effects of these two therapeutic interventions.

Analysis of the relationship between blood pressure lowering and serum potassium concentration with eplerenone in essential hypertensives has produced some surprising results.⁷³ Two titration-to-effect clinical trials with similar study designs were used to determine whether the blood pressure-lowering response to eplerenone was related to changes in serum potassium. One would presume that serum potassium changes are a marker of eplerenone inhibition of aldosterone effects on sodium and potassium excretion in the distal tubule, a classic epithelial target tissue of aldosterone. A total of 397 patients from two double-blind, randomized, multicenter, placebo-controlled, lead-in, parallel-group, titration-to-effect studies were included in the analysis. After a 4-week placebo run-in, patients were given 50 mg of eplerenone once daily. If after 4 weeks any participant did not meet blood pressure goals, he or she was up-titrated to 100 mg. After 8 weeks, patients not achieving goals were further up-titrated to 200 mg once daily. Antihypertensive response status was defined by diastolic blood pressure (< 90 mm Hg were responders; ≥ 90 mm Hg were nonresponders). Figure 70-9 shows the reduction in systolic blood pressure in “responders”

†Adjusted to treatment, center, and baseline value.

**p*-Value eplerenone vs. eplerenone + enalapril: *p* = .017

Figure 70-8 Systolic and diastolic blood pressure after 9 months of treatment in hypertensive patients with LVH treated with eplerenone, enalapril, or the combination of enalapril plus eplerenone. LVH was diagnosed by either ECG or echocardiogram. After withdrawal of antihypertensive medications, patients took placebo for a 14-day, single-blind, run-in period. Patients were then randomly assigned to receive once-daily eplerenone (200 mg), enalapril (40 mg), or eplerenone (200 mg) with enalapril (10 mg). These doses were reached after a 4-week forced titration schedule. If blood pressure was not controlled (diastolic blood pressure ≥ 90 mm Hg or systolic blood pressure > 180 mm Hg at week 8), patients received open-label hydrochlorothiazide 12.5-25 mg and/or amlodipine 10 mg. (Redrawn with permission from Pitt B, Reichek N, Willenbrock R, et al. Effects of eplerenone, enalapril, and eplerenone/enalapril in patients with essential hypertension and left ventricular hypertrophy. and “nonresponders” and changes in serum potassium over time. Interestingly, the change in serum potassium did not predict the antihypertensive response to eplerenone at any dose. Such findings suggest that the antihypertensive action of eplerenone is linked to blockade of aldosterone effects on nonclassic, nonepithelial target tissues (brain, heart, vascular smooth muscle) rather than classic, epithelial, electrolyte transporting target tissues, such as the kidney.

SUMMARY

There is now compelling evidence that aldosterone mediates significant deleterious effects on the cardiovascular system by binding and activating MR in the heart, brain, and blood vessels. These effects include vascular inflammation and injury, endothelial dysfunction, myocardial and vascular fibrosis, proarrhythmic, and hypertrophic effects on cardiomy-

Figure 70-9 Changes in systolic blood pressure (**A**) as a function of changes in serum potassium concentration (**B**) for responders and nonresponders at each week/dose interval in patients from two clinical studies conducted as part of the eplerenone Phase III hypertension development program. Data from essential hypertensive patients in the two double-blind, randomized, multicenter, placebo-controlled, titration-to-effect studies were pooled for analysis. Patients were given 50 mg of eplerenone once daily, and if after 4 weeks, blood pressure goals were not met, these patients were up-titrated to 100 mg of eplerenone once daily. An additional up-titration to 200 mg once daily occurred, if necessary. (With permission from Levy DG, Rocha R, Funder JW. Distinguishing the antihypertensive and electrolyte effects of eplerenone. *J Clin Endocrinol Metab* 89:2736-2749, 2004.)

ocytes and centrally mediated hypertensive effects. In addition to the classic genomic effects of aldosterone, nongenomic actions have been identified in vascular tissue. Blockade of aldosterone at MR produces target organ protective effects in hypertensive patients by reducing LVH and microalbuminuria. Eplerenone is significantly more selective for MR than spironolactone, and this improved selectivity measured in vitro has translated into improved tolerability compared

with spironolactone. Interestingly, preliminary studies suggest that eplerenone blocks nongenomic effects of aldosterone in vascular tissues, whereas spironolactone does not. However, it is not clear whether nongenomic effects of aldosterone contribute to the detrimental action of aldosterone on the cardiovascular system. Eplerenone lowers blood pressure quite effectively in essential hypertensive patients, irrespective of race, age, or gender. This could be due to the fact that primary aldosteronism is a substantially more common cause of hypertension than was previously appreciated.⁷⁴⁻⁷⁶ although this hypothesis remains somewhat controversial.⁷⁷ Nonetheless, with only a minority of treated hypertensive patients actually reaching target blood pressures, eplerenone (Inspra) represents an important addition to the armamentarium of agents to treat this disorder.

Vasopeptidase Inhibitors

Luis Miguel Ruilope

INTRODUCTION

Studies performed in the past 50 years have clearly documented that hypertension is a major risk factor for cardiovascular morbidity and mortality.¹ Furthermore, the reduction of diastolic and systolic blood pressure with drugs is associated with a reduction of almost all hypertension-related diseases, such as stroke, myocardial infarction (MI), heart failure, and vascular mortality.²⁻⁶ Treatment with any commonly used regimen reduces the risk of total major cardiovascular events, and larger reductions in blood pressure produce larger reductions in risk.⁶ These findings have made research on antihypertensive drugs extremely active, with the development of a wide range of agents that act through different mechanisms and thus attack high blood pressure from different angles.

Vasopeptidase inhibitors are a class of drugs that simultaneously inhibit both angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP). ACE inhibitors have a well-established clinical role in hypertension and heart failure⁷ (see Chapter 35).

NEP is a membrane-bound metalloprotease found principally in the brush-border membrane of renal tubules, in the lungs, intestine, adrenal, brain, heart, and peripheral blood vessels.^{8,9} NEP plays a role in the initial enzymatic degradation of the bioactive carboxyterminal portions of the natriuretic peptides and has many other substrates, for example, adrenomedullin, angiotensins I and II, endothelin, bradykinin, substance P, chemotactic peptide, enkephalins, and the amyloid (β) peptide.^{10,11}

The natriuretic peptides constitute a family of peptides involved in the regulation of blood pressure and plasma volume.¹² The atrial and brain-derived natriuretic peptides are produced principally in the myocardium in response to atrial distention. C-type natriuretic peptide, found in the kidney, heart, lung, and vascular endothelium, is released in response to shear stress.⁹ These peptides bind to specific, high-affinity cell-surface receptors. Natriuretic peptides exert physiologic effects at several sites, resulting in vasodilation, natriuresis, diuresis, decreased aldosterone release, decreased cell growth, and inhibition of the sympathetic nervous system and the renin-angiotensin-aldosterone system.¹² Atrial natriuretic peptide also inhibits production of endothelin.¹³

NEUTRAL ENDOPEPTIDASE INHIBITION

Because inhibition of NEP protects the natriuretic peptides and bradykinin from catabolism, it should be beneficial in hypertension and congestive heart failure treatments. However, discordant findings have been reported in hypertensive patients.¹⁴⁻¹⁷ The variable effect of NEP inhibition on blood pressure and systemic vascular resistance is likely to be due to increased levels of some vasoconstrictors such as Ang II

and endothelin and to reduced levels of the vasodilator Ang-(1-7). Increased blood pressure during NEP inhibition in healthy volunteers was associated with an increase in plasma endothelin levels.¹⁷ Both animal and clinical studies show that NEP inhibition increases the plasma levels of angiotensins I and II, aldosterone, and catecholamines.^{14,15,18,19}

In patients with congestive heart failure, NEP inhibitors have beneficial hemodynamic effects. NEP inhibition is associated with reduced cardiac filling pressures and decreased indices of the renin axis.²⁰ NEP inhibition may also directly protect endothelial function and reduce atheromatous changes in the vascular wall.²¹

Vasopeptidase Inhibitors: Rationale for Combining ACE and NEP Inhibitors

Like ACE, NEP is a peptidase found in both endothelial and epithelial cells, mainly in the lungs, kidneys, and blood vessels,^{8,9} that blocks the renin system at different levels (see Chapter 9). Therefore, NEP inhibition protects natriuretic peptides from inactivation, whereas ACE inhibition attenuates the formation of angiotensin II, which acts as a physiologic antagonist of the atrial natriuretic peptide. ACE inhibition^{22,23} not only interrupts the renin-angiotensin system, but also increases bradykinin, nitric oxide, and prostacyclin. Potential benefits of bradykinin include natriuretic, vasodilator, and cardioprotective effects; antihypertrophic and antiarrhythmic effects; and improved glucose uptake by myocytes.²⁴

Simultaneous inhibition of both ACE and NEP lowers blood pressure more than inhibition of either enzyme alone in both animals and humans. For example, in patients given candoxatril (a NEP inhibitor) for a month, the blood pressure was unchanged,²⁵ and in healthy volunteers, candoxatril administration was followed by a rise in systolic pressure in association with an increase in the plasma concentration of endothelin.¹⁷ However, in spontaneously hypertensive rats the combination of a NEP inhibitor (SCH 42495) and the ACE inhibitor captopril, as well as the dual NEP/ACE inhibitor S21402, reduced systolic blood pressure more effectively than the ACE inhibitor or the NEP inhibitor alone.²⁶ Favrat et al.¹⁶ compared a NEP inhibitor (sinorphan) with captopril and with the two drugs in combination in patients with essential hypertension. Neither agent alone produced significant day-long blood pressure changes, but there were substantial decreases with the combination treatment.

Inhibition of NEP and ACE results in vasodilator effects and, possibly, tissue protective effects, at least in part to reduced formation of angiotensin II and reduced degradation of natriuretic peptides (Figure 71-1). Because NEP and ACE inhibitors are intimately concerned with regulating structural and functional properties of the heart and blood vessels, the term *vasopeptidase inhibitor* has been coined for this new drug class.

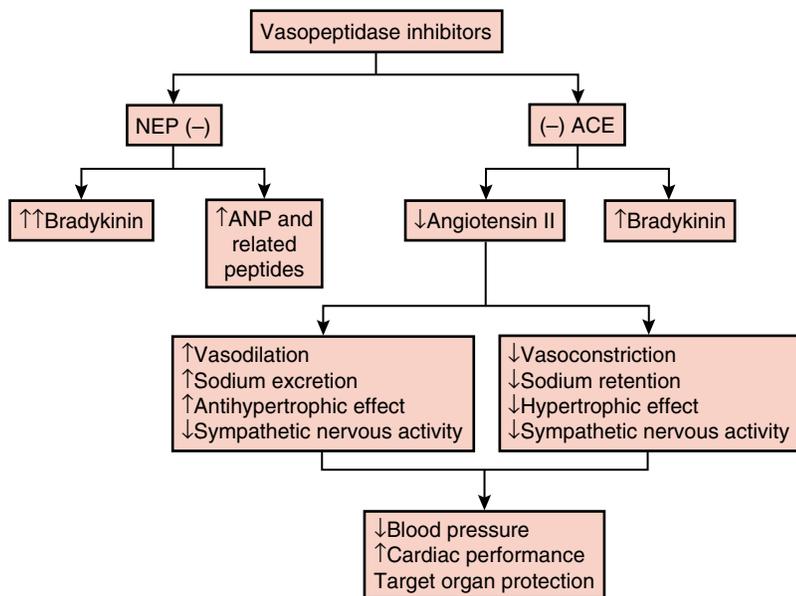

Figure 71-1 Functional effects of vasopeptidase inhibition. NEP, neutral endopeptidase; ACE, angiotensin-converting enzyme; ANP, atrial natriuretic peptide.

VASOPEPTIDASE INHIBITORS: AVAILABLE COMPOUNDS

Several dual ACE/NEP inhibitors have been developed; some have been assessed clinically, and others have not. The most studied vasopeptidase inhibitor is omapatrilat. After preclinical and preliminary clinical studies, omapatrilat was considered a very promising agent for treating patients with hypertension and congestive heart failure, the two main indications for which vasopeptidase inhibitors were targeted. However, an unacceptable high incidence of angioedema,²⁷ threefold higher than that of ACE inhibitors, has likely stopped the development of this new class of agents.

A description of some vasopeptidase inhibitors follows.

Sampatrilat

Sampatrilat is a dual inhibitor of NEP and ACE, developed by Pfizer and Shire for the potential treatment of hypertension.²⁸ Sampatrilat reduced mean arterial pressure, improved daily sodium excretion, increased renal blood flow, and decreased left ventricular mass in a dog model of heart failure. In hypercholesterolemic rabbits, sampatrilat suppressed atherogenesis and improved endothelial function.²⁹ In rats with congestive heart failure following left coronary artery ligation (CAL), sampatrilat improved hemodynamic function and cardiac remodeling through a direct action on the failing heart.³⁰ Sampatrilat (30 mg/kg/day) was administered orally from the first to sixth week after the operation. Sampatrilat reduced the mortality of the rats with CAL (20% vs. 57% for untreated rats). Treatment with sampatrilat for 5 weeks suppressed tissue ACE and NEP activities. Sampatrilat did not affect arterial blood pressure but attenuated CAL-induced increases in the left ventricular end-diastolic pressure, heart weight, and collagen content of the viable left ventricle. The mechanism by which sampatrilat improved cardiac remodeling may be attributable to direct inhibition of cardiac fibrosis, possibly through the cardiac natriuretic peptide system. In humans, sampatrilat was tested clinically in a comparison with lisinopril in

120 patients with mild-to-moderate essential hypertension.³¹ By day 10, 200 mg sampatrilat was nearly as effective as lisinopril 20 mg in lowering systolic pressure but was less effective in lowering diastolic pressure. ACE activity decreased by only 40% to 50%, and plasma renin activity during sampatrilat treatment was unchanged. In a study of African American patients with hypertension,³² sampatrilat produced a sustained decrease in mean ambulatory blood pressure over the 56-day treatment period, with a greater treatment effect on diastolic blood pressure than lisinopril at day 56. Treatment-emergent adverse events were similar in both treatment groups.

MDL 100,240

MDL 100,240 is a prodrug that, on conversion to MDL 100,173, acts as a potent dual inhibitor of ACE and NEP with a balanced effect on both enzymes. Studies in experimental models of hypertension and congestive heart failure confirmed the vasodilator and natriuretic effects of MDL, which appear to be independent of the degree of activation of the renin-angiotensin-aldosterone system. In addition, MDL 100,240 was effective both in preventing and regressing hypertension-induced vascular remodeling and cardiac hypertrophy.³³ In a transgenic rat model of hypertension³⁴ with severe cardiovascular damage due to enhanced tissue synthesis of angiotensin II both MDL 100,240 and ramipril significantly lowered blood pressure compared with placebo. Both drugs regressed left ventricular hypertrophy. MDL 100,240 also prevented aortic dilation and hypertrophy of the mesenteric arterioles and reduced constrictor responses to phenylephrine and endothelin-1, as well as plasma aldosterone and creatinine levels. Thus, severe hypertension and related cardiovascular disease were regressed by MDL 100,240. In 12 healthy volunteers, single 25-mg (intravenous) doses of the drug reduced systolic blood pressure, provided the diet contained no more than 80 mg sodium per day. Urinary flow rate increased significantly during the first 2 hours after dosing, together with an increase in sodium excretion. MDL 100,240 also increased excretion of uric acid.³⁵ In

normal volunteers, MDL 100,240 had a half-life of about 7.5 hours during once daily administration.³⁶ There was no evidence of accumulation when it was administered over an 8-day period.

Gemopatrilat

This azepinone derivative BMS-189921 showed blood pressure-lowering properties similar to omapatrilat in animal models of hypertension.³⁷ In normotensive Wistar nephrotic rats, the renoprotective actions of gemopatrilat were dependent on dietary-sodium intake: During a low-sodium diet, gemopatrilat was renoprotective but less effective than lisinopril. However, its therapeutic efficacy was completely abolished by a high-sodium diet.³⁸

Fasidotril

This compound also proved to be effective in animal models of hypertension.³⁹ Fasidotril treatment (100 mg/kg twice daily for 3 weeks) resulted in a progressive and sustained decrease in systolic blood pressure (−20 to −30 mm Hg) in spontaneously hypertensive and Goldblatt (renovascular) rats compared with vehicle-treated rats and prevented the progressive rise in blood pressure in DOCA-salt hypertensive rats.³⁹ At a dose of 100 mg twice daily, it was studied in a placebo-controlled trial in 57 patients with essential hypertension. After 42 days, supine and standing systolic and diastolic blood pressures were 7.4/5.4 mm Hg and 7.6/6.8 mm Hg lower, respectively, in the drug-treated than in the placebo group.³⁹

Mixanpril

Mixanpril is a benzothioacetate prodrug of S21402, which has been studied extensively in various rat rodent models.⁴⁰ S21402 decreased blood pressure similarly in DOCA-salt and renovascular hypertensive rats, indicating that the antihypertensive effect is independent of the renin-angiotensin system. In diabetic spontaneously hypertensive rats, mean systolic blood pressure (200 ± 5 mm Hg) was reduced by mixanpril (176 ± 2 mm Hg) as it was by captopril (162 ± 5 mm Hg), valsartan (173 ± 5 mm Hg), and amlodipine (159 ± 4 mm Hg), and was further reduced by the combination of captopril with valsartan (131 ± 5 mm Hg). Only mixanpril and the combination of captopril and valsartan significantly reduced mesenteric weight. The mesenteric wall:lumen ratio was reduced by all drugs but to a greater extent by the combination of captopril and valsartan.⁴¹

Z-13752A

This drug has been studied in a canine model of coronary-artery occlusion, where it proved to be protective against the adverse consequences of intervention.⁴² This protection was largely due to potentiation of released bradykinin.⁴³ Pharmacokinetic studies in healthy volunteers suggested that a once-daily dosing could be appropriate.⁴³

Omapatrilat

The most extensively investigated ACE/NEP inhibitor is omapatrilat (Bristol Myers Squibb). This compound has similar inhibitory activity against both ACE and NEP.⁴⁴

ANIMAL STUDIES

As reviewed by Weber⁴⁴ and more recently by Campbell,⁴⁵ multiple experimental studies have demonstrated that omapatrilat lowers blood pressure in animals. The major characteristic of omapatrilat is that it lowers blood pressure in all models of hypertension whatever the degree of activity of the renin-angiotensin system.⁴⁶ In Dahl salt-sensitive rats, a high-sodium diet significantly impaired endothelium-dependent relaxation. When these animals were treated with omapatrilat, there was a far greater return toward normal responsiveness than there was with captopril.⁴⁷ Relaxation was reduced to 31% of baseline by the high-salt diet, and was then increased to 86% by omapatrilat, and to only 56% by captopril. In spontaneously hypertensive rats, omapatrilat induced a sustained lowering of systolic blood pressure (−68 mm Hg) without change in cardiac rate. Blood pressure normalization was accompanied by increases in plasma angiotensins I, II, and (1-7) levels, with important increases in urinary excretion rates of angiotensin I and (1-7) but not angiotensin II.⁴⁸ On the other hand, in conscious dogs made hypertensive by bilateral renal wrapping, intravenous administration of omapatrilat reduced peak left ventricular pressure through arterial vasodilation and preload reduction. Omapatrilat increased plasma levels of adrenomedullin, whereas levels of the natriuretic peptides and cyclic guanosine monophosphate were unchanged.⁴⁹

Experimental studies have also reported that omapatrilat has beneficial cardiorenal and humoral actions in different models of congestive heart failure.^{45,46} In a cardiomyopathic hamster model, treatment with omapatrilat decreased left-ventricular end-diastolic pressure and left-ventricular systolic pressure. The changes were associated with a 40% increase in cardiac output, a 47% decrease in peripheral vascular resistance, and a decrease in mean arterial pressure. In rats, survival 24 hours after MI improved with omapatrilat.⁵⁰ Omapatrilat reduced infarct size 24 hours after MI and reduced ventricular arrhythmia score 1 to 12 hours after. Rats treated with omapatrilat had reduced left ventricular diastolic and systolic dimensions and left and right ventricular weights compared with controls, indicating a decrease in reactive hypertrophy. Improvement in cardiac remodeling was accompanied by improved ventricular function.⁵⁰ Cardiomyocyte apoptosis occurs at a high level late after MI and contributes to adverse cardiac remodeling.⁵¹ Myocardial apoptosis was reduced by ACE inhibition, but vasopeptidase inhibition was even more effective in preventing adverse cardiac remodeling after myocardial infarction.⁵¹

In insulin-resistant Zucker fatty rats, omapatrilat resulted in a lower rate of endogenous glucose production than placebo both at baseline and after insulin administration at low and high doses. The insulin-sensitizing effects of omapatrilat were blocked by HOE-140 (a bradykinin, B₂ receptor antagonist) and NG-nitro L-arginine methyl ester (a nitric oxide synthase inhibitor) in all tissues except myocardium. This insulin-sensitizing effect was greater than that of ramipril.⁵² Furthermore, a greater attenuation of albuminuria was afforded by omapatrilat than perindopril in diabetic spontaneously hypertensive rats. Omapatrilat reduced renal NEP binding by 33%, associated with a reduction in albuminuria and prevention of renal structural injury (assessed by glomerulosclerotic index and tubulointerstitial area).⁵³

PHARMACOLOGY

Omapatrilat has a plasma half-life of 14 to 19 hours at the 10- to 80-mg/day dose.⁵⁴ It is absorbed rapidly, and peak concentrations are reached in only 0.5 to 2.0 hours. The ratio of the area under the curve on day 10 to that of day 1 when this drug was given constantly during a 10-day period was 1.65. The drug has a prolonged elimination profile. There is only a small tendency to accumulation, and accumulation seems to not be increased in the presence of reduced renal function.⁵⁵ Omapatrilat reduces serum ACE activity by more than 80% during the full 24-hour dosing interval at all doses. NEP is also inhibited.⁵⁴ Changes in urinary atrial natriuretic peptide excretion during chronic (7 weeks) treatment with omapatrilat were dose-dependent,⁵⁴ and were sustained for more than 24 hours postdose.

Preliminary Human Studies

Omapatrilat lowers blood pressure dose dependently^{56,57} at doses ranging between 1 and 80 mg/dl in normotensive persons and in patients with mild to moderate hypertension, regardless of age, race, or gender.

In patients with hypertension, omapatrilat produces greater decreases in systolic, diastolic, and pulse pressure than ACE inhibition alone.^{44,45,58} Omapatrilat (80 mg/dl) was a more effective hypotensive agent than was enalapril (40 mg/dl) over 12 weeks of therapy in hypertensive persons studied 24 hours after the last administration. Comparison with the calcium channel blocker amlodipine also revealed more pronounced antihypertensive effects of omapatrilat.⁵⁹

Clinical Trials in Hypertension

The Omapatrilat Cardiovascular Treatment Assessment Versus Enalapril (OCTAVE)²⁷ study randomized 25,302 hypertensive patients to either omapatrilat titrated up to 80 mg daily or enalapril titrated up to 40 mg/day for a period of 24 weeks. Compared with enalapril, omapatrilat reduced blood pressure further (3 mm Hg, systolic and 2 mm Hg, diastolic). Although antihypertensive efficacy was an important outcome, the chief interest in this study was to assess the relative incidence of angioedema in the two treatment groups. Angioedema was reported in 2.17% of the patients who received omapatrilat and in 0.68% of those receiving enalapril. Individual episodes of angioedema with omapatrilat were more severe and occurred earlier, the majority within the first few hours after the initial dose. The overall relative risk for angioedema was 3.1 times higher in the omapatrilat group, and the risk for angioedema requiring hospitalization was 9.5 times higher. However, most patients did not require aggressive treatment: 59% and 76% of persons experiencing angioedema with omapatrilat and enalapril, respectively, received either no treatment or were treated with antihistamines only. Risk factors predisposing to angioedema included Black race and smoking. In Black patients, the rate of angioedema was increased approximately threefold with both omapatrilat and enalapril (5.54% and 1.62%, respectively) compared with other racial/ethnic groups. The rate of angioedema was also increased in current smokers receiving omapatrilat (3.93%) but not enalapril (0.81%). The cause of angioedema in patients taking omapatrilat is not known,

although mediation by bradykinin has been suggested, because inhibition of ACE and of NEP can each produce increases in bradykinin.

A large international placebo-controlled trial was proposed to study the effects of omapatrilat in elderly patients with isolated stage 1 systolic hypertension.⁶⁰ OPERA (Omapatrilat in Persons with Enhanced Risk of Atherosclerotic Events) was designed to study 12,600 participants in a 5-year multinational, randomized, double-blind, placebo-controlled trial. The primary objective of OPERA was to test the hypothesis that omapatrilat significantly enhances survival and reduces cardiovascular outcomes in older (>65 years) men and women with enhanced risk of atherosclerotic events due to stage 1 isolated systolic hypertension. OPERA would also determine whether treatment was justified in older patients with mild systolic hypertension because there is no clear evidence that any therapeutic intervention is of clinical value in this patient group. The OPERA study, which was planned before OCTAVE, was dropped when the results of OCTAVE became available.

Clinical Trials in Congestive Heart Failure

Omapatrilat produces an acute dose-related hemodynamic improvement in heart failure patients that is maintained for at least 12 weeks.^{61,62} Omapatrilat not only reduced blood pressure in patients with heart failure but also reduced the augmentation index and increased postobstructive brachial artery reactive hyperemia.⁶³ In 48 patients in New York Heart Association (NYHA) functional class II or III, with left ventricular ejection fraction less than or equal to 40% and in sinus rhythm, omapatrilat improved functional status at 12 weeks. Dose-dependent improvements in left ventricular ejection fraction and left ventricular end-systolic wall stress (sigma) were seen, together with a reduction in systolic blood pressure. There was evidence of a natriuretic effect, and total blood volume decreased. Omapatrilat induced an increase in postdose plasma atrial natriuretic peptide levels in the high-dose groups, with a reduction in predose plasma brain natriuretic peptide and epinephrine levels after 12 weeks of therapy.⁶⁴

The IMPRESS (Inhibition of Metallo Protease by BMS-186716 in a Randomized Exercise and Symptoms Study in Subjects with Heart Failure) trial⁶⁵ compared 289 patients treated with omapatrilat (target dose 40 mg daily) and 284 patients given lisinopril (target dose 20 mg daily). All patients had previously been on an ACE inhibitor. Omapatrilat was more effective in producing improvements in class III/IV patients. By the end of the 7-month observation period, omapatrilat had a significant advantage in the combined endpoint of mortality, admission for worsening heart failure, and discontinuation of study medication because of worsening heart failure.

These promising findings led to a large clinical trial: Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE). The OVERTURE study⁶⁶ assigned 5770 patients with NYHA classes II to IV heart failure to treatment with either enalapril (10 mg twice daily) or omapatrilat (40 mg once daily) for a mean of 14.5 months. Enalapril or omapatrilat was added to conventional therapy that included β -blockers in 50% patients. The primary endpoint of combined risk of death or hospitalization for heart failure was not different for the two treatment groups, fulfilling prespecified criteria for noninferiority but not for superiority.

Analysis of secondary outcomes showed that the omapatrilat group had a 9% lower risk of cardiovascular death or hospitalization and a 6% lower risk of death. Posthoc analysis showed an 11% lower risk for hospitalization for heart failure in patients treated with omapatrilat.

Although angioedema was reported more commonly with omapatrilat than enalapril, the absolute frequency, incremental risk, and severity in the OVERTURE study was lower than that reported in hypertensive patients. This was attributed to the possibility that patients with heart failure may be resistant to the ability of bradykinin to produce cutaneous exudation, as it was reported in dogs with experimental heart failure.⁶⁷ Hypotension and dizziness were more frequent with omapatrilat (19.5% and 19.4%, respectively) than with enalapril (11.5% and 13.9%), but heart failure and renal impairment were less frequent with omapatrilat (22.6% and 6.8%) than with enalapril (25.6% and 10.1%). The incidence of cough was similar for omapatrilat and enalapril therapy (9.7% and 9.0%, respectively). In conclusion, the OVERTURE trial demonstrated that omapatrilat reduced morbidity and mortality in patients with moderate-to-severe heart failure but was not more effective than ACE inhibition alone in reducing the risk of a primary clinical event. Secondary and posthoc analyses focused on all cardiovascular events suggested the possibility of between-group differences in favor of omapatrilat. Furthermore, omapatrilat treatment has been shown to increase endothelin-1 and antiinflammatory cytokine levels in patients with chronic heart failure.⁶⁸ Sheth et al.⁶⁸ randomized 107 patients with ischemic or dilated cardiomyopathy, NYHA functional classes II to III, with left ventricular ejection less than 40%, and on ACE inhibitor therapy either to omapatrilat 40 mg daily or lisinopril 20 mg/day. C-terminal atrial natriuretic peptide levels decreased with lisinopril but not with omapatrilat. Endothelin-1 levels increased in both groups, but the increase reached statistical significance only with omapatrilat. Levels of the proinflammatory cytokine interleukin-6 tended to decrease, and the anti-inflammatory cytokine interleukin-10 increased in both groups but with statistical significance only for omapatrilat therapy. These effects of omapatrilat on endothelin-1 and antiinflammatory cytokines may provide potential explanations for differences in clinical outcomes in heart failure patients.

PERSPECTIVES

The natriuretic peptides have actions that might be considered beneficial for hypertensive patients—vasodilation, natriuresis, and inhibition of the sympathetic nervous system and the renin-angiotensin-aldosterone system.^{45,69} Several studies with omapatrilat have shown that it is a highly potent antihypertensive agent, more potent than some of the leading antihypertensives, such as losartan, amlodipine, and lisinopril.⁴⁴ One factor that may give vasopeptidases the edge over ACE inhibitors because antihypertensives may be their greater potentiation of bradykinin is perhaps their Achilles' heel, as well. The angioedema risk with omapatrilat has cast a shadow over the entire ACE/NEP inhibitor class.

The future of the vasopeptidase inhibitors will depend on the ability to improve the risk:benefit ratio either by developing agents that produce less angioedema, or by defining more precisely a high-risk population that could benefit from dual

ACE/NEP inhibition. The NEP drug class probably does have a role in hypertension, although probably only in otherwise difficult-to-manage patients, where the risk of angioedema is counterbalanced by having effected blood pressure control. Furthermore, omapatrilat reduced albuminuria, prevented renal structural injury, and increased insulin sensitivity in diabetic spontaneously hypertensive rats.⁵³ Patients with diabetic renal failure represent a rapidly growing population with high cardiovascular and renal risk. Whether vasopeptidase inhibitors would help in retarding the progression of renal failure in these patients is not known. Additional studies are warranted in this high-risk population.

Renin Inhibitors

Jürg Nussberger

PRINCIPLES

One century after the discovery of renin by Tigerstedt and Bergman,¹ it is well established that antagonizing the renin-angiotensin-aldosterone system is a successful treatment for cardiovascular and renal disease. This system maintains cardiovascular homeostasis by up- and down-regulating receptor-mediated effects of the key hormone angiotensin II (Ang II). It appears to primarily regulate the renal Ang II concentration.² Ang II is an octapeptide with potent vasoconstrictor and sodium-retaining activity. It also stimulates adrenal aldosterone release, pituitary vasopressin release, and endothelial endothelin-1 release; it centrally stimulates sympathetic activity; and it promotes growth and inflammation. Any means to reduce the activity of Ang II would therefore tend to vasodilate, to reduce body sodium and water and hence decrease blood pressure, (BP), to reduce cardiac afterload and cell hypertrophy, and to be antiinflammatory and antifibrotic and favorably influence atherosclerotic and fibrotic disease.

The action of Ang II can be antagonized by blocking Ang II at the receptor site or by reducing the generation of Ang II (Figure 72–1). The receptor blockade was first clinically tested by infusion of peptide analogs of Ang II such as saralasin³ and then more recently and very successfully by the orally active Ang II receptor blockers such as losartan.⁴ Reduced generation of Ang II can also be obtained by β -adrenergic receptor blocking drugs that reduce the β -adrenergic receptor-mediated release of renin from the kidneys.^{5,6} The renal enzyme renin catalyzes the rate-limiting step of the renin-angiotensin cascade, and its key product Ang II inhibits renal renin secretion. Human active renin is an aspartyl protease of 340 amino acids and 40,000 Dalton molecular weight with two *N*-glycosylation sites. It is secreted by the renal juxtaglomerular granular epithelioid cells. Human renin cleaves at optimal pH 6.0 from its natural substrate angiotensinogen (Ang-N), a mainly hepatogenic α_2 -globulin, the physiologically inactive aminoterminal decapeptide angiotensin I (Ang I). Ang I is activated by the dicarboxypeptidase converting enzyme (angiotensin-converting enzyme [ACE], kininase II) into the octapeptide Ang II. Active renin levels are highly correlated with Ang II levels both in circulating plasma and at tissue sites.^{7,8}

Renin secretion from the renal juxtaglomerular cells does not exclusively depend on β -adrenergic receptor activity. Chloride transport across the renal macula densa cells, as well as Ang II receptor activity and renal perfusion pressure, also play important roles in renin release. β -Adrenergic blockade alone can therefore only partially decrease the secretion of renin and reduce the generation of Ang II. Specific blockade of secreted renin was therefore attempted early on with analogs of the renin substrate Ang-N.^{9–13}

However, the most-successful drugs in reducing the generation of Ang II were the converting enzyme inhibitors.^{8,14} The enzyme converting the inactive decapeptide Ang I into the

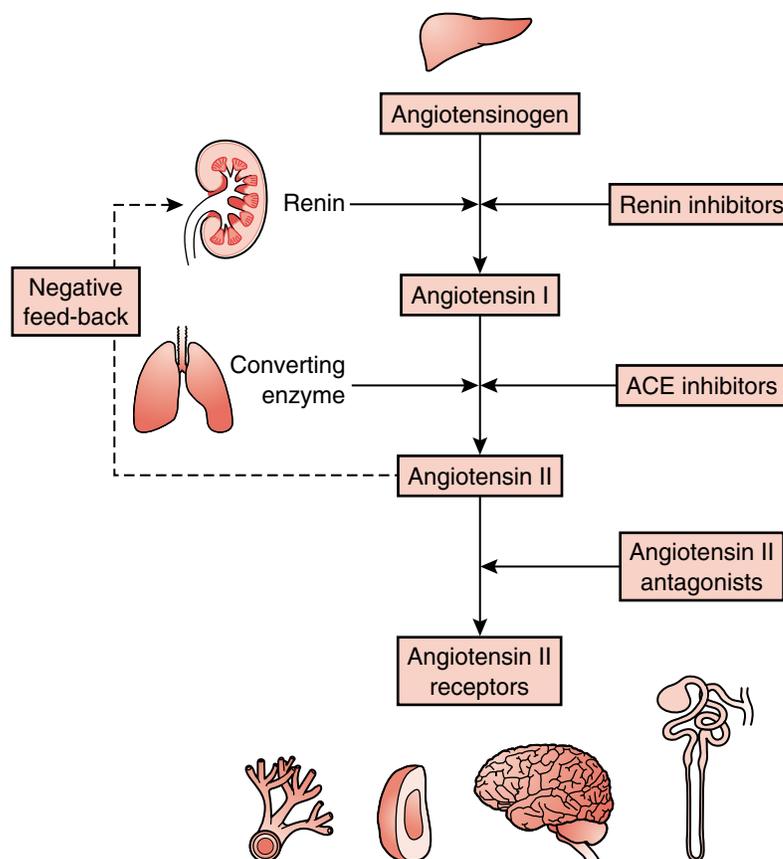

active octapeptide Ang II is identical with the kininase II that inactivates bradykinin. The discovery in the venom of the snake *Bothrops jararaca* of a peptide that blocked kininase II^{15,16} led to the synthesis of potent orally active inhibitors of the enzyme that were soon better known under the name ACE.¹⁷ ACE inhibitors are well documented to decrease Ang II generation, and large clinical trials have established their clinical benefit in hypertension, heart failure, and protection of renal function (see Chapters 9 and 65). ACE inhibitors also cause cough in 10% of patients and angioedema in 1% of patients, side effects that are attributed to accumulation of substance P and bradykinin rather than to the decrease in Ang II levels.

Taken together, there is good clinical evidence that antagonizing Ang II favorably influences cardiovascular and renal disease. Both reduced generation of Ang II and blockade of the Ang II effects at the receptor site appear successful. However, β -adrenergic receptor blocking agents provide incomplete suppression of renal renin secretion and generation of Ang II; ACE inhibitors cause side effects and Ang II receptor antagonists block only a single subtype of Ang receptors, exposing other unprotected Ang receptors to feedback-enhanced circulating Ang levels. Extreme experimental and clinical conditions indicate that renal renin secretion and peripheral renin activation are never fully turned off by feedback mechanisms¹⁸ and that very small amounts of circulating renin still participate in BP regulation.¹⁹ Therefore specific inhibitors of active renin remained a goal of pharmaceutical research over the last three decades.

WHY RENIN INHIBITION?

In the 1970s, the regulatory role of the renin-angiotensin-aldosterone system in cardiovascular homeostasis was well known.²⁰ However, the debate continued on whether this system is more a marginal phylogenetic leftover from several hundred million years ago when vertebrates evolved out of the sea into fresh water and later on land and then needed to defend their salt and water balance or whether renin in modern humans is of key importance in normal physiology as well as in many disease states. Renin acts on a unique and species-specific substrate (Ang-N) and is the rate-limiting enzyme for the generation of Ang II, an octapeptide with both potent vasoconstrictor and sodium- and water-retaining capacities. It was therefore tempting to test the blockade of this hormonal system that controlled both vasoconstrictor and volume components of the blood pressure equation. In early clinical tests, Ang II analog peptides with receptor-blocking properties did indeed decrease elevated blood pressure and thus proved the concept that antagonizing the renin-angiotensin system was of pharmacologic interest.³ However, partial agonistic properties of the Ang II analog peptides and lack of biooral avail-

Figure 72-1 The renin-angiotensin system and the levels of its pharmacologic inhibition. Activation of the Ang II receptor of the subtype 1 inhibits secretion of active renin from renal juxtaglomerular cells (feedback regulation of renal Ang II concentration). Specific renin inhibitors, ACE inhibitors, or Ang II receptor antagonists increase renin secretion by reducing feedback suppression of renin secretion. Renin inhibitors and ACE inhibitors decrease, whereas Ang II antagonists increase circulating levels of Ang II.

ability placed the Ang II receptor blockers on ice for another decade.

Even more extended—over almost three decades—was the development of specific renin inhibitors. It made sense to block renin and stem the tide of the renin-angiotensin cascade at the source, since renin is rate limiting for the generation of all angiotensins. Blockade of renin activity would not enhance the activation of unprotected angiotensin receptor subtypes as seen with selective Ang II receptor antagonists. The exclusive specificity of renin for its substrate Ang-N made it unlikely that the blockade of this enzyme's activity would produce unwanted effects by cumulating other peptides as with ACE inhibitors. Finally, in contrast to β -adrenergic receptor blockers, specific renin inhibitors should antagonize all active renin independent of the mechanism of its generation or release. Thus, even constitutive (unregulated) renal secretion of renin could be blocked.¹⁸

RENIN-SPECIFIC ANTIBODIES

Renin-specific purified antibodies, or their Fab fragments, have been demonstrated in sodium-depleted dogs to decrease circulating Ang II levels and BP.²¹ However, parenteral administration of these short-lived proteins was necessary, and immunologic complications (antigenic properties, cross-reactions of antibodies, inflammation) were to be expected, as with active immunization against the renin-angiotensin system.²² The hypotensive effect of a crude renin antiserum that had been tested in animals half a century earlier was never fully accepted as a proof of concept.²³

PEPSTATIN AND STATIN DERIVATIVES

Pepstatin is a strong inhibitor of aspartyl proteases such as pepsin, cathepsin D, and renin. This natural pentapeptide isolated from actinomycetes was for many years the classic renin inhibitor *in vitro*.²⁴ Pepstatin is not specific for renin and is poorly soluble in water. Structural derivatives of pepstatin increased its solubility and specificity for renin by several orders of magnitude.²⁵⁻²⁷ Pepstatin contains the unusual γ amino acid statin that may substitute for the two amino acids at the scissile bond of the protein substrate and block substrate cleavage because of the structural analogy to a transition state of the peptide bond hydrolysis by aspartyl proteases²⁷ (see later). However, none of these compounds was used clinically. Structural formulas and published potencies of these and subsequent early renin inhibitors were summarized by Hui and Haber.²⁸

ANGIOTENSINOGEN ANALOGS

Several specific renin inhibitors were synthesized as of the 1970s, but low efficacy, lack of oral availability, or high costs of synthesis prevented them from becoming successful drugs. Early renin inhibitors were modified analogs of the octapeptide from Ang-N that had previously been shown to be the minimal substrate for renin.²⁹ The cleavage site in human renin substrate Ang-N is between residues Leu-10 and Val-11, which differs from the Leu-10–Leu-11 scissile bond sequence in nonprimate species.³⁰ The replacement or addition of single

amino acids around the scissile P1-P1' bond of the substrate led to oligopeptides that were weak renin inhibitors.^{9,29,31-33} Nevertheless it could be demonstrated that such a renin-inhibiting decapeptide (RIP) administered intravenously decreased BP in monkeys³⁴ and humans.¹²

PRORENIN FRAGMENTS

Prosegment peptidic fragments of pepsinogen are known to inhibit pepsin. By analogy, several attempts were made to inhibit renin with peptidic analogs of prorenin fragments.^{35,36} Such renin inhibitors were found to reach low micromolar affinities, but this was not sufficient for compounds administered parenterally. Although innovative, the prorenin fragments approach to renin inhibition was abandoned.

TRANSITION-STATE ANALOGS

The hypothesis that peptide bond hydrolysis by aspartyl proteinases such as renin proceeds through a tetrahedral transition state is supported by conformational studies of the pepstatin-enzyme complex.³⁷ A substrate analog that would bind tightly to the active site of renin but could not be cleaved was expected to be a good renin inhibitor. Accordingly, Szelke and colleagues replaced in a minimal renin substrate decapeptide the scissile peptide bond (-CO-NH-) between the Leu-10 and Val-11 positions with a reduced and nonscissile bond (-CH₂-NH-) mimicking the hypothetical transition state conformation; they thus founded a new family of renin inhibitors.³⁸ The reduced bond peptide renin inhibitor H142 was clinically tested: In normal volunteers on a low-salt diet, 30-minute infusions of H142 (1 mg/kg/hr and 2.5 mg/kg/hr) decreased diastolic BP by 19% and 23%, respectively, and plasma renin activity as well as levels of Ang I and II were decreased, while a reactive rise in circulating active renin was documented.³⁹

Following the same hypothesis about nonscissile transition state analogs of renin substrate, the pepstatin derivatives and the statin-containing renin inhibitory peptides (SCRIP) were tested, since statin mimicked the transition state of the scissile bond of the renin substrate but did also not contain a dihydroxyl species required for the amide bond hydrolysis (see above). Numerous other substitutions at the scissile bond have subsequently been tested, including dihydroxyethylene⁴⁰ and stabilized peptides such as CGP 29287⁴¹ or shorter dipeptides or peptide-like compounds.^{28,40,42,43}

EVALUATION OF RENIN INHIBITORS

Renin inhibitors are designed to decrease the generation of Ang II. In contrast to ACE inhibitors, generation of the inactive decapeptide Ang I rather than its conversion into the active octapeptide Ang II is inhibited. Both renin inhibitors and ACE inhibitors reduce concentrations of Ang II in body fluids and at tissue sites close to the specific Ang II receptors, and both drug classes stimulate renin secretion by the same mechanism as the Ang II receptor blockers: They interrupt the negative feedback of Ang II at the juxtaglomerular cells of the kidneys. Circulating levels of active renin are therefore expected to be increased by any of the currently used specific

inhibitors of the renin-angiotensin system. The beneficial cardiovascular effects of these specific inhibitors are primarily due to reduced activation of the Ang II type 1 receptor AT₁. Any additional vasodilator, natriuretic, diuretic, or growth-inhibiting effects of ACE inhibitors or Ang II antagonists mediated by other Ang peptides or receptors would necessarily be enhanced by increased Ang I generation as a consequence of the increased active renin levels. ACE inhibitors (kininase II inhibitors) may have additional effects related to the accumulation of kinins.

Effective renin inhibitors must decrease Ang II levels. A reliable measurement of plasma and tissue concentrations of Ang-(1-8)octapeptide is therefore required for evaluation of renin inhibitors.^{7,44,45} Changes in plasma Ang II levels during renin inhibition with different renin inhibitors are well correlated with BP changes in hypertensive patients,⁴⁶ monkeys,⁴⁷ and sheep.⁴⁸ Misleading conclusions have often been drawn about decreasing Ang II levels and hypotensive effects of renin inhibitors versus ACE inhibitors because of blood-sampling artifacts⁴⁹: ACE inhibitors cause high Ang I levels and therefore tend to generate Ang II in vitro after blood sampling. Renin inhibitors cause low Ang I levels, and Ang II generation in vitro is prevented.⁵⁰ Unless Ang II generation in vitro is prevented by adding sufficient renin inhibitor to the blood-sampling cocktail, Ang II levels during ACE inhibition may be falsely elevated. This contrasts with ACE inhibitor-induced hypotensive effects, which may be greater than those found during a weak renin inhibition, where no Ang II is generated in vitro and plasma levels are found to be accurately decreased. Interestingly, Ang II levels, if accurately measured, are decreased to a greater extent during potent ACE inhibition than during weak renin inhibition. Blood pressure effects of both drug classes are well predictable from accurately measured Ang II levels.

Another flaw in the screening of renin inhibitors was the surprising unreliability of conventional and well-established assays for measurement of plasma renin activity.^{51,52} Renin assays that have been in use for decades are not reliable for testing renin inhibitors. They may overestimate the potency of renin inhibitors by several orders of magnitude because of chemicals added to the assays to protect generated Ang I from degradation during plasma incubation or because of pH changes. More renin-inhibiting activity is found in the assay than in vivo, and renin may appear fully inhibited for several hours after administration of a renin inhibitor, while plasma angiotensin levels and BP increase immediately after discontinuation of the drug⁴⁶ (Figure 72-2). Methods that protect Ang I generated during plasma incubation by trapping antibodies provide accurate estimations of the IC₅₀s of renin inhibitors.⁵³ Few publications describing renin inhibitors took account of this observation, and promising IC₅₀s and overestimated potencies of certain renin inhibitors after oral administration brought inappropriate molecules into clinical testing and led to disappointing results, particularly when these renin inhibitors were compared with potent ACE inhibitors, which did effectively decrease Ang II levels. Adding to the confusion was the fact that artifactually measured plasma Ang II levels were minimally decreased during ACE inhibition, while marginal decreases in Ang II levels during renin inhibition were less prone to artifacts and therefore appeared greater than those obtained with the ACE inhibitors (see earlier). Since the artifact of the renin activity measurement falsely labeled the renin inhibitors as potent and underestimated the potency of the ACE inhibitors, it was not surprising that investi-

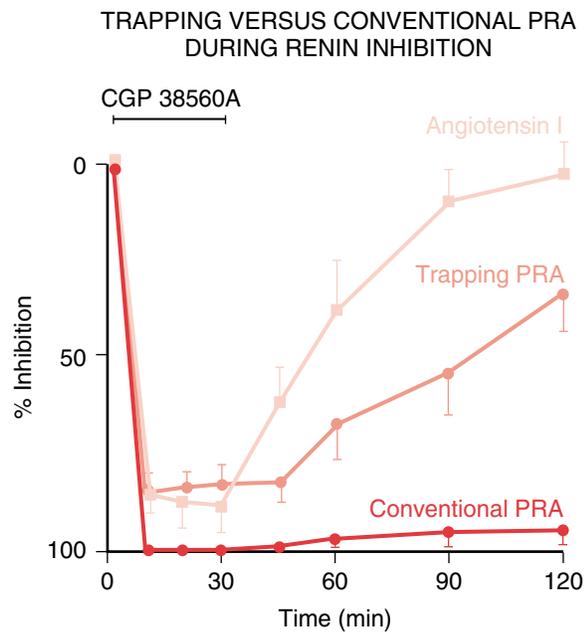

Figure 72-2 Artfactual overestimation of renin inhibition by conventional measurement of plasma renin activity (PRA) after a 30-minute infusion of the renin inhibitor CGP 38560A in hypertensive patients. PRA appears completely suppressed for hours when measured by the conventional PRA assay. The more-physiologic PRA assay using Ang I trapping antibodies and the circulating immunoreactive Ang I levels indicate shorter effects of the renin inhibitor. (From Jeunemaître X, Ménard J, Nussberger J, et al. Plasma angiotensins, renin and blood pressure during acute renin inhibition by CGP 38560A in hypertensive patients. *Am J Hypertens* 2:819-827, 1989.)

gators hypothesized additional, non-Ang II-mediated hypotensive effects of ACE inhibitors. The supposedly strong renin inhibitors that supposedly decreased Ang II levels more than ACE inhibitors had less BP effect than ACE inhibitors. Actually, weak renin inhibitors were compared with strong ACE inhibitors. The confusion based on biased biochemical evaluation discredited renin inhibition as a therapeutic principle. More than a dozen pharmaceutical companies abandoned their research on renin inhibitors over the last two decades.

The classic hormonal profiles during renin inhibition show parallel dose-related decreases in plasma renin activity and Ang I and Ang II levels and a slightly delayed increase in plasma active renin concentration (Figures 72-3 and 72-4). Based on accurately measured hormone profiles and knowledge of the inhibition constant K_i of a renin inhibitor, enzyme kinetic considerations allow calculation of the necessary (minimal) plasma inhibitor concentration to be reached for any hypothetical plasma active renin concentration to achieve a desired plasma Ang II level⁵⁴ (Box 72-1, Figure 72-5). Assuming Michaelis-Menten kinetics for competitive inhibition and steady state conditions, the formula of Box 72-1 calculates the Ang I generation rate (V) in plasma from the measured plasma drug (I) and renin levels (E). The measured plasma Ang I concentrations are in excellent correlation with the theoretical angiotensin I generation rate (Figure 72-5).⁵⁴ The decrease in plasma renin activity induced by renin inhibitor therapy is also correlated with the decreases in blood pressure,⁵⁵ since plasma renin activity and angiotensin concentrations are related. Since the renin-angiotensinogen reaction is exquisitely specific to species, animal models for evaluation of renin inhibitors are of limited value. Tests in primates such as the marmoset monkeys are preferred. Ultimately, clinical testing with accurate methodology is mandatory.

CLINICAL EXPERIENCE

Over the last two decades, several renin inhibitors have been tested in human subjects. The first clinical experience with a specific renin inhibitor was obtained with the angiotensinogen analog decapeptide RIP.¹² This renin-inhibiting peptide did indeed decrease BP during intravenous administration in humans, but there was evidence for a direct cardiodepressing effect unrelated to the renin inhibition, and the compound was abandoned. The first successful clinical testing of a renin inhibitor was obtained with H142, a reduced peptide bond transition state analog.³⁹ This peptide was infused into slightly salt-depleted healthy male volunteers. The H142 decreased BP in parallel with decreases in plasma renin activity and Ang I and II levels, and plasma active renin concentrations were increased. Heart rate effects were inconsistent, but heart rate increased when BP fell with the higher doses of H142. Generally, renin inhibitors do not change heart rate in salt-replete individuals. This is in agreement with observations for Ang II antagonists or ACE inhibitors, since Ang II mediates reflex tachycardia during hypotension by increasing central sympathetic outflow and by resetting of the baroreflex.

Subsequent clinical testing of other inhibitors of renin (suffix *-kiren*) in healthy volunteers even on mild salt restriction did not show BP or heart rate changes but did evoke dose-dependent decreases in plasma renin activity, Ang I, and Ang II that were rapidly reversed after termination of infusion of enalkiren⁵⁶ or CGP 38560A⁵⁷ or oral dosing of remikiren.⁵⁴ A massive and long-lasting rise in plasma active renin concentrations was consistently observed. In renin-dependent hypertension, the transition state analog renin inhibitor CGP 38560A was infused for 30 minutes⁴⁶ (Figures 72-1, 72-6, and 72-7): BP fell dose-dependently in parallel with the decreases in plasma renin activity and Ang I and II levels while active renin increased. Antihypertensive action in essential hypertensives was demonstrated for high intravenous bolus doses of

enalkiren, particularly in salt-depleted patients, while heart rate remained unchanged⁵⁵ (Figure 72-8). Similarly, a weak antihypertensive effect of orally administered remikiren was reported, but these results were never confirmed.⁵⁸ Promising early clinical testing has also been reported for the strong peptidic renin inhibitor R-PEP-27⁵⁹ and for the orally active renin inhibitors zankiren⁶⁰ and FK 906,⁶¹ but no follow-up has been published, and the compounds appear to have been abandoned.

All of these renin inhibitors provided the classic hormonal profile when tested with valid methods. However, the peptides or peptide-like renin inhibitors generally required parenteral administration and were therefore without great clinical potential. Few renin inhibitors have been tested with oral administration, and so far only one, aliskiren⁶² (Figure 72-9), appears to become a commercially viable therapeutic agent.

ORALLY ACTIVE RENIN INHIBITORS

Several renin inhibitors have been tested after oral administration,^{54,58,60-63} In humans, no renin inhibitor has been more than 3% absorbed. Nevertheless, even with low bioavailability, significant and long-lasting decreases in BP can be obtained in hypertensive patients⁶³ (Figure 72-10).

ALISKIREN

Clinical testing of the orally active renin inhibitor aliskiren indicates that renin inhibitors have therapeutic potential similar to that of other antagonists of the renin-angiotensin system. Early observations indicate that tolerability should be comparable to or better than that of established drugs. Aliskiren is a low-molecular-weight (MW 552, free base) non-peptidic renin

EFFECTS OF THE RENIN INHIBITOR (RO 42-5892)
ON THE RENIN-ANGIOTENSIN SYSTEM
AFTER ORAL ADMINISTRATION

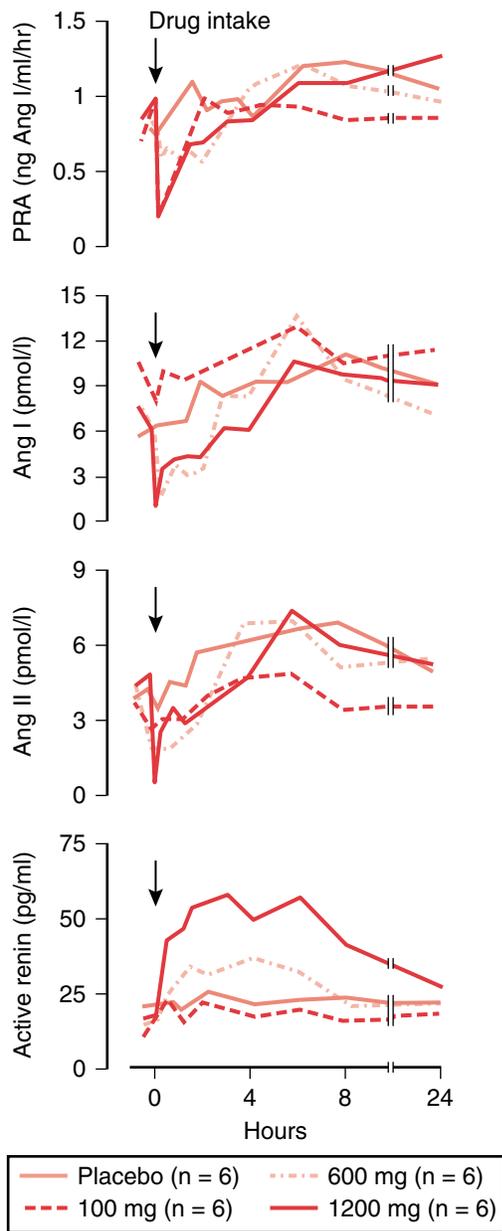

Figure 72-4 Time profiles of mean plasma renin activity (PRA), Ang I, Ang II, and active renin in 6 healthy men after oral single administration of the renin inhibitor remikiren at three doses or placebo. Remikiren decreases in a dose-related manner PRA, Ang I, and Ang II, and it increases active renin. The decreases in plasma levels of Ang I and Ang II remain significant for maximally 2 hours, and the increase in active renin lasts for 8 hours. (From Camenzind E, Nussberger J, Juillerat L, et al. Effect of the renin response during renin inhibition: Oral Ro 42-5892 in normal humans. *J Cardiovasc Pharmacol* 18:299-307, 1991.)

Box 72-1 Calculation of Angiotensin I Generation Rate

$$V = \frac{k_p \times [E] \times [S]}{K_M (1 + [I]/K_i) + [S]}$$

V = angiotensin I generation rate

$k_p \approx k_{cat}$ = rate constant = 0.6/s

$[E]$ = active renin concentration

$[S]$ = angiotensinogen = 1.35 μ M

K_M = Michaelis-Menten constant = 0.4 μ M

$[I]$ = drug concentration

K_i = inhibitor constant = 0.4 nM

Formula for the calculation of the generation rate of angiotensin I (and Ang II) during renin inhibition assuming Michaelis-Menten kinetics for competitive inhibition and assuming steady state conditions. K_M and k_{cat} for renin and K_i of any renin inhibitor of interest are known constants. Concentrations of the inhibitor (I), the enzyme active renin (E), and the substrate angiotensinogen (S) can be measured. (From Camenzind E, Nussberger J, Juillerat L, et al. Effect of the renin response during renin inhibition: Oral Ro 42-5892 in normal humans. *J Cardiovasc Pharmacol* 18:299-307, 1991.)

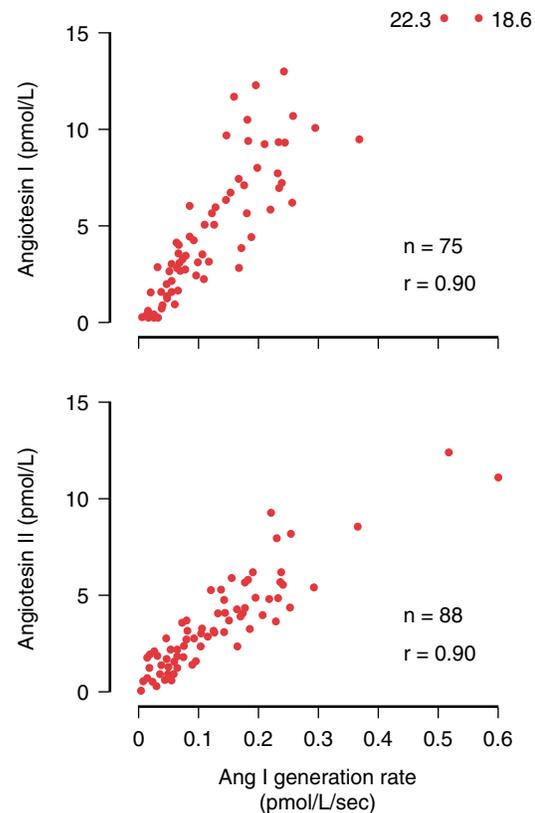

Figure 72-5 Correlation between the actually measured plasma Ang I (upper panel) and Ang II (lower panel) levels and the calculated Ang I generation rates according to the formula of Box 72-1 applied to the renin inhibitor study of Figure 72-4. $K_M = 0.4 \mu$ M, $k_{cat} = 0.6/s$, $K_i = 0.4$ nM, angiotensinogen (S) = 1.35 μ M. The good correlation allows the prediction of levels of renin inhibitor to be achieved at a given renin concentration to obtain a required reduction in angiotensin concentrations. (From Camenzind E, Nussberger J, Juillerat L, et al. Effect of the renin response during renin inhibition: Oral Ro 42-5892 in normal humans. *J Cardiovasc Pharmacol* 18:299-307, 1991.)

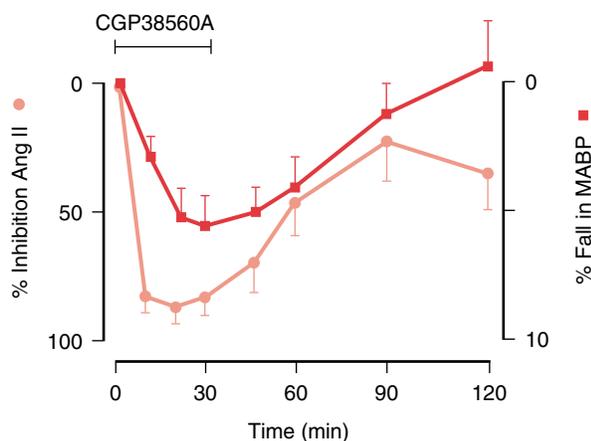

Figure 72-6 Parallel changes in plasma angiotensin II concentrations and mean arterial BP (MABP) in hypertensive patients during and following a 30-minute infusion of the renin inhibitor CGP 38560A. Maximal effects are reached by the end of the infusion, and a return toward baseline conditions occurs within the following hour (see also Figure 72-2). (From Jeunemaître X, Ménard J, Nussberger J, et al. Plasma angiotensin, renin and blood pressure during acute renin inhibition by CGP 38560A in hypertensive patients. *Am J Hypertens* 2:819-827, 1989.)

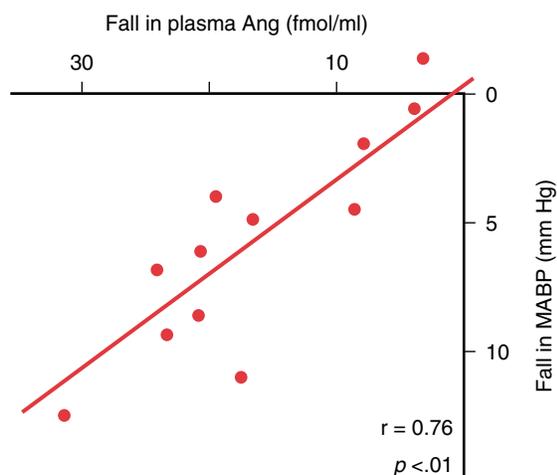

Figure 72-7 Correlation between the maximal fall in plasma angiotensin concentrations and the maximal fall in mean arterial BP (MABP) in 12 hypertensive patients during infusion of the renin inhibitor CGP 38560A (see also Figure 72-6). Angiotensin II concentrations may control the BP of these patients.⁴⁶

inhibitor that consists of a substituted octanamid (see Figure 72-9). It is a competitive transition state analog and specific inhibitor of human renin. After acute and repeated ingestion by healthy volunteers, aliskiren causes the classical decreases in plasma renin activity and Ang I and Ang II levels and an increase in plasma active renin⁶² (see Figure 72-3). It decreases urinary aldosterone excretion as much as enalapril (see Figure 72-11) and has a natriuretic effect.⁶² In hypertensive patients, aliskiren at a daily oral dose of 300 mg was at least as effective as 150 mg irbesartan or 100 mg losartan in reducing BP⁶³ (Figure 72-10).

Figure 72-8 Time profiles of systolic (upper panel) and diastolic BP (middle panel) and heart rate (lower panel) in patients with essential hypertension receiving increasing bolus doses of the renin inhibitor enalkiren at 45-min intervals. Dose-related antihypertensive effects of the renin inhibitor are enhanced after diuretic pretreatment with hydrochlorothiazide (**B vs. A**). Heart rate remains unchanged and placebo has no effect (**C**). (From Weber MA, Neutel JM, Essinger I, et al. Assessment of renin dependency of hypertension with a dipeptide renin inhibitor. *Circulation* 61:1768-1774, 1990.)

OUTLOOK

Although it took three decades to reach today's insight into the utility of renin inhibition, it now appears that renin inhibitors could become, after ACE inhibitors and AT₁-receptor blockers, yet another class of useful drugs antagonizing the renin-angiotensin system. Renin inhibition does exactly what investigators anticipated some 30 years ago: It decreases Ang II

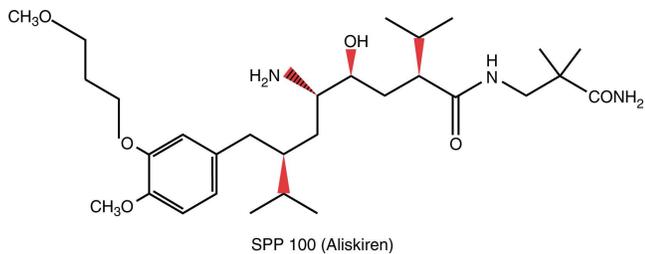

Figure 72-9 Structural formula of aliskiren, the first clinically successful orally active renin inhibitor. This substituted octanamid is a competitive transition state analog and specific inhibitor of human renin.⁶²

generation with all the physiologic consequences, including decreasing BP and cardiac afterload. Improved bioavailability should reduce the cost of renin inhibitors. Early results with combination therapy including both a renin inhibitor and an ACE inhibitor, AT₁ receptor blocker or mineralocorticoid receptor antagonist, suggest synergistic rather than additive effects, and more-complete blockade of the renin-angiotensin system appears advantageous in most forms of hypertension. With favorable low incidences of side effects, renin inhibitors combined with AT₁ receptor blockers or mineralocorticoid receptor antagonists may become widely used cardiovascular drugs.

Secondary Hypertension

Chapter 73

Obstructive Sleep Apnea and Hypertension

Apoor S. Gami, Virend K. Somers

INTRODUCTION AND EPIDEMIOLOGY

Obstructive sleep apnea (OSA) is common in men and women of varied ethnic and geographic origins.¹⁻⁴ In general, about 25% of men and 10% of women have pathologic OSA, whereas 4% of men and 2% of women actually experience symptoms consistent with the OSA syndrome.^{3,4} A prospective, population-based, cohort study has estimated that the 5-year cumulative incidence of OSA in American adults is about 16%.⁵

In 2003, the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure acknowledged that OSA is an important secondary cause of systemic hypertension.⁶ This causal link is substantiated by studies of integrated physiology and a preponderance of epidemiologic data^{2,7-10} that have been substantiated by a large prospective population-based study.¹⁰ Cross-sectional studies show that about half of patients with OSA have hypertension,^{8,9} and the strong association exists regardless of gender, age, race, and body mass index.⁸ The most compelling evidence comes from a study of more than 700 patients followed over 4 years after OSA diagnosis, in whom there was a direct linear relationship between the severity of OSA and the *incidence* (i.e., new cases) of hypertension (Figure 73-1).¹⁰ Patients with mild OSA had twice the risk, and patients with moderate-severe OSA had almost three times the risk of developing hypertension as persons without OSA. This relationship was independent of obesity, smoking, alcohol, age, gender, and baseline blood pressure.¹⁰

OBSTRUCTIVE SLEEP APNEA

Patients with OSA experience recurrent occlusions of the pharyngeal airway during sleep, resulting in partial or total cessation of airflow and hypoxemia.¹¹ This is followed by arousal to a lighter stage of sleep (usually without overt awakening) and restoration of airflow. This sequence of apneas and arousals can occur hundreds of times during the night.¹² Risk factors for OSA include male gender; middle age; retroposition of the mandible; decreased palatal height; and increased body mass index, waist circumference, and neck circumference.^{4,13-15}

Polysomnography is the gold standard to diagnose and assess the severity of OSA. Full polysomnography includes the

simultaneous measurement during sleep of the electrocardiogram, electrooculogram, electroencephalogram, electromyogram, thoracoabdominal movements by strain belts, and nasooral airflow (Figure 73-2). An obstructive apnea is defined as the absence of airflow for at least 10 seconds in the presence of thoracoabdominal movements. An obstructive hypopnea is defined as at least a 50% decrease in airflow associated with either a decrease in oxygen saturation greater than 4% or evidence of arousal on the electroencephalogram. The apnea-hypopnea index (AHI), the number of apneic and hypopneic events per hour of sleep, is used to quantify the severity of OSA. An AHI less than 5 is normal; 5 to 15 is classified mild OSA; 15 to 30, moderate OSA; and greater than 30, severe OSA.¹⁶

BLOOD PRESSURE IN NORMAL SLEEP

Normally, in patients without OSA, rapid eye movement (REM) sleep is characterized by marked fluctuations in blood pressure and heart rate, as well as increased sympathetic activity to muscle blood vessels. In general, however, heart rate and blood pressure are lower during sleep than during waking hours.¹⁷⁻²¹ Decreases in blood pressure are mild and due to reductions in both cardiac output and systemic vascular resistance.^{22,23} These normal changes are most apparent during deep non-REM sleep, and they appear to be related to cardiovascular autonomic function during sleep,¹⁹ characterized by increased vagal activation and decreased sympathetic drive.^{17,19,24}

BLOOD PRESSURE IN OBSTRUCTIVE SLEEP APNEA

Acute Nocturnal Changes in Blood Pressure

The sleep stage-dependent changes of normal sleep are disrupted in patients with OSA, in whom blood pressure markedly increases during sleep.²⁵⁻²⁷ The mechanisms responsible for this increase include sympathetic activation due to chemoreflex excitation and the effects of circulating vasoconstrictors. Sympathetic activity and blood pressure

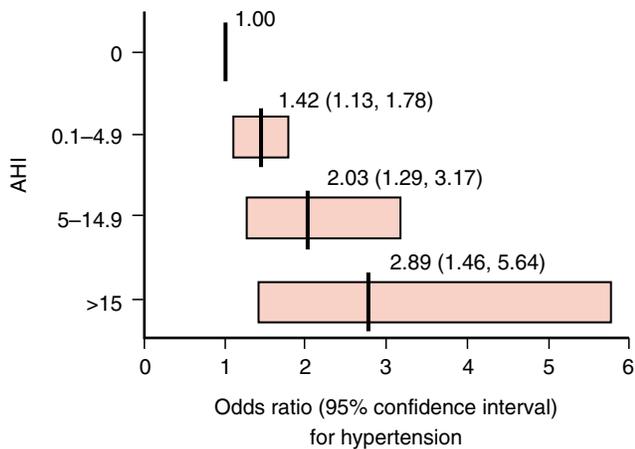

Figure 73-1 Odds ratio for presence of hypertension at 4 years, based on baseline apnea-hypopnea index (AHI), after adjustment for baseline hypertension status, body mass index, neck and waist circumference, age, sex, and weekly use of alcohol and cigarettes. An AHI of 0 is used as the reference category. The odds ratios for the presence of hypertension at follow-up were 1.42 with an AHI 0.1 to 4.9, 2.03 with an AHI 5.0 to 14.9, and 2.89 with an AHI 15.0 or greater. (Data from Peppard PE, Young T, Palta M, et al. Prospective study of the association between sleep-disordered breathing and hypertension. *N Engl J Med* 342:1378-1384, 2000.)

progressively increase during an apnea.²⁵ At termination of apnea, blood pressure surges, sometimes to levels as high as 240/130 mm Hg, and sympathetic activity is abruptly inhibited.²⁵ The numerous repetitive apneic episodes result in large fluctuations in sympathetic activity and blood pressure throughout the night (Figure 73-3). These changes occur more often during stage II and REM sleep, when apnea severity is greatest. In addition, the normal nocturnal decrease in blood pressure may not occur or is blunted in patients with OSA (i.e., they are often “nondippers”).^{25,28} The increases in sympathetic activity during apneic episodes are due to the synergistic effects of hypoxemia and hypercapnia on peripheral and central chemoreceptors,²⁹⁻³² the effects of which are further augmented by the apnea-related absence of sympathetic inhibitory signals from the thoracic afferents.^{33,34}

Chronic Daytime Changes in Blood Pressure

The development of hypertension may be due to the daytime carryover of various nocturnal mechanisms of increased blood pressure in patients with OSA, in addition to other factors that are not directly related to the sleep-wake cycle.

Sympathetic Activity

Increases in sympathetic activity, evident during sleep, persist during daytime normoxic wakefulness in patients with OSA.^{25,31,35-37} Abnormalities in both baroreflex function^{32,38,39} and chemoreceptor activation^{31,32} may contribute to this sustained daytime sympathetic excitation.

Cardiovascular Variability

In otherwise healthy patients with OSA, heart rate variability is decreased and blood pressure variability is increased in parallel with the severity of the sleep disorder.⁴⁰ In individuals without high blood pressure, decreased heart rate variability confers an increased risk of developing hypertension.⁴¹ Increased blood pressure variability in patients with hypertension and decreased heart rate variability in patients with cardiovascular disease are both associated with adverse outcomes.⁴²⁻⁴⁶ Thus, abnormalities in cardiovascular variability may be related to the development of hypertension and other cardiovascular diseases in patients with OSA.

Endothelial Dysfunction

Patients with hypertension have impaired endothelium-dependent vascular relaxation,⁴⁷ and this may be partly explained by associations with OSA. Endothelium-dependent vasodilation of conductance and resistance vessels is abnormal in otherwise healthy patients with OSA.⁴⁸⁻⁵⁰ Increased sympathetic drive, decreased nitric oxide production, inflammation, and humoral factors may mediate or contribute to endothelial dysfunction and hypertension in patients with OSA. Patients with OSA have lower endothelial nitric oxide synthase activity, and OSA may also be accompanied by lower circulating levels of nitric oxide.^{51,52}

Humoral Factors

Endothelin-1 is a potent vasoconstrictor with sustained activity and may be partly responsible for daytime hypertension associated with OSA. Endothelin-1 is elevated in patients with untreated OSA but not in patients with normal sleep.⁵³ Hypoxia is a strong stimulus for endothelin-1 production. In an animal model, intermittent hypoxia (such as in OSA) increases endothelin-1 and blood pressure, whereas treatment with an endothelin-1 blocker lowers blood pressure.⁵⁴ Leptin, an adipocyte-derived hormone with effects in various organ systems, may be associated with an increased risk of cardiovascular events.⁵⁵ Leptin levels are increased in obese patients and are even higher in patients with OSA.⁵⁶ In an animal model, administration of leptin increases blood pressure and renal sympathetic drive.^{57,58} As such, in addition to its associations with obesity and cardiovascular disease events, leptin may contribute to sustained daytime hypertension in patients with OSA.

Inflammation

OSA is characterized by marked local and systemic inflammation, independent of obesity and other comorbidities. Pharyngeal airway tissues of patients with OSA are congested with inflammatory cells, which may result in anatomic narrowing and functional impairments of the airway that predispose to apneas.⁵⁹ Systemic inflammation is evidenced by elevated circulating levels or activity of C-reactive protein,^{60,61} cytokines such as interleukin-6 and tumor necrosis factor- α ,^{61,62} adhesion molecules,⁶³⁻⁶⁶ and reactive oxygen species.⁶⁷⁻⁶⁹ Hypertension, is also independently associated with elevated plasma concentrations of C-reactive protein.⁷⁰ Middle-aged individuals with higher C-reactive protein levels, even those with low blood

Figure 73–2 Polysomnographic tracing with obstructive apneas. Shown are (A) electrooculography, (B) electroencephalography, (C) electromyography, (D) electrocardiography, (E) thermistor measures of airflow, (F) sonography, (G) pulse oximetry, (H) measures of thoracoabdominal movements via excursion belts, and (I) blood pressure measurements during 90 seconds of REM sleep. Arrow 1 marks the initiation of an obstructive apnea, and arrow 2 marks its termination. (From Gami AS, Caples SM, Somers VK. Obesity and obstructive sleep apnea. *Endocrinol Metab Clin N Am* 32(4):869-894, 2003; with permission.)

pressure and no comorbidities, have a significantly increased risk of developing incident hypertension in less than a decade.⁷¹ The inflammatory milieu in these conditions is likely related to endothelial dysfunction and may have potential implications for related cardiovascular complications.

Predisposition to Obesity

The relationship between obesity and hypertension is likely mediated by multiple interacting factors, including genetics, neural and metabolic abnormalities, fat distribution, and OSA.⁷² Obesity is thought to be the most powerful risk factor for OSA. About 70% of patients with OSA are obese, and a 10% weight gain is associated with a sixfold increase in the

risk of OSA.¹⁰ Although numerous mechanisms are implicated in the causal pathway from obesity to OSA, it is possible, conversely, that OSA itself is a risk factor for obesity. Patients with newly diagnosed OSA have reported weight gain in the time before the diagnosis.^{53,56} As discussed later, treatment of OSA results in weight loss and redistribution of fat.^{73,74} Multiple mechanisms may explain this relationship (such as decreased activity due to daytime somnolence, resistance to the satiety signal of the leptin hormone,⁵⁶ and effects of leptin on respiratory control during sleep).⁷⁵ Thus, although obesity may cause OSA in some patients, in others OSA may lead to weight gain. This is important because the combination of OSA and obesity synergistically increase the risk of hypertension.^{8,76,77}

Figure 73-3 Sympathetic nerve activity (SNA), respirations, and intraarterial blood pressure (BP) in an individual with obstructive sleep apnea **(A)** when awake, **(B)** during rapid eye movement (REM) sleep with obstructive apneas, and **(C)** during REM sleep with continuous positive airway pressure (CPAP) therapy. SNA is increased when awake, and it is higher during REM sleep. BP is normal when awake and exceeds 250/110 mm Hg at termination of the apneas during REM sleep. CPAP therapy during REM sleep abolishes apneas, resulting in decreased SNA and elimination of BP fluctuations. (Republished with permission of Journal of Clinical Investigations, from Somers VK, Dyken ME, Clary MP, et al. Sympathetic neural mechanisms in obstructive sleep apnea. *J Clin Invest* 96:1897–1904, 1995; permission conveyed through Copyright Clearance Center, Inc.)

OBSTRUCTIVE SLEEP APNEA THERAPY

Weight Loss

Weight loss can potentially cure OSA and may also attenuate associated comorbidities, especially hypertension.⁷⁸⁻⁸² Even a small weight reduction can elicit significant improvements in symptoms and severity of OSA.^{83,84} Due to generally poor success in obesity treatment, other therapies for OSA are often necessary.

Positive Airway Pressure

Continuous positive airway pressure (CPAP) is most commonly administered via a nasal mask. Applied during sleep, the pressurized air exerts an outward force and essentially splints the airway open, preventing obstruction during ventilation.⁸⁵ In most patients without specific indications for surgical treatments (i.e., craniofacial abnormalities), CPAP is the most effective therapy for OSA and improves daytime symp-

toms and function in patients with moderate or severe OSA.⁸⁶⁻⁸⁸ The main obstacle to treating patients with CPAP is poor compliance, due to discomfort or inconvenience of the apparatus. Only half of patients accept the recommendation for its use, and a small fraction are compliant.⁸⁹⁻⁹² Strategies to increase its use include more comfortable masks,⁹³ humidified air,⁹⁴ different inspiratory and expiratory pressures (bilevel positive airway pressure, or BiPAP),^{95,96} and team-based approaches to managing patients.⁸⁹ Treatment with CPAP has been shown to significantly lower nocturnal and daytime blood pressure levels (discussed later).

Oral Appliances

Oral appliances are intended to alleviate OSA by repositioning the tongue and/or mandible to prevent airway occlusion during sleep. Results are fair (up to 60% efficacious) with various designs,⁹⁷⁻¹⁰⁰ and they may be more useful for patients with supine OSA.¹⁰¹ Patients prefer oral appliances to other modes

of treatment,⁹⁷ and they should be offered to patients who do not tolerate or are not candidates for other therapies. It is unknown whether use of oral appliances results in decreased daytime blood pressure.

Surgery

Surgery can cure OSA when specific craniofacial abnormalities, such as severe retrognathia, tonsillar hypertrophy, or deviated nasal septum, cause airway obstruction.^{102,103} Despite its popularity, uvulopalatoplasty (UPP) is often ineffective, and more than half of patients will still have severe OSA (AHI >20) 2 years after surgery.¹⁰⁴ Patients who may benefit more from UPP are those with milder OSA and those who weigh less.¹⁰⁴ Bariatric surgery, including the Roux-en-Y gastric bypass, gastroplasty, and gastric banding, results in substantial weight loss in patients who are severely obese. This usually results in improvement or cure of OSA and many associated comorbidities.^{82,105-110} However, as in nonsurgical weight loss, OSA returns when weight is regained.¹⁰⁹ The definitive and immediate treatment of OSA, reserved for debilitating cases that are unresponsive to other therapies or during medical illnesses that preclude their use, is tracheostomy, which allows ventilation to completely bypass the collapsible airway.¹¹¹

BLOOD PRESSURE EFFECTS OF OBSTRUCTIVE SLEEP APNEA THERAPY

Positive Airway Pressure

The widely used, titratable, and effective therapy for OSA, nasal CPAP, has beneficial effects on numerous mechanisms of hypertension, acute nocturnal blood pressure surges, daytime hypertension, and the complications of hypertension.

Both short- and long-term use of CPAP attenuate many of the mechanisms related to hypertension in patients with OSA. It has been shown to markedly decrease sympathetic activity acutely during the night²⁵ and during daytime wakefulness.¹¹² Its use is also associated with decreased production of superoxide by polymorphonuclear neutrophils,⁵¹ increased nitric oxide,⁶⁷ and attenuated white cell adhesion to cultured endothelial cells,⁶⁵ which may improve endothelial function. Sustained CPAP therapy reduces circulating levels of angiotensin II¹¹³ and leptin.^{52,74,114,115} There is even evidence that long-term use of CPAP aids weight loss^{73,116} and changes the distribution of fat (decreasing visceral adiposity),⁷⁴ both of which have important effects on hypertension.^{117,118}

There are unequivocal beneficial effects of CPAP on blood pressure and hypertension. During sleep, CPAP decreases acute nocturnal blood pressure surges^{25,119,120} and helps reestablish the normal dip in nocturnal blood pressure.²⁵ The carry-over of these effects into the daytime has been shown by numerous observational studies¹²⁰⁻¹²⁵ and now more randomized controlled trials.^{92,125} Becker et al. randomized 60 patients with moderate or severe OSA to either effective CPAP or subtherapeutic CPAP for 9 weeks. Although only 32 patients completed the study (again highlighting technical and compliance issues related to CPAP), the results showed a significant decrease of about 10 mm Hg in mean, systolic, and diastolic blood pressures during the night and daytime in patients using effective CPAP (Figure 73–4).⁹²

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

Figure 73–4 Changes in mean arterial pressure (MAP), systolic pressure, and diastolic pressure with use of effective continuous positive airway pressure (CPAP) therapy (*closed bars*) and subtherapeutic CPAP therapy (*open bars*). Blood pressures were measured continuously and noninvasively in an ambulatory setting before and after an average of 2 months of effective or subtherapeutic CPAP therapy in a predominantly hypertensive group of patients with moderate to severe obstructive sleep apnea syndrome. Asterisks indicate $p < .05$. (From Becker HF, Jerrenstrup A, Ploch T, et al. Effect of nasal continuous positive airway pressure treatment on blood pressure in patients with obstructive sleep apnea. *Circulation* 107:68–73, 2003; with permission.)

The magnitude of blood pressure reduction with CPAP therapy appears to be greatest in patients using antihypertensive medications.¹²⁵ It also appears that the magnitude of blood pressure reduction correlates with the severity of OSA.¹²⁵ These data add to the evidence that OSA may be a cause of resistant hypertension,¹²⁶⁻¹³⁰ which may be more responsive to pharmacologic therapy after initiation of CPAP (see Chapter 59 for a discussion of resistant hypertension).

In addition to direct effects on hypertension, OSA therapy may conceivably decrease the incidence and the severity of complications of hypertension, such as left ventricular hypertrophy,¹³¹ congestive heart failure,¹³²⁻¹³⁵ atrial fibrillation,¹³⁶ and ischemic heart disease.¹³⁷ Of special note are the beneficial effects of CPAP therapy on several components (in addition to hypertension) of the metabolic syndrome, including visceral adiposity,⁷⁴ insulin resistance,¹³⁸⁻¹⁴¹ and dyslipidemia.^{142,143}

SUMMARY

1. OSA is a secondary cause of systemic hypertension.
2. OSA is prevalent in patients with hypertension.
3. Risk factors for OSA include male gender, age, body mass index, waist circumference, neck circumference, and oral cavity dimensions.
4. Patients with resistant hypertension (patients whose blood pressure is not at goal while taking adequate doses of two or more appropriately chosen medications) should be considered for polysomnography to rule out OSA.

5. Polysomnography is the gold standard for diagnosing and assessing the response to therapy for OSA.
6. Effective therapies for most patients with OSA include sustained weight loss (ideal) and CPAP (most widely used).
7. Treatment of OSA with CPAP may have important beneficial effects for treatment of hypertension and mitigating its serious complications, including arrhythmias, congestive heart failure, and ischemic heart disease.

Renovascular Hypertension: Diagnosis and Treatment

Samuel Spitalewitz, Ira W. Reiser

SIGNIFICANCE

Renovascular hypertension results from renal ischemia and is usually caused by a partially or completely occlusive lesion of one or both renal arteries. It may affect up to 5% of patients with hypertension and is the most common cause of correctable (secondary) hypertension. Renovascular hypertension may lead to ischemic nephropathy and even end-stage renal disease (ESRD) in a significant proportion of affected patients.^{1,2} It is a major public health problem.

INCIDENCE AND CAUSE

Most patients with renovascular disease present with moderate to severe hypertension, although blood pressure may be normal or only mildly elevated. Renovascular disease is less common in African Americans than in Caucasians, in whom it may cause accelerated or malignant hypertension in as many as 10% to 45% of affected patients.^{3,4} In African American patients with clinical features, suggestive of renovascular disease, the incidence of accelerated or malignant hypertension may be as high as 20%.⁴

Hypertension may result from any form of ischemic renal disease (e.g., scleroderma, vasculitis of the kidney or renal artery, atheroembolic disease, aneurysms, or other extrinsic compression of the renal arteries). Atherosclerotic renal artery disease accounts for more than two thirds of cases of renovascular hypertension, but most of the remainder are caused by fibromuscular dysplasia.¹ Atherosclerotic renovascular disease typically presents in patients older than 40 years of age, most commonly involves the renal ostium (extending from an aortic atherosclerotic plaque) or the proximal third of the renal artery, and has a male:female ratio of 2:1.^{1,5} Fibromuscular dysplasia, of which there are four types (medial fibroplasia, perimedial fibroplasia, medial hyperplasia, and intimal fibroplasia), is more commonly seen in younger patients, usually Caucasian females. Medial fibroplasia is the most common type and accounts for approximately two thirds of cases. The lesions of fibromuscular dysplasia are generally bilateral and, unlike those seen with atherosclerotic renovascular disease, affect the more distal portion of the renal artery.⁶

CLINICAL SIGNS AND SYMPTOMS

Because of its low incidence in uncomplicated hypertensives, screening all hypertensive patients for renovascular disease is not cost-effective.⁷ The clinician should screen those hypertensive patients who present with one or more of the following signs or symptoms^{1,8-14}:

1. Severe or refractory hypertension, with evidence of grade 3 or 4 hypertensive retinopathy (particularly in Caucasian patients)
2. Abrupt onset of moderate to severe hypertension, particularly in a previously well-controlled hypertensive or normotensive patient
3. Onset of hypertension before age 20 (early onset) or after age 50 (late onset), particularly in the absence of a family history of hypertension
4. Unexplained significant deterioration in renal function with or without hypertension or proteinuria (which may be in the nephrotic range)
5. A rise in serum creatinine concentration of greater than 20% to 30% in association with the administration of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs), or with a reduction of blood pressure to “normal” with other antihypertensive agents
6. Paradoxical worsening of hypertension with diuretic therapy
7. Spontaneous hypokalemia
8. Recurrent “flash” pulmonary edema or otherwise unexplained episodes of congestive heart failure
9. Generalized vascular disease
10. The presence of a systolic-diastolic abdominal bruit that lateralizes to one or both flanks (a systolic bruit alone is more sensitive but less specific)
11. Stigmata of cholesterol emboli

To better predict which patients should be selected for renal angiography, Krijnen et al. have weighted some of the aforementioned and other signs and symptoms to derive a clinical assessment score for patients.¹⁵ At best, each score assigned to a patient had only a 72% sensitivity and 90% specificity in predicting which patients had renovascular disease. In addition, their cohort excluded African Americans and their definition of renal artery disease (greater than a 50% lesion by angiography) was independent of a response to treatment.¹⁶ Similarly, a prospective method utilizing ACE inhibition to predict the presence and severity of renal artery disease and other predictive efforts are too nonspecific to rule out its presence or absence.^{9,17-20} Therefore, a suggestive history remains the best and most practical criterion to determine whether to proceed with the screening tests described later.

SCREENING TESTS

There are several screening tests for renal artery disease, each with its own advantages and disadvantages. The tests we find most useful are radioisotope scanning, magnetic resonance

angiography (MRA), and spiral (helical) computed axial tomography (CT).²¹ Because a negative screening test does not entirely preclude the presence of a renal artery lesion, if our clinical suspicion is high and a radiologic or a surgical intervention is deemed emergent, we proceed directly to angiography (Figure 74–1).

Radioisotope Scanning

Renal scintigraphy, with and without ACE inhibition, is our most frequently used initial screening test in patients without renal insufficiency (Figure 74–2).^{1,22} A scintigraphic study without ACE inhibition (nonstimulated), using either I¹³¹ orthiodohippurate (OIH) or ^{99m}Tc diethylenetriamine pentaacetic acid (DTPA) as the radioisotope, is only as sensitive and specific as an intravenous pyelogram (see later) and is, therefore, of limited value as a screening test.^{22–24} However, both the sensitivity and the specificity of the study can be greatly improved (90%–95%) with a stimulated (captopril) scan.^{25–28} When the precaptopril and postcaptopril (nonstimulated vs. stimulated) renograms are compared, a decrement in renal function may be seen in the involved kidney. This occurs because ACE inhibition attenuates the angiotensin-mediated vasoconstriction (in the efferent arteriole more so than the afferent arteriole) distal to the renovascular lesion, thereby reducing intraglomerular capillary pressure and, as a consequence, the glomerular filtration rate (GFR). Less often, an improvement in function may be demonstrated on the uninvolved side.^{24,29,30} The sensitivity of ACE-enhanced renography appears to be better than that of an ARB enhanced scan. Angiotensin receptor blockade results in efferent arteriole vasodilation through its action on angiotensin II type 1 (AT₁) receptors, as well as afferent arteriole vasodilation via

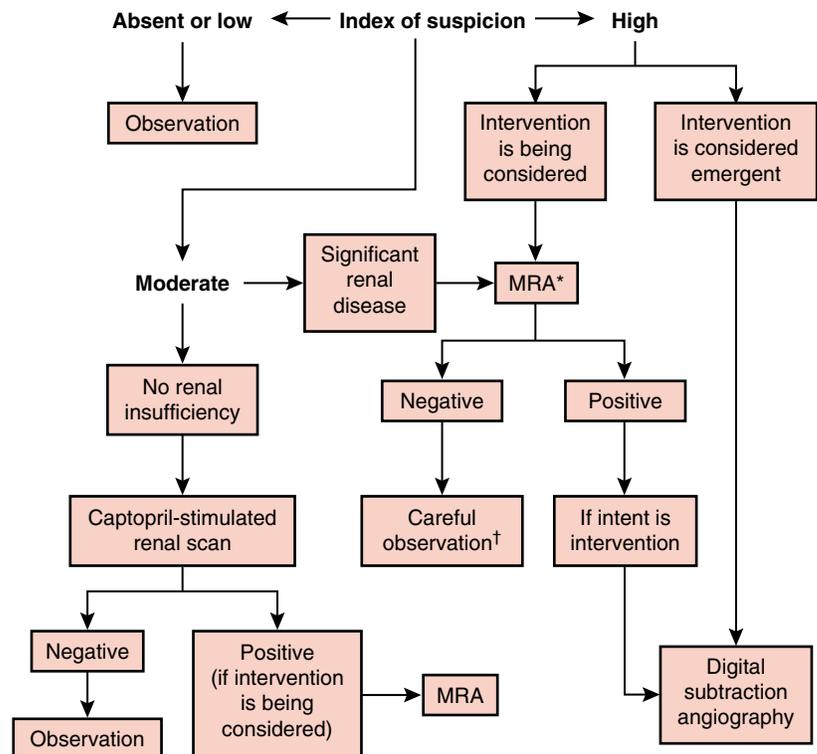

angiotensin II–induced stimulation of AT₂ receptors. As a result of the physiologic effects of angiotensin II and its receptors, GFR is more likely to be maintained distal to a renal artery lesion with an ARB when compared with an ACE inhibitor, thereby diminishing the scan's sensitivity.^{14,31,32} In addition to its high sensitivity and specificity, ACE inhibition renography is easy to perform, does not require discontinuing antihypertensive medications (except ACE inhibitors and ARBs at least 48 hours prior to the study), and may predict the blood pressure response to revascularization.^{25,26,28,33–37} The following are consistent with a positive study:

1. Decreased relative uptake by the involved kidney, which in turn contributes less than 40% of the total renal function
2. Almost twice the usual time (5 minutes) to peak uptake of the isotope on the affected side
3. Delayed washout of the radioisotope of more than 5 minutes on the involved side compared with the contralateral kidney

The radionuclides of choice are DTPA, a marker of glomerular filtration, and OIH, a marker of renal plasma flow. No statistically significant difference in quantitative or qualitative accuracy has been demonstrated between the two markers in the absence of significant renal insufficiency.³⁸ However, in the presence of moderate renal insufficiency, OIH is more sensitive.³³ Mercaptoacetyl triglycine (Mag₃), a radionuclide with transport properties similar to those of hippuran, has also been utilized and is particularly useful when colabeled with ⁹⁹Tc, with which it better delineates renal anatomy and can estimate renal blood flow.³⁹

Although uncommon, an occasional patient, when given captopril prior to renal scintigraphy, may experience a hypotensive episode, which is unrelated to the presence of

Figure 74–1 Schematic approach to the diagnostic investigation of renal artery stenosis. *A spiral computed tomography scan may be substituted for an MRA if there is no renal insufficiency or if an MRA is contraindicated or both. †If a patient's renal function significantly deteriorates or blood pressure cannot be controlled medically, proceed to angiography.

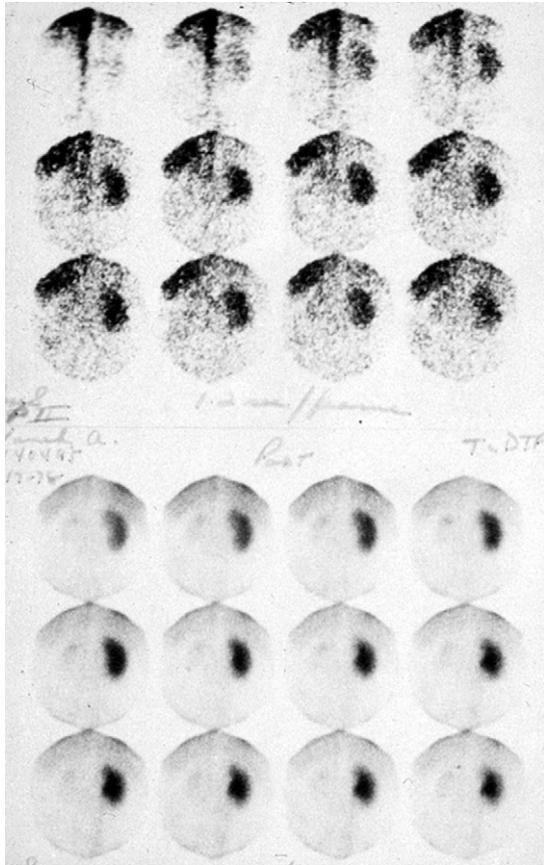

Figure 74-2 Renal scan, using ^{99m}Tc DPTA as the radionuclide, demonstrates reduced and delayed blood flow to the left kidney due to renovascular disease of the left renal artery.

significant renal artery stenosis (RAS).⁴⁰ Because prostaglandin metabolism may play a pathophysiologic role in renovascular hypotension, to avoid hypotension, an alternative method to increase the sensitivity of renal scintigraphy may be by inhibiting prostaglandin synthesis.⁴¹ Preliminary experience utilizing acetylsalicylic acid in place of captopril indicates that it may be an acceptable alternative to ACE inhibition.^{42,43} Thus far, no patient studied with this procedure has had a clinically significant episode of hypotension.

Stimulated renal scintigraphy is a practical screening test with high sensitivity and specificity, but its use is limited in patients with advanced azotemia or bilateral renovascular disease. It has been suggested that stimulated renal scans not be used in patients with creatinine clearances of less than 20 ml/min because of diminished accuracy at this level of renal dysfunction.^{23,24,28,30,44-46} However, furosemide when combined with OIH in stimulated scintigraphy has been found to be both sensitive (96%) and specific (95%) in screening patients with varying degrees of renal insufficiency (serum creatinine concentrations 1.8 to 5.3 mg/dl). This study was done in only a small number of patients and must be confirmed by larger trials.³³

Radioisotope scanning is most useful in patients with normal renal function and “resistant” or difficult-to-control hypertension. If the scan is negative, and the patient’s moderate to severe hypertension is likely to be due to inadequate

Figure 74-3 Time-of-flight MRA demonstrates a small area of narrowing 6 mm from the origin of the right renal artery and a severe occlusion of the left renal artery at its origin with poststenotic dilation.

therapy or noncompliance, we will not proceed with any further screening tests. If the scan is positive, we usually proceed with MRA.

Magnetic Resonance Angiography

Prospective studies indicate that three-dimensional phase contrast MRA with the paramagnetic contrast material gadopentetate dimeglumine (gadolinium), which is non-nephrotoxic, may be more sensitive than other screening tests (Figure 74-3).^{21,47,48} As an example, 80 patients were studied in trials comparing MRA with digital subtraction angiography (DSA) (see later) or conventional renal angiography.^{49,50} A sensitivity approaching 100% and a specificity of 71% to 96% was found with MRA. A meta-analysis of studies comparing MRA with conventional angiography has confirmed these findings and notes the superiority of gadolinium-enhanced studies compared with nonenhanced studies.⁵¹ When combined with cardiac synchronization, three-dimensional MRA can sharply delineate virtually the entire length of the major renal arteries. However, the visualization of distal, intrarenal, and accessory renal arteries that may have hemodynamically significant occlusive lesions remains suboptimal but has improved with the use of breath-hold high-spatial resolution, three-dimensional MRA with gadolinium.⁵²⁻⁶² In a study by Thornton et al. comparing MRA with breath-holding with conventional DSA, 2 of 10 (20%) accessory renal arteries were missed by MRA but detected by conventional DSA.⁵⁸ Although the percentage of nondemonstrable accessory renal arteries by MRA in this study appears high, it must be

noted that these arteries were less than 2 mm in size and clinically insignificant. The demonstration of stenoses and/or occlusions of arteries *with clinical significance* was therefore 100%, with one false positive. In another study by Shetty et al., all 11 accessory arteries were successfully detected using this MRA technique.⁶⁰ Results similar to these have also been obtained in patients with renal occlusive disease resulting in renal insufficiency. False-negative studies are rare, but overestimation of the degree of RAS because of overlying atherosclerotic plaques or tortuous vessels remains problematic and may lead to a false positive diagnosis in a small percentage of patients.

Despite these shortcomings, MRA is the single most reliable noninvasive method of detecting RAS and may soon, if negative, obviate the need for conventional angiography.^{51,63-65} MRA can also noninvasively determine both the absolute renal blood flow and the GFR and thus assess the functional significance of renovascular lesions.^{54,55} Furthermore, preliminary data suggest that the use of triple dose gadolinium may result in better imaging resolution and a greater confidence in diagnosis when compared with the conventional dose.⁶⁶ However, its safety in patients with renal insufficiency is unknown and, therefore, the role of high-dose gadolinium is not yet established.

MRA is extremely valuable in providing a noninvasive method of visualizing the arterial anatomy and is often the decisive factor in determining whether reperfusion is warranted. This excellent screening modality remains limited by its expense, its lack of general availability, and its contraindication in patients with metallic clips and implants, such as pacemakers and defibrillators.

Computed Axial Tomography

Spiral (helical) CT angiography with intravenous contrast administration has been used as a screening test for detecting renovascular lesions in patients with normal renal function. With this technique, the diagnostic accuracy in detecting renal artery lesions is quite good, with some investigators reporting a 98% sensitivity and a 94% specificity.⁶⁷ In a prospective study comparing spiral CT angiography and intraarterial DSA in 50 patients with normal renal function suspected of having RAS and in potential kidney donors, spiral CT angiography demonstrated 27 of 28 accessory renal arteries and 100% of stenoses of 50% or more in the main renal arteries.⁶⁸ These results were reconfirmed in a larger study by Wittenberg et al.⁶⁹ In this study, 197 arteries were examined in 82 patients and only one significant renal occlusive lesion was missed. In another prospective study comparing it with Doppler ultrasound, spiral CT angiography was the more accurate screening technique.⁷⁰ If these initial observations are confirmed by larger studies in patients without renal insufficiency, spiral CT angiography may become the noninvasive screening technique of choice. However, both the sensitivity and the specificity of this test decline (to 93% and 81%, respectively) in the presence of renal insufficiency (serum creatinine concentration >1.7 mg/dl).⁶⁷ Furthermore, the risk of radiocontrast-induced nephrotoxicity is significant because the volume of radiocontrast required is large (approximately 100 ml). These shortcomings have been the major limitations to its usefulness in our patient population, many of whom have significant renal insufficiency at presen-

tation. We use spiral CT angiography, if an MRA is contraindicated and there is no renal insufficiency nor an emergent need for nonmedical intervention.

Angiography

Negative screening tests do not totally exclude the presence of a renal artery lesion, especially in the distal vessels.²¹ Therefore, the clinical index of suspicion should determine which screening tests, if any, should be done. The clinician may opt to proceed immediately with conventional renal angiography or an intraarterial DSA, both of which remain the diagnostic gold standards (Figure 74-4).^{23,24,29} This is done when emergent percutaneous or surgical intervention is deemed appropriate. Because intraarterial DSA requires the administration of less radiocontrast (25-50 ml) than conventional angiography (100 ml), it is preferred, especially in patients with compromised renal function.

Carbon dioxide (CO₂) digital angiography has been used as an effective alternative to iodinated contrast agents in patients with renal insufficiency. When used in combination with digital subtraction, intraarterial CO₂ angiography provides diagnostic imaging similar to that achieved using standard contrast studies, while eliminating the potential nephrotoxicity of radiocontrast.^{71,72} Despite the absence of renal toxicity with CO₂ angiography, it may not provide adequate visualization of the more distal vasculature and requires an experienced technician, as well as sophisticated programming with electronic enhancement. In addition, the procedure may be complicated by air embolization, neurotoxicity, and renal ischemia due to "vapor lock." It still remains an investigational tool. Spinosa et al. have established the usefulness of gadolinium-enhanced CO₂ angiography when compared with CO₂-enhanced renal angiography.^{73,74} Gadolinium appears to be nonnephrotoxic even when given intraarterially and can also be used to

Figure 74-4 Selective renal angiography of the left renal artery demonstrates a 99% stenosis of the artery at its origin.

supplement CO₂ angiograms or, when necessary, confirm CO₂-enhanced angiographic findings. Although promising, the results of these studies were not directly compared with conventional angiography in the same patients, making it impossible to determine whether areas of arterial occlusion were missed with this technique.

Compared with intraarterial injection, *intravenous* DSA is less invasive and does not pose a risk of cholesterol embolization. However, the renal vasculature is not as well delineated as with intraarterial injection; the amount of radiocontrast required is greater (150-200 ml); and the sensitivity and specificity are 90% or less, compared with arterial studies.^{75,76} In addition, it requires more dye and is less reliable than a spiral CT scan. Therefore, we no longer use this test.

Duplex Doppler Ultrasonography

Similar to scintigraphy with Mag₃ colabeled with ⁹⁹Tc, ultrasonic duplex scanning of the renal arteries can provide both anatomic and functional information. This technique combines direct visualization of the main renal arteries via B-mode ultrasound imaging with Doppler measurements of various hemodynamic parameters characteristic of renal artery lesions. Stenotic lesions are detected by comparing the acceleration time, the resistive indexes of each kidney and artery, and the systolic or end-diastolic flow in the involved renal artery to that in the aorta. Early experience with this technique demonstrated a significant false-negative rate of 8% to 20%. However, studies have demonstrated greatly improved sensitivity and specificity when sonography was performed before and then compared with the results of angiography.⁷⁷⁻⁸⁴ As with radioisotope scanning, captopril (stimulated) Doppler ultrasound studies have further increased the sensitivity of the technique. The specific Doppler wave forms distal to the vascular lesion are enhanced by captopril and the sensitivity of the study may increase significantly and may approach 100% following captopril administration.⁸⁵

Duplex ultrasonography by utilizing intrarenal echo-Doppler velocimetric indexes (particularly the acceleration time and index) have been used to assess the success of dilation procedures, predict re-stenosis, and detect re-stenosis in arteries previously revascularized by angioplasty, stent placement, or surgery.^{29,79-81} A prospective study compared duplex Doppler scanning with captopril-stimulated renography in terms of their ability to detect hemodynamically significant renovascular lesions and to predict the fall in blood pressure following percutaneous transluminal angioplasty. No significant difference between the two tests was found, and the positive predictive value of both for blood pressure cure or improvement approached 90%.⁸⁶ Radermacher et al.⁸⁷ utilized the Doppler determined renal resistive index, a measure of structural alterations in distal smaller renal arteries and arterioles, to predict which of 138 patients with 50% or greater stenosis of unilateral or bilateral renal arteries would have an improvement in blood pressure and/or renal function following revascularization. Although specific information about individual patients regarding the degree of stenosis, whether the lesions were unilateral or bilateral and the type of procedure performed was not given, a resistance index (1 minus end-diastolic velocity divided by maximal systolic velocity × 100) of greater than 80 identified with reasonable accuracy (80%-97%) those patients in whom angioplasty and/or sur-

gery did not improve blood pressure, renal function, or kidney survival. Patients with a resistance index less than 80 were likely to have a successful intervention. The resistance index is potentially a useful guideline but should not be the sole factor in determining which patients should undergo interventional procedures.⁸⁸

Duplex Doppler scanning is noninvasive, does not require discontinuing any antihypertensive medications, and does not involve exposure to radiation or radiocontrast. Unlike the other screening tests described, it may be used with accuracy in patients with renal failure, and it provides information regarding the presence of bilateral disease.

Despite these advantages, the usefulness of duplex Doppler ultrasonography as a screening tool is limited because it is very time-consuming, operator-dependent, and technically difficult to perform, and extensive training in the procedure is necessary for an accurate study to be performed. In addition, intrarenal vascular lesions and multiple (and even main) renal arteries may be missed, particularly in obese patients or in those with overlying intestinal gas.^{29,77,84,86} MRA is also considerably more sensitive and specific than duplex sonography, particularly in detecting accessory renal arteries (96% vs. 5%).⁸⁹ Therefore, sonography's major use at present is to follow lesions in patients in whom an MRA is contraindicated and who have significant renal insufficiency, precluding a spiral CT scan.

SCREENING TESTS OF LITTLE CLINICAL USEFULNESS

Intravascular Ultrasonography

This invasive sonographic procedure provides structural detail of the renal vascular lesion and, therefore, can distinguish between fibromuscular dysplasia and atherosclerotic renal artery lesions.⁹⁰ Compared with noninvasive sonography, it can more accurately assess the severity of occlusion and closely correlates with angiographic findings.^{90,91} Because it estimates volumetric flow, it has also been used to assess the patency of renal arteries before and after angioplasty and stent placement.^{92,93} Intravascular ultrasonography is invasive and requires radiocontrast to guide the placement of the intra-arterial ultrasound probe. Therefore, its usefulness as a screening test is limited, especially in patients with impaired renal function.

Intravenous Pyelography

Decreased function of the kidney with renovascular disease may be detected by conventional intravenous pyelography (IVP), but greater sensitivity is achieved with a "hypertensive" IVP. With the latter technique, additional radiographs are taken at 1, 2, 3, 4, and 5 minutes. Thus, the hypertensive IVP is more likely to demonstrate a delay in the calyceal appearance or nephrogram of the affected kidney, which may be missed if only later films are viewed, as in a conventional IVP. Other IVP findings suggestive of renal artery disease include discrepancy in renal size or cortical thickness, hyperconcentration of the radiocontrast in the involved kidney, ureteral notching due to collateral circulation, and a prolonged nephrogram effect in the later films.¹ An IVP is now seldom

used as a screening test for renovascular hypertension because of its low sensitivity and specificity (both approximately 75%), the risk of radiocontrast-induced nephrotoxicity, and its relatively high radiation dose.^{29,94} Furthermore, in the presence of bilateral renal artery disease, many of the previously mentioned findings may be absent, especially if there is little difference in function between the two kidneys.²³

Plasma Renin Activity

Elevated baseline plasma renin activity (PRA) is found in only 50% to 80% of patients with renovascular hypertension and may be observed in 16% of patients with essential hypertension. Thus, an elevated baseline PRA is of limited diagnostic significance, and its absence in no way excludes renovascular hypertension. The predictive value of PRA may be enhanced by measuring its increase 1 hour after the ingestion of 25 to 50 mg of captopril.^{23,29,30} This “captopril test” improves the diagnostic accuracy of PRA, but the reported sensitivity and specificity of the procedure vary widely (63%-100% and 72%-100%, respectively), even when strict criteria for a positive result are met.^{23,30,95,96} In addition, to perform this test accurately, antihypertensive agents affecting PRA must be discontinued, which may be dangerous in these patients, most of whom have moderate to severe hypertension. The usefulness of the captopril test is further limited because it is impractical and requires strict standardization; its accuracy is reduced in the presence of mild renal insufficiency (serum creatinine concentration >1.5-2.0 mg/dl), and its predictive value is less than that of a renogram obtained following ACE inhibition (see later).^{22,25-27,97}

Because ACE inhibition may impair renal function in patients with bilateral renal artery disease, van de Van et al.⁹ utilized the effects of ACE inhibition on the plasma creatinine concentration in 108 patients at high risk for bilateral atherosclerotic renal artery disease to predict its presence prior to undergoing angiography. An increase in the plasma creatinine concentration of 20% or greater identified all patients who on angiography had severe bilateral disease (defined as 50% or more bilateral stenosis). As could be anticipated, many patients with unilateral and/or less severe disease also had an increase in serum creatinine concentration. Thus, although highly sensitive, this test yielded a specificity of only 70%, giving it little clinical usefulness.

DOES A RENAL ARTERY LESION CAUSE HYPERTENSION?

The mere presence of a renal artery lesion does not mean that it is the cause of hypertension. Therefore, prior to any intervention aimed at eliminating or controlling hypertension, the physiologic significance of a lesion should be proven.¹ ACE inhibitor scans, renal vein renin (RVR) measurements, and the pressure gradient across the renal artery lesion have been used to determine whether a stenosis is cause for hypertension.⁹⁸ If a lesion is the cause of “renin-dependent” hypertension, renin secretion by the kidney distal to the renal vascular lesion should be increased, and secretion by the contralateral kidney should be suppressed, resulting in an RVR ratio of 1.5 or more (affected:nonaffected side). When the RVR ratio is used to predict reduction in blood pressure following inter-

vention, a sensitivity of only 80% and a specificity of 62% have been reported.⁷⁵ However, the predictive accuracy of the RVR can be improved with the administration of ACE inhibitors prior to testing.²³ With unilateral renal artery disease and a captopril-stimulated lateralizing RVR, an improvement in blood pressure after revascularization is seen in up to 90% of patients.²⁴ However, the absence of lateralization does not necessarily mean that there will be no fall in blood pressure after intervention, for as many as 60% of these patients may still have an improvement in their blood pressures following revascularization.²⁴ Because of its low predictive value, the need for renal vein catheterization with radiocontrast injection, and the need to discontinue medications that may affect renin secretion, RVR measurements are no longer commonly used. More predictive than RVR measurements is the pressure gradient across the renal artery lesion as determined by intraarterial renal angiography. The absence of a significant pressure gradient (10-15 mm Hg) suggests that the lesion is of little physiologic significance and that revascularization in this setting will be of little benefit.

Because no single test is reliable enough to determine a causal relationship between a renal artery lesion and hypertension, the signs and symptoms previously described (items 1 through 8 under the Clinical Signs and Symptoms section), if present, should alert the clinician that it is highly likely that the lesion is causing hypertension. Once the diagnosis of renovascular hypertension is made, the clinician may attempt to control the patient's blood pressure with medical therapy alone and/or with percutaneous transluminal renal angioplasty (PTR), placement of a vascular endoprosthesis (a stent), or surgery. The therapeutic approach is determined by the type of lesion causing the hypertension, the site and extent of renal artery involvement, the overall medical status of the patient, and the perceived risks which are, in part, based on the interventionist's skills in performing the procedures. The effectiveness of each approach in controlling hypertension as well as the role of revascularization in preserving renal function (many of these patients have associated ischemic nephropathy and renal insufficiency) are reviewed later.

MEDICAL THERAPY FOR HYPERTENSION

Medical therapy for renovascular hypertension is similar to that for essential hypertension, but because severe hypertension is more common in patients with renovascular disease, combination drug therapy is frequently necessary in that group. Nevertheless, blood pressure control is usually achieved in more than 90% of cases. Because the hypertension may be dependent on angiotensin II, antihypertensives that inhibit renin or angiotensin II production or block their actions are especially useful in renovascular hypertension. Therefore, β -blockers, ACE inhibitors, and ARBs have been extensively utilized, with ACE inhibitors being especially efficacious.⁹⁹⁻¹⁰² Studies have demonstrated control of blood pressure in 80% of patients when ACE inhibitors are used alone and in up to 90% when they are combined with diuretic therapy.^{100,101} However, ACE inhibitors should be used with caution, particularly in patients with bilateral RAS (see later). Although there is less clinical experience with the newer ARBs, in experimental models of renovascular hypertension, they are as potent as ACE inhibitors.¹⁰³

Despite control of blood pressure with medical therapy, several studies have demonstrated that atherosclerotic renal artery lesions progress in 40% to 60% of patients within 7 years (with half of these lesions progressing within 2 years).¹⁰⁴⁻¹⁰⁶ Patients with an initial stenosis of more than 75% have the fastest rate of progression, with total occlusion occurring in 40% of these lesions.¹⁰⁴ Renal function, however, may not necessarily decline concomitantly. In addition to the “natural” progression of the atherosclerotic vascular lesion, medical therapy, by reducing blood pressure, may result in chronic hypoperfusion distal to the lesion and may hasten tubular atrophy, interstitial fibrosis, and glomerulosclerosis in the affected kidney or kidneys.¹⁰⁷⁻¹⁰⁹ Some investigators have demonstrated in animal models that at a given level of blood pressure, ACE inhibitors are more likely than other antihypertensive agents to induce these structural changes.^{107,108} However, to date, there are no clinical studies suggesting that ACE inhibitors or ARBs irreversibly hasten the loss of renal function when given on a long-term basis to patients with unilateral or bilateral atherosclerotic renovascular disease.¹¹⁰ Nevertheless, when these drugs are used, especially when they are combined with diuretic therapy, patients’ renal function should be monitored frequently. In addition to monitoring renal function with serum creatinine concentrations and 24-hour creatinine clearances, it has also been suggested that renal size and renal cortical blood flow velocity also be monitored using duplex scanning, because these parameters may provide earlier signs of irreversible renal function loss.¹¹¹ In a study of 122 patients, persistent stenosis increased the risk of long-term loss of renal mass, but this loss was more closely associated with the degree of RAS and the level of systolic blood pressure than with the use of ACE inhibitors. In addition to a possible association with *chronic* hypoperfusion and nephron loss, ACE inhibitors, as well as the ARBs, may result in *acute* (usually reversible) renal failure in 10% to 20% of patients with bilateral RAS or with RAS affecting a solitary kidney. This is most likely to occur when patients are volume-contracted.

Compared with atherosclerotic RAS, the risk of progressive occlusion and renal ischemia with medial fibroplasia, the predominant form of fibrous renal artery disease, is low.^{103,104} In contrast, the lesions of perimedial fibroplasia, medial hyperplasia, and intimal fibroplasia frequently progress and may result in a deterioration of renal function similar to that seen with atherosclerotic RAS.^{112,113} Therefore, renal function must be carefully monitored in these patients.¹⁰⁴

ANGIOPLASTY AND STENTING FOR HYPERTENSION

PTRA is an angiographic technique by which stenotic renal arteries are dilated with a catheter containing a cylindrical inflatable balloon at its tip (Figure 74–5). The success rate of PTRA is dependent on the site and type of the vascular lesion; it is most likely to be successful in lesions in which there is incomplete arterial occlusion, the length of the stenosis is less than 10 mm, and in lesions which do not involve the renal os.^{114,115}

Most studies of PTRA in patients with fibromuscular dysplasia report a high technical success rate (87%-100%), an improvement in or cure of the hypertension in as many

as 90% of patients, and a low incidence (10%) of re-stenosis.^{113,115-119} In contrast to fibromuscular dysplasia, the technical success rate of PTRA when performed for unilateral atherosclerotic renovascular lesions may be as low as 70%, and long-term improvement in or cure rates of the hypertension vary widely.^{113,115-119} The improvement in or cure of hypertension depends in large part on the location of the lesion. In a study of 100 patients, Canzanello et al. demonstrated an improvement in blood pressure of 86% in patients with nonostial unilateral lesions compared with 46% for patients with ostial unilateral lesions.¹¹⁹ Acute reversible renal insufficiency complicated 21% of the procedures, and mechanical complications, such as thrombosis, perforation, or dissection of renal arteries or diffuse atheroembolism occurred in 14% of the patients.

The preceding data were generated in uncontrolled trials. A randomized prospective trial comparing medical therapy (in 26 patients) with PTRA (in 23 patients) for unilateral RAS demonstrated that PTRA reduced the number of drugs necessary for blood pressure control at 6 months.¹²⁰ At baseline, 54% of the medically treated patients needed more than two antihypertensive medications, compared with 34% in the angioplasty group. With time, 88% of the medically treated group required two or more medications, compared with 35% of those who were postangioplasty. PTRA was complicated by one case of dissection with segmental renal infarction, and by re-stenosis in 18%. It should be noted, however, that more patients with ostial lesions at baseline (46% vs. 30%) were treated medically. Thus, the more favorable outcome observed with PTRA may reflect this selection bias. Of the medically managed patients, 27% were terminated from the study and subsequently underwent angioplasty because of refractory hypertension. It was not specified whether these “refractory” patients had ostial lesions and whether PTRA was successful. The results of this study are therefore difficult to interpret, and others are needed for a better comparison of these two approaches.

In contrast, no improvement in blood pressure was observed in a group of 13 patients with unilateral RAS randomized to PTRA as compared with 14 treated with medical therapy and followed for up to 54 months (range, 3-54 months).¹²¹ Major outcome events, such as death, myocardial infarction, heart failure, stroke, and dialysis, did not differ between the two groups. In addition, 28% of the patients who underwent angioplasty experienced complications attributable to the procedure, the most common of which was bleeding at the arterial puncture site (8 patients). Thus, it appears that when PTRA is used to control hypertension due to unilateral RAS, the potential gain, if any, is often outweighed by the risk and the discomfort of the procedure. Similarly, in the largest prospective blood pressure control study thus far, unimpressive results were obtained by van Jaarsveld et al.¹²² As defined by the presence of RAS 50% or greater, 75% of the patients had unilateral disease and 25% had bilateral disease. One hundred seven patients with similar clinical characteristics and a serum creatinine concentration 2.3 mg/dl or less at baseline were randomly assigned to medical therapy or PTRA (all but two without stenting). Based on an intent-to-treat analysis, the angioplasty group demonstrated only minimal improvement in blood pressure control at 3 months, but none at 12 months’ follow-up. Although 50% of the PTRA group reoccluded at 12 months, the lack of response in blood

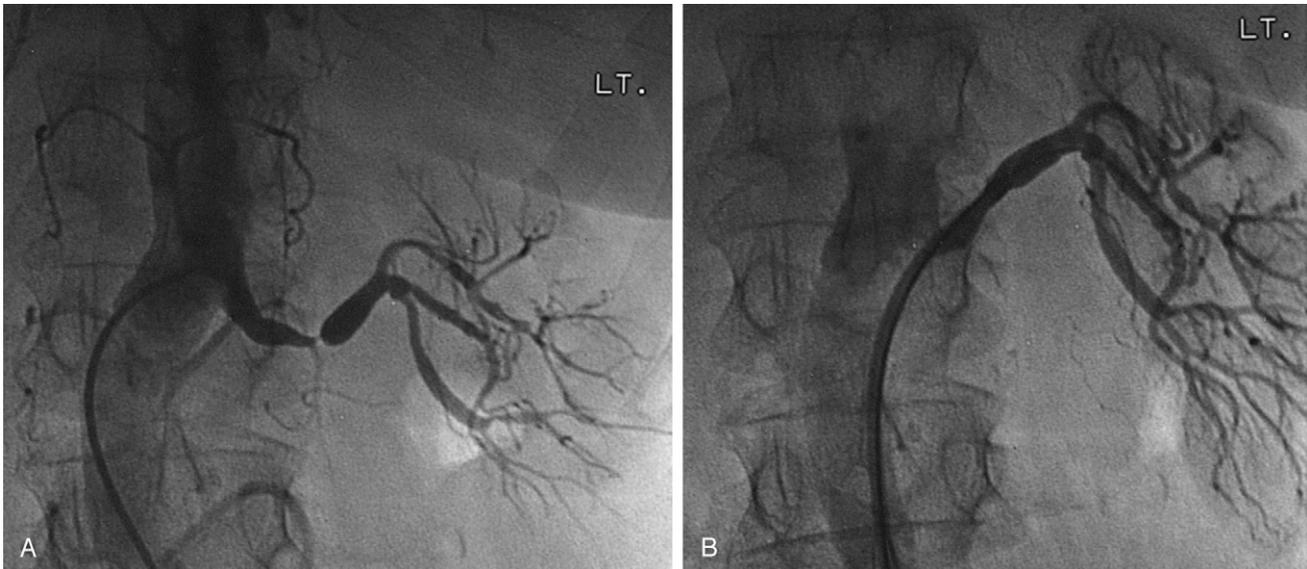

Figure 74-5 Nonostial renal artery lesion before (A) and after (B) percutaneous transluminal angioplasty.

pressure control was unrelated to either re-stenosis (proven by repeat angiography) at 12-month follow-up or to worsening of renal function. Blood pressure in the reoccluded group was similar to the group that did not reocclude and to the medically treated group. Although renal function appeared to be better in the angioplasty group than in the medical therapy group at 3 months, it was similar in both groups at 1-year follow-up. These apparent “negative” results with PTRAs, however, must be taken in context. It is important to note that approximately 50% of the patients who were assigned to receive antihypertensive drug therapy alone subsequently underwent “rescue” angioplasty because of inadequate blood pressure control. These patients, however, were analyzed as “medical therapy” patients. The success or at least the need of angioplasty may, therefore, have been significantly greater than reported. In addition, 25% of the patients had bilateral renal artery disease, which is considered to be less easily treated (by either method) than unilateral, but the results of their treatment is not separately reported. Successful treatment of unilateral disease both with regard to blood pressure control and/or preservation of renal function may have been better than bilateral disease. These data, however, cannot be gleaned from this study. The authors’ conclusion that it is still prudent to “restrict” PTRAs seems justified, although their study is inconclusive and does little to clarify the issues it was designed to study.¹²³

The results of PTRAs in patients with bilateral RAS are equally unimpressive, due, at least in part, to the high incidence of ostial or completely occluding lesions, both of which are more difficult to dilate and are associated with a high complication rate.^{114,116,119} Ramsay and Waller have reviewed 10 series of patients who underwent PTRAs for treatment of atherosclerotic RAS.¹¹⁶ In general, the selection criteria were ill-defined, and the patients chosen for the PTRAs were carefully selected, which probably biased the findings in favor of angioplasty. The studies cited had significant variations in the technical failure rates and the estimates of cure or improvement in blood pressure. Furthermore, the types of lesions treated were often not characterized. Despite the limitations of these stud-

ies, it appears that in bilateral atherosclerotic lesions, the technical failure rate may be as high as 60% and the cure rate for hypertension as low as 8%, with improvement in blood pressure in only 43%.¹¹⁶ The results are especially disappointing when the bilateral disease is associated with an atrophic kidney, because total renal artery occlusion of the atrophic kidney is observed in half of the cases.¹¹⁵ As demonstrated by Geyskes, PTRAs in a patient with an atrophic kidney resulted in an improvement in blood pressure in only 8 of 57 (14%) and in a cure of the hypertension in only 5 patients (9%).¹¹⁵

In view of these data, it is reasonable to attempt PTRAs only in the patients in whom medical therapy has failed and in whom an incomplete but high-grade (75%-90%) unilateral RAS distal to the os is present. Even with an initial successful therapeutic outcome, the incidence of re-stenosis following PTRAs for RAS is significant (30% for nonostial lesions and 50% for ostial lesions) and may occur soon after the procedure (15%-30% by 2 years). Reocclusion, however, does not preclude a repeat PTRAs.⁹⁹

To prevent or treat re-stenosis and improve blood pressure control with PTRAs for atheromatous ostial lesions, intravascular stents have been placed during angioplasty (Figure 74-6).¹²⁴⁻¹²⁶ One group of investigators has now performed this procedure without nephrotoxic radiocontrast by using a combination of intraarterial carbon dioxide and gadopentetate dimeglumine, avoiding the risk of contrast-induced acute renal failure.¹²⁷ Initial studies of intravascular stenting reported a success rate of 65% to 70% and a risk of re-stenosis ranging from 13% to 39%.^{124,125} More encouraging results were demonstrated in 68 patients with ostial lesions after stent placement for unsuccessful PTRAs.¹²⁶ The technical success rate was 100%; re-stenosis (defined as reocclusion of more than 50% of the vessel diameter) occurred in only 11% during a mean follow-up time of 27 months, and either cure or improvement of the hypertension was noted in 78%. No major complications were reported in this study. It is important to note that the majority of the patients (64%) were followed for only 12 months, with only 9% followed long-term (60 months). Furthermore, patients with a residual stenosis of

Figure 74-6 The renal ostial lesion depicted in Figure 74-5 is shown after placement of an intravascular stent.

up to 50% of the arterial lumen were classified as complete technical successes, even though they remain at a substantial risk for reocclusion. The study demonstrates the safety and short-term efficacy of the procedure but does not provide sufficient evidence to support long-term efficacy of endovascular stenting.¹²⁸ Nevertheless, it appears that renal arterial stenting may prove to be most useful in patients with ostial disease, restenosis after PTRA, or complications due to PTRA, such as dissection.¹¹³

Primary renal artery stenting (i.e., without antecedent PTRA) has also been performed in atherosclerotic RAS.¹²⁹ Most radiologists propose primary stent placement for those lesions within the aortic wall or within 10 mm of the aortic lumen, or if there is elastic recoil with PTRA with a residual stenosis of 30% or greater. The technical success rate is high and the rate of serious complications is low. Although the investigators do not specify what percentage of the patients had nonostial lesions, approximately 60% demonstrated cure or improvement of their blood pressure (regardless of whether there was unilateral or bilateral disease) at 6 months. At 1 and 4 years' follow-up, the improvement rate fell to 42%, and only 1% remained cured of their hypertension.^{130,131} At 6 months, 25% of the lesions were re-stenosed (proven angiographically), but longer-term patency rates of the stents are unknown because of lack of angiographic follow-up.¹²⁹⁻¹³¹

Two other studies have been done in patients who have undergone primary and/or secondary stenting.^{132,133} In both studies, no clinically significant improvement in blood pressure was observed. In the study with the longest follow-up (5 years), despite an initial diminution in the number of antihypertensive medications required at 3 to 6 months, the number increased subsequently and was no different from before stent placement. Patency was angiographically determined at a mean of 8 months \pm 5 months (range 2-24 months). A restenosis rate of 50% or more occurred in 14%.¹³³

A prospective study directly compared the outcomes of angioplasty alone versus primary angioplasty plus stent placement for ostial atherosclerotic RAS.¹³⁴ In this trial, 85 patients were randomized to one or the other intervention, with stent

placement if angioplasty alone failed within 6 months. Angioplasty plus stent was associated with a significantly higher initial success rate (88% vs. 57%), a much higher patency rate at 6 months (75% vs. 29%), and a lower restenosis rate (14% vs. 48%). Twelve patients underwent secondary stenting for primary or late failure within the 6 months' follow-up period with a similar success rate to primary stenting. Regarding control of hypertension, the combined procedure and angioplasty alone lowered blood pressure to the same extent, but was not compared with medical therapy. These results, at least for the short-term follow-up at 6 months, suggest that primary stenting for atherosclerotic lesions is superior to angioplasty alone because it eliminates the need for reintervention. No conclusions, however, can be drawn regarding blood pressure control (by either intervention) versus medical therapy.

Based on these data, stenting for control of blood pressure alone is not generally recommended. To date, no investigators have cited criteria that clearly define which patients with nonostial lesions should undergo primary renal artery stenting. We perform primary renal artery stenting in nonostial lesions in the patients in whom angiography demonstrates a very high-grade stenosis (90%) and/or a stenosis of 7 to 10 mm or longer, because the probability of success with PTRA alone is low.

Following successful PTRA, a reduction in blood pressure may be seen as early as 4 to 6 hours after the procedure, but the maximal antihypertensive effect is commonly achieved well after 48 hours.^{99,118} In some cases, the full antihypertensive benefit may not be observed until after several weeks. The absence of an early decline in blood pressure suggests that significant long-term improvement of the hypertension is unlikely.¹¹⁸

Although PTRA and stenting are generally safe procedures, complication rates of approximately 5% to 15% have been reported. Most of these complications, such as hematoma formation at the puncture site and renal artery spasm, are of minor clinical significance. However, if it is severe, renal artery spasm can lead to local thrombosis and renal infarction. This

can be prevented or reversed by the administration of intraarterial nitroglycerin. Major complications frequently include reversible, contrast-induced acute tubular necrosis (approximately 20%) and, infrequently (<5%), renal artery perforation, dissection, or irreversible acute renal failure due to atheroembolization.

SURGERY FOR HYPERTENSION

Surgical revascularization for renovascular hypertension involves bypassing the site of the arterial lesion by grafting or anastomosing another vessel distal to the lesion and/or removing an atrophic kidney. Because PTRA is highly successful in patients with fibromuscular dysplasia, is less invasive, and is associated with lower morbidity and mortality rates than is surgical revascularization, surgery is not recommended as primary therapy for these patients. It is done, however, when PTRA is unsuccessful or is technically not feasible, as is the case when branch renal artery disease is present (30% of patients with fibrous renal artery disease).^{135,136} When surgery is performed, 90% to 95% of patients with fibromuscular dysplasia are cured or see substantial improvement of their hypertension.^{75,113,136-138}

Although surgical revascularization in patients with atherosclerotic RAS may result in cure or improvement of the hypertension in as many as 80% to 90% of patients, surgery other than a simple nephrectomy of an atrophic kidney is not recommended for blood pressure control alone in patients with unilateral or with bilateral atherosclerotic renal artery disease. These patients are generally older and commonly have extensive extrarenal vascular disease. Their long-term survival rate following surgery, particularly if they have bilateral RAS and diffuse atherosclerosis, is poor. Furthermore, their hypertension can usually be controlled with medical therapy. If surgery becomes the only option, the probability of successful control of blood pressure in unilateral RAS is inversely related to the duration of and vascular damage caused by preexisting essential hypertension, as well as to the degree that the renin angiotensin system is activated in the contralateral kidney (see later). In the presence of underlying contralateral RAS with renal ischemia, parenchymal small-vessel disease, or both, the antihypertensive response to surgery is significantly diminished.^{113,136-140}

The morbidity and mortality with surgical revascularization is significant. As with any major intraabdominal vascular surgery, complications include those due to manipulation of the aorta (thrombosis, dissection, and atheroembolization), acute renal failure due to renal ischemia, pancreatitis, hemorrhage, splenic infarction, renal graft aneurysm formation, and postoperative RAS or renal artery thrombosis. Because of their younger age and absence of extrarenal vascular disease, mortality rates are very low in patients with fibromuscular disease. In contrast, mortality rates are significantly higher in patients with atherosclerotic disease unless they are carefully selected, in which case mortality rates may be as low as 3% to 5%. Mortality rates increase in patients older than 65 years of age, particularly if generalized atherosclerosis (coronary or cerebral vascular disease), congestive heart failure or significant renal disease is present. To decrease mortality, screening for and surgical correction of significant carotid or coronary artery disease should be accomplished before revascularization.¹³⁵

Hypertension may recur after surgery and is most often due to either recurrent atherosclerotic disease or anastomotic neointimal hyperplasia. Although recurrent lesions are generally clinically silent, in as many as 15%, either PTRA or another surgical procedure may be required. In approximately 10% of patients, bypass graft re-stenosis will occur and may be seen as late as 10 years after surgical revascularization.⁹⁹

To date, no prospective randomized trials have been done comparing medical therapy, PTRA, and surgery in controlling atherosclerotic renovascular hypertension. However, the results of several nonrandomized studies have suggested that surgery is the most successful, whereas other studies have demonstrated no difference in control of blood pressure among the three approaches.^{99,141-143} Many of these studies were done prior to the widespread use of ACE inhibitors, and recent advances in surgical techniques make these earlier comparisons irrelevant to current management strategies.

In a more recent prospective randomized trial comparing PTRA and surgical revascularization in a group of patients with unilateral RAS, a higher success rate and a lower incidence of re-stenosis were found in the surgical group after 2 years. However, the effect on blood pressure was not different when both interventions were successful.¹⁴⁴

Recommendations for the Management of Hypertension in Patients with Renal Artery Stenosis

Consistent with current data, we manage hypertension in patients with RAS as follows:

1. Because of its low risk:benefit ratio, high success rate, and low rate of re-stenosis, PTRA is the treatment of choice for fibromuscular dysplasia uncomplicated by branch renal artery disease. If PTRA is unsuccessful, or if branch renal artery disease is present, surgical revascularization should be undertaken, because these patients are generally young and have excellent responses to surgery, obviating the need for long-term medical therapy.
2. Medical therapy should be the primary management in patients with atherosclerotic RAS with mild, controllable hypertension or with comorbid conditions such as diffuse atherosclerosis that place them at high operative risk. Because renal function may decline with progression of the underlying atherosclerotic lesions or with the medical therapy itself, we monitor renal function closely in these patients. In addition, a renal scan can be performed soon after goal blood pressure is attained to assess the degree to which treatment has lowered the filtration rate in the stenotic kidney. If therapy includes ACE inhibitors or ARBs, and if there is a significant decrement in renal function, treatment may be switched to a calcium channel blocker and/or other agents less likely to impair autoregulation. If after alteration in the medical regimen renal functional deterioration persists, or if renal size(s) over time begin(s) to diminish significantly, PTRA or surgery should be performed in an attempt to preserve or improve renal function. As discussed later, the modality chosen is highly individualized.
3. In the absence of diffuse vascular disease or other comorbid conditions that may increase operative risk, revascularization should be undertaken in those generally younger

(age 50-60) patients with atherosclerotic RAS and moderate to severe hypertension (particularly if associated with episodes of flash pulmonary edema) only if blood pressure is not well controlled by medical therapy or if deterioration of renal function occurs with blood pressure control. PTRAs, with or without intravascular stenting, should then be done in the presence of a nonostial, partially occluding vascular lesion. In view of more technically successful results with intravascular stenting, we attempt this procedure in patients with ostial lesions, with nonostial lesions that have re-stenosed after PTRAs, and with lesions that have more than 90% stenosis or are 7 to 10 mm in length or longer, particularly in patients in whom the surgical risk is considerable. If the above approach is unsuccessful, surgical revascularization is performed, particularly in patients with unilateral RAS or when concomitant aortic surgery is required, as for an abdominal aortic aneurysm.

PRESERVATION OF RENAL FUNCTION

As previously discussed, atherosclerotic renal artery lesions may progress. However, it is not known how many patients with bilateral renovascular disease develop ischemic nephropathy or ESRD, and it is not known over what time period this occurs and which, if any, factors exist which may help reliably predict its incidence.^{145,146} Two retrospective studies examined these issues.^{147,148} In the first study, the investigators reviewed the medical records of 51 patients with particularly severe bilateral RAS (total occlusion or stenosis of 90% or more in one renal artery, with at least 50% stenosis on the opposite side).¹⁴⁷ Only medical therapy had been offered to these patients because of physician or patient preference, because the lesions were not amenable to angioplasty, because the kidneys were too small to salvage, or because the patient was not clinically suitable for surgical intervention. The overall mortality rate was high—38% within 2 years of renal angiography and 45% at 5 years. The incidence of ESRD was 12% at 5 years. The rate of decline of the GFR for all patients was 4 ml/min/year (range 1-16 ml/min/year). Those most likely to reach ESRD were those with more advanced renal failure (GFR <25 ml/min) at the time of angiography and those whose renal function showed a decline in GFR of greater than 8 ml/min/year. It is impressive that in a large percentage of patients, little or no serial change in renal function was observed despite the presence of severe bilateral disease. Progressive renal dysfunction and narrowing of the arterial lumen does not inevitably occur, and the development of collateral circulation to the kidneys may offset the reduction in flow in the major renal arteries. Hence, even in the presence of severe RAS, collateral circulation may maintain renal viability and function.^{149,150}

In the second study, a cohort of 593 consecutive patients underwent DSA because of peripheral vascular disease.¹⁴⁸ Of this group, the presence of RAS (defined as an occlusion ≥50%) could be assessed in 397 patients and was found coincidentally in 126. These “incidentally found” lesions were unilateral in 70% and bilateral in the remainder. Although renal function varied widely within this group (the creatinine clearance as estimated by the Cockcroft Gault formula was 58.2 ± 22.3 ml/min), none of these patients required renal replacement therapy during a 10-year follow-up. Remarkably, no dif-

ferences in renal function were found between patients with unilateral and bilateral RAS. Nevertheless, the group with bilateral disease, although at higher risk of ESRD, did not progress. It is important to note, however, that many renal arteries were not visualized and a significant number of “incidental” renal artery lesions may have been excluded from follow-up. These favorable results are not always the case, however, and it is clear that with medical therapy alone, progressive and/or rapid decline in renal function can result from renal artery disease. Renal failure is potentially reversible, perhaps more so in those with a more rapid decline in renal function.¹⁵¹

It has been estimated that ischemic nephropathy is the cause of renal failure in 5% to 15% of patients older than the age of 50 years, and it may account for 10% to 20% of all patients with ESRD. Despite dialytic therapy, mortality rates are high (>50% over 3 years), and 5- and 10-year survival rates are only 18% and 5%, respectively. In view of these grim statistics, restoration of renal function (either by surgery or by PTRAs with or without stenting) is critically important and should be attempted whenever indicated.^{106,112,152-154}

PTRAs in patients with renal dysfunction due to ischemic nephropathy improves renal function in 40% of patients and stabilizes function in an additional 30% to 40%.^{106,119,152,155,156} The majority of patients included in these studies had nonostial lesions. Because the success rate is reasonable and is comparable to that of surgical revascularization, which has a higher morbidity and mortality rate, PTRAs should be the initial intervention in patients with nonostial atherosclerotic lesions who have deteriorating renal function.¹⁵⁷ Re-stenosis occurs in 10% to 30% of these patients, and many of them are amenable to repeat PTRAs.¹⁵²

Only 15% to 20% of atherosclerotic lesions are nonostial.¹⁵⁷ With ostial atherosclerotic lesions, PTRAs without stenting has been largely ineffective because of the high technical failure rate due to elastic recoil of the artery and because of neointimal hyperplasia or recurrent atherosclerosis, both of which commonly result in eventual failure.¹⁵⁷ As previously discussed, the placement of intravascular stents for ostial atherosclerotic lesions is a promising new technique to improve the safety and possibly the long-term patency rate and efficacy of PTRAs.

Studies have examined the role of intravascular stenting in the preservation of renal function.^{126,130,132,158-160} Following unsuccessful angioplasty, 68 patients with ostial lesions underwent stenting. None of the 48 patients with normal renal function at baseline (serum creatinine concentration <1.4 mg/dl) had worsening of renal function at a mean follow-up of 27 months. Similarly, no deterioration of renal function was observed in the 30% of patients who had significant renal insufficiency at baseline.¹²⁶ In another study, 32 patients with a median serum creatinine concentration of 2.9 mg/dl underwent renal artery stenting and were followed for a mean of 8 months (range 0-29 months). Of the 32 patients, 11 (34%) showed significant improvement in renal function, 11 (34%) stabilized, and 9 (28%) worsened. In a subset of 23 patients, in whom the level of renal function prior to stenting was known for a sufficient time period that the reciprocal of the serum creatinine versus time could be plotted, the rate of progression of renal failure was slowed in 18 (78%) following the procedure. Patients with baseline serum creatinine levels of less than 4.5 mg/dl were most likely to benefit from stenting.¹³² Similar data were reported by Beutler

et al. who followed 63 patients (46% of whom “failed” PTRAs) who were stented and followed for a mean of 23 months.¹⁵⁸ Data for at least 1 year prior to study were available regarding renal function. Twenty-eight patients had stable renal function (<20% change in serum creatinine) prior to stenting. One patient died at 6 months with ESRD and 1 became dialysis-dependent at 5 months. Of the remaining 26 patients within this group, renal function was unchanged in 18 (69%) and improved in only 2 (8%) after the procedure. However, 6 patients (23%) showed worsening of their previously stable renal (dys)function. Of those 35 patients who had declining renal function prior to study (>20% rise in serum creatinine), after stenting 13% continued to deteriorate, but 66% stabilized with 20% more improved. Further analysis of the data revealed that of all patients who exhibited deterioration of renal function after stenting, those with baseline serum creatinine concentration of greater than 3.4 mg/dl were far more likely to do so (5 of 10 patients). However, only 10 of 53 patients (19%) whose serum creatinine concentrations at baseline were less than 3.4 mg/dl had deterioration of renal function during follow-up. Based on the aforementioned data, it can be concluded that renal artery stenting for bilateral disease is likely to at least stabilize or improve renal function in those patients with initial mild renal failure who manifested significant worsening of their renal function prior to the procedure. It is unlikely to reverse advanced renal failure, particularly if renal sizes are less than 8.0 cm.¹⁴⁰

Although their study was not designed to specifically examine preservation of renal function, Burket et al. demonstrated an improvement in renal function in 43%, no change in 24%, and worsening in 32% of the 37 patients with baseline renal insufficiency (serum creatinine concentration >1.6 mg/dl) stented for primarily ostial lesions.¹⁶⁰ The follow-up ranged from 1 to 52 months (mean 15 ± 14 months).

A meta-analysis of 10 studies done by Isles et al. demonstrated results consistent with those previously cited.¹⁶¹ The average follow-up for these patients, however, was less than 1 year. Results of stenting for ischemic nephropathy in patients followed for longer periods have been reported.^{131,133,159,162} Of 163 patients who underwent primary stenting, Dorros et al. followed 145 for approximately 4 years.¹³¹ The outcome of renal function was stratified according to whether the lesion was initially bilateral or unilateral. The baseline serum creatinine concentration in both groups was approximately 2.0 mg/dl. Of those with unilateral disease, 67% experienced improved or stable renal function, and the remainder progressed as reflected by an increase in the serum creatinine concentration of more than 0.2 mg/dl above baseline. Of those with bilateral disease, 75% had stable or improved renal function, and 25% deteriorated. Overall survival, however, was worse for those with poorer renal function at baseline, regardless of whether stenting was successful. Survival at 4 years was good in patients with normal baseline renal function (92% ± 4%), fair (74% ± 7%) in those with mildly impaired renal function (serum creatinine concentration 1.5-1.9 mg/dl), and poor (52% ± 7%) in patients with serum creatinine levels of 2.0 mg/dl or more. The rate of re-stenosis is not reported in this study. These authors have also published the results of a larger series of patients (1058) followed for up to 4 years.¹⁶² Their results were more promising and demonstrated that stabilization or improved renal function could be achieved in 70% of those with unilateral lesions and 92% of those with bilateral lesions. It is important to note, how-

ever, that there was no comparison with medical therapy alone and no prior knowledge of stability of renal function and that the mean baseline serum creatinine concentration was less than 2.0 mg/dl (1.7 ± 1.1 mg/dl).

Tuttle et al. followed 129 patients after primary or secondary stenting for a mean of 24 months.¹³³ During this follow-up time, renal function, as assessed by creatinine clearances, remained stable, but no improvement in renal function was demonstrated regardless of baseline creatinine clearance (range 23 ± 3-53 ± 3 ml/min). However, of the 129 patients studied, 4 of the 8 who were initially dialysis-dependent recovered renal function after stenting. Their mean serum creatinine concentration was 2.3 ± 0.5 mg/dl at 15 ± 6 months (range 9-24 months). As demonstrated by angiography in 46 patients with a total of 49 stents, the re-stenosis rate was 14% at 8 ± 5 months.¹³³ Rundback et al. followed 45 patients with azotemia (serum creatinine concentration >1.5 mg/dl) and atheromatous RAS untreatable by, or recurrent after, PTRAs for a mean of 54 months. Similar to the findings of Tuttle et al., renal function remained stable (serum creatinine concentration approximately 2.1 mg/dl).¹⁵⁹

These reports are limited by the absence of a control group treated with medical therapy alone and by the fact that (except in two studies cited above 132,158) no data are provided about whether intervention was performed because of ongoing deterioration of renal function prior to stenting.¹²⁶ Nevertheless, PTRAs with intravascular stenting may prove to be the best therapeutic option for patients with ostial atherosclerotic RAS who are deemed poor surgical risks or have refused surgery and are demonstrating worsening renal function or are on dialysis. In the presence of renal insufficiency, when possible, stent placement should be performed with CO₂ and/or gadolinium guidance.¹¹⁷

The results of *surgical* revascularization for the preservation of renal function in patients with atherosclerotic RAS have been similar to or slightly better than results with PTRAs and, on occasion, have even reversed ESRD.* Improvement in renal function has been observed in approximately 50%, and stabilization of renal function has occurred in approximately 35%.[†]

Prospective randomized studies comparing medical therapy with surgical treatment of RAS are rare. Uzzo et al. prospectively randomized 52 patients with atherosclerotic RAS affecting their entire nephron mass to medical versus surgical management.¹⁶⁶ All patients had angiographic confirmation of bilateral RAS involving greater than 75% of the luminal diameter, high-grade (>75%) disease involving a solitary kidney, or unilateral high-grade (>75%) stenosis with azotemia (serum creatinine concentration >1.5 mg/dl and a GFR of <70 ml/min). Patients were excluded if the serum creatinine concentration was greater than 4.0 mg/dl, if their blood pressure was poorly controlled despite attempts at adequate medical management, or if there were comorbid conditions precluding surgery. The primary aim was a comparison of stop-point events between the medical and surgical groups. Four stop-points were defined: (1) development of poorly controlled hypertension (diastolic blood pressure >100 mm Hg); (2) reduction of GFR 50% or greater from baseline, an increase in serum creatinine concentration to greater than 4 mg/dl

*References 106, 112, 137, 152, 157, 163, 164.

†References 106, 112, 137, 152, 157, 159, 163, 165.

(5 mg/dl if baseline serum creatinine concentration was between 2 and 4 mg/dl), doubling of the serum creatinine from baseline or the development of ESRD; (3) intercurrent myocardial infarction or cerebrovascular accident; and (4) death. There was no statistically significant difference in the endpoints reached between the groups, and the time to reach an endpoint was not dissimilar. Overall survival, dialysis free survival and/or blood pressure control were not significantly different between the two groups. Patients with baseline azotemia (serum creatinine concentration 2-4 mg/dl), however, when surgically revascularized were less likely to die or to develop uncontrollable hypertension. Due to its small sample size, firm conclusions cannot be drawn from this study, but it underscores the need for further large-scale prospective studies.¹⁶⁶

Because the operative morbidity and mortality rates (11% and 3%-6%, respectively) are significant, careful patient selection is imperative.^{106,138,140,163} If the disease is progressing, if PTRAs with or without stenting has failed, and if other patient-specific risk factors favor long-term survival, and the patient fulfills the strict criteria outlined subsequently, surgical revascularization should be undertaken before advanced renal failure is evident. The best window of opportunity for renal survival achieved by surgical revascularization is when the serum creatinine concentration is between 1.5 and 3.0 mg/dl.¹⁴⁰ Patients with diffuse atherosclerotic disease and congestive heart failure, or those undergoing simultaneous bilateral renal artery repair or revascularization in combination with another major vascular procedure, pose the greatest surgical risk.¹⁵⁷ As with surgical correction for renovascular hypertension, underlying coronary or cerebrovascular disease needs to be corrected prior to surgery in order to reduce operative risk. Although balloon angioplasty can be performed for in-stent re-stenosis, stenting does not preclude future surgical revascularization but does make it more difficult because the stent becomes endothelialized and difficult to remove.

Successful surgical revascularization depends on the degree of renal insufficiency present, the rate at which renal function has deteriorated preoperatively, and the anatomy of the renal vasculature distal to the renoocclusive lesion or lesions. In the presence of advanced renal failure (serum creatinine concentration above 4.0 mg/dl), revascularization offers little benefit because significant irreversible renal parenchymal disease is invariably present.^{135,140} In addition to the absolute level of renal function, it appears that patients with the most rapid decline in renal function in the 6 months prior to surgery have the greatest recovery of renal function following revascularization.¹⁶⁷ Adequate collateral renal circulation is critical for surgical revascularization because it is necessary for maintaining viable glomeruli. Therefore, recovery or stabilization of renal function is more likely postoperatively when one or more of the following is present preoperatively^{135,168-170}:

1. Visualization of the collecting system on an IVP or during the pyelogram phase of the arteriogram
2. Renal length greater than 9.0 cm
3. Demonstration of retrograde filling of the distal renal vasculature from collateral circulation on the side of total renal artery occlusion during angiography
4. The presence of viable glomeruli on renal biopsy (performed before or at the time of revascularization)

Because of the higher attendant risk of surgery, and comparable results with PTRAs and stenting, and perhaps with

medical therapy, we adhere very strictly to these guidelines and patient selection before recommending surgery and have become more inclined to attempt percutaneous intervention.

Recommendations for the Management of Chronic Renal Failure Due to Ischemic Renal Disease (RAS)

1. Medical therapy should be the primary management, particularly in older patients who are poor operative risks and especially if renal dysfunction is stable. Careful follow-up is indicated because progressive atherosclerosis can lead to worsening hypertension and renal insufficiency.
2. PTRAs with intravascular stenting is the best therapeutic option for older patients who have demonstrated deterioration of their mild to moderate renal insufficiency (serum creatinine concentration 1.5 to \leq 3.5 mg/dl), who are generally considered to be poor operative risks. Whenever possible, PTRAs with stenting should be attempted with CO₂ and/or gadolinium guidance to avoid nephrotoxicity.¹²⁷
3. As success with PTRAs with stenting is improving, the role of surgical intervention is declining. We and others reserve it for the occasional "younger" patient with an overall more favorable prognosis with high-grade ostial lesions in whom PTRAs and stenting have failed.¹⁷¹ These patients should have minimal or insignificant untreated extrarenal vascular disease and exhibit declining mild to moderate renal dysfunction (serum creatinine concentration 1.5 to \leq 3.5 mg/dl). In addition, they should fulfill the strict criteria previously outlined. Surgical revascularization is suggested, if concomitant aortic surgery is required, such as an abdominal aortic aneurysm repair.
4. If there is far advanced renal failure (serum creatinine concentration >4.0 mg/dl) both PTRAs with or without stenting and surgical revascularization are unlikely to significantly reverse renal failure. However, because of the occasional patient who may respond, we may offer PTRAs with stenting, particularly if the procedure can be done with CO₂ and/or gadolinium guidance, in a final effort to avoid dialysis.^{127,159}

It is important to note that although the methods for diagnosis and treatment of RAS have improved, the use of invasive diagnostic techniques and treatment early in the course of the disease still have no proven benefit.¹⁷² The effects of revascularization (surgical and percutaneous) on long-term renal and cardiovascular outcomes should be compared with those of comprehensive pharmacologic treatment. Until such a comparison is made, the immediate risks versus the potential, unproven long-term benefits must be carefully considered and individualized to each patient.¹⁷¹ Until then, the emphasis should be on identifying those patients at risk for renal failure and treating and preventing those factors which accelerate their atherosclerosis and progression to more advanced stages of renal failure. Particular attention should be directed toward lowering lipid levels, which may restore vessel patency in atherosclerotic RAS through regression of the stenotic plaque, similar to the regression demonstrated in coronary, carotid, and peripheral arteries.¹⁷³

Renal artery disease is a major health problem and is the cause of high rates of morbidity and mortality. Appropriate management requires the combined expertise of

nephrologists, interventional angiographers, and vascular surgeons. The correct therapeutic approach, which is highly individualized, may lead to better management of blood pressure, stabilization, or restoration of renal function and, perhaps, improved patient survival; it represents a continuing challenge to those caring for these patients. Large-scale trials that will determine the best therapeutic modality for patients with the clinical consequences of RAS are long overdue.^{146,174}

Adrenal Cortex Hypertension

William F. Young, Jr.

Adrenal cortex–dependent hypertension is not common in the general population of hypertensives, but an accurate diagnosis provides clinicians with a unique treatment opportunity, that is, to render a surgical cure or to achieve a dramatic response with pharmacologic therapy. Forms of adrenal cortical hypertension that may be amenable to surgery include overproduction of aldosterone, deoxycorticosterone, and cortisol, resulting in the syndromes of primary aldosteronism, hyperdeoxycorticosteronism, and Cushing's syndrome, respectively. In this chapter the key features of the clinical presentation, diagnosis, and treatment of each of these disorders are reviewed.

PRIMARY ALDOSTERONISM

Hypertension, hypokalemia, suppressed plasma renin activity (PRA), and increased aldosterone excretion characterize the syndrome of primary aldosteronism, first described in 1955.¹ Aldosterone-producing adenoma (APA) and bilateral idiopathic hyperaldosteronism (IHA) and are the most common subtypes of primary aldosteronism (Box 75–1). A much less common form, unilateral hyperplasia or primary adrenal hyperplasia (PAH), is caused by hyperplasia of the zona glomerulosa of predominantly one adrenal gland. Familial hyperaldosteronism (FH) is also rare, and two types have been described: FH type I and FH type II. FH type I, or glucocorticoid-remediable aldosteronism (GRA), is autosomal dominant in inheritance and associated with variable degrees of hyperaldosteronism, high levels of hybrid steroids (e.g., 18-hydroxycortisol and 18-oxocortisol), and suppression with exogenous glucocorticoids.² FH type II was reported initially in five families (13 patients) and refers to the familial occurrence of APA or IHA or both.³

Prevalence

In the past, clinicians would not consider the diagnosis of primary aldosteronism unless the patient presented with spontaneous hypokalemia, and then the diagnostic evaluation would require discontinuing antihypertensive medications for 2 weeks. The “spontaneous hypokalemia/no antihypertensive drug” diagnostic approach resulted in predicted prevalence rates of less than 0.5% of hypertensive patients.^{4–9} However, it is now recognized that most patients with primary aldosteronism are not hypokalemic^{10–13} and that screening can be completed with a simple blood test (plasma aldosterone concentration [PAC]:plasma renin activity [PRA] ratio) while the patient is taking antihypertensive drugs.^{14–20} Using the PAC:PRA ratio as a screening test followed by aldosterone suppression confirmatory testing has resulted in much higher prevalence estimates (5%–13% of all patients with hypertension) for primary aldosteronism.^{10,21–27}

Clinical Presentation

The diagnosis of primary aldosteronism is usually made in patients who are in the third to sixth decade of life. Few symptoms are specific to the syndrome. Patients with marked hypokalemia may have muscle weakness, cramping, headaches, palpitations, polydipsia, polyuria, or nocturia, or a combination of these. There are no specific physical findings. The degree of hypertension is usually moderate to severe and may be resistant to usual pharmacologic treatments.^{28–29} (See Chapter 59 for a discussion of primary aldosteronism in the setting of resistant hypertension.) Hypokalemia is frequently absent; thus, all patients with hypertension are candidates for this disorder. Several studies have shown that patients with primary aldosteronism may be at higher risk than other patients with hypertension for target organ damage of the heart and kidney.^{30–41}

Diagnosis

The diagnostic approach to primary aldosteronism can be considered in three phases: screening tests, confirmatory tests, and subtype evaluation tests.

Screening Tests

Spontaneous hypokalemia is uncommon in patients with uncomplicated hypertension and, when present, strongly suggests associated mineralocorticoid excess. However, normokalemia does not exclude primary aldosteronism. Several studies have shown that most patients with primary aldosteronism have baseline serum levels of potassium in the normal range.^{21,42,43} Therefore, hypokalemia is not required to make the diagnosis of primary aldosteronism. Patients with hypertension and hypokalemia, regardless of presumed cause (e.g., diuretic treatment), and most patients with treatment-resistant hypertension should undergo screening for primary aldosteronism (Figure 75–1).

In patients with suspected primary aldosteronism, screening can be accomplished by measuring a morning, nonfasting (preferably 8 A.M.) ambulatory paired random PAC and PRA (see Figure 75–1). This test may be performed while the patient is taking antihypertensive medications and without postural stimulation.^{19,44} Hypokalemia reduces the secretion of aldosterone, and it is optimal to restore the serum level of potassium to normal before performing diagnostic studies. Aldosterone receptor antagonists (e.g., spironolactone and eplerenone) are the only medications that will absolutely interfere with interpretation of the ratio. Angiotensin-converting enzyme (ACE) inhibitors and antitension receptor blockers (ARBs) have the potential to “falsely elevate” PRA. Therefore, in a patient treated with an ACE inhibitor or an ARB, the findings of a detectable PRA level or a low PAC:PRA ratio do not exclude the diagnosis

Box 75-1 Adrenocortical Causes of Hypertension**Primary Aldosteronism**

Aldosterone-producing adenoma (APA)
 Bilateral idiopathic hyperplasia (IHA)
 Primary (unilateral) adrenal hyperplasia (PAH)
 Aldosterone-producing adrenocortical carcinoma
 Familial hyperaldosteronism (FH)
 Glucocorticoid-remediable aldosteronism (FH type I)
 FH type II (APA or IHA)

Hyperdeoxycorticosteronism

Congenital adrenal hyperplasia
 11 β -Hydroxylase deficiency
 17 α -Hydroxylase deficiency
 Deoxycorticosterone-producing tumor
 Primary cortisol resistance

Apparent Mineralocorticoid Excess (AME)/11 β -Hydroxysteroid Dehydrogenase Deficiency

Genetic
 Type I AME
 Type II AME
 Acquired
 Licorice or carbenoxolone ingestion (type I AME)
 Cushing's syndrome (type II AME)

Cushing's Syndrome

Exogenous glucocorticoid administration—most common cause
 Endogenous
 ACTH-dependent (85%)
 Pituitary
 Ectopic
 ACTH-independent (15%)

 Primary pigmented nodular adrenal disease (rare)

ACTH, adrenocorticotrophic hormone.

of primary aldosteronism. In addition, a strong predictor for primary aldosteronism is a PRA level undetectably low in a patient taking an ACE inhibitor or an ARB.

The PAC:PRA ratio, first proposed as a screening test for primary aldosteronism in 1981,¹⁴ is based on the concept of paired hormone measurements.¹⁶ For example, in a hypertensive hypokalemic patient (1) secondary hyperaldosteronism should be considered when both PRA and PAC are increased and the PAC:PRA ratio is less than 10 (e.g., renovascular disease), (2) an alternate source of mineralocorticoid receptor agonism should be considered when both PRA and PAC are suppressed (e.g., hypercortisolism), and (3) primary aldosteronism should be suspected when PRA is suppressed and PAC is increased (Figure 75-2). Fourteen prospective studies have been published on the use of the PAC:PRA ratio in screening for primary aldosteronism.* Although there is some uncertainty about test characteristics and lack of standardization,²⁰

*References 14, 19, 21, 23-26, 42-52.

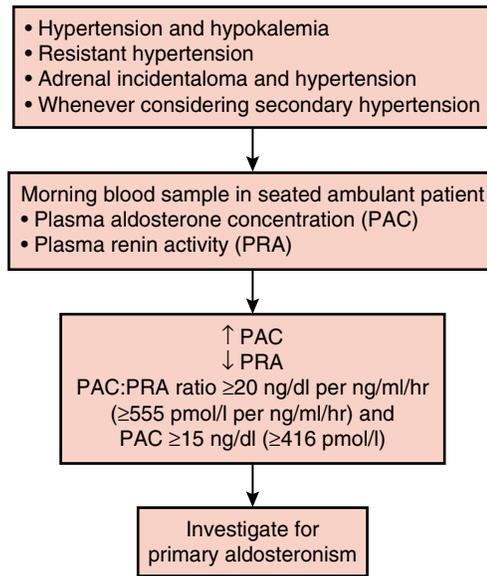

WHEN TO CONSIDER SCREENING FOR PRIMARY ALDOSTERONISM

Figure 75-1 Use of the plasma aldosterone concentration: plasma renin activity ratio to screen for primary aldosteronism.

the PAC:PRA ratio is widely accepted as the screening test of choice for primary aldosteronism.^{53,54}

It is important to understand that the lower limit of detection varies among different PRA assays and can have a dramatic effect on the PAC:PRA ratio.⁵⁵⁻⁵⁷ As an example, a very different ratio is obtained if the lower limit of detection for PRA is 0.6 ng/ml/hour rather than 0.1 ng/ml/hour; for a PAC of 16 ng/dl, the PAC:PRA ratio would be 27 and 160, respectively. Thus, the cutoff for a “high” PAC:PRA ratio is laboratory dependent and, more specifically, PRA assay-dependent. Weinberger et al.¹⁸ found that the combination of a PAC:PRA ratio greater than 30 and PAC greater than 20 ng/dl had a sensitivity of 90% and a specificity of 91% for APA. Hirohira et al.⁵⁷ found that a PAC:PRA ratio greater than 32 had a sensitivity of 100% and a specificity of 61% for APA. At the Mayo Clinic, a PAC (in ng/dl):PRA (in ng/ml/hour) ratio 20 or greater and PAC 15 or greater are found in more than 90% of patients with surgically confirmed APA. In patients without primary aldosteronism, most of the variation occurs within the normal range. A high PAC:PRA ratio is a positive screening test result, a finding that warrants further testing.

Confirmatory Testing

An increased PAC:PRA ratio is not diagnostic by itself, and primary aldosteronism must be confirmed by demonstrating inappropriate aldosterone secretion. The list of drugs and hormones capable of affecting the renin-angiotensin-aldosterone axis is extensive, and frequently in patients with severe hypertension, a “medication-contaminated” evaluation is unavoidable. Calcium channel blockers, α -adrenergic receptor blockers, and β -adrenergic receptor blockers do not affect the diagnostic accuracy in most cases.⁵⁸ It is impossible to interpret data obtained from patients receiving treatment with aldosterone receptor antagonists (e.g., spironolactone, eplerenone) when PRA is not suppressed. Therefore, treatment with an

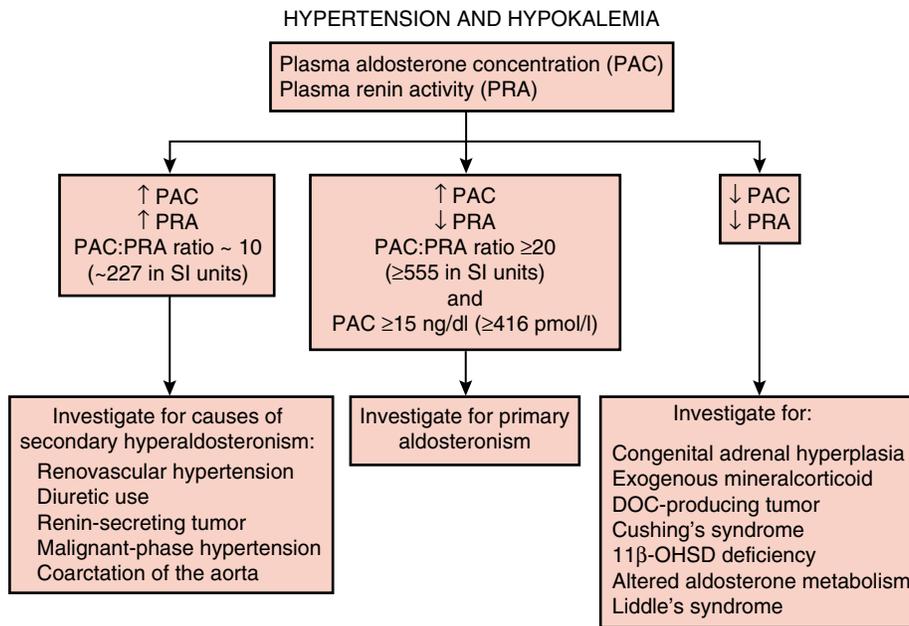

Figure 75-2 Use of the plasma aldosterone concentration:plasma renin activity ratio to differentiate among different causes of hypertension and hypokalemia. SI units, international system of units. (Modified from Young WF Jr, Hogan MJ. Renin-independent hypermineralocorticoidism. *Trends Endocrinol Metab* 5:97-106, 1994.)

aldosterone receptor antagonist should not be initiated until the evaluation has been completed and the final decisions about treatment have been made. If primary aldosteronism is suspected in a patient receiving treatment with spironolactone or eplerenone, the treatment should be discontinued for at least 6 weeks before further diagnostic testing.

Aldosterone suppression testing can be performed with orally administered sodium chloride and measurement of urinary aldosterone or with intravenous sodium chloride loading and measurement of PAC.^{42,58,59} After hypertension and hypokalemia are controlled, patients should receive a high-sodium diet (supplemented with sodium chloride tablets if needed) for 3 days. The risk of increasing dietary sodium in patients with severe hypertension must be assessed in each case. Because the high-salt diet can increase kaliuresis and hypokalemia, vigorous replacement of potassium chloride may be needed, and the serum level of potassium should be monitored daily. On the third day of the high-sodium diet, a 24-hour urine specimen is collected for measurement of aldosterone, sodium, and potassium. To document adequate sodium repletion, the 24-hour urinary sodium excretion should exceed 200 mEq. Urinary aldosterone excretion greater than 12 $\mu\text{g}/24$ hours in this setting is consistent with autonomous aldosterone secretion.⁶⁰

Subtype Studies

Following screening and confirmatory testing, the third management issue guides the therapeutic approach by distinguishing APA and PAH from IHA and GRA. Unilateral adrenalectomy in patients with APA or PAH results in normalization of hypokalemia in all; hypertension is improved in all and is cured in approximately 30% to 60% of these patients.⁶¹ In IHA and GRA, unilateral or bilateral adrenalectomy seldom corrects the hypertension.⁵⁸ IHA and GRA should be treated medically.

Primary aldosteronism subtype evaluation may require one or more tests, the first of which is imaging the adrenal glands with computed tomography (CT) (Figure 75-3). When a solitary unilateral macroadenoma (>1 cm) and normal contralat-

eral adrenal morphology are found on CT in a young patient (<40 years) with primary aldosteronism, unilateral adrenalectomy is a reasonable therapeutic option (Figure 75-3). However, in many cases, CT may show normal-appearing adrenals, minimal unilateral adrenal limb thickening, unilateral microadenomas (≤ 1 cm), or bilateral macroadenomas (Figure 75-4). In these cases, additional testing is required to determine the source of excess aldosterone secretion. Small APAs may be labeled incorrectly as “IHA” on the basis of CT findings of bilateral nodularity or normal-appearing adrenals. Also, apparent adrenal microadenomas may represent areas of hyperplasia, and unilateral adrenalectomy would be inappropriate. In addition, nonfunctioning unilateral adrenal macroadenomas are not uncommon, especially in older patients (>40 years) (Figure 75-4).⁶²

In general, patients with APAs have more severe hypertension, more frequent hypokalemia, and higher plasma (>25 ng/dl) and urinary (>30 $\mu\text{g}/24$ hour) levels of aldosterone and are younger (<50 years) than those with IHA.^{58,63} Patients fitting these descriptors are considered to have a “high probability of APA” (Figure 75-3). However, these factors are not absolute predictors of unilateral versus bilateral adrenal disease. With the addition of adrenal venous sampling, we have found unilateral APAs in 36% of those with clinically “high-probability” APA who had normal findings or unilateral adrenal limb thickening on CT.⁶⁴ Gordon et al.⁶⁵ reported that CT contributed to lateralization in only 59 of 111 patients with surgically proven APA; CT detected fewer than 25% of the APAs that were less than 1 cm in diameter. Magill et al.⁶⁶ reported that in 38 patients who had both CT and adrenal venous sampling, CT findings were either inaccurate or provided no additional information for 68% of patients with primary aldosteronism. Therefore, adrenal venous sampling is essential to direct appropriate therapy in patients with primary aldosteronism who have a high probability of APA and seek a potential surgical cure.

Adrenal venous sampling is the reference standard test to differentiate unilateral from bilateral disease in patients with primary aldosteronism.⁶⁷ Adrenal venous sampling is a difficult

Figure 75-3 Subtype evaluation of primary aldosteronism. See text for details. APA, aldosterone-producing adenoma; AVS, adrenal venous sampling; CT, computed tomography; GRA, glucocorticoid-remediable aldosteronism; IHA, idiopathic hyperaldosteronism; PAH, primary adrenal hyperplasia. (Modified from Young WF Jr, Hogan MJ. Renin-independent hypermineralocorticoidism. Trends Endocrinol Metab 5:97-106, 1994.)

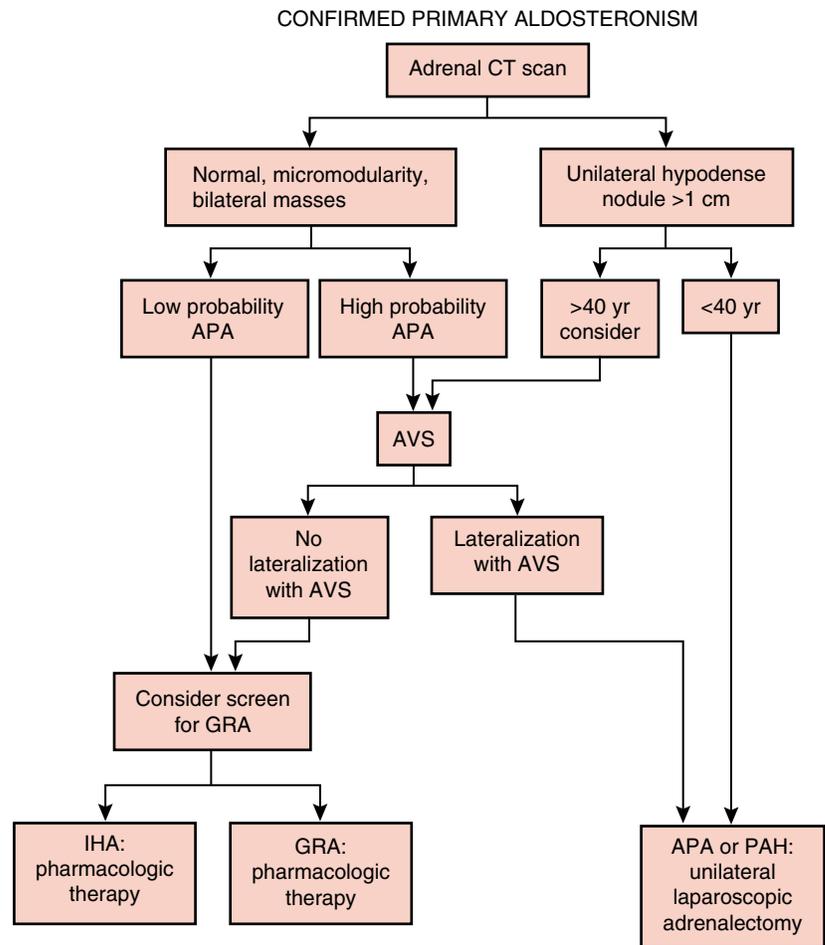

Figure 75-4 Appearance of a 1.8-cm right adrenal nodule and 0.7-cm left adrenal nodule (arrows) on contrast-enhanced CT in a 49-year-old man. The patient had been hypertensive for 20 years, with poor control for the last 4 years; his antihypertensive medication program included an ACE inhibitor, a calcium channel blocker, thiazide diuretic, and a β -adrenergic blocker. The screening test for primary aldosteronism was positive, with a plasma aldosterone concentration (PAC) of 53 ng/dl and low plasma renin activity (PRA) at <0.6 ng/ml/hr (PAC:PRA ratio >88). The 24-hour urinary excretion of aldosterone was increased at 40 μ g (urinary sodium = 236 mEq/24 hr).

procedure because the right adrenal vein is small; the success rate depends on the proficiency of the angiographer (Figure 75–5).⁶⁵ According to a review of 47 reports, the success rate for cannulating the right adrenal vein in 384 patients was 74%.⁵⁸ With experience, the success rate increased to 90% to 93%.^{64,65} Some centers perform adrenal venous sampling in all patients with the diagnosis of primary aldosteronism.⁶⁵ A more practical approach is the selective use of adrenal venous sampling outlined in Figure 75–3. To minimize stress-induced fluctuations in aldosterone secretion, an infusion of 50 µg of cosyntropin per hour is initiated 30 minutes before adrenal vein catheterization and continued throughout the procedure.⁶⁴ The adrenal veins are catheterized through the percutaneous femoral vein approach, and the position of the catheter tip is verified by gentle injection of a small amount of nonionic contrast medium and radiographic documentation (Figure 75–5). Blood is obtained from both adrenal veins and the inferior vena cava (IVC) below the renal veins and assayed for aldosterone and cortisol concentrations. The venous sample from the left side typically is obtained from the inferior phrenic vein immediately adjacent to the entrance of the adrenal vein. The right adrenal vein may be especially difficult to catheterize because it is short and enters the IVC at an acute angle.⁶⁷ The cortisol concentrations from the adrenal veins and IVC are used to confirm successful catheterization. The adrenal vein:IVC cortisol ratio is typically greater than 10:1 (mean values at Mayo Clinic are 32:1 on the right and 22:1 on the left).

Dividing the right and left adrenal vein PACs by their respective cortisol concentrations corrects for the dilutional effect of the inferior phrenic vein flow into the left adrenal vein; these are termed “cortisol-corrected ratios” (Table 75–1). In patients with APA, the mean cortisol-corrected aldosterone ratio (APA-side PAC/cortisol:normal adrenal PAC/cortisol) is 18:1 (range, 3.7:1–79:1).⁶⁴ A cutoff of the cortisol-corrected aldosterone ratio from high side to low side greater than 4:1 is used to indicate unilateral aldosterone excess.⁶⁴ Usually in patients with unilateral aldosterone excess, the contralateral aldosterone:cortisol ratio is less than

the IVC aldosterone:cortisol ratio, reflecting a lower proportional contribution of aldosterone from the contralateral adrenal gland (Table 75–1).^{64,67} In patients with IHA, the mean cortisol-corrected aldosterone ratio is 2:1 (high side:low side; range, 1:0–3:5); a ratio less than 3:1 is suggestive of bilateral aldosterone hypersecretion.⁶⁴ In patients with IHA, the “low-side” aldosterone:cortisol ratio is usually greater than in the IVC. Adrenal venous sampling is essential to direct appropriate therapy for patients with primary aldosteronism who have a high probability of APA and CT findings of unilateral adrenal limb thickening.

Principles of Treatment

Normalization of blood pressure should not be the only goal in managing the patient with primary aldosteronism. In addition to the kidney and colon, mineralocorticoid receptors are present in the heart, brain, and blood vessels. A number of animal studies indicate that aldosterone exerts deleterious effects when plasma concentrations are inappropriate for salt status.^{68–70} In experimental models of hypertension and heart failure, the nonepithelial effects of aldosterone are mediated via classical mineralocorticoid receptors, and are largely or completely abolished by administration of an aldosterone receptor blocker or by reduction of circulating aldosterone by adrenalectomy.^{68,71} It has been demonstrated that selective aldosterone blockade (at doses that do not alter blood pressure) markedly reduces tissue (brain, heart, kidney) damage in saline-drinking spontaneously hypertensive rats.⁶⁸ Aldosterone induces myocardial fibrosis by either stimulation of cardiac fibroblasts and/or vascular fibrinoid necrosis.⁷² A clinical correlate of these laboratory studies was the Randomized Aldactone Evaluation Study (RALES) where spironolactone produced a 30% reduction in mortality in patients with stage IV congestive heart failure.^{73,74} Increased risk of ischemic cardiac events is associated with activation of the renin-angiotensin-aldosterone system.⁷⁵ Plasminogen activator inhibitor-1 (PAI-1) is a major physiologic inhibitor

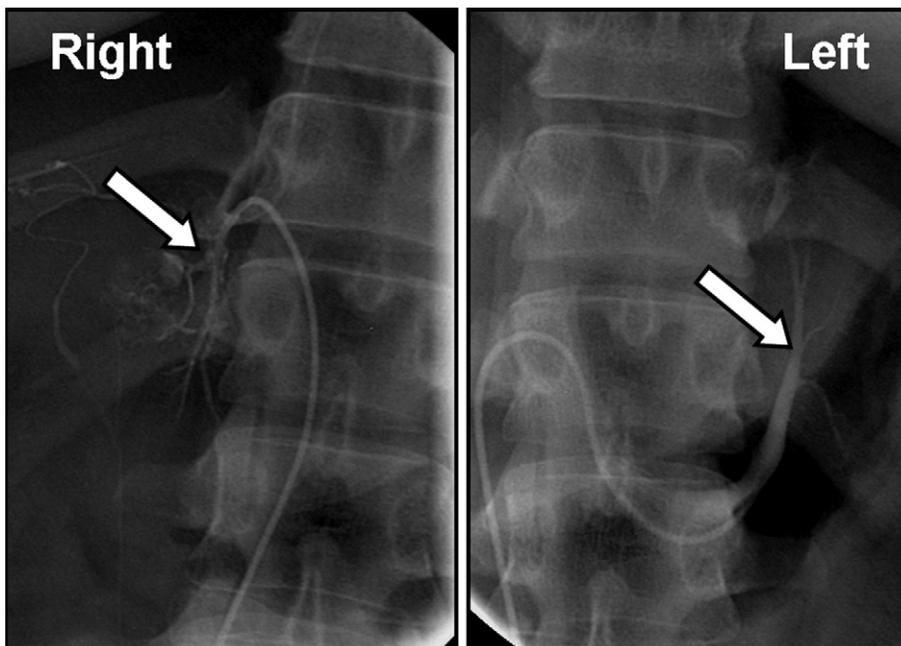

Figure 75–5 Adrenal venous sampling radiographs from the patient described in Figure 75–4. Adrenal veins are noted by arrows.

Table 75-1 Adrenal Vein Sampling

RT Adrenal Vein	782	1105	0.7	
LT Adrenal Vein	8504	700	12.1	17.3:1*
IVC	87	31	2.8	

*Left adrenal vein A:C ratio divided by right adrenal vein A:C ratio; IVC, inferior vena cava.

Adrenal venous sampling (AVS) data from the 49-year-old man with primary aldosteronism described in Figure 75-4. Because of bilateral adrenal abnormalities on CT and the patient's desire for surgically induced improved blood pressure control, AVS was completed. AVS localized the tumor to the left adrenal gland. He had laparoscopic left adrenalectomy, and an 0.8-cm cortical adenoma was found. The postoperative PAC was <1.0 ng/dl. Hypertension was subsequently controlled with one anti-hypertensive agent.

of fibrinolysis.^{76,77} Aldosterone increases PAI-1 expression in vascular smooth muscle and endothelial cells⁷⁸ and levels correlate with plasma concentrations of aldosterone⁷⁹—a correlation inhibited by spironolactone.⁸⁰

It has been reported that patients with primary aldosteronism, when matched for age, blood pressure, and duration of hypertension, have greater left ventricular (LV) mass measurements when compared with patients with other types of hypertension (e.g., pheochromocytoma, Cushing's syndrome, and essential hypertension).⁸¹ In addition, when 26 APA patients were matched (age, sex, race, body mass index, blood pressure, duration of hypertension) with 26 essential hypertension patients, it was found that aldosterone excess was associated with both increased LV wall thickness and mass, as well as decreased early diastolic LV filling indexes.⁸² The LV hypertrophy in primary aldosteronism appears to be asynchronous with other sites of target organ damage. In essential hypertensive patients, it has been shown that there is a strong correlation between LV mass and the severity of hypertensive retinopathy and renal involvement.⁸³ However, in patients with primary aldosteronism, the LV hypertrophy was found to be markedly advanced despite mild extracardiac target organ damage.⁸³ The LV wall thickness and mass decreased markedly by 1 year following adrenalectomy for APA, but not in those on medical therapy.⁸⁴ It should be noted that other studies have been unable to find differences in the degree of LV hypertrophy in patients with primary aldosteronism when compared with patients with renovascular and essential hypertension.⁸⁵

The results of studies on small resistance arteries in fat biopsies from patients with primary aldosteronism suggest that there may be some unique vascular remodeling. For example, in patients with primary aldosteronism and renovascular hypertension, a marked increase in the media-lumen ratio has been found when compared with patients with essential hypertension or pheochromocytoma.^{86,87} Therefore, normalization of circulating aldosterone or aldosterone recep-

tor blockade should be part of the management plan for all patients with primary aldosteronism.

The cause of the primary aldosteronism determines the appropriate treatment. Although the hypertension in patients with APA and unilateral hyperplasia is frequently cured with unilateral adrenalectomy, the average cure rate for IHA is only 19% after unilateral or bilateral adrenalectomy.⁵⁸ IHA and GRA should be treated medically.⁵⁵

Surgical Treatment of Aldosterone-Producing Adenoma and Unilateral Hyperplasia

The treatment of choice for APA and unilateral hyperplasia is unilateral total adrenalectomy. Laparoscopic adrenalectomy is the preferred surgical approach and is associated with shorter hospital stays and less long-term morbidity.⁸⁸ The blood pressure response to aldosterone receptor blockade preoperatively often predicts the blood pressure response to unilateral adrenalectomy in patients with APA. To decrease the surgical risk, hypokalemia should be corrected with spironolactone or eplerenone preoperatively; treatment with this drug should be discontinued postoperatively.

Aldosterone concentrations in blood or urine should be measured shortly after the operation. For the first few weeks postoperatively, a generous sodium diet should be followed to avoid the hyperkalemia of hypoaldosteronism that may occur because of the chronic suppression of the renin-angiotensin-aldosterone axis. Typically, the hypertension resolves in 1 to 3 months postoperatively. Although blood pressure control improves in nearly 100% of patients postoperatively, average long-term cure rates after unilateral adrenalectomy for APA are 30% to 60%.⁶¹ Persistent hypertension following adrenalectomy for APA is correlated directly with having more than one first-degree relative with hypertension, use of more than two antihypertensive agents preoperatively, older age, and duration of hypertension, and is most likely due to coexistent primary hypertension.^{61,89}

Pharmacologic Treatment of Idiopathic Hyperaldosteronism

Dietary sodium restriction (<100 mEq sodium/day), maintenance of ideal body weight, avoidance of alcohol, and regular aerobic exercise contribute significantly to the success of pharmacologic treatment. Potassium supplementation either as a medication or a diet rich in potassium (in the absence of severe sodium restriction) is ineffective for correcting the hypokalemia of primary aldosteronism. No placebo-controlled randomized trials have evaluated the relative efficacy of drugs in the treatment of primary aldosteronism.⁹⁰ For more than three decades, spironolactone has been the drug of choice to treat primary aldosteronism. However, it is not selective for the aldosterone receptor. For example, antagonism at the testosterone receptor may result in painful gynecomastia, impotence, and menstrual irregularity. The incidence of gynecomastia in 699 patients treated with spironolactone was dose-dependent (6.9% at doses <50 mg/day and 52% at doses >150 mg/day).⁹¹ The starting dose of spironolactone is 25 to 50 mg once daily with food; the dose may be increased weekly to a maximum of 200 mg twice daily. Blood pressure and the serum levels of potassium and creatinine should be monitored frequently. Treatment goals are

normotension without the aid of other antihypertensive drugs and normokalemia without potassium supplementation.

Eplerenone is a new steroid-based antimineralocorticoid that acts as a competitive and selective aldosterone receptor antagonist that has been approved by the U.S. Food and Drug Administration for the treatment of uncomplicated essential hypertension and post myocardial infarction congestive heart failure. The 9,11-epoxide group in eplerenone results in a significant reduction of the progestational and antiandrogenic actions of the molecule compared with spironolactone.⁹² Compared with spironolactone, eplerenone has 0.1% of the binding affinity to androgen receptors and less than 1% of the binding affinity to progesterone receptors.⁹³ Eplerenone has been effective in the treatment of mild to moderate essential hypertension and was well tolerated with the incidence of adverse events similar to placebo.^{94,95} The doses used ranged from 50 to 400 mg once daily. In a separate study, the addition of eplerenone to an ACE inhibitor or an ARB resulted in significant lowering of blood pressure in patients with suboptimally controlled essential hypertension.⁹⁶

For primary aldosteronism it is anticipated that the starting dose of eplerenone will be 25 to 50 mg twice daily. Potency studies with eplerenone show 25% to 50% less milligram-per-milligram potency compared with spironolactone. Treatment trials comparing the efficacy of eplerenone versus spironolactone for the treatment of primary aldosteronism have not been published. Presumably eplerenone will be the superior drug if it is shown to be as effective as spironolactone for the treatment of mineralocorticoid-dependent hypertension and if it lacks the limiting antiandrogen side effects of spironolactone. Because of the higher cost of eplerenone and lack of data in patients with primary aldosteronism, spironolactone should remain the aldosterone receptor antagonist of choice. Eplerenone should be considered in the spironolactone intolerant patient. As with spironolactone, blood pressure and the serum levels of potassium and creatinine need to be monitored closely.

For patients who are intolerant of eplerenone or spironolactone, amiloride may be prescribed for its potassium-sparing properties. The starting dose of amiloride is usually 5 mg once or twice daily and increased up to 15 mg twice daily if needed to correct the hypokalemia. Amiloride is not an effective antihypertensive agent for patients with primary aldosteronism, and if hypertension persists, a second-step agent (e.g., a thiazide diuretic) should be added.

Hypervolemia is a major reason for drug resistance in patients with primary aldosteronism. Low doses (e.g., 12.5-25 mg of hydrochlorothiazide daily) of a thiazide or a related sulfonamide diuretic potentiate the control of blood pressure when given in combination with a potassium-sparing diuretic.⁹⁷ ACE inhibitors, by inhibiting the generation of angiotensin II, may preferentially decrease blood pressure in patients with IHA because of their enhanced adrenal sensitivity to angiotensin II in secreting aldosterone.⁹⁸ However, the blood pressure-lowering effect of ACE inhibitors in patients with primary aldosteronism is not marked.^{99,100} Angiotensin receptor antagonists should be similar to ACE inhibitors in decreasing blood pressure in patients with primary aldosteronism caused by IHA.

Pharmacologic Treatment of GRA

Typically, GRA is diagnosed in the first to third decades of life. Of interest is that most of these patients are normokalemic, a

finding likely explained by the diurnal character of the disorder.⁴³ Also, the patients usually have a family history of onset of hypertension at a young age. Although GRA is an unusual cause of primary aldosteronism, it is important that it be diagnosed because of the risk of hemorrhagic stroke. Of 167 patients with proven GRA, 18% had cerebrovascular complications at an average age of 32 years.⁴³ The cerebrovascular event was hemorrhagic stroke in 70% of the patients and was fatal in 61% of them. It appears that patients with GRA, like those with polycystic kidney disease, are at risk for cerebrovascular aneurysms. Glucocorticoids administered in physiologic to suppressive doses to patients with GRA correct the hypertension and hypokalemia. For example, dexamethasone at doses of 0.125 to 0.5 mg daily suppresses pituitary corticotropin secretion. However, because of the risk of subclinical iatrogenic Cushing's syndrome, aldosterone receptor antagonists may be preferred.

Surgical and Pharmacologic Therapy for Patients with Aldosterone-Producing Adrenal Malignancy

Adrenal carcinoma should be suspected if a patient has an aldosterone-producing tumor larger than 3 cm in diameter. Malignancy is difficult to diagnose histologically. The only absolute criterion is the presence of local invasion or metastatic lesions. The treatment of choice for adrenocortical carcinoma is complete surgical resection with the anterior abdominal approach.¹⁰¹ Even if the resection is apparently complete, the recurrence rate is high, and the 5-year survival rate for all patients with adrenocortical carcinoma is approximately 16% to 30%.^{102,103} Mitotane should be given to patients with incompletely resected tumors. This drug is an adrenal cytolytic agent that inhibits adrenal steroid synthesis and destroys normal and neoplastic adrenocortical cells. The initial dosage is one 500-mg tablet with food twice daily. The total dosage is increased by 500 mg every 3 days until the maximal tolerated dosage or a maximal dose of 10 g daily is attained. In most patients, the dosage is limited by nausea, anorexia, diarrhea, somnolence, skin rash, and pruritus. Mitotane is lipophilic and has a long half-life (0.5 to 6 months). Therefore, it is contraindicated for women desiring fertility within 2 to 5 years after treatment. This drug also destroys the normal contralateral adrenal gland, and concomitant therapy with dexamethasone 0.5 mg daily should be administered.

Because of the high recurrence rate of adrenocortical carcinoma, adjuvant treatment with mitotane should be considered even for patients who appear to have had a surgical cure. The patient's condition is reevaluated with CT or magnetic resonance imaging (MRI) at 3, 6, and 12 months postoperatively. If recurrent disease is not evident at 12 months postoperatively, adjuvant mitotane therapy may be discontinued. Aldosterone receptor antagonists are effective in blocking the effects of excessive aldosterone secretion.

HYPERDEOXYCORTICOSTERONISM

Deoxycorticosterone (DOC) is a mineralocorticoid receptor agonist. Hypersecretion of DOC is found in two forms of congenital adrenal hyperplasia (CAH), DOC-secreting tumors, and primary cortisol resistance (see Box 75-1).

Congenital Adrenal Hyperplasia

CAH is caused by enzymatic defects in adrenal steroidogenesis that result in deficient secretion of cortisol. The lack of inhibitory feedback by cortisol on the hypothalamus and pituitary produces an adrenocorticotrophic hormone (ACTH)-driven buildup of cortisol precursors proximal to the enzymatic deficiency. A deficiency of both 11β -hydroxylase and 17α -hydroxylase causes hypertension and hypokalemia because of hypersecretion of the mineralocorticoid 11-DOC. The mineralocorticoid effect of increased circulating levels of DOC also decreases PRA and aldosterone excretion. These defects are autosomal recessive in inheritance and are typically diagnosed in childhood. However, partial enzymatic defects have been shown to cause hypertension in adults.¹⁰⁴

11β -Hydroxylase Deficiency

Approximately 5% of all cases of CAH are due to 11β -hydroxylase deficiency; the prevalence in whites is 1 in 100,000.¹⁰⁵ In addition to high levels of DOC and 11-deoxycortisol, the substrate mass effect results in increased levels of adrenal androgens. Females present in childhood with hypertension, hypokalemia, and virilization, and pseudoprecocious puberty appears in males. Approximately two thirds of patients have mild to moderate hypertension.¹⁰⁶ The clinical scenario in combination with markedly increased levels of DOC, 11-deoxycortisol, and adrenal androgens (dehydroepiandrosterone and androstenedione) confirm the diagnosis. Glucocorticoid replacement normalizes the steroid abnormalities and hypertension. Glucocorticoid replacement options in adults include dexamethasone (0.5-0.75 mg daily), prednisone (5 mg in the A.M. and 2.5 mg in the P.M.), or hydrocortisone (20 mg in the A.M. and 10 mg in the P.M.). For screening, family members should have the cosyntropin stimulation test for cortisol and 11-deoxycortisol.¹⁰⁵

17α -Hydroxylase Deficiency

The 17α -hydroxylase deficiency form of CAH is rare.¹⁰⁷ The deficiency results in decreased production of cortisol and sex hormones. Genetic 46,XY males present with either pseudohermaphroditism or as phenotypic females, and 46,XX females present with primary amenorrhea. Therefore, a person with this form of CAH may not come to medical attention until puberty. The biochemical findings include low concentrations of plasma adrenal androgens, plasma 17α -hydroxyprogesterone, aldosterone, and cortisol and increased plasma concentrations of DOC, corticosterone, and 18 -hydroxycorticosterone, which suppress PRA. As with 11β -hydroxylase deficiency, glucocorticoid replacement normalizes the steroid abnormalities and hypertension. Sex steroids also need to be replaced. For screening, family members should have the cosyntropin stimulation test for cortisol and 17 -hydroxypregnenolone.¹⁰⁷

Deoxycorticosterone-Producing Tumor

DOC-producing adrenal tumors are usually large and malignant.^{108,109} Some of them secrete androgens and estrogens in addition to DOC, which may cause virilization in women and feminization in men. A high level of plasma DOC or urinary tetrahydrodeoxycorticosterone and a large adrenal tumor seen

on CT confirm the diagnosis. Optimal treatment is complete surgical resection.

Primary Cortisol Resistance

Increased cortisol secretion and plasma cortisol concentrations without evidence of Cushing's syndrome are found in patients with primary cortisol resistance, a rare familial syndrome.¹¹⁰ The syndrome is characterized by hypokalemic alkalosis, hypertension, increased plasma concentrations of DOC, and increased adrenal androgen secretion, which are probably caused by several defects in glucocorticoid receptors and the steroid-receptor complex. The treatment for mineralocorticoid-dependent hypertension is blockade of the mineralocorticoid receptor with an aldosterone receptor antagonist or suppression of ACTH secretion with dexamethasone at the same dosages as mentioned previously for primary aldosteronism and CAH, respectively.¹¹¹

APPARENT MINERALOCORTICOID EXCESS SYNDROMES

Cortisol can be a potent mineralocorticoid. The microsomal enzyme 11β -hydroxysteroid dehydrogenase (11β -OHS; EC 1.1.1.146) is responsible for the renal metabolism of cortisol to the metabolically inactive cortisone. Deficiency of this enzyme results in a high intrarenal concentration of cortisol as well as hypertension, hypokalemia, suppressed PRA, and low aldosterone levels.^{112,113} An increased ratio of urinary metabolites of cortisol (tetrahydrocortisol [THF] + 5α -tetrahydrocortisol [allo-THF]) to those of cortisone (tetrahydrocortisone [THE]) confirms the diagnosis. The ratio of (THF + alloTHF) to THE is approximately 1:1 in normal subjects but is greater than 7:1 in patients with 11β -OHS deficiency. Two types of defects have been described in the renal metabolism of cortisol (see Box 75-1). Type I apparent mineralocorticoid excess (AME) syndrome refers to deficiency in the 11β -OHS enzyme. Type II AME is due to a deficiency in the A-ring reduction metabolic pathway.¹¹³ Treatment includes blockade of the mineralocorticoid receptor with an aldosterone receptor antagonist or suppression of endogenous cortisol secretion with dexamethasone. The congenital forms are rare autosomal-recessive disorders.¹¹³

The acquired forms are more common and include licorice-induced hypertension and Cushing's syndrome. Glycyrrhetic acid in licorice is a potent inhibitor of the 11β -HSD enzyme.¹¹⁴ Analyses of urinary F to E ratios in patients with licorice-induced hypertension have documented a reversible acquired 11β -HSD deficiency (type I AME).^{114,115}

CUSHING'S SYNDROME

Hypertension occurs in 75% to 80% of patients with Cushing's syndrome.¹¹⁶ The mechanisms of hypertension include increased production of DOC, increased vascular reactivity to catecholamines, and cortisol inactivation overload with stimulation of the mineralocorticoid receptor. Deficient cortisol ring-A reduction caused by overload of metabolizing enzymes results in a functional type II AME in

patients with severe hypercortisolism.¹¹⁷ Cushing's syndrome is a symptom complex that results from prolonged exposure to supraphysiologic concentrations of glucocorticoids.¹¹⁸ The source of excess glucocorticoids may be exogenous (iatrogenic) or endogenous. Endogenous Cushing's syndrome is caused by (1) hypersecretion of corticotropin (ACTH), referred to as *ACTH-dependent Cushing's syndrome*, or (2) primary adrenal hypersecretion of glucocorticoids, referred to as *ACTH-independent Cushing's syndrome*. The overall treatment program for patients with Cushing's syndrome includes the resolution of hypercortisolism, the concomitant treatment of the complications of the syndrome (e.g., hypertension, osteoporosis, and diabetes mellitus), and after definitive treatment, the management of glucocorticoid withdrawal and hypothalamic-pituitary-adrenal (HPA) axis recovery.

Presentation

Typical signs and symptoms of Cushing's syndrome include weight gain with central obesity, facial rounding and plethora, dorsocervical fat pad, easy bruising, fine "cigarette paper skin," poor wound healing, purple striae, proximal muscle weakness, emotional and cognitive changes (e.g., irritability, crying, depression, restlessness), hypertension, osteoporosis, opportunistic and fungal infections (e.g., mucocutaneous candidiasis, tinea versicolor, pityriasis), altered reproductive function, and hirsutism.

Iatrogenic Cushing's syndrome, more common than the endogenous forms, is usually due to the known administration of glucocorticoids orally, intraarticularly, epidurally, or topically (inhaled, nasal, dermal).^{119,120} Excess ACTH secretion by a pituitary tumor or a neoplastic source elsewhere is the cause of endogenous Cushing's syndrome in 85% of patients. ACTH-independent forms of Cushing's syndrome (adrenal adenoma, adrenal carcinomas, and adrenal nodular hyperplasias) are responsible for the other 15% of the endogenous cases.

Diagnosis

Accurate diagnosis of Cushing's syndrome and subtype is essential to direct the appropriate treatment program. Because of the known manifestations of the disorder, hypercortisolism must be suspected and then confirmed with measurement of the serum and 24-hour urine concentrations of cortisol. Autonomous hypercortisolism is confirmed with the low-dose dexamethasone suppression test (dexamethasone 0.5 mg orally every 6 hours for 48 hours); a 24-hour urinary cortisol excretion of 20 µg or greater confirms the diagnosis. The plasma ACTH concentration classifies the subtype of hypercortisolism as either ACTH-dependent ("normal" to high levels of ACTH) or ACTH-independent (undetectable ACTH) (Figure 75–6).

The pituitary of patients with ACTH-dependent Cushing's syndrome should be examined with MRI. If a pituitary tumor is not found on computed imaging, further evaluation is indicated, with imaging of the lung and sampling of the inferior petrosal sinuses for ACTH with ovine corticotropin-releasing hormone stimulation.

In patients with ACTH-independent hypercortisolism, the high-dose dexamethasone suppression test shows no suppression in urinary cortisol excretion. In these patients, computed

imaging of the adrenal glands usually indicates the type of adrenal disease (Figure 75–6).

Principles of Treatment

Selective pituitary adenectomy by transsphenoidal surgery (TSS) is the treatment of choice for pituitary-dependent disease. The long-term surgical cure rate for ACTH-secreting microadenomas is approximately 90%.^{121,122} If pituitary surgery is not curative, bilateral laparoscopic adrenalectomy, pituitary irradiation, or both are adjunctive treatment options.^{123,124} Surgical extirpation of an adrenal adenoma or carcinoma or the source of ectopic ACTH production is the treatment of choice for primary adrenocortical disease or ectopic ACTH production. Bilateral laparoscopic adrenalectomy is the preferred treatment for ACTH-independent bilateral macronodular or micronodular hyperplasia.¹²⁵ Pharmacologic therapy is reserved for patients with disease not cured by these surgical approaches.

Iatrogenic Cushing's Syndrome

Iatrogenic Cushing's syndrome is usually the result of the appropriate treatment of a life-threatening or debilitating inflammatory disorder (e.g., vasculitis or severe asthma) with supraphysiologic doses of glucocorticoids. The most frequently used preparation is prednisone. It has been suggested, but not proven, that alternate-day steroid therapy results in fewer side effects and less suppression of the HPA axis. HPA axis suppression can occur with high-dose (>25 mg prednisone or equivalent per day) glucocorticoid therapy for more than 1 week or lower doses (>12.5 mg prednisone or equivalent per day) for more than 4 weeks. If glucocorticoid therapy must be continued, the lowest possible dose that effectively treats the underlying disorder should be sought.

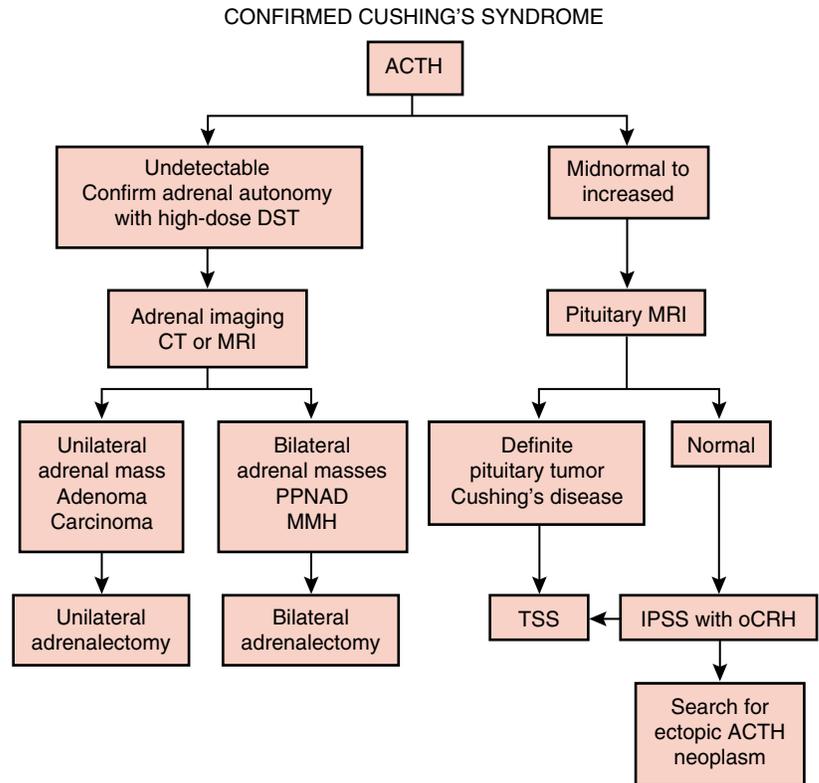

Pituitary-Dependent Cushing's Syndrome

The treatment of choice for pituitary-dependent Cushing's syndrome is transsphenoidal selective adenectomy by an experienced neurosurgeon. Inferior petrosal sinus sampling for ACTH should be considered in patients without an obvious pituitary tumor found on MRI examination of the sella. If no tumor is obvious intraoperatively, lateralization of ACTH secretion from the preoperative inferior petrosal sinus sampling study guides the surgeon in performing a hemihypophysectomy. The goal is to remove the adenoma selectively and preserve normal pituitary tissue. At pituitary surgery centers, the mortality of TSS is 1% or less.^{122,126} The incidence of perioperative morbidity is approximately 10% and includes transient diabetes insipidus, hyponatremia (due to inappropriate secretion of antidiuretic hormone), cerebrospinal fluid leak, and meningitis.¹²⁶ Potential permanent complications are infrequent (<5%) and include diabetes insipidus, partial or complete anterior pituitary failure, and injury to the carotid arteries, optic nerve, or cranial nerves in the cavernous sinus.¹²⁶

Postoperative Management

Patients whose disease is cured by TSS develop sudden secondary adrenal insufficiency. For this reason, all our patients receive a glucocorticoid preparation preoperatively on the morning of

Figure 75-6 Subtype evaluation of Cushing's syndrome. See text for details. ACTH, adrenocorticotrophic hormone; CT, computed tomography; DST, dexamethasone suppression test; IPSS, inferior petrosal sinus sampling; MMH, massive macronodular hyperplasia; MRI, magnetic resonance imaging; oCRH, ovine corticotropin-releasing hormone; PPNAD, primary pigmented nodular adrenal disease; TSS, transsphenoidal surgery.

the operation and again on the evening of the operation. Plasma cortisol concentrations are measured at 8 A.M. and 4 P.M. on the day after the operation. Most patients whose disease is cured develop symptoms of adrenal insufficiency 24 to 36 hours after the last dose of glucocorticoid. Patients are warned about these symptoms and advised to report them promptly; a blood sample is then obtained for cortisol measurement, and glucocorticoid is promptly administered intramuscularly. If the plasma cortisol concentrations are less than 3 $\mu\text{g}/\text{dl}$, a short-term cure is ensured.¹²⁷ Some patients with long-term cures have had postoperative plasma cortisol concentrations between 3 and 20 $\mu\text{g}/\text{dl}$.¹²⁷ Observation and reevaluation several weeks later with baseline 24-hour urinary cortisol excretion is indicated for these patients.

Most patients have been exposed to endogenous hypercortisolism for many years, and abrupt postoperative institution of replacement doses of glucocorticoid results in prominent withdrawal symptoms. Typically, patients are dismissed from the hospital on a regimen of prednisone 5 mg orally in the morning and 5 mg orally before the evening meal; 1 to 2 weeks later, the dosage is decreased to 5 mg in the morning and 2.5 mg in the afternoon. Even with this cautious tapering program, all patients have withdrawal (recovery) symptoms of myalgias, depression, and fatigue. Perioperative counseling about the anticipated recovery phase is necessary.

Full recovery of the HPA axis may require 6 to 24 months. The recovery of hypothalamic corticotrophin-releasing hormone secretion is the primary and limiting determinant for recovery. Some degree of adrenal insufficiency must occur during recovery from suppression of the HPA axis. By 2 to 3 months postoperatively, it is important to change the dosing to a single morning dose of a short-acting glucocorticoid (e.g., 20 mg hydrocortisone). This lower dosage facilitates HPA recov-

ery by causing relative cortisol deficiency in the afternoon and evening. If the symptoms of adrenal insufficiency cannot be tolerated, 5 to 10 mg of hydrocortisone may be added at 4 P.M. daily for 2 to 3 weeks. Morning plasma cortisol concentrations are measured every 1 to 2 months to assess recovery of the HPA axis. When the daily dosage of hydrocortisone is 20 mg, it is rarely necessary to taper the dose further. When the basal level of plasma cortisol is 10 $\mu\text{g}/\text{dl}$ or greater, therapy may be discontinued. Depending on the degree of HPA suppression, it may take up to 2 years before the plasma cortisol concentration normalizes. Cosyntropin stimulation testing is superfluous in this setting. Also, alternate-day glucocorticoid administration is not usually necessary or helpful in the withdrawal process. Patients should receive stress glucocorticoid coverage and wear medical alert identification for 1 year after they have stopped taking exogenous glucocorticoids. Also, it is important to assess the status of the pituitary-thyroid and pituitary-gonadal axes 6 to 12 weeks postoperatively.

Failed Transsphenoidal Surgery

If TSS fails to cure Cushing's syndrome, a second operation should be considered. The role of total hypophysectomy in this situation is controversial, and many factors, such as hypopituitarism and the desire for future reproductive function, should be considered. In patients with severe Cushing's syndrome that TSS has failed to cure (and in certain patients with mild-to-moderate persistent disease), a quick and definitive cure of hypercortisolism with bilateral laparoscopic adrenalectomy can be lifesaving.¹²³ Nelson's syndrome (an aggressive ACTH-secreting tumor) correlates with preoperative invasive features of the pituitary tumor and is not caused by adrenalectomy.

In patients with mild Cushing's syndrome who have persistent disease after TSS, combined sellar radiation and pharmacotherapy may be considered. If the residual adenoma can be identified on MRI, gamma-knife radiosurgery is preferred because it is more rapidly effective and associated with less hypopituitarism than conventional radiotherapy.^{128,129}

Until radiotherapy is effective, some form of pharmacotherapy must be continued. Drugs directed at decreasing pituitary tumor ACTH secretion (e.g., cyproheptadine, bromocriptine, valproic acid, and octreotide) are rarely effective. The two agents most commonly used to inhibit steroidogenesis are ketoconazole and mitotane (1,1-dichloro-2[o-chlorophenyl]-2-[p-chlorophenyl]-ethane, o,p' DDD [Lysodren]). Ketoconazole is an imidazole-derivative antimycotic agent that inhibits 17,20-desmolase, 11 β -hydroxylase, and other enzymes in the adrenal cortex. Dosages range from 200 to 600 mg administered twice daily on an empty stomach. Because drug absorption requires an acidic environment, antacids and agents that decrease stomach acidity should be avoided. Side effects include liver dysfunction, renal dysfunction, gynecomastia, and gastrointestinal upset. Liver function tests, serum creatinine, and urinary cortisol excretion should be followed every 6 to 8 weeks. The use of mitotane is discussed subsequently (see Adrenocortical Carcinoma).

Ectopic ACTH Syndrome

The optimal treatment for ectopic ACTH production ("ectopic ACTH syndrome") is resection of the ACTH- or corticotrophin-releasing hormone-secreting tumor. However, this may not be possible for two reasons: (1) inability to localize the source of ectopic ACTH production (in 20% of cases at time of presentation) and (2) inability to completely resect the ectopic ACTH-secreting tumor (unresectable or metastatic disease). Ectopic ACTH syndrome was diagnosed in 106 patients at the Mayo Clinic between 1956 and 1998.¹³⁰ Bronchial carcinoid was the most frequent cause (25%), followed by islet cell cancer (16%), small cell lung carcinoma (11%), medullary thyroid cancer (8%), disseminated neuroendocrine tumor of unknown primary source (7%), thymic carcinoid (5%), pheochromocytoma (3%), disseminated gastrointestinal carcinoid (1%), and other tumors (8%). No tumor was found in 16% of patients. Twenty-eight patients were managed medically, and the others had either curative tumor resection (13 patients) or bilateral adrenalectomy (65 patients). The diagnoses of Cushing's syndrome and ACTH-secreting neoplasm were usually made concurrently; however, there were remarkable cases in which the two conditions were diagnosed several years apart.

In patients with an occult ectopic source of ACTH, a quick definitive cure with bilateral adrenalectomy can be lifesaving. Pharmacotherapy in these patients rarely completely controls the hypercortisolism, and the associated morbidity and risk of mortality persist.

Metastatic or Unresectable ACTH-Secreting Tumor

For an unresectable or metastatic ACTH-secreting tumor, bilateral laparoscopic adrenalectomy offers a quick definitive cure and is the treatment of choice.¹²³ Pharmacotherapy is rarely effective in controlling hypercortisolism because of the markedly elevated levels of plasma ACTH. In some cases, such

as small cell lung carcinoma, tumor-specific chemotherapy may produce a hormonal cure.

The perioperative glucocorticoid therapy for bilateral adrenalectomy is the same as discussed above for patients having TSS. However, prednisone at a dosage of 5 to 7.5 mg daily (or an equivalent of hydrocortisone) is required lifelong. In many cases, the full replacement dosage is not needed because of a small amount of residual functioning adrenocortical tissue. Patients are instructed about stress steroid coverage and the need to wear medical identification. In addition, orally administered mineralocorticoid replacement in the form of fludrocortisone at a dosage of 0.05 to 0.1 mg/day is started before dismissal from the hospital. The proper dosage is determined by serum electrolytes and supine and standing blood pressures.

Adrenocortical Carcinoma

The treatment of choice for adrenocortical carcinoma is complete surgical resection by the anterior abdominal approach.¹⁰³ This malignant tumor should be suspected in patients with marked hypercortisolism (24-hour urinary cortisol >1000 μ g) and adrenal tumors greater than 6 cm in the largest lesional diameter on computed imaging. Even if resection is apparently complete, the recurrence rate is high and the 5-year survival rate is 20% to 30%.¹⁰³ Treatment with mitotane should be administered, if tumor resection is incomplete. This drug is an adrenal cytolytic agent that inhibits adrenal steroid synthesis and destroys normal and neoplastic adrenocortical cells. Treatment is started 3 to 6 weeks after adrenalectomy. The initial dosage is one 500-mg tablet with food twice daily. The total dosage is increased by 500 mg weekly until the maximal tolerated dosage or a maximal dose of 10 g daily is attained. In most patients, the dosage is limited by nausea, anorexia, diarrhea, somnolence, skin rash, and pruritus. Mitotane is lipophilic and has a long half-life (0.5 to 6 months). Therefore, mitotane is contraindicated for women desiring fertility within 2 to 5 years after treatment. This drug may also destroy the normal contralateral adrenal gland, and concomitant therapy with dexamethasone (0.5 mg daily) or prednisone (5 mg daily) should be administered. In addition, low-dose mineralocorticoid replacement may be needed, and this is determined by periodic measurement of the serum concentration of potassium. If hyperkalemia develops, treatment is started with fludrocortisone 0.05 mg daily and adjusted to maintain the serum level of potassium in the normal range.

Because of the high recurrence rate of adrenocortical carcinoma, adjuvant treatment with mitotane should be considered for patients with apparent surgical cure.

Adrenal Adenoma

Cushing's syndrome caused by an adrenal adenoma is cured by unilateral adrenalectomy. This operation is usually performed laparoscopically. The patient should be told that it may take 4 to 18 months before the HPA axis recovers. The rate-limiting step in axis recovery is the hypothalamic corticotropin-releasing hormone neuron or higher regulatory inputs or both. At approximately 6 weeks after the operation, treatment is switched to a shorter-acting glucocorticoid (e.g., hydrocortisone 20 mg in the A.M. and 10 mg in the P.M.). The afternoon dose is tapered and discontinued over 2 to 8 weeks.

The single morning dosage allows for relative nocturnal glucocorticoid insufficiency and stimulation of the hypothalamic neurons. The concentration of plasma cortisol at 8 A.M. (before hydrocortisone administration) is measured every 6 to 8 weeks. Hydrocortisone treatment may be discontinued when the plasma cortisol concentration is 10 µg/dl or greater. Patients are instructed about the need for stress steroid coverage for approximately 1 year after exogenous treatment is discontinued. Mineralocorticoid replacement is usually not required for patients after unilateral adrenalectomy.

Hypertension and Cushing's Syndrome

The hypertension associated with Cushing's syndrome should be treated until a surgical cure is achieved.¹³¹ Spironolactone, at dosages used to treat primary aldosteronism, is effective in reversing the hypokalemia. Second-step agents include thiazide diuretics, β-adrenergic receptor blockers, ACE inhibitors, and calcium antagonists. The hypertension associated with the hypercortisolism usually resolves over several weeks after the surgical cure, and treatment with antihypertensive agents can be tapered and withdrawn.

Pheochromocytoma: Detection and Management

Marion R. Wofford, Daniel W. Jones

INTRODUCTION

Pheochromocytomas are catecholamine-secreting tumors that arise from chromaffin cells. Although extremely rare, the recognition and localization of these tumors are critical to the cure of hypertension, which may be paroxysmal and lethal to the patients that harbor them. The incidence of pheochromocytoma is estimated to be 2 to 8 in 100,000 per year among hypertensive patients.^{1,2} The Mayo Clinic reported that only 13 of 54 autopsy-proven pheochromocytomas had been diagnosed prior to death.³ Pheochromocytomas are classically associated with paroxysmal hypertension. Patients present with a wide variety of signs, symptoms, and potentially life-threatening consequences of catecholamine excess. Clinicians must maintain a high index of suspicion and perform an evaluation when pheochromocytoma is suspected. Most pheochromocytomas are sporadic, but familial forms should be considered a possibility in all patients. The evaluation for pheochromocytoma includes establishment of catecholamine excess, genetic analysis in many patients, and localization of the tumor. Treatment is usually surgical resection.

PATHOPHYSIOLOGY

In embryonic development, primitive stem cells migrate from the neural crest giving rise to chromaffin cells. Chromaffin bodies regress in the prenatal period, but remnants may remain. In adults most chromaffin cells are found in the adrenal medulla, the predominant site of pheochromocytomas, but may occur along the sympathetic ganglia or in chromaffin body remnants in other locations.⁴ The term *pheochromocytoma* refers to adrenal chromaffin tissues, whereas *paraganglioma* refers to extra-adrenal chromaffin bodies.^{5,6} Pheochromocytoma generally refers to tumors in both locations.

Chromaffin cells of pheochromocytomas produce catecholamines from tyrosine. The intermediate metabolites dopa and dopamine are converted to norepinephrine, the end-product of extraadrenal pheochromocytomas. In the adrenal medulla norepinephrine is metabolized to epinephrine; however, epinephrine is rarely the sole catecholamine secreted by pheochromocytomas. Norepinephrine and epinephrine are subsequently converted to the *O*-methylated metabolites, normetanephrine and metanephrine.⁷ Dopamine and the urinary metabolite, homovanillic acid, are uncommonly secreted by pheochromocytomas and occur most often in malignant forms.⁸

The clinical manifestations of pheochromocytoma are variable and related to the heterogeneous secretion of catecholamines and their metabolites. In addition to catecholamines, pheochromocytomas may secrete a variety of

peptides including opioids, endothelin, erythropoietin, parathyroid hormone-related protein, neuropeptide Y, and chomogranin A.⁹ It is not known why some pheochromocytomas secrete catecholamines intermittently, causing paroxysmal signs and symptoms, while others release neurohormones continuously, causing refractory hypertension without paroxysms.⁴

In general, patients with tumors that secrete predominantly epinephrine have more β receptor-mediated tachycardia, systolic hypertension, hyperhidrosis, flushing, and anxiety.¹⁰ Tumors producing epinephrine alone may present with hypotensive symptoms.¹¹ Patients with norepinephrine-secreting tumors have α -adrenergic receptor-mediated vasoconstriction with related diastolic hypertension and generally have fewer symptoms classically associated with pheochromocytomas.^{3,10}

Clinical Features

A high index of suspicion for pheochromocytoma is critical in making the diagnosis as the presentation is variable (Box 76-1). The classic triad of global headache, tachycardia, and diaphoresis usually associated with hypertension should prompt a consideration of pheochromocytoma. Two of the three symptoms are usually present. The Mayo Clinic reported results of 54 autopsy-proven pheochromocytoma cases. Hypertension had been diagnosed in 54% of the cases: 27% had headaches, and 17% had diaphoresis and palpitations.¹²

Paroxysmal hypertension should generate a suspicion for pheochromocytoma, although most patients with this history do not have this tumor. Patients with signs and symptoms of pheochromocytoma may have essential hypertension or other forms of secondary hypertension, such as renovascular hypertension; hypertension of pregnancy; hypertensive crises associated with withdrawal of β -blockers, clonidine, or drugs of abuse; anxiety and panic attacks; intracranial tumors; or self-administration of sympathomimetic amines.

There is no correlation between levels of circulating catecholamines and blood pressure in patients with pheochromocytoma.¹² Some pheochromocytoma patients may have episodic hypertension with normal levels of catecholamines, whereas others have high circulating catecholamines but are without symptoms. Ninety percent of patients with pheochromocytoma have hypertension. Paroxysmal hypertension often prompts the search for a catecholamine-secreting tumor, but the hypertension is more often sustained, leading to the misdiagnosis of primary hypertension.⁴ Patients with sporadic pheochromocytomas may present in hypertensive crisis that is often severe and resistant to standard antihypertensive medications. Hypertension related to pheochromocytoma in children is more likely to be sustained.¹³ Patients who should be considered for evaluation of pheochromocytoma have

hypertension resistant to conventional therapy, hypertension of new onset, paroxysmal hypertension, or a familial syndrome associated with pheochromocytoma.

Orthostatic hypotension is common among patients with pheochromocytoma and is often related to a reduced plasma volume.¹⁴ It has been postulated that prolonged catecholamine exposure alters normal sympathetic nervous system (SNS) reflex responses to upright blood pressure, contributing to the postural hypotension. Animal models of pheochromocytoma,¹⁵ as well as clinical studies,¹⁶ suggest that the SNS is intact and may play a role in increasing the blood pressure in pheochromocytoma patients but is not related to orthostasis. Levenson reported that orthostasis in patients with pheochromocytoma was related to decreased stroke volume and impaired adaptation of total peripheral resistance during tilt maneuvers.¹⁷

The cardiac manifestations of pheochromocytomas include tachycardia, cardiac arrhythmias, angina, and myocardial infarction in the absence of coronary disease.¹⁸ Hypertrophic or congestive cardiomyopathy and noncardiogenic pulmonary edema have been reported.¹⁹

Crises due to catecholamine secretion may cause hypertensive retinopathy, stroke, dissecting aortic aneurysm, renal failure, disseminated intravascular coagulation, rhabdomyolysis, or tumor hemorrhage. Other presentations include pallor or flushing, sweating, paroxysmal symptoms suggesting seizure disorder, anxiety attacks, tremulousness, weakness, fatigue, weight loss, and paresthesias.¹²

Although lower levels of plasma catecholamines may be present between crises, there may be an increase in metabolic rate and weight loss. Hyperglycemia may occur due to elevated catecholamines that suppress insulin production and increase hepatic gluconeogenesis. Vascular constriction with diminished plasma volume or the formation of erythropoietin by the tumor may cause an elevated hematocrit.

Catecholamine release from a pheochromocytoma is not mediated by neuronal activity but can occur with physical stimuli, tumor necrosis, or changes in blood flow. Classic presentations are an acute hypertensive crisis during surgery, physical activity, abdominal trauma, or in patients with bladder pheochromocytoma, voiding. A number of drugs have provocative effects on pheochromocytomas, including imaging agents, glucagon, histamine, guanethidine, metoclopramide, and phenothiazines.¹²

Pseudopheochromocytoma refers to a condition that causes paroxysmal hypertension in the absence of biochemical evidence of excess catecholamines consistent with pheochromocytoma. Patients with pseudopheochromocytoma are characterized by abrupt elevation of blood pressure; abrupt symptoms of nausea, palpitations, chest pain, and dizziness; and absence of triggers related to fear or panic. The denial of emotional stress is misleading, so the consideration of a psychosocial relationship is often delayed. In one series, 21 patients referred for evaluation of extreme fluctuations in blood pressure were found to have labile blood pressure related to unrecognized emotional stress. These patients were treated effectively with antihypertensive drugs, psychopharmacotherapeutic agents, and counseling, either alone or in combination.²⁰

Tumor Location

About 85% of pheochromocytomas are found in the adrenal medulla. In adults, up to 18% of pheochromocytomas are extraadrenal locations such as the organ of Zuckerkandl at the aortic bifurcation, carotid body, glomus jugulare of cranial nerves IX and X, aortic chemoreceptors, the urinary bladder, or other sites along the sympathetic chain of the abdomen or pelvis.⁶ Approximately 10% of the extraadrenal tumors are intrathoracic, usually in the posterior mediastinum. There are reported cases in the heart,²¹ neck, base of the skull, or exotic sites such as the middle ear.⁶ Thirty percent of pheochromocytomas in children are extraadrenal.²²

After the age of 60 years, the most common location for pheochromocytomas is the adrenal gland. When associated with familial syndromes, adrenal tumors are often bilateral. Extraadrenal pheochromocytomas are rarely associated with familial syndromes and are more likely to be found in persons younger than 20 years of age.²³

Malignant pheochromocytomas, accounting for 19% of tumors, are more likely to be >5.0 cm in size. These tumors cannot be distinguished from benign pheochromocytomas by histology. Malignancy is defined as local extension or the presence of metastasis.²⁴ The most common sites for metastasis include liver, lung, bone, and lymph nodes.²⁵

Familial Syndromes

Most pheochromocytomas are sporadic and noninherited (Box 76–2).⁴ Sporadic pheochromocytomas are usually diagnosed in the fourth through sixth decades, whereas familial

Box 76–2 Molecular Genetics Associated with Familial Pheochromocytoma

Genetic Disorder	Associated Syndrome
VHL gene on chromosome 3p	VHL syndrome
<i>RET</i> protooncogene on chromosome 1	MEN types 2A and 2B
NF1 gene on chromosome 17q	Neurofibromatosis
SDHD and SDHB on mitochondrial DNA	Paraganglioma of head and neck

VHL, von Hippel-Lindau; MEN, multiple endocrine neoplasm; NF1, neurofibromatosis 1; SDHD, succinate dehydrogenase subunit D; SDHB, succinate dehydrogenase subunit B.

tumors are often detected early in life by surveillance in high-risk patients. Patients with sporadic tumors characteristically have a negative family history, a unilateral extraadrenal tumor, and lack the characteristics of neuroendocrine syndromes. In some series of patients with pheochromocytoma, only 10% had a familial disorder, including the multiple endocrine neoplasm (MEN) syndromes, von Hippel-Lindau (VHL) syndrome, or neurofibromatosis.^{26,27}

With advances in molecular genetics, patients with apparent sporadic tumors have been found to have mutations.²⁸ In a cohort of 277 patients with sporadic pheochromocytoma, Neumann et al.²⁸ found that 66 patients (25%) had a mutation of one of four autosomal-dominant genes associated with pheochromocytoma. Thirty percent had the VHL gene and 12% had protooncogene *RET* associated with MEN syndromes. Two susceptibility genes associated with pheochromocytomas and glomus tumors, known as SDHD and SDHB (succinate dehydrogenase subunit D and subunit B), were found in 17% and 18%, respectively.²⁸

A careful family history, higher index of suspicion for familial syndrome, and careful physical examination in patients with “presumed” sporadic tumors might lead to detection of genetic disorders. Molecular testing for the *RET* mutation is available and recommended in patients with sporadic pheochromocytoma. Tests for other mutations related to pheochromocytoma are not commercially available.²⁹

Familial pheochromocytoma is inherited in an autosomal-dominant pattern with variable penetrance.^{27,28} The components of MEN type 2A (Sipple’s syndrome) include pheochromocytoma, medullary thyroid carcinoma (MTC), and parathyroid hyperplasia or neoplasia. The MEN type 2B syndrome may present with pheochromocytoma, MTC, and mucosal neuromas. The syndromes are the result of a “gain-of-function” mutation of the *RET* protooncogene on chromosome 10, which activates the tyrosine kinase receptor causing hyperplasia and possibly neoplastic change.³⁰ Pheochromocytoma occurs in 40% to 50% of affected individuals in MEN 2A families. The tumors are usually due to adrenomedullary hyperplasia causing multicentric and bilateral epinephrine-secreting tumors. Extraadrenal pheochromocytomas are rare in the MEN syndromes.²⁸ Although rarely associated with familial syndromes, 4.4 % of MEN 2A patients in one series had a malignant form of pheochromocytoma.³¹

Thyroid carcinoma associated with MEN is a high-grade malignancy and may present in the first years of life.

Associated pheochromocytomas present later in life and rarely metastasize. Fifty percent of patients with MEN2 syndromes are asymptomatic, so early detection and surveillance for MTC and pheochromocytoma is important.²⁷

In the VHL syndrome, a “loss-of-function” mutation of the VHL suppressor gene on chromosome 3p causes alterations in the normal degradation of proteins, including hypoxia-inducible factor.³² This mutation results in tumor formation with variable penetrance and expression.³³ The syndrome consists of a variety of neoplasms and masses, including cerebellar and retinal hemangioblastomas, renal cell carcinoma, pancreatic and renal cysts, and pheochromocytoma.³⁴ The pheochromocytomas of VHL secrete norepinephrine, but the levels may not be high enough to cause hypertension or other symptoms.³⁵

The SDHD and SDHB genes, as with the VHL mutation, cause a defect in the oxygen-sensing pathways. These susceptibility genes are part of the mitochondrial complex II.³⁶ Alterations in the respiratory chain may result in malignant hyperplasia.³² The SDHD and SDHB are associated with hereditary paragangliomas of the head and neck.²⁹

Neurofibromatosis type 1 (NF1) is rarely associated with pheochromocytoma. Although pheochromocytomas are extremely rare in neurofibromatosis, among hypertensive patients with this syndrome the prevalence may be higher than 50%.³⁷ The effect of these tumors becomes apparent at a later age than pheochromocytomas in MEN and VHL. Although patients may not have symptoms of catecholamine excess, the presence of neurofibromas, café-au-lait spots, and hypertension should prompt a search of pheochromocytoma. The NF1 tumor suppressor gene has been isolated to chromosome 17q and encodes for the protein neurofibromin.³⁸ Type 2 neurofibromatosis is not associated with pheochromocytoma.

Diagnosis

Screening for pheochromocytoma should be conducted in any patient with signs, symptoms, or family history that suggests the disorder. Failure to make a diagnosis may result in catastrophic outcomes.

Consideration should be given in patients with the classic triad of tachycardia, diaphoresis, and headaches, and also in those with paroxysmal symptoms; unexplained hemodynamic changes during surgery, pregnancy, coitus, or micturition; or after use of certain drugs.

The choice of diagnostic tests may be limited by the availability of certain assays (Box 76–3). Although a number of tests are available, there is no single test with absolute accuracy.^{39,40} Further complicating the diagnostic approach are the variability of catecholamines and metabolites produced by pheochromocytomas and the intermittent secretion and possibly low levels of catecholamines associated with symptoms. The measurement of urine or plasma catecholamines is diagnostic in 95 % of patients. Most patients can be identified with a single test when abnormal values are several-fold higher than the normal range. However, in a few patients values are only slightly elevated, yet clinical suspicion may be high.²⁴ In these cases the diagnosis is most challenging.

Biochemical tests used to measure catecholamines and metabolites include plasma catecholamines and metanephrines, urinary catecholamines and metanephrines, and urinary vanillylmandelic acid.^{23,24} Urinary “fractionated” metanephrines provide more information than “total” metanephrines. The

†Tests to be performed by experienced clinician.

development of liquid chromatographic measurement of plasma metanephrines provides a more convenient assessment of catecholamine production.⁴¹ False-negative tests may result with any of these methods leading to missed diagnosis. Because pheochromocytoma is so rare and all of these tests lack 100% specificity, false-positive tests are also possible.

Plasma-free metanephrines measured by liquid chromatography has been recommended as the best initial test.³⁹ In a multicenter cohort of patients tested for pheochromocytoma, 214 patients of 644 tested had confirmation of the diagnosis. The sensitivity of plasma-free metanephrines was 99%. In those patients with pheochromocytoma, the concentration of plasma-free metanephrines was 21-fold higher in sporadic and 7-fold higher in familial pheochromocytomas compared with those without a pheochromocytoma. In hereditary syndromes and sporadic forms, plasma-free metanephrines had a specificity of 96% and 82%, respectively.³⁹

A retrospective chart review of patients seen at the Mayo Clinic for evaluation of pheochromocytoma was recently conducted to determine the diagnostic efficacy of plasma-free metanephrines and 24-hour urine total metanephrines and catecholamines taken from patients with confirmed pheochromocytoma.⁴⁰ The investigators found that plasma metanephrines had a high sensitivity but lacked specificity compared with 24-hour urine collections for metanephrines and catecholamines. False-negative 24-hour urine results were found in asymptomatic patients or in patients at high risk for familial syndromes. These investigators suggest that in patients with familial syndromes, a measure of fractionated plasma metanephrines is the best approach. For patients tested for sporadic tumors, measures of 24-hour urinary catecholamines and metanephrines provide 98% specificity with a low false-positive rate.

The clonidine-suppression test is rarely needed to diagnose pheochromocytoma but helps distinguish patients with pheochromocytoma from those with false-positive biochemical tests.⁴² Clonidine decreases the release of norepinephrine from the brain and terminal sympathetic axons. Failure to suppress norepinephrine levels is consistent with pheochromocytoma, whereas a fall of >50% supports sympathetic activation. This test is helpful when the biochemical measures of plasma catecholamines or metabolites are not diagnostic.^{43,44} Provocation of catecholamine release with glucagon may be used with caution when patients have symptoms of pheochromocytoma but blood pressure is near normal and the plasma catecholamine level is not very high (500-1000 pg/ml).²⁶

Consideration should be given to the possibility of false positives if the results of biochemical tests are equivocal. Acetaminophen has been shown to interfere with catecholamine assays, so patients should avoid this agent for 5 days prior to testing.²³ Tricyclic antidepressants, labetalol,

and phenoxybenzamine have been shown to cause false-positive plasma metanephrines.⁴⁴ Collection of plasma for testing is optimized if patients have been fasting overnight and avoided caffeinated beverages, are supine for 20 minutes prior to collection, and are taking no interfering medications.

A combination of tests may be required in centers where plasma-free metanephrines are not available. Sensitivity and specificity increase when multiple tests are carried out. Plasma catecholamines (norepinephrine and epinephrine) greater than 2000 pg/ml and urinary metanephrines (metanephrine and normetanephrine) of at least 1.8 mg/24 hours are diagnostic in sporadic and familial pheochromocytomas 98% of the time.²³ Additional studies are needed to determine the best biochemical test for different risk groups.

Imaging

Computed tomography (CT) (Figure 76-1) or magnetic resonance imaging (MRI) should be obtained to determine the location of a pheochromocytoma only after biochemical confirmatory tests have been performed. Special attention should be given to the adrenal glands and the sympathetic chain. About 95% of the tumors are located in the abdomen and 90% are adrenal.⁴⁵ The most common extraadrenal sites are paraaortic (75%), bladder (10%), thoracic (10%), and pelvic (5%).⁶ Sporadic tumors are located with either CT or MRI, because they tend to be >3 cm in size. CT may miss small tumors of familial syndromes.⁴⁵

If further imaging is thought necessary, an MIBG (131-I-metaiodobenzylguanidine) scan may detect tumors missed by CT or MRI. The National Institutes of Health consensus report recommends that even if CT or MRI is positive, an MIBG scan should be obtained to detect multiple lesions. This test has a specificity of 100% but a sensitivity of 78%.²⁴

Medical Management

Medical management of pheochromocytoma must always precede surgical resection, and surgery is needed to remove the potentially lethal tumor. The goal of antihypertensive therapy is to control blood pressure, treat symptomatic tachycardia, and avoid hypertensive emergency. The α -adrenergic blocker phenoxybenzamine has been recommended as the treatment of choice during the preoperative period.⁴⁶ However, intraoperative reports do not confirm a benefit of this adrenergic blocker in patients undergoing surgical removal of pheochromocytoma and, in fact, suggest more complications with phenoxybenzamine.^{47,48} With the development of improved surgical and anesthetic techniques, it may not be necessary to treat a patient with phenoxybenzamine in the absence of hemodynamic instability.

Selective α -adrenergic blockers may be used to control blood pressure. Doxazosin, prazosin, and terazosin do not cause the reflex tachycardia that may result from nonselective α -adrenergic blockade. Calcium channel blockers have also been used safely in patients with pheochromocytoma alone or combined with α -adrenergic blockers. Nifedipine GITS has been used to control blood pressure even during glucagon provocative testing.⁴⁹

β -Blockers should be used only after α -blockade. A hypertensive crisis may occur due to unopposed α -mediated vasoconstriction if β -blockers are used alone. β -Blockade may be

He was found to have medullary thyroid carcinoma consistent with MEN2. Arrows represent pheochromocytoma of adrenal glands.

added to control tachycardia related to catecholamine secretion, but when used alone may result in pulmonary edema caused by decreased cardiac output.⁵⁰

Surgery

Surgical excision of pheochromocytoma can be performed with low mortality and morbidity and may result in a high cure rate for hypertension. Although the surgical approach and outcome have changed dramatically with the development of laproscopic techniques for removal of pheochromocytoma,⁵¹ perioperative complications may be severe.⁵²

The management of hypovolemia prior to and during surgery is critical to a successful outcome. Surges in the blood pressure may occur with tumor manipulation, requiring the use of intraoperative phentolamine, labetalol, or nicardipine.⁵⁰

The postoperative complications include orthostatic hypotension due to decreased intravascular volume. Postoperative hypertension may occur with vigorous volume repletion, underlying primary hypertension, or the presence of residual tumor.⁵¹

Anesthesia and Hypertension

Scott T. Reeves, J. G. Reves

INTRODUCTION

This chapter reviews the current knowledge of anesthesia and surgery in the hypertensive patient. It is hoped that internists, surgeons, and anesthesiologists will be able to use this information to better prepare patients for surgery by understanding how hypertension, its treatment, and anesthesia interact. Emphasis is placed on the cardiovascular pharmacology of anesthetic drugs, anesthetic techniques, the preoperative evaluation of the patient, and the implications of the operative procedure for management strategies. The risks of perioperative hypertension and the best way to minimize those risks are also discussed.

Elsewhere in this book the pathophysiology and treatment of hypertension are discussed in detail. This chapter reviews the effects of anesthesia and surgery on the hypertensive patient from a physiologic, pharmacologic, and clinical outcome perspective. Hypertension (blood pressure [BP] >140/90 mm Hg) and surgery are both prevalent, particularly in the elderly.¹

It is important to have an understanding of the effect that hypertension has on anesthesia and surgery, as well as the effect that surgery and anesthesia have on hypertensive patients. It has been estimated that severe hypertension (BP \geq 180/110 mm Hg) is found in 11% of surgical patients.² The prevalence of hypertension depends on the surgical population; it is increased in older patients and in those undergoing vascular and cardiac surgery.³ Hypertension is common during surgery, occurring in 57% of patients undergoing abdominal aortic surgery, in 29% of those undergoing peripheral vascular surgery, and in 8% of those undergoing intraperitoneal procedures.⁴ In patients having carotid artery or open heart surgery, the incidence of hypertension varies between 40% and 80%.^{5,6}

Patients who develop hypertension in the perioperative period can be divided into four classes of hypertensive patients (Table 77–1). The first includes normotensive patients who respond to the many stresses of the perioperative period, such as anxiety, pain, or a distended bladder, that evoke catecholamine release and the subsequent development of hypertension.⁷ This form of hypertension is usually transient (self-limited) and can be successfully treated by removing the precipitating stimulus. The second class includes those with a history of hypertension controlled (BP \leq 140/90 mm Hg) by pharmacologic therapy. These patients are likely to respond to the multiple perioperative stressors of surgery with hypertension, but to a lesser degree than the third and fourth classes of patients. The third class includes those with undiagnosed or uncontrolled hypertension (BP 160/90 to 180/110 mm Hg). These patients are likely to have recurrent hypertension in the perioperative period. The fourth class includes hypertensive patients who may or may not be treated, but who present for anesthesia with uncontrolled hypertension (BP

\geq 180/110 mm Hg). This class is at highest risk for perioperative hypertension, hypotension, and a labile hemodynamic course, as well as morbid events. They should generally have surgery delayed until the hypertension can be better controlled.^{4,8}

It is important to recognize that hypertensive patients often have comorbid diseases, such as diabetes, renal disease, cerebrovascular disease, peripheral vascular disease, and cardiac disease, including coronary artery disease, left ventricular hypertrophy, and congestive heart failure (CHF). Hypertensive patients are at increased risk of hemodynamic fluctuations during the perioperative course,^{9–12} which may result in myocardial ischemia,^{9–11,13} myocardial infarction,^{4,14} postoperative renal dysfunction,^{15,16} and an increased incidence of postoperative neurologic deficits.^{16–18} Hypertension generally confers added risk to anesthesia and surgery, as discussed later in the chapter.

Figure 77–1 illustrates the effects of hypertension on the heart and identifies the important determinants of BP that are affected by anesthetic and antihypertensive drugs. The hypertensive patient is likely to have elevated systemic vascular resistance (SVR), reduced total blood volume, impaired cardiac contractility, and a hypertrophied myocardium. The hypertrophied left ventricle (which by its very pathology has higher oxygen requirements and potentially less oxygen supply) is vulnerable to subendocardial ischemia,^{9,19} particularly if there is tachycardia and/or if the coronary perfusion pressure decreases during anesthesia. Almost all anesthetic drugs and most anesthetic techniques will produce vasodilation (see the next section), and most inhalation anesthetics are direct negative inotropic drugs. Thus, hypertensive patients who may be volume depleted,²⁰ who have high SVR, and who may have depressed ventricular function commonly experience hypotension with the induction of anesthesia. This hypotension can compromise myocardial oxygen delivery, which may lead to ischemic ventricular dysfunction.

The treatment of hypertension is particularly important for patients undergoing anesthesia and surgery for two reasons. It is well documented that hypertensive patients whose BP is controlled have fewer hemodynamic fluctuations in the perioperative period.^{16,19–21} The fewer the hemodynamic fluctuations (particularly tachycardia), the less likely patients are to have myocardial ischemia.^{9,22} Also, many of the drugs commonly used in the treatment of hypertension have pharmacologic interactions with anesthetics. Anesthetic drugs and techniques (general, spinal, epidural) require a complex set of homeostatic reflexes to maintain cardiac output and BP, as illustrated in Figure 77–2.²³ Antihypertensive drugs that lower plasma volume (e.g., diuretics),²⁴ vasodilators, and β -adrenergic antagonists accentuate the hypotensive effects of anesthesia and impair the autoregulatory responses of increased heart rate (HR), contractility, and vasoconstriction that are triggered by anesthesia.

Table 77-1 Perioperative Hypertensive Patients

Classification*	BP† (mm Hg)	Commentary‡	Disposition
1. Normotensive	<140/90	Controlled, resolves with removal of stressor	Treat q.s.
2. Controlled hypertensives	<140/90	Adequately controlled	Treat q.s.
3. Poorly controlled or undiagnosed hypertensives	140/90 ≤ 180/110	Poorly controlled	Dx and Rx; better Rx; arrange appropriate medical follow-up
4. Uncontrolled or undiagnosed hypertensives	≥110 diastolic	Uncontrolled	Dx and Rx; better Rx; arrange appropriate medical management; <i>delay elective surgery</i>

BP, blood pressure; q.s., as needed during the perioperative period; Dx, diagnose; Rx, treat.

*Classification adapted from literature review and definitions of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. The sixth report. Arch Intern Med 157:2413-2446, 1997.

†BP at preoperative evaluation or before anesthesia induction.

‡Hypertensive response (≥140/90 mm Hg) during the preoperative or perioperative period in patients who are diagnosed as hypertensive or not diagnosed as hypertensive but who develop hypertension during the perioperative period.

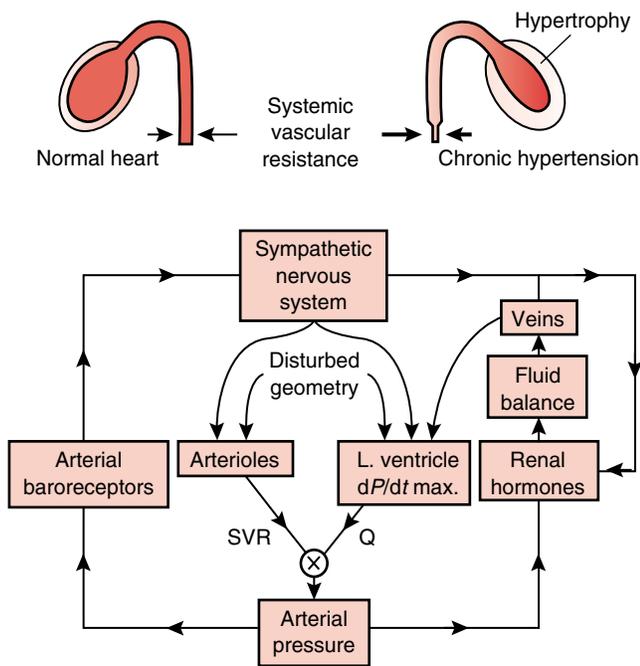

Figure 77-1 Schema of the hemodynamic perturbations induced in the hypertensive patient demonstrates the interactions of adaptive hypertrophy of the arteriolar media and of the left ventricle, with sympathetic nervous activity. SVR, systemic vascular resistance. (From Prys-Roberts C. Anaesthesia and hypertension. Br J Anaesth 56:711-724, 1984.)

Two classes of antihypertensive drugs that are especially helpful in the perioperative management of hypertensive patients are the β -adrenergic antagonists and the α_2 -agonists. β -Blockers attenuate the hypertensive and tachycardiac responses to perioperative stress and reduce myocardial ischemia.^{9,25,26} α_2 -Agonists, such as clonidine, reduce the incidence of hypertension and tachycardia, as well as the need for additional anesthesia.²⁷ Patients whose hypertension is treated with these classes of drugs will likely have smoother perioper-

ative courses. The failure of diuretics to provide smooth hemodynamics during anesthesia is attributed to the lower total blood volume, increased circulating vasoactive substances, and potassium depletion.⁹ There is insufficient information on the many new antihypertensive drug classes, such as angiotensin II receptor, II-imidazole receptor, and selective aldosterone receptor antagonists, to know how these agents affect the perioperative course.

CARDIOVASCULAR PHARMACOLOGY OF SEDATIVE AND ANESTHETIC DRUGS

To better understand the hemodynamic effects of sedative, inhalation, and intravenous anesthetics, we review the major cardiovascular effects of drugs used in anesthesia, as well as the cardiovascular effects of common anesthetic techniques. This section is a synopsis of material presented in earlier reviews of the pharmacology of anesthetic drugs.^{23,28-31} The cardiovascular effects of the various drugs and anesthetic techniques are summarized in Table 77-2.

Anesthetic Techniques

Anesthetic techniques can be divided into four categories. The first is general anesthesia, which is accomplished with a wide variety of intravenous and inhalation anesthetic drugs. The majority of general anesthetics are given with a hypnotic (usually a barbiturate or a benzodiazepine), an analgesic (an opioid and/or an inhalation drug), and a muscle relaxant (neuromuscular blocking drugs). A second form of anesthesia is neuraxial block, which is accomplished by placing a local anesthetic in the spinal or epidural space. A third technique is regional nerve block with a local anesthetic. The final anesthetic technique involves sedation of the patient and local anesthetic infiltration at the site of the surgery. This is called *monitored anesthesia care* (MAC).

We have examined the effect of anesthetic technique on hypertensive patients.³² General and neuraxial techniques result in the greatest hypotension because both result in vasodilation (Figure 77-3). Loss of consciousness, as seen in

Figure 77-2 The multiple effects of anesthetic drugs on the cardiovascular system are shown. Direct (solid arrows) and indirect (broken arrows) effects of intravenous (IV) anesthetics on cardiovascular function. SVR, systemic vascular resistance; HR, heart rate; CO, cardiac output; BP, blood pressure. (From Reves JG, Gelman S. Cardiovascular effects of intravenous anesthetic drugs. In Covino F, Rehdel K, Strichartz GR [eds]. Effects of Anesthesia. Bethesda, MD, American Physiological Society, 1985; pp 179-193.)

normal sleep,³³ reduces HR, cardiac output, and BP. Most drugs used for general anesthesia have hemodynamic effects that, together with loss of consciousness, cause hypotension. Neuraxial block produces hypotension by creating a complete sympathectomy to (or slightly above) the dermatome level of the anesthesia. This causes profound vasodilation, reduced preload, lower cardiac output, and hypotension. The use of epidural anesthesia with general anesthesia significantly lowers the incidence of operative hypertension, but is associated with greater hypotension and can evoke hypertension when it is withdrawn postoperatively.³⁴ Regional block and MAC have minimal hemodynamic effects and are less likely to cause hypotension in hypertensive patients. Hypertensive patients often have hypertensive responses during anesthesia, and all anesthetic techniques are associated with similar peak incidences of hypertension (Figure 77-4; see also Figure 77-3).

CARDIOVASCULAR PHARMACOLOGY OF GENERAL ANESTHETICS

General Anesthetic Induction Drugs

Thiopental

Thiopental (Pentothal) has survived the test of time as an intravenous anesthetic drug. Since Lundy introduced it in 1934, thiopental has become the most widely used induction agent because of the rapid hypnotic effect (one arm-brain circulation time), highly predictable effect, lack of vascular irri-

tation, and general overall safety.³⁵ The principal hemodynamic change produced by thiopental is a decrease in myocardial contractility³⁶⁻³⁸ due to reduced availability of calcium to myofibrils.³⁹ There is also an increase in HR.³⁷⁻⁴¹ The cardiac index (CI) is unchanged^{41,42} or reduced,³⁷ whereas the mean arterial pressure (MAP) is maintained^{41,43} or slightly reduced.⁴⁴ When thiopental is given to hypovolemic patients, which could include poorly controlled hypertensive patients, there is a significant reduction in cardiac output and an important decrease in BP. Thus, patients without adequate compensatory mechanisms may have serious hemodynamic depression with a thiopental induction.⁴⁵ This probably explains the disastrous results of thiopental administration at Pearl Harbor,⁴⁶ where many wounded men who were hypovolemic experienced shock with the rapid administration of the newly released anesthetic thiopental.

Diazepam

Diazepam (Valium) is probably the most widely used benzodiazepine in the world. It was introduced in the United States in 1963 and is used for sedation and anesthesia induction. The presumed mechanism of action of diazepam and other benzodiazepines in the central nervous system is by potentiation of the inhibitory effect of γ -aminobutyric acid on neuronal transmission.⁴⁷ All benzodiazepines have hypnotic, anticonvulsant, muscle relaxant, amnesic, and anxiolytic properties. Induction with diazepam is characterized by hemodynamic stability. Filling pressures and CI remain unchanged,⁴⁸⁻⁵³ with

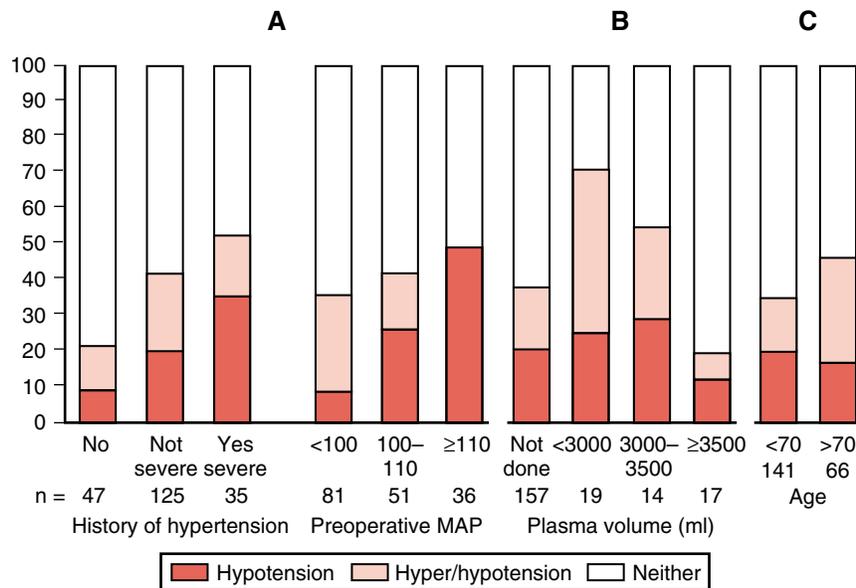

Figure 77-3 Percentage of patients with intraoperative hypotension (black), hypertension/hypotension (cross-hatched), or neither high-risk pattern (white), according to preoperative characteristics. **(A)** Patients are compared based on their history of hypertension and preoperative mean arterial pressure (MAP). A preoperative MAP >110 mm Hg was a significant ($p < .001$) predictor of intraoperative hypotension. **(B)** Patients are compared based on their initial plasma volume as determined using Evans blue. Decreased plasma volume was a significant ($p = .03$) predictor of intraoperative hypotension and was associated with a higher incidence of intraoperative hypertension/hypotension. **(C)** Patients are compared based on age. Age >70 years was a significant ($p < .006$) predictor of intraoperative hypertension/hypotension. Age alone did not significantly increase the incidence of intraoperative hypotension. *Preoperative hypertension* was defined as a systolic BP >160 mm Hg or a diastolic BP >95 mm Hg. *Severe preoperative hypertension* was defined as diastolic BP ≥ 120 mm Hg. *Intraoperative hypotension* was defined as a decrease of >20 mm Hg from preoperative MAP lasting 1 hour or longer. *Intraoperative hypertension/hypotension* was defined as an increase of ≥ 20 mm Hg above the usual MAP lasting >15 minutes combined with a decrease of >20 mm Hg in MAP lasting <1 hour. (A-C From Charlson MD, MacKenzie CR, Gold JP, et al. Preoperative characteristics predicting intraoperative hypotension and hypertension among hypertensives and diabetics undergoing noncardiac surgery. *Ann Surg* 212[1]:66-81, 1990.)

variable but modest changes in HR.⁴⁸⁻⁵⁴ Although diazepam may be safely combined with other anesthetic drugs, there is some potential for hemodynamic depression.⁵⁵ The effect of the combination of diazepam and morphine (indeed of any benzodiazepine and opioid) in patients who have ischemic heart disease^{56,57} and valvular heart disease⁵⁸ has been reported. The combination of diazepam (0.125-0.5 mg/kg) and fentanyl (50 μ g/kg) used to induce anesthesia in patients for coronary artery bypass graft surgery⁵⁹ led to a supra-additive fall in BP was more pronounced in hypovolemic hypertensive patients. The authors concluded from this that diazepam ablates normal sympathetic tone.⁵⁹

Midazolam

Midazolam (Versed) is a water-soluble benzodiazepine synthesized in the United States in 1975. It is unique among benzodiazepines with its rapid onset and short duration of action and relatively rapid plasma clearance.⁶⁰ It is the most commonly used benzodiazepine in anesthetic practice. The hemodynamic changes that result from the intravenous administration of midazolam (0.2 mg/kg) in premedicated patients who have coronary artery disease are usually minor.^{53,61} Changes of potential importance include a decrease in MAP of 20% and

an increase in HR of 15%.⁶¹ The CI is maintained.^{53,61} Filling pressures are either unchanged or decreased in patients who have normal ventricular function^{53,61} but are significantly decreased in patients who have an elevated pulmonary capillary wedge pressure (≥ 18 mm Hg).⁶² Interactions between midazolam and other drugs are relatively mild and predictable. The combination of nitrous oxide (N_2O) (50%) with midazolam (0.2 mg/kg) does not cause increased cardiovascular depression.⁵³ The safe combination of N_2O and midazolam contrasts with the well-known additive depression of N_2O and narcotic agents.⁶³ Midazolam is routinely combined with fentanyl for induction and maintenance of general anesthesia during cardiac surgery without adverse hemodynamic sequelae.⁶⁴⁻⁶⁶ However, if midazolam is given to patients who have received fentanyl, significant hypotension may occur, as seen with diazepam and fentanyl.⁵⁹

Ketamine

Although ketamine (Ketalar) produces rapid hypnosis and profound analgesia, respiratory and cardiovascular functions are not depressed as much as with most other induction agents. Disturbing psychotomimetic activity (described as vivid dreams, hallucinations, or other mental disturbances on

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

Figure 77-4 The effect of anesthetic technique on maximal changes in BP is shown. BP drops (average intraoperative [Intra-OP] lowest mean vs. average preoperative mean) are significantly ($p < .001$) greater with general and neuraxial anesthetic techniques compared with regional (major nerve block) and monitored anesthetic care (MAC) techniques. The average intra-OP highest mean BP was similar among anesthetic techniques. *Regional anesthesia* refers to major peripheral nerve blocks, such as brachial plexus blocks, lumbar plexus blocks, sciatic nerve blocks, and paravertebral blocks; *general anesthesia* refers to general anesthesia; *neuraxial anesthesia* refers to spinal, epidural, or combined spinal/epidural anesthesia. See text for more details on anesthetic technique. (From Gould JD, Reves JG, D'Ercole FJ, et al. Effect of anesthetic technique on blood pressure response in hypertensive patients. *Anesth Analg* 88:SCA62, 1999.)

emergence from ketamine anesthesia) as well as undesirable increases in myocardial oxygen consumption have limited the use of ketamine. One unique feature of ketamine is stimulation of the cardiovascular system. The most prominent hemodynamic changes are significant increases in HR, CI, SVR, and systemic and pulmonary artery pressures. Because of the hypertension after ketamine, this drug is seldom used in hypertensive patients.

Propofol

Propofol (Diprivan) was introduced into clinical practice in 1977.⁶⁷ It is an alkylphenol (substituted derivative of phenol) with hypnotic properties. The hemodynamic effects of propo-

fol have been compared with the most commonly used induction drugs, including the thiobarbiturates and etomidate.⁶⁸⁻⁷² Systolic pressure falls 15% to 40% after intravenous induction with ± 2 mg/kg and maintenance infusion of ± 100 μ g/kg/min propofol. Similar changes are seen in both diastolic pressure and MAP. The effect of propofol on HR is variable. Despite a significant decrease in MAP, some studies have shown no change in HR,⁷³ a decrease in HR,⁷² or an increase in HR.⁷⁴ The majority of studies have demonstrated significant reductions in SVR (9%-30%), CI, stroke volume, and left ventricular stroke work index after propofol. In summary, propofol alone or in combination causes significant decreases in arterial pressure and CI secondary to increased venodilation with decreased myocardial contractility. Its use in uncontrolled hypertensives could be problematic.

Drugs for Maintenance of Anesthesia

Inhalation Anesthesia

Contemporary inhalation anesthesia includes the use of six drugs—the volatile liquids halothane, enflurane, sevoflurane, desflurane, and isoflurane, and the inert gas N_2O . Each inhalation anesthetic has a specific cardiovascular profile, but all except N_2O are vasodilators and negative inotropes. As with the intravenous agents, their hemodynamic effects depend on several factors that include the drug per se, the cardiovascular status of the patient, and concurrent pharmacologic therapy. Unlike the intravenous drugs, the cardiovascular effects of the inhalation agents are more similar to one another than they are different. The inhalation anesthetics often reduce cardiac output. All of the inhalation agents exert a direct, dose-dependent negative inotropic effect on the myocardium in humans.⁷⁵⁻⁷⁷ There are small differences among agents in the degree of myocardial depression and in the mechanism of myocardial suppression. In general, halothane and enflurane reduce cardiac output to a greater degree than isoflurane in healthy patients. Volatile anesthetics further depress myocardial contractility in disease states, such as ischemic heart disease.⁷⁸ The influences of age, myocardial disease, premedication, and adjuvant drugs are important additive depressant factors. Inhalation anesthetics must be used judiciously in hypertensive patients because of their propensity to cause hypotension.

Narcotics

Opioids are also used to provide analgesia during general anesthesia and postoperatively. The drugs commonly used are morphine, fentanyl, sufentanil, alfentanil, and remifentanyl. Morphine causes more hemodynamic perturbations than the others. Morphine, because of release of histamine, causes vasodilation that may produce hypotension. The other synthetic opioids are devoid of this action, and their administration is marked by maintenance of SVR. All opioids tend to be vagomimetic, causing a decrease in HR. Opioids have little effect on cardiac output, stroke volume, cardiac filling, or baroreflex function. They are used in hypertensive patients to blunt sympathetic responses to painful stimuli. They are useful in this setting because they tend to minimize hemodynamic fluctuation, but they must be combined with other anesthetic drugs to accomplish total anesthesia. The hemodynamic

interactions with these drugs can cause vasodilation and hypotension.

EVALUATION AND PREPARATION OF THE HYPERTENSIVE SURGICAL PATIENT

There is no area in medicine where the collaborative team approach to patient care can be better employed than in evaluating and preparing the hypertensive patient for surgery. The internist (cardiologist, generalist), the surgeon, and the anesthesiologist all have important roles in the optimal care of these high-risk patients.⁷⁹ The objectives of the evaluation are listed in Box 77-1. Each specialist has a specific role: The surgeon must determine the appropriate operation; the internist must optimize the medical therapy; and the anesthesiologist must choose the appropriate monitoring, anesthetic technique, and postoperative pain strategy.

Table 77-1 lists the categories into which hypertensive patients fall when presenting for surgery. Patients who are optimally medically managed before, during, and after surgery have a smoother hemodynamic course. Patients in groups 3 and 4 of Table 77-1 have more labile courses than patients in groups 1 and 2.^{2-4,16,20,80} It is important when evaluating the hypertensive patient that comorbid conditions be detected (Table 77-3) and that antihypertensive therapy be optimized (BP \leq 140/90 mm Hg).

The preoperative evaluation listed in Box 77-1, including relevant history and physical examination (see Table 77-3), can be made by the internist, the surgeon, or the anesthesiologist. It does not matter who has the initial responsibility. What is vital is that all of the objectives in Box 77-1 are successfully attained before surgery. The cause of hypertension should be determined, remembering that essential hypertension is most common. Knowing, wherever possible, the causes and pathophysiology of the hypertension (see Figure 77-1) is critical to proper perioperative management. It is important to determine what antihypertensive medications the patient is taking, what the dosing regimen is, and whether this regimen should be continued or changed during the perioperative period. If the regimen cannot be continued, an alternative strategy must be developed. Studies support the continuation of the patient's antihypertensive medicines until the morning of surgery.^{2-4,9,16,19,79-81} The discontinuation of antihypertensive medication, especially β -blockers and/or clonidine, may precipitate rebound hypertension, tachycardia, or myocardial ischemia,^{19,81} which will be problematic in the perioperative management of the patient. In patients unable to take oral medications, intravenous β -blockade or transdermal clonidine can be utilized.⁸¹ Antihypertensive therapy should be

continued after surgery and throughout the perioperative period as the patient's course dictates. Occasionally, patients with newly diagnosed mild hypertension (type I or II) may have the institution of therapy delayed until after surgery to avoid the creation of instability in HR or BP.⁸¹

The single most important and most obvious preoperative assessment (see Table 77-3) is the adequacy of BP control. If BP is greater than 110 mm Hg diastolic at the preoperative evaluation, it is generally recommended to delay elective surgery until BP can be better controlled.* The introduction of a β -blocker preoperatively minimizes BP fluctuations and decreases the number and duration of perioperative coronary ischemic events.⁸¹ Unless the surgery is emergent or urgent, it is best to get the resting BP as close to the normal range as possible, or at least to less than 110 mm Hg diastolic. It should be remembered that many patients who are faced with the prospect of surgery have conditions that may artifactually raise their BP, for example, anxiety or pain. Therefore, a preoperative BP that is above the "normal" range, as defined by office readings in relaxed patients, is acceptable for the preoperative patient. It is also useful to obtain a supine and a standing BP as an assessment of the orthostatic component of BP control. This measurement can also indirectly gauge the blood volume.

Routine perioperative evaluation of the newly diagnosed hypertensive patient includes a comprehensive physical examination searching for target organ damage and evidence of associated cardiovascular pathology. A few simple tests, including an electrocardiogram and chest radiograph (looking for evidence of left ventricular hypertrophy), serum electrolytes (especially in patients treated with diuretics), blood urea nitrogen/creatinine to evaluate renal status, and a baseline hematocrit should be performed.⁸¹ Additional tests may be indicated based on the results of the patient's history and physical examination and initial studies. According to American College of Cardiology/American Heart Association guidelines, if the initial evaluation of the patient undergoing noncardiac surgery establishes hypertension as mild or moderate and there are no associated metabolic or cardiovascular abnormalities, there is no reason to delay surgery.⁸¹

Preoperative evaluation of the surgical patient may reveal not only hypertension but also other important coexisting diseases (cardiac, renal, cerebrovascular). Each of these requires lifelong management, and one benefit of routine preoperative evaluation may be the discovery of these potentially life-threatening diseases.⁷⁹ Medical consultation should be obtained to be certain that the extent of the comorbid disease is fully understood and that a long-term plan for management after surgery is put into place.

Consultations have an important role in the preoperative evaluation of the hypertensive patient. To be most informative to the professionals involved, as well as to provide optimal patient care, consultations should include a number of important elements.⁷⁹⁻⁸⁴ Box 77-2 lists suggestions to make the consultative process most effective.⁷⁹ It is generally unproductive for professionals to stray from their own realm of expertise, no matter how great the temptation. Thus, medical consultants who "clear patients for surgery" encroach on the surgeon's ultimate decision. Likewise, internists' advice to anesthesiologists regarding monitoring or anesthetic techniques is noncontributory. The four key questions that

Box 77-1 Objectives of the Preoperative Evaluation of Hypertensive Patients

- Diagnosis of hypertension (cause)
- Ascertain antihypertensive medical therapy
- Determine adequacy (optimization) of therapy
- Identify comorbid diseases (see Table 77-4)
- Obtain appropriate consultative services
- Devise appropriate postoperative antihypertensive plan

surgeons and anesthesiologists have for their medical consultants follow:

1. What diseases does the patient have?
2. Are the diseases being appropriately treated?
3. Is there any further medical therapy that should be instituted?
4. Who will be responsible for the postoperative treatment of the medical conditions that are identified?

HYPERTENSION, ANESTHESIA, AND SURGERY

After the preoperative evaluation, the anesthetic plan is made. It must include choice of anesthetic technique; monitoring strategy; method of anesthesia induction, maintenance, and emergence; and postoperative disposition. The patient's coexisting diseases, the planned operative procedure, and the duration of the procedure all influence the anesthetic plan.

In general, anesthetic technique falls into one of four categories: centroneuraxial anesthesia, regional (major nerve block) anesthesia, MAC, and general anesthesia. *Centroneuraxial* anesthesia includes spinal and epidural anesthesia. *Major nerve block* anesthesia includes, but is not limited to, brachial plexus blocks

Box 77-2 Essentials of Effective Perioperative Consultation

- Establish clear communication.
- Ask specific questions in the realm of consultant's expertise.
- Avoid general statements on "clearance for surgery."
- Avoid specific advice on matters for which another professional has ultimate decision.
- Specify whether anything can be done to improve patient status.

A condensation of the authors' thoughts and those of Kleinman et al.⁷⁹ and Lee et al.⁸³

(interscalene, supraclavicular, and axillary) for upper extremity surgery, lumbar plexus blocks and femoral-sciatic nerve blocks for lower extremity surgery, and paravertebral blocks for trunk surgery. In simplest terms, *MAC* involves intravenous sedation, patient monitoring, and local anesthetic infiltration at the operative site. *Regional* anesthesia provides profound analgesia and muscle relaxation to a limited portion of the body, allowing the patient to maintain normal respiratory control, easy assessment of neurologic status, and minimal physiologic disturbance. *General* anesthesia involves inducing a state of unconsciousness with analgesia, amnesia, and immobility. Frequently, endotracheal intubation, mechanical ventilation, complete paralysis, and hemodynamic support are part of a general anesthetic.

Choice of Technique in Hypertensive Patients

With regard to anesthetic technique, two main questions need to be addressed:

1. How does the choice of anesthetic technique affect perioperative cardiovascular, neurologic, and renal morbidity and mortality in the hypertensive patient?
2. What effect (consequence) does the chosen anesthetic technique have on the incidence of perioperative hypertension, hypotension, hemodynamic lability, and myocardial ischemia?

General Anesthesia

Most of the literature evaluating the cardiovascular responses of hypertensive patients to anesthetic techniques relates to use of general anesthesia. The cardiovascular responses of hypertensive patients undergoing general anesthesia tend to be labile.^{2,9,10,13} Hypertensive patients become hypotensive with induction and have hypertensive responses to laryngoscopy, intubation, noxious stimuli, and emergence. Their response to rapid changes in anesthetic depth is also exaggerated.

Intraoperative BP lability, hypertension, and hypotension place hypertensive patients at increased risk of myocardial ischemia,⁹ myocardial reinfarction,¹⁴ and perioperative renal dysfunction.^{16,20} Charlson et al.²⁰ have looked at the association between preoperative patient characteristics and intraoperative hemodynamics. Figure 77–3 shows these results. Patients older than 70 years (see Figure 77–3,C) with a preoperative MAP 110 or greater (see Figure 77–3,A) are at greatest risk for intraoperative hemodynamic lability (hypertensive/hypotensive episodes). Charlson et al.'s data²⁰ also support a role for appropriate fluid management in decreasing hemodynamic lability; patients with a plasma volume greater than 3500 ml had a decreased incidence of intraoperative hypotension and hypertension episodes (see Figure 77–3,B).

Other than a few studies of spinal anesthesia,^{16,21} there have been no studies comparing anesthetic effects (MAC, regional, centroneuraxial, and general) on BP response in hypertensive patients. To this end, we analyzed more than 120,000 anesthetic records stored in the Duke Anesthesia Database compiled by an automated anesthesia information system used at Duke University.³² From the database 15,211 hypertensive patients were identified; their mean BP was recorded before initiating an anesthetic technique (MAC, centroneuraxial, major nerve block, or general) and then compared with their intraoperative highest and lowest mean BPs. Figure 77–4 shows the differences in change in MAP after induction of anesthesia among the anesthetic techniques. Reductions in BP are significantly ($p < .001$) greater with general and centroneuraxial anesthetics compared with MAC and major nerve block. The maximal mean BP intraoperatively was similar with all techniques. Patients with higher initial MAP had larger intraoperative reductions in BP after initiating anesthesia, regardless of the choice of techniques, confirming previous studies (see Figure 77–3,A).²⁰ These data support the notion that better BP control intraoperatively may be achieved with major nerve block anesthesia compared with general or centroneuraxial techniques. Many operations cannot be performed with nerve block anesthesia, however.

Regional Anesthesia (Neuraxial and Major Nerve Blocks)

Regional anesthesia has theoretic advantages in the high-risk patient.⁸⁵ Because regional techniques do not involve intubation, paralysis, or mechanical ventilation with positive pressure, they are less physiologically intrusive and therefore may be better tolerated in patients predisposed to hemodynamic lability. Furthermore, the dense block provided by regional techniques almost eliminates the hypertensive response to surgical stimuli, and excellent postoperative analgesia (with major nerve block or epidural) may prevent hypertensive or ischemic responses to postoperative pain.³⁴

Epidural and spinal anesthesia involve the injection of local anesthetic in or around the spinal cord to interrupt afferent impulses. The result is usually a dense sensory and motor block to the lower half of the body (T4-T10 dermatomal level and below depending on dose and technique). This block also produces a profound sympathectomy to the lower extremities and part of the splanchnic circulation, with resultant vasodilation and venodilation of these vascular beds. This reduction in preload, particularly in a hypertensive patient with mild

hypovolemia, left ventricular hypertrophy, and diastolic dysfunction, can cause a marked drop in cardiac output and BP. Racle et al.²¹ compared the cardiovascular responses of normotensive and hypertensive patients after spinal anesthesia and found that hypertensive patients, on average, had a significantly larger drop in systolic, diastolic, and mean BPs compared with normotensive patients.

In general, patients with well-controlled hypertension tolerate lumbar and thoracic epidural block without unpredictable or profound decreases in arterial pressure. In contrast, a small group ($n = 5$) of patients with untreated hypertension showed an average decrease of 44% in systolic BP. Three of these patients required active intervention to correct the problem.⁸⁶ Finally, in a study by Garnett et al.³⁴ of patients (42% hypertensive) undergoing elective aortic surgery, epidural anesthesia in combination with general anesthesia reduced the risk of intraoperative hypertension compared with general anesthesia alone. Epidural anesthesia did not prevent, and possibly intensified, hypotension during the procedure. The hypotension was associated with a higher incidence of electrocardiographic evidence of myocardial ischemia.

Hypertensive patients have perioperative hemodynamic characteristics that are associated with increased perioperative complications. Untreated patients and those with severe hypertension are at particularly high risk. The hemodynamic patterns of the various anesthetic techniques in hypertensive patients are different, and improved perioperative outcome has not been demonstrated unequivocally for any of them. Each anesthetic technique has certain benefits and risks, as well as certain desirable and undesirable characteristics. For example, a technique that prevents hypertensive responses may make the patient prone to hypotension and ischemia. Rather than anesthetic technique, it is more likely that acute, aggressive treatment of perioperative hypotension, hypertension, tachycardia and ischemia is the key to improving perioperative outcomes. Brief periods of hypertension, hypotension, tachycardia or ischemia, if treated appropriately and promptly, are unlikely to have negative sequelae, whereas prolonged periods place the patient at increased risk.²⁰ Thus, an anesthesiologist familiar with the consequences of the anesthetic technique, appropriate intraoperative monitoring to detect rapid hemodynamic changes and ischemia, and aggressive correction of the hemodynamic disturbances, are more important than the choice of anesthetic technique alone.

Outcome Studies

The majority of studies evaluating the effects of anesthetic technique (centroneuraxial, regional, or general) on cardiac morbidity and mortality were carried out in patients undergoing peripheral vascular surgery⁸⁷⁻⁹⁰ or carotid endarterectomy.⁹¹⁻⁹⁴ The studies in patients undergoing peripheral vascular surgery all compare a centroneuraxial technique with general anesthesia. The largest study by Bode⁸⁷ randomly assigned 423 patients scheduled for elective femoral-distal vessel bypass surgery to one of three anesthetic techniques (spinal, epidural, or general). Using an intent-to-treat analysis, they reported no statistically significant differences between groups with regard to in-hospital mortality, nonfatal myocardial infarction, angina, or CHF. Other studies comparing general anesthesia with combined epidural-general

anesthesia for abdominal aortic surgery found no differences in perioperative cardiovascular outcome.^{95,96} The carotid endarterectomy literature comparing regional anesthesia with general anesthesia has also failed to demonstrate a significant difference in cardiac outcome between techniques. Charlson,²⁰ looking at patients at risk for postoperative renal dysfunction (hypertensives and diabetics), concluded that patients whose MAP fell below the preoperative baseline (<20 mm Hg) for 60 minutes or greater or rose above baseline (>20 mm Hg) for greater than 30 minutes and received less than 3000 ml/hour of fluids had significantly increased postoperative renal dysfunction. Postoperative renal dysfunction varied with the anesthetic technique. The incidence of renal dysfunction was higher in patients receiving regional or centroneuraxial anesthesia than in those receiving general anesthesia. However, after further analysis, taking into account the occurrence of the three significant predictors of renal dysfunction listed previously, the type of anesthesia was not an independent predictor of postoperative renal dysfunction in these patients.

The incidence of perioperative stroke in the general surgery population is low, and it is unlikely that a study comparing the effects of different anesthetic techniques on stroke rate in hypertensive patients would show significant differences among techniques. A prospective study of this issue by Larsen¹⁸ found that anesthetic technique was not a significant predictor of postoperative cerebrovascular accidents. Furthermore, the carotid endarterectomy literature has failed to demonstrate a difference in neurologic outcome between regional and general anesthetic techniques. There are no particular anesthetic techniques or specific drug combinations that have been shown to be better than others for the hypertensive patient. *The choice of general or regional anesthesia, or a combination of both, depends primarily on the skill and experience of the anesthesiologist rather than on the apparent suitability of any technique in the hands of others.*¹⁶

Choice of Monitoring in Hypertensive Patients

Monitoring is a decision the anesthesiologist must make. A history of hypertension, by itself, is not a indication for additional hemodynamic monitoring. Rather, the patient's coexisting diseases (coronary artery disease, CHF, renal insufficiency, cerebrovascular disease), the planned operative procedure, and the duration of the procedure weigh more heavily into monitoring decisions. Routine monitoring for anesthesia includes noninvasive BP cuff, pulse oximetry, capnography, continuous electrocardiographic monitoring, and temperature monitoring. Invasive hemodynamic monitors (arterial line, central venous pressure, or pulmonary artery catheter) should not be used without considering the risks. Five-lead electrocardiographic monitoring should be used in hypertensive patients, because it enhances ischemia detection with no additional patient risk. Bladder catheterization should be considered for longer procedures to monitor urine output.

Intracranial, intrathoracic, major vascular, and cardiac surgery require invasive monitoring based on the hemodynamic insults and hemodynamic requirements of the procedure alone. Whereas a patient with severe renal disease, hypertension, angina, and a history of CHF could undergo the creation

of a primary arteriovenous fistula under MAC with routine monitors, the same patient would require invasive arterial and central venous monitoring for a total hip replacement. For major or prolonged operations, it is preferable to monitor BP through an arterial line. When an arterial line is planned, it should be inserted before induction, because induction is one of the phases when cardiovascular lability is greatest.² In extensive surgeries, procedures with large intravascular volume shifts, hypertensive emergencies, and in the presence of severe myocardial dysfunction, central monitoring with a central venous or pulmonary artery catheter should be undertaken.^{2,16,19} When uncertainty exists regarding monitoring, it is probably safer to err in favor of the monitoring device. Increased monitoring of high-risk cardiac patients during the perioperative period has been shown to decrease postoperative morbidity.⁹⁷

In summary, although various monitoring approaches can be recommended, we believe that there is no preponderant evidence to support any particular anesthetic approach over another in the hypertensive patient.

OPERATIVE COURSE

Before inducing anesthesia, the anesthesiologist must have a plan for managing intraoperative hemodynamics. This plan includes setting certain hemodynamic limits that will be tolerated intraoperatively. What are the safe levels for hypertension and hypotension? Some anesthesiologists attempt to maintain a patient's BP within 20% of the "preoperative baseline." Others review the medical record and pick a range of pressures at which the patient "normally lives" symptom free. For example, if a patient has a BP of 180/100 mm Hg during the daytime and 100/60 mm Hg at night, with neither causing physiologic insult, the patient should be able to tolerate these extremes under anesthesia. A patient's coexisting disease(s), the effect of hypertension on cerebral autoregulation, and the operative procedure are all considered. Thresholds may be lowered to prevent rupture of vascular anastomoses and may be raised to prevent cerebral ischemia during carotid endarterectomy.

The goal of this section is to not define acceptable limits or give management strategies based on certain procedures, but rather to illustrate some of the issues involved in the decision-making process. After setting the physiologic parameters, the pharmacologic means to achieve these goals must be considered. Again, the operative procedure is a major factor. For example, aortic and cardiac surgery demand precise hemodynamic control, and the use of a sodium nitroprusside infusion is routine. The management of cerebrovascular surgery also demands strict hemodynamic control. In this instance, the choice of pharmacologic intervention must take into account effects on cerebroautoregulation and intracranial pressure. Other procedures, such as resection of a carcinoid tumor or pheochromocytoma, have unique perioperative management strategies based on the pathophysiology of the hemodynamic derangement. For the majority of patients undergoing general surgical or orthopedic procedures, intermittent intravenous boluses of appropriate vasoactive drugs are used to control hemodynamics, whereas continuous infusion is used if the causes of hemodynamic perturbation are judged to be persistent.

Induction and Intubation

Induction of anesthesia with rapidly acting intravenous drugs is acceptable, recognizing that an exaggerated decrease in BP may occur. The choice of induction agent is not as critical as the method of administration. A large initial bolus is more likely to cause hypotension than a slower, titrated induction. Use of pharmacologic agents that cause peripheral vasodilation in a population with elevated SVR and mild hypovolemia explains the common occurrence of hypotension. Giving a small volume load before induction may help attenuate this hypotensive response.

Laryngoscopy and intubation of the trachea can result in a hypertensive and tachycardic response in normotensive patients. The response in hypertensive patients, even those considered to be well treated, can be exaggerated. There are many ways of controlling the hemodynamic response to laryngoscopy and intubation.⁹⁸ Preoperative clonidine, topical treatment of the airway with lidocaine, intravenous lidocaine, intravenous nitroprusside, and intravenous esmolol before intubation are some of the reported methods.^{25,99-101} Using a modest dose of narcotic (fentanyl 5-8 µg/kg) before intubation and limiting laryngoscopy to 15 seconds or less are also very effective in reducing the hemodynamic response. After intubation, the patient is often placed on mechanical, positive-pressure ventilation. This can cause a reduction in preload with a resultant drop in cardiac output and BP. Usually, gentle volume expansion resolves this problem.

Maintenance and Emergence

The goal during maintenance of anesthesia is to anticipate surgical stimuli and adjust the anesthetic depth to minimize hemodynamic responses. This can be accomplished with any of a number of techniques. Often, a “balanced” technique is used. The combination of N₂O, a narcotic, and a low-dose inhalation agent provides a technique that is rapidly titratable to operative stimuli and hemodynamic responses. Both inhalation and intravenous drugs should be given to maintain therapeutic levels; thus, continuous administration is the most rational method.¹⁰² Appropriate fluid management to minimize direct and indirect intravascular volume change also limits hemodynamic lability during maintenance. Preoperative treatment with clonidine improves intraoperative hemodynamics in hypertensive patients,^{103,104} and perioperative β-blocker administration can blunt the hypertensive and tachycardic response to noxious stimuli.^{12,105} The benefits of perioperative β-blocker treatment in reducing perioperative ischemia⁹ and decreasing cardiovascular morbidity and mortality in high-risk patients²⁶ cannot be overemphasized.

Hypertension that occurs during maintenance of anesthesia can be treated by increasing anesthetic depth or by administering an intravenous antihypertensive agent. Drugs commonly used intraoperatively include labetalol, esmolol, metoprolol, and hydralazine. Intravenous calcium channel blockers and angiotensin-converting enzyme inhibitors are also available. Severe, resistant hypertension is usually managed with intravenous infusions of sodium nitroprusside or nitroglycerin, or a combination of both. Fenoldopam, a selective dopamine D₁-agonist, is useful in the management of resistant/emergent hypertensive episodes. Administered by a continuous infusion, fenoldopam has efficacy and titratability

similar to those of nitroprusside. In addition to lowering BP, fenoldopam significantly increases urine flow, sodium excretion, and creatinine clearance.¹⁰⁵⁻¹⁰⁸ Fenoldopam may be the antihypertensive drug of choice in certain patient populations (i.e., those with renal insufficiency).

Intraoperative hypotension can be treated by decreasing anesthetic depth, increasing intravenous fluids, or giving a sympathomimetic drug, such as phenylephrine or ephedrine. Although phenylephrine and ephedrine usually resolve hypotension and help preserve vital organ perfusion, this treatment should be considered a temporizing measure until the underlying problem is identified and corrected.

Emergence from anesthesia involves turning off the anesthetic agent and allowing the patient to awaken. Tracheal stimulation from the endotracheal tube and operative pain can cause severe hypertension at this point secondary to catecholamine responses.⁷ Pharmacologic means of blunting the pressor responses are options for managing emergence.

POSTOPERATIVE MANAGEMENT

Perioperative hypertension is associated with many adverse outcomes (Box 77-3) and should be prevented. Aggressive treatment to prevent myocardial ischemia, CHF, stroke, bleeding, and rupture of vascular suture lines is necessary. One of the most significant predictors of postoperative hypertension is a history of preoperative hypertension.¹⁰⁹ Although the hypertension may not have an identifiable cause, secondary etiologies should be considered. Excluding postoperative pain, hypoxia, and hypercarbia should be routine. Iatrogenic hypervolemia can cause hypertension, as can a distended bladder. Aggressive postoperative pain management may decrease the incidence of postoperative hypertension and cardiac morbidity.¹¹⁰ Management of hypertension in the immediate postoperative period should be an extension of the intraoperative plan. Invasive monitoring should be continued until the patient becomes hemodynamically stable. The same intravenous agents used intraoperatively can be used postoperatively until the patient can return to his or her oral regimen, which should be restarted as soon as possible.¹¹¹ In some settings, it is appropriate to have an internist and/or cardiologist consultant assist in the postoperative control of BP.

Box 77-3 Consequences of Perioperative Hypertension

- Mortality
- Myocardial ischemia
- Myocardial infarction
- Increased hemorrhage (surgical bleeding)
- Intracranial hemorrhage
- Disruption of vascular surgical incision sites
- Congestive heart failure
- Increased intracranial pressure
- Hypertensive encephalopathy
- Prolonged hospital stay
- Added hospital costs

From Skarvan K. Perioperative hypertension: New strategies for management. *Curr Opin Anaesthesiol* 11:29-35, 1998.

SUMMARY

Hypertension is the most prevalent circulatory disorder in the United States, affecting approximately 60 million people. Surgical patients with hypertension are at increased risk for perioperative hemodynamic lability, myocardial ischemia, myocardial infarction, CHF, renal failure, and stroke (see Box 77–3). Hypertensive patients often have significant coexisting disease, and appropriate preoperative evaluation and use of consultants are necessary to optimize these patients' medical management and minimize their perioperative risk. Patients with well-controlled hypertension have a lower risk for perioperative complications than patients with uncontrolled hypertension. Elective procedures should be postponed and appropriate medical management initiated when uncontrolled hypertension is evident (BP \geq 110 mm Hg diastolic). No particular anesthetic technique (general, centroneuraxial, major nerve block, MAC) has been shown to improve morbidity and mortality in the hypertensive patient. However, familiarity with the hemodynamic consequences of the various anesthetic techniques; knowledge of the interactions between antihypertensive medications and anesthetic agents; appropriate hemodynamic monitoring; and early recognition and treatment of intraoperative hypertension, hypotension, tachycardia, and ischemia are necessary. The development of postoperative hypertension also requires swift detection and treatment to prevent perioperative complications. In short, the hypertensive surgical patient is at increased risk for perioperative morbidity and mortality. These risks can be minimized with optimal preoperative preparation and prompt assessment and treatment of adverse hemodynamic changes in the intraoperative and postoperative period.

Management of Hypertensive Emergencies and Urgencies

Donald G. Vidt

The term *hypertensive crisis* includes a spectrum of clinical situations with different severities of blood pressure (BP) elevation and variable degrees of urgency of initial treatment. Hypertensive crisis affects upward of 500,000 Americans each year. Although the incidence of hypertensive crisis is low, affecting fewer than 1% of hypertensive adults, more than 50 million American adults suffer from hypertension. Hypertensive crises are classified as hypertensive emergencies or hypertensive urgencies, based on the presence or absence of progressive target organ dysfunction.¹

Hypertensive emergencies are severe elevations in BP that are complicated by evidence of progressive target organ dysfunction such as coronary ischemia, disordered cerebral function, a cerebrovascular event, pulmonary edema, or renal failure.^{2,3} These patients warrant immediate admission to an intensive care unit (ICU) for parenteral administration of antihypertensive agents. Hypertensive urgencies are severe elevations in BP, without evidence of progressive target organ dysfunction and can usually be managed by orally administered medications initiated in the emergency department (ED) with appropriate follow-up within 24 hours to several days, depending on individual characteristics of the patient.

Most hypertensive urgencies or emergencies are preventable and are the result of inadequate treatment of mild-to-moderate hypertension or nonadherence to antihypertensive therapy. Improved treatment of hypertension in the United States, despite suboptimal control rates, has resulted in progressive decline in patients presenting with crisis levels of BP. Hypertensive crises continue to be a major problem in many other parts of the world and, in the United States, may still represent approximately 5% of patients seen in the EDs of large urban hospitals.⁴ Previously unrecognized forms of secondary hypertension, such as renovascular hypertension, renal parenchymal disease, or pheochromocytoma, and rarely, primary hyperaldosteronism, may be responsible and will require early recognition if a specific therapy is to be initiated. Prompt, thorough assessment by ED staff will identify the clinical status of the patient, provide clues to an underlying etiology for the hypertension, assess the degree of target organ involvement, and assist in selecting the most appropriate pharmacologic agent and method of administration.

Etiology

The manifestations seen in patients presenting with hypertensive crises are due to an extreme, or sometimes rapid elevation in BP. Such emergencies may present as progressive worsening of long-standing chronic hypertension as represented by the syndrome of accelerated or malignant hypertension, or as a rapid or sudden rise in BP in a previously normotensive

patient.^{5,6} Examples of this latter presentation may be associated with conditions, such as acute glomerulonephritis, preeclampsia, or scleroderma renal disease, in which the rapid progress of the disease is associated with sudden onset and rapid acceleration of hypertension. Further risk to target organ function results from vascular damage or circulatory disturbances caused by the extreme elevation of BP.

Hypertensive emergencies occur in association with underlying target organ complications, such as acute myocardial infarction or acute aortic dissection, or in association with progressive deterioration in target organ function, such as hypertensive encephalopathy, acute congestive heart failure, or rapidly deteriorating renal function. Although these conditions require immediate antihypertensive therapy, keep in mind that the presenting level of BP alone does not determine the presence or absence of a hypertensive emergency. Rather, BP must be viewed together with other comorbidities and the degree of target organ dysfunction. The patient with a long history of hypertension who presents with malignant hypertension and hypertensive encephalopathy is likely to have a markedly elevated BP in the range of 220 to 240 over 140 mm Hg. In contrast, a patient presenting with an aortic dissection or acute pulmonary edema may have only modest elevations of BP in the range of 150 to 160 over 100 mm Hg. Yet, both represent hypertensive emergencies and require immediate therapy.

Accelerated or Malignant Hypertension

Malignant hypertension constitutes a syndrome of severe elevations of mean arterial pressure (MAP) often to or exceeding 140 mm Hg, manifested clinically by retinal hemorrhages, exudates, and papilledema. The term *malignant* hypertension was formerly reserved for those patients who exhibited advanced fundoscopic changes, including papilledema, whereas the term *accelerated* hypertension was used when the syndrome was observed without papilledema.

The distinction between accelerated and malignant hypertension has been deemphasized because the short- and long-term prognoses are independent of the presence or absence of papilledema, and both the pathogenesis and clinical management of accelerated and malignant hypertension are the same.^{7,8} In addition, the presence of papilledema may be difficult to detect on fundoscopic examination and is subject to observer interpretation.⁹

Vascular damage is believed to relate both to the duration and severity of the elevated MAP. Untreated or inadequately treated essential hypertension represents the most common antecedent of malignant hypertension and has been observed to be more common among smokers.¹⁰ With improved hypertension control efforts, progression to the malignant phase of

hypertension is seen less commonly. Secondary etiologies of hypertension are more prevalent among patients who do progress to accelerated or malignant hypertension.

Pathophysiology

The vascular lesions of accelerated-malignant hypertension consist predominately of myointimal proliferation and fibroid necrosis.¹¹ The myointimal proliferation is a common feature of sustained hypertension, and its severity will vary with the severity and duration of the hypertension. The combination of medial thickening and cellular intimal proliferation contribute to the “onion skin” appearance of small arteries. These changes reduce lumen diameter over time.^{5,11}

The accelerated phase of hypertension is characterized by fibrinoid necrosis, which can further compromise the lumen and small vessels. Fibrinoid necrosis within the kidney contributes to rapid progression of renal insufficiency, but these changes may be reversible with aggressive lowering of BP.

In Caucasians, essential hypertension accounts for only 20% to 30% of malignant hypertension, whereas among African Americans, essential hypertension is the predominant cause of malignant hypertension, accounting for upward of 80% of all cases. Hypertension-related morbidity and mortality from causes such as stroke, end-stage renal disease (ESRD), and heart failure are three to five times higher among African Americans. Interaction of genetic and environmental factors appears to play a role, as does low socioeconomic status.

Renal parenchymal disease and renovascular hypertension account for the majority of secondary causes of accelerated-malignant hypertension in all populations. Vascular changes within the kidney correlate well with the development of renal failure, and impaired perfusion caused by occlusion of renal vessels leads to ischemic damage, renal scarring, and glomerulosclerosis.

Endocrine and paracrine mediators and the renin-angiotensin system are activated in accelerated-malignant hypertension, and increased angiotensin II can lead to further renal vasoconstriction and ischemia.¹²⁻¹⁴ Volume depletion due to pressure natriuresis stimulates further renin release and worsens the hypertension. Stimulation of other humoral factors, such as catecholamines and vasopressin, contributes to the pathophysiologic process of accelerated-malignant hypertension, although much of the documentation relating levels of BP elevation to vascular changes is drawn from animal models. Whether these animal models are applicable to all human accelerated-malignant hypertension remains uncertain. Experimental models of renal artery stenosis share some pathophysiologic features with renovascular hypertension in humans, a well-documented cause of accelerated-malignant hypertension.

Initial Assessment

Early triage is critical in an effort to assure the most timely and appropriate therapy for each patient. Prompt evaluation by the ED is designed to establish the clinical status of the patient, provide clues to a possible underlying etiology of the hypertension, assess the degree of target organ involvement, and facilitate selection of the most suitable pharmacologic agent and method of administration.¹⁵

Initial History

A brief but thorough history should address the duration and the severity of hypertension, all current medications, including prescription and nonprescription drugs, and the use of recreational drugs. A history of other comorbid conditions and prior cardiovascular or renal disease is critical to the initial evaluation.

Patients should be questioned directly regarding the level of compliance with current antihypertensive medications in an effort to establish current adequacy of therapy. Frequent or continuous monitoring of BP should be established during this evaluation. Historical information about neurologic, cardiovascular, and/or renal symptoms and specific manifestations, such as headache, seizures, chest pain, dyspnea, and edema, should be sought. In patients with encephalopathic symptoms and impaired cognitive function, the availability of a close family member may be critical to obtaining part or all of the history.

Physical Examination

Begin with an assessment of BP, using an appropriate sized cuff, in both upper extremities. Careful funduscopic examination should detect any hemorrhages, exudates, and/or papilledema. Verify brachial, femoral, and carotid pulses. A careful cardiovascular examination and a thorough neurologic examination, including mental status assessment, should be conducted. Your physical assessment should help determine the degree of involvement of affected target organs and will often provide clues to the possible existence of a secondary form of hypertension, such as renovascular hypertension. If a secondary cause of hypertension is suspected, appropriate blood and urine samples should be obtained before aggressive therapy is initiated.

Initial Laboratory Studies

A urinalysis with sediment examination, a stat chemistry profile, and an electrocardiogram should be obtained immediately. The urinalysis may show significant proteinuria, red blood cells, and/or cellular casts. Cellular casts are suggestive of renal parenchymal disease. Electrolyte abnormalities, particularly hypokalemia or hypomagnesemia, increase the risk of cardiac arrhythmias, and the chemistry profile may also provide evidence of renal dysfunction. The electrocardiogram can provide evidence of coronary ischemia or left ventricular hypertrophy. A computed tomography (CT) scan of the head should be obtained when the physical examination suggests stroke, or in the comatose patient.

This initial evaluation should identify the patient with a hypertensive emergency as opposed to a hypertensive urgency or severe elevated BP.¹⁵ The algorithm outlined in Table 78-1 will assist the clinician in distinguishing the characteristics of the hypertensive emergency from those of a hypertensive urgency or elevated BP. In the case of a hypertensive emergency, BP reduction should not be delayed until the results of all diagnostic tests are available, but should be initiated as soon as the patient's clinical status is established. Initial therapy will often be based on a presumptive diagnosis made during the initial triage evaluation.

Table 78-1 Algorithm: Triage Evaluation

BP (mm Hg)	Group I—High BP >180/100	Group II—Urgency ≥180/110	Group III—Emergency Usually >220/140
Symptoms	<ul style="list-style-type: none"> • Headache • Anxiety • Often asymptomatic 	<ul style="list-style-type: none"> • Severe headache • Shortness of breath • Edema 	<ul style="list-style-type: none"> • Shortness of breath • Chest pain • Nocturia • Dysarthria • Weakness • Altered consciousness
Examination	<ul style="list-style-type: none"> • No target organ damage (TOD) • No clinical cardiovascular (CV) disease 	<ul style="list-style-type: none"> • TOD • Clinical CV disease present or stable 	<ul style="list-style-type: none"> • Encephalopathy • Pulmonary edema • Renal insufficiency • Cerebrovascular accident • Cardiac ischemia
Therapy	<ul style="list-style-type: none"> • Observe 1-3 hours • Initiate/resume medication(s) • Increase dosage of inadequate agent 	<ul style="list-style-type: none"> • Observe 3-6 hours • Lower BP with short-acting oral agents • Adjust current therapy 	<ul style="list-style-type: none"> • Baseline laboratory tests • Intravenous line • Monitor BP • May initiate parenteral therapy in the emergency department
Plan	<ul style="list-style-type: none"> • Arrange follow-up >72 hours • If no prior evaluation, schedule appointment 	<ul style="list-style-type: none"> • Arrange follow-up evaluation <24 hours 	<ul style="list-style-type: none"> • Immediate admission to ICU • Treat to initial goal BP • Additional diagnostic studies

Hypertensive Emergencies

The clinical characteristics of a hypertensive emergency are listed in Box 78-1. Keep in mind the important caveat that the level of BP alone does not determine a hypertensive emergency; rather, it is the degree of target organ involvement that determines the rapidity with which BP should be treated and reduced to a safer level to prevent or limit further target organ damage.

In both hypertensive and normotensive individuals, cerebral blood flow is effectively autoregulated, enabling the brain to maintain a constant blood flow, despite changes in perfusion pressure. A rightward shift in autoregulation is seen in patients with chronic hypertension.^{16,17} As a result, the lowest tolerated BP at which symptoms of hypoperfusion develop is higher in hypertensive than in normotensive individuals (Figure 78-1).¹⁷ Thus, caution must be used in both the rate of reduction of BP and in setting the initial BP goal to protect against the risk of cerebral hypoperfusion. It is recommended that the initial reduction in MAP not exceed 20% to 25% of the pretreatment BP, or to an initial diastolic BP goal of 100 to 110 mm Hg.

Ruling Out Secondary Causes of Hypertension

Renal parenchymal disease; renovascular hypertension; or one of the endocrine forms of hypertension, particularly pheochromocytoma, Cushing's syndrome, or rarely, primary aldosteronism, may be associated with progressive hypertension.¹⁸ Renal parenchymal disease may, of course, be primary and be associated with hypertension as the disease progresses

Box 78-1 Clinical Characteristics of the Hypertensive Emergency

Blood pressure	Usually >220/140 mm Hg
Funduscopic findings	Hemorrhages, exudates, papilledema
Neurologic status	Headache, confusion, somnolence, stupor, visual loss, seizures, focal neurologic deficits, coma
Cardiac findings	Prominent apical pulsation, cardiac enlargement, congestive heart failure, S ₃ gallop, arrhythmia
Renal symptoms	Azotemia, proteinuria, oliguria, hematuria
Gastrointestinal symptoms	Nausea, vomiting

S₃, third heart sound. (Adapted from Vidt DG. Emergency room management of hypertensive urgencies and emergencies. *J Clin Hypertens* [Greenwich] 3:158-164, 2001.)

or may be secondary to long-standing, poorly controlled arterial hypertension. In either case, a vicious cycle of worsening hypertension may accompany progressive renal insufficiency.

Renovascular hypertension, often of sudden onset, may be observed with renal artery stenosis due to fibromuscular disease among younger patients, particularly women. The most common subgroup of fibromuscular disease, medial fibroplasia

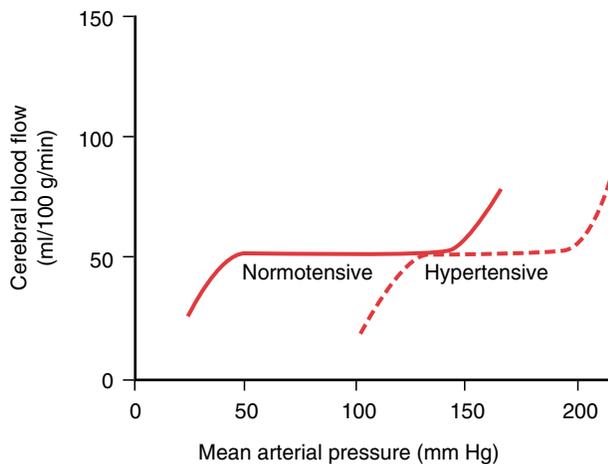

Figure 78-1 Idealized curves of cerebral blood flow at varying levels of systemic blood pressure in normotensive and hypertensive subjects. (Appeared in Kaplan NM. *Lancet* 344:1335, 1994, but originally from Strandgaard et al. *BMJ* 1:507-510, 1973.)

with aneurysm formation, rarely progresses to loss of a kidney.¹⁹ In contrast, medial hyperplasia and perimedial fibroplasia are both progressive lesions, frequently associated with severe hypertension, and may lead to sudden renal artery obstruction and kidney loss.

Atherosclerotic renal vascular disease is much more common than fibromuscular disease, usually involves the ostium of one or both renal arteries, and is often associated with progressive renal insufficiency and severe or refractory hypertension because it is frequently a manifestation of generalized vascular disease.²⁰ It often presents with refractory hypertension, complicated by renal insufficiency or acute congestive heart failure.²⁰

Characteristic symptoms or “spells” usually suggest the diagnosis of pheochromocytoma, whereas body habitus changes offer valuable clues to Cushing’s syndrome. Few clinical clues other than hypokalemia suggest the diagnosis of primary aldosteronism, but this diagnosis is likely in the patient who presents with accelerated-malignant hypertension with low plasma renin activity. Box 78-2 outlines the clinical clues that may suggest one of the previously mentioned secondary causes of hypertension during initial evaluation.

Oral Agents for Hypertensive Urgencies

Several antihypertensive agents provide a rapid onset of action following oral administration and can be used in the ED when it is deemed that a patient requires therapy and reduction of BP before being discharged (Table 78-2).¹⁵ Caution should be exerted to avoid overly aggressive initial reductions in BP. A goal BP in the range of 160/100 to 110 mm Hg would be appropriate. The patient can then be discharged on a long-acting agent, and medication can be titrated at subsequent scheduled outpatient visits.

Most readers remember the problems experienced with short-acting oral nifedipine, which was formerly a widely used initial therapy for hypertensive emergencies and urgencies.²¹ Even modest doses of 10 to 20 mg of nifedipine, given orally or sublingually, were often accompanied by precipitous reduc-

Box 78-2 Clinical Clues to Selected Secondary Causes of Hypertension

Cushing’s syndrome

- Recent change in appearance and weight gain
- Extreme weakness, muscle wasting
- Typical body habitus with moon facies and hirsutism
- Skin changes: bruising, plethora, purplish skin striae
- Glucose intolerance, diabetes
- Neutrophilia with relative lymphocytopenia

Pheochromocytoma

- Symptomatic spells, including headaches, tachycardia, palpitations, pallor, tremor, perspiration
- Unusual lability of BP or orthostatic hypotension
- Substandard weight or recent weight loss
- Pressor response to antihypertensive drugs or during reduction of anesthesia
- History of neurocutaneous syndromes or multiple endocrine neoplasia
- Abnormal glucose tolerance

Primary aldosteronism

- Hypokalemia, spontaneous or diuretic-induced
- History of inordinate weakness of proximal muscle groups
- History of paresthesias, periodic paralysis (rare)
- Polyuria, nocturia

Renovascular disease

- Systolic-diastolic epigastric bruit
- Onset of hypertension age <30 or >50
- Unilateral small kidney discovered by any investigative study
- Azotemia, cigarette smoking, extensive vascular disease
- Renal insufficiency in response to ACE inhibitors
- Any unexplained impairment in renal function
- Any history of arterial thrombus or emboli, trauma, retroperitoneal fibrous or neurofibromatosis

Renal parenchymal disease

- Renal insufficiency, proteinuria, hematuria
- Prior renal ultrasound, KUB showing a small kidney
- Urine light chains (by sulfosalicylic acid)
- Family history of renal disease
- Long history of untreated or uncontrolled hypertension

ACE, angiotensin-converting enzyme; KUB, kidney, ureter, bladder.

tions in BP within 15 to 30 minutes after administration. As reports accumulated regarding ischemic cardiac and cerebral events following short-acting nifedipine administration, a moratorium was placed on use of this agent for the treatment of hypertensive urgencies or emergencies. Unfortunately, a few centers still use this agent in their EDs and do so at their own risk because short-acting nifedipine is not approved by the U.S. Food and Drug Administration for the treatment of hypertension.

Captopril, an angiotensin-converting enzyme (ACE) inhibitor, is well tolerated and has effectively reduced BP in hypertensive urgencies. Given by mouth, captopril is usually

Table 78-2 Oral Agents for Hypertensive Emergencies

Agent	Dose	Onset/Duration of Action (after discontinuation)	Precautions
Captopril	25 mg PO, repeat as needed SL, 25 mg	15-30 min/6-8 hr SL 15-30 min/2-6 hr	Hypotension, renal failure in bilateral renal artery stenosis
Clonidine	0.1-0.2 mg PO, repeat hourly as required to total dose of 0.6 mg	30-60 min/8-16 hr	Hypotension, drowsiness, dry mouth
Labetalol	200-400 mg PO, repeat every 2-3 hr	30 min-2 hr/2-12 hr	Bronchoconstriction, heart block, orthostatic hypotension

effective within 15 to 30 minutes and may be repeated in 1 to 2 hours, depending on the response.²² The drug has been administered sublingually with an observed onset of action within 10 to 20 minutes and a maximum effect within 1 hour.²³ Captopril has been very effective in the initial therapy of patients with malignant hypertension, particularly when responsiveness is enhanced by the administration of a loop diuretic, such as furosemide.²⁴ For patients who respond to captopril, you may wish to change to a long-acting ACE inhibitor at the time of release from the ED. Medication can be added or up-titrated at scheduled outpatient visits.

Clonidine is a centrally-acting, α -adrenergic agonist with onset of action within 30 to 60 minutes following oral administration. Maximal effects are seen within 2 to 4 hours. Although most commonly administered in a loading regimen of 0.1 to 0.2 mg followed by 0.1 mg/hour for several hours,^{25,26} evidence suggests that a comparable response may be seen with a single 0.2-mg dose. The most common adverse effects of clonidine are drowsiness and dryness of the mouth, affecting upward of 50% of patients. If clonidine is to be continued, efforts should be made to limit the average daily dosage to 0.2 mg twice daily, in view of adverse effects that are clearly dose related. Diuretics and/or other agents can be used in combination to minimize the daily dosage of clonidine and provide optimal BP control.

Labetalol is a combined α - and β -adrenergic blocking agent, which is effective orally in a dose of 200 to 400 mg, which may be repeated after several hours. The onset of effect is usually observed within 1 to 2 hours.^{27,28} Like other β -blocking agents, labetalol carries a potential to induce heart block and worsen symptoms of bronchospasm in the patient with established asthma. It is best avoided in patients with more than first-degree heart block, symptomatic bradycardia, or congestive heart failure. Antihypertensive effects of labetalol can be potentiated by the use of an oral diuretic or other add-on agents.

Urapidil is available for the treatment of hypertensive emergencies in Europe but is not yet approved for the treatment of hypertension in the United States. Urapidil is a peripheral α_1 receptor blocker and a central 5-hydroxytryptamine_{1a} receptor antagonist.²⁹ Intravenous urapidil has been proven useful in the management of hypertensive crises and hypertension during and after surgery.^{30,31} Oral administration of urapidil following intravenous administration can maintain lower BPs for periods of 12 hours or longer in patients with severe hypertension. This approach has been shown both to facilitate early discharge and reduce the risk of further hypertensive episodes within 12 hours.³² Extensive clinical experience with urapidil has been reported from other parts of the world over the past decade.

For the majority of patients with elevated BP, most of whom are noncompliant with medications or inadequately treated, the addition or initiation of a long-acting antihypertensive agent in the ED is appropriate. You may wish to consider utilizing a long-acting, fixed-combination product, the dosage of which can then be modified or up-titrated at subsequent outpatient visits.

Parenteral Agents for Hypertensive Emergencies

The following parenteral agents are effective in treating hypertensive emergencies (see Table 78-3). They act primarily as peripheral vasodilators or adrenergic inhibitors.

Peripheral Vasodilation

Sodium nitroprusside is a potent vasodilator that is exceptionally predictable when administered in a hypertensive crisis of any etiology. It has an extremely rapid onset of action, within seconds of initiating an infusion, and a very rapid offset of effect within 1 to 2 minutes, which necessitates constant supervision of BP.³³ Its popularity relates in part to its effectiveness in reducing both preload and afterload, as well as decreasing myocardial oxygen demand, and the ability to achieve a controlled titration of BP. Nitroprusside does not cause sedation or somnolence but is rapidly degraded by light, requiring periodic exchange of solutions. One of the major concerns in using sodium nitroprusside is its metabolism to cyanogen and to thiocyanate.³⁴ In patients with significant impairment in renal function, accumulation of thiocyanate may occur over several days, with toxic effects, including encephalopathic symptoms. In patients with impaired hepatic function and poor renal perfusion, cyanide poisoning has been reported. Nitroprusside may also increase intracranial pressure, which can be a concern in patients with cerebrovascular emergencies.

Nitroglycerin may be of particular efficacy in hypertensive emergencies with coexistent coronary ischemia.³⁵ Nitroglycerin dilates collateral coronary vessels and, like nitroprusside, has a rapid onset and offset of effect, requiring close monitoring. Nitroglycerin dilates capacitance vessels primarily when infused at low doses of 5 to 10 μ g/min, whereas much higher infusion rates effect arteriolar vasodilation. The infusion rate of nitroglycerin may be increased at 3- to 5-minute intervals until the desired effect is achieved. BP effects of nitroglycerin are neither as predictable nor as large as those seen with nitroprusside. Nitroglycerin may be particularly useful

Table 78-3 Parenteral Agents for Hypertensive Emergencies

Agent	Dose	Onset/Duration of Action (after discontinuation)	Precautions
Parenteral Vasodilators			
Sodium nitroprusside	0.25-10 $\mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ as IV infusion	Immediate/2-3 min after infusion	Nausea, vomiting, muscle twitching; with prolonged use cause thiocyanate intoxication, methemoglobinemia acidosis, cyanide poisoning; bags, bottles, and delivery sets must be light resistant
Nitroglycerine	5-100 μg as IV infusion*	2-5 min/5-10 min	Headache, tachycardia, vomiting, flushing, methemoglobinemia; requires special delivery systems due to the drug's binding to PVC tubing
Nicardipine	5-15 mg/hr IV infusion	1-5 min/15-30 min, but may exceed 12 hr after prolonged infusion	Tachycardia, nausea, vomiting, headache, increased intracranial pressure; hypotension may be protracted after prolonged infusions
Verapamil	5-10 mg IV; can follow with infusion of 3-25 mg/hr	1-5 min/30-60 min	Heart block (1, 2, and 3 degrees), especially with concomitant digi- talis or β -blockers, bradycardia
Diazoxide	50-150 mg as IV bolus, repeated or 15-30 mg/min	2-5 min/3-12 hr	Hypotension, tachycardia, aggra- vation of angina pectoris, nausea and vomiting, hyperglycemia with repeated injections
Fenoldopam mesylate	0.1-0.3 $\text{mg}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ IV infusion	<5 min/30 min	Headache, tachycardia, flushing, local phlebitis
Hydralazine	10-20 mg as IV bolus or 10-40 mg IM, repeat every 4-6 hr	10 min IV/>1-4 hr (IV), 20-30 min IM/4-6 hr (IM)	Tachycardia, headache, vomiting, aggravation of angina pectoris
Enalaprilat	0.625-1.25 mg every 6 hr IV	15-60 min/12-24 hr	Renal failure in patients with bilat- eral artery stenosis, hypotension
Parenteral Adrenergic Inhibitors			
Labetalol	20-80 mg as IV bolus every 10 min; up to 2 mg/min as IV infusion	5-10 min/2-6 hr	Bronchoconstriction, heart block, orthostatic hypotension
Esmolol	500 $\mu\text{g}/\text{kg}$ IV bolus injection or 25-100 $\mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ by infusion; may repeat bolus after 5 min or increase infusion rate to 300 $\mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$	1-5 min/15-30 min	First-degree heart block, congestive heart failure, asthma
Phentolamine	5-15 mg as IV bolus	1-2 min/10-30 min	Tachycardia, orthostatic hypotension

*Requires special delivery system.

IV, intravenous; PVC, polyvinyl chloride; IM, intramuscularly.

in patients with severe coronary ischemia in whom BPs are only modestly elevated or in patients with post-coronary artery bypass hypertension. Tolerance to intravenous nitroglycerin may occur within 24 to 48 hours of initiating an infusion, and unpredictable absorption in polyvinyl chloride containers and tubing necessitates the use of glass containers.

Both nitroprusside and nitroglycerin release nitric oxide and are considered nitric oxide donors, an important mechanism for the vasodilation induced by these agents. Isosorbide dinitrate is also a nitric oxide donor, and when administered in aerosol form to the oral mucosa, has a rapid onset of action. It has proved effective in the treatment of myocardial ischemia and hypertensive emergencies. In one study, the efficacy of isosorbide dinitrate was compared to sublingual nifedipine in patients with severe hypertension. While nifedipine produced a precipitous fall in BP, the isosorbide dinitrate aerosol produced a more gradual and predictable decline in BP over a period of 60 to 90 minutes.³⁶

Nicardipine is an intravenous dihydropyridine calcium antagonist that has proved effective in a high percentage of hypertensive emergencies, particularly at higher infusion rates. The growing popularity of this agent can be attributed to its ease of administration as a continuous infusion, starting at 5 mg/hour. The infusion rate is increased by 2.5 mg/hour at intervals of 15 to 20 minutes until a maximum recommended infusion rate of 15 mg/hour is obtained, or until the desired reduction in BP is achieved. An excellent correlation has been demonstrated between plasma concentration and dose response of BP, and the dosing of nicardipine does not appear dependent on the patient's body weight.³⁷ Although nicardipine has been shown to reduce both cerebral and coronary ischemia, headache, nausea and vomiting may accompany its use, and modest tachycardia and increased myocardial oxygen demand limit its use in patients with severe coronary ischemia.

Diazoxide is rarely used today in the treatment of hypertensive emergencies. Although a potent vasodilator, large doses of 300 mg were associated with severe hypotension. Smaller mini-boluses of 50 mg administered every 10 to 15 minutes can provide a controlled reduction in BP but lead to reflex tachycardia, hyperglycemia, hyperuricemia, and sodium and water retention.³⁸ Diazoxide is contraindicated in patients with coronary ischemia or suspected aortic dissection and offers no advantage over several other agents that have more acceptable adverse effect profiles.

Fenoldopam mesylate is a selective, peripherally acting dopamine-1 receptor agonist that provides systemic vasodilation, particularly in the renal circulation, and it also has effects on renal proximal and distal tubules.^{39,40} It does not bind to dopamine-2 receptors or β -adrenergic receptors and has no α -adrenergic agonist effects, but is an α_1 -antagonist and does not cross the blood-brain barrier. Fenoldopam lowers BP by causing peripheral arterial vasodilation with little to no effect on preload.

The onset of clinical effect is usually seen within 5 minutes and effects dissipate within 30 minutes following discontinuation of the infusion. Side effects include headache, flushing, tachycardia, and dizziness. Bradycardia has occasionally been noted, and a dose-related increase in intraocular pressure has been observed in normotensive and hypertensive patients. Inactive metabolites are eliminated primarily in the urine, and

no dosage adjustments are required for patients with renal or hepatic impairment.

In contrast to other parenteral antihypertensive agents, fenoldopam's unique effects on the kidney provide increased urine flow rate, sodium and potassium excretion, and creatinine clearance, making this agent especially attractive in hypertensive emergencies with renal impairment.⁴¹ Nitroprusside has opposite effects on renal urodynamics. In congestive heart failure, incremental doses of fenoldopam have been shown to increase cardiac index in association with decreased BP, variable effects on pulmonary capillary or wedge pressure, and no change in right atrial pressure.

Hydralazine, a direct arterial vasodilator, has no significant effects on venous tone. Reductions in arterial BP are accompanied by reflex increases in heart rate, increased myocardial oxygen demand, sodium, and water retention. Hydralazine use has also been associated with increases in intracranial pressure. The use of hydralazine today is restricted to pregnant women with preeclampsia, because hydralazine can improve uterine blood flow.⁴² Five to ten mg may be effective intravenously as a bolus injection and may be repeated. Flushing and headache may be observed.

Enalaprilat, the active metabolite of enalapril, can be administered intravenously in a dose of 1.25 mg at 6-hour intervals. The onset of action is usually seen within 30 minutes, but the response to enalaprilat in hypertensive emergencies can be unpredictable, partially due to variations in volume status and in plasma renin concentration.⁴³ Enalaprilat may be particularly useful in hypertensive emergencies associated with congestive heart failure or high plasma angiotensin II concentrations.

Parenteral Adrenergic Inhibitors

Labetalol is an α -blocker and noncardioselective β -blocker, which has proved especially effective when used in bolus intravenous injections in the initial treatment of hypertensive emergencies. It can provide controlled reduction in BP to a predetermined goal.⁴⁴ Once a goal pressure is achieved, injections are stopped and the long duration of action facilitates conversion to effective oral therapy. Infusion of labetalol at a rate of 2 mg/minute offers an alternative method of administration and is associated with a gradual yet controlled reduction in BP.⁴⁵ Because β -blocking effects predominate, bradycardia or heart block may occur in patients with intrinsic heart disease, and bronchospasm can limit its usefulness in patients with asthma.

Esmolol is an intravenous, ultra-short-acting β -adrenergic blocker. Onset of effect is seen between 1 and 5 minutes, with a rapid offset of effect within 15 to 30 minutes following discontinuation.^{46,47} Esmolol is administered as a 500- μ g/kg/min bolus injection, which may be repeated after 5 minutes. Alternatively, an infusion of 50 to 100 μ g/kg/min may be initiated and increased to 300 μ g/kg/min as needed. It is most often used in surgical units for the intraoperative or postoperative short-term control of BP and can also be useful in the setting of myocardial ischemia or infarction. Adverse effects include heart block, congestive heart failure, and bronchoconstriction.

Phentolamine, a nonselective α -adrenergic blocking agent, is reserved for use in suspected excess catecholamine states, such as pheochromocytoma or cocaine withdrawal. It may be

useful as a diagnostic agent administered as a bolus injection of 5 to 10 mg in patients with suspected high circulating levels of catecholamines.^{3,48} Acute BP lowering will be seen within several minutes and may last 10 to 30 minutes in the setting of catecholamine excess. Tachycardia is common and may precipitate myocardial ischemia in high-risk patients. Nitroprusside and labetalol are more easily titrated in the management of hypertensive emergencies associated with high circulating levels of catecholamines; therefore, phentolamine is rarely used therapeutically today.

Management of Specific Hypertensive Emergencies (see Table 78-4)

Hypertensive encephalopathy is a lethal complication of severe hypertension and occurs when an increase in BP exceeds the brain’s autoregulatory ability to maintain constant cerebral perfusion, resulting in disruption of the blood-

brain barrier and diffuse cerebral edema.⁴⁹ This diagnosis should be suspected when a severe elevation in BP is accompanied by neurologic signs and symptoms characteristic of encephalopathy. Clinical signs include obtundation or confusion, focal neurologic deficits, retinopathy with papilledema, and occasional focal seizures. This is a diagnosis of exclusion and requires that stroke, intracranial hemorrhage, seizure disorder, other mental disorders, mass lesions, vasculitis, and encephalitis be considered. When suspected, BP should be promptly lowered as recommended in the management of a hypertensive emergency. A CT scan or magnetic resonance imaging (MRI) of the head should be obtained as soon as it is feasible.

Agents with a rapid onset of effect that can be titrated to a desirable initial BP goal are preferred.⁵⁰ Sodium nitroprusside is an agent of choice because its rapid onset of action and short half-life allow for minute-to-minute control of BP and because it has minimal effects on cerebral blood flow.

Table 78-4 A Quick Reference for Preferred Parenteral Drugs for Selected Hypertensive Emergencies

Emergency	*Preferred Drugs	Drugs to Avoid
Hypertensive encephalopathy	Nitroprusside Nicardipine Labetalol Fenoldopam	Diazoxide (rapid decrease in cerebral blood flow)
Malignant hypertension (when IV therapy is indicated)	Labetalol Nicardipine Nitroprusside Fenoldopam Enalaprilat	
Cerebrovascular accidents	Nicardipine Labetalol Nimodipine (in SAH) Nitroprusside	Diazoxide, hydralazine (may increase intracerebral pressure)
Myocardial infarction, unstable angina	Nitroglycerin Nitroprusside Nicardipine Nitroprusside	Diazoxide, hydralazine (increase heart rate, myocardial oxygen demand) Labetalol and esmolol (decrease cardiac output)
Congestive heart failure	Nitroglycerin Enalaprilat Loop diuretics	
Aortic dissection	Nitroprusside Esmolol Labetalol	Diazoxide Hydralazine Nicardipine
Adrenergic crisis	Phentolamine Nitroprusside Labetalol	Labetalol (in cocaine crisis)
Postoperative hypertension	Nitroglycerin Nitroprusside Labetalol Nicardipine Fenoldopam	
Preeclampsia, eclampsia of pregnancy	Hydralazine Labetalol Nicardipine	Nitroprusside Enalaprilat

*The “Preferred Drugs” are listed in the order of preference for use. IV, intravenous; SAH, subarachnoid hemorrhage.

Nicardipine and labetalol have also proved to be particularly effective in the management of hypertensive encephalopathy. Fenoldopam proves an appropriate alternative in view of its rapid onset of action and lack of adverse cerebral effects. Frequent neurologic assessments during the period of titration are imperative. BP reduction is often associated with dramatic improvement in sensorial function in the patient with hypertensive encephalopathy. Further deterioration in neurologic function in the face of effective BP reduction requires consideration of other possible diagnoses.

Cerebrovascular Accidents—Optimal treatment of severe hypertension in the presence of cerebrovascular accidents, such as intracerebral and subarachnoid hemorrhage or cerebral infarction, remains debatable.⁵¹ Keep in mind that high BP may be a contributor to or the result of the acute neurologic event. The risks of elevated BP causing cerebral edema or possible rebleeding must be weighed against the risks of worsening cerebral ischemia with too rapid or excessive BP reduction.

The protective rise in BP immediately following a stroke is an attempt to maintain adequate perfusion to ischemic cerebral tissue. The benefits to be derived from acute reductions in BP are not well founded in controlled clinical studies. One recent study has shown no significant relationship between admission systolic and diastolic BP and the outcome at 3 months. They also observed that high nighttime systolic and low nighttime diastolic values were identified as independent predictors of stroke outcome. Their data suggested that a spontaneous BP decrease in the first 5 days poststroke may be independently related to poor outcome. These findings warn against a too rigorous lowering of early poststroke BP.⁵²

Following a thrombotic stroke, BP rises acutely but tends to decline without any specific therapy over the next 24 to 48 hours. An acute rise in BP may not occur following an intracerebral hemorrhage. Our recommendation is that acute therapy be considered only for severely elevated BP (diastolic BP >130 mm Hg). Even then, BP should be very cautiously reduced with a rapid-acting agent to an initial goal of no more than 20% to 25% below the pretreatment BP, or to a diastolic pressure level of 100 to 110 mm Hg during the initial 24 hours. Nicardipine by continuous infusion or labetalol given by repeated small boluses or by continuous infusion are both appropriate agents and have been used effectively in this setting. Nitroprusside is attractive because of its rapid onset and offset of effect, but it could further increase intracranial pressure. A cerebroselective dihydropyridine calcium antagonist, nimodipine, has proven beneficial following subarachnoid hemorrhage to reduce cerebral vasospasm.⁵³ The effects of nimodipine on BP in this setting are negligible. Agents such as diazoxide or hydralazine should be avoided because they raise intracranial pressure.

Myocardial Infarction and Unstable Angina—In the patient with severe ischemic coronary disease, nitroglycerin is the agent of choice if BPs are only modestly elevated.⁵⁴ Nitroglycerin has the advantages of improving collateral coronary blood flow and myocardial oxygen utilization. The major effect of nitroglycerin at lower infusion rates is on preload, whereas much higher infusion rates are required to induce arteriolar vasodilation and reduce afterload. Intravenous labetalol can also be effective and when hypertension is severe, use of nitroprusside should be considered.⁵⁵ β -Blockers have little acute antihypertensive effect, but their early use may

reduce infarct size and provide significant secondary cardioprotection, including reduced in-hospital mortality. Vasodilator drugs, such as diazoxide and hydralazine, can induce reflex increases in heart rate and increase myocardial oxygen demand. To assist in the management of acute pain and anxiety, narcotic analgesics and/or modest sedation should be considered. When BP has been lowered, thrombolytic therapy can be considered.

Congestive Heart Failure—Acute left ventricular failure is often precipitated by an acute rise in systemic vascular resistance and further compromise in left ventricular compliance. In patients with typical systolic heart failure, intravenous nitroprusside or nitroglycerin is appropriate therapy. Intravenous enalaprilat can be used, but responses are not as predictable as those observed with nitroprusside. The importance of concomitant use of oxygen, intravenous loop diuretics, and morphine should not be underestimated. β -Blockers, including labetalol, should be avoided because they may worsen cardiac function. Once the patient has been stabilized and is ready for discharge, the addition of a β -blocker may be considered, as recommended for chronic congestive heart failure.

A bedside echocardiogram may be useful to evaluate global left ventricular function, because diastolic dysfunction may contribute to congestive heart failure in the setting of severe hypertension. Although patients with diastolic dysfunction benefit from reductions in systolic and diastolic BP, diastolic dysfunction provides an indication for considering a β -blocker or a nondihydropyridine calcium antagonist, such as verapamil.⁵⁶

Acute aortic dissection is the most lethal of the diseases involving the aorta. Hypertension is found in more than 90% of patients with acute aortic dissection. Typically, a patient with acute aortic dissection is an elderly male with a long history of hypertension who presents with severe acute chest pain. Chest pain is present in 94% of patients, is severe, excruciating, and abrupt at onset.⁵⁷ Often described as a “ripping or tearing” pain in the anterior chest, it occasionally extends to the back and radiates down toward the abdomen or flank areas. BP is elevated in most cases, particularly those with distal dissection. Hypotension may be a prominent feature in patients with proximal aortic dissection. Absent or unequal pulses in the extremities are seen in 35% to 50%, and new aortic insufficiency can be an important clinical sign. Neurologic manifestations may include ischemic neuropathy, stroke, paraplegia, and paresis. Involvement of the mesenteric artery can cause nausea, vomiting, abdominal pain, or hematemesis.

Medical treatment aims at decreasing the velocity and the slope of the pulse wave (dP/dt max) and lowering BP, using intensive drug therapy in an effort to prevent progression of the dissection.⁵⁸ Emergency reduction of BP to the lowest tolerated level (systolic, 100-110 mm Hg), with drugs that do not increase heart rate and contractility, is required. The treatment of choice for acute aortic dissection is nitroprusside, in combination with a β -blocker, such as esmolol or propranolol. β -Blockade must be established early to avoid reflex cardiac stimulation following acute reduction in BP. Labetalol is a useful alternative, particularly in patients with coronary artery disease because it also reduces myocardial oxygen consumption and enhances coronary artery perfusion. It may be administered as repeated miniboluses or as a continuous intravenous infusion. Agents, such as hydralazine, diazoxide, and nicardipine are best avoided because they may lead to

reflexive cardiac stimulation. If an aortic dissection is suspected, definitive diagnostic studies must be accomplished as soon as BP is controlled. The aortogram is the most definitive method to confirm a dissection because it shows the intimal tear and reveals false channels. CT scanning with contrast enhancement, transesophageal echocardiography, and MRI are also useful in establishing the diagnosis. Dissections of the ascending aorta and aortic arch require immediate surgical repair, whereas dissections distal to the left subclavian artery can usually be managed medically, unless complicated by leaking or vascular compromise of an organ or limb, continued or recurrent pain, or extension of dissection, despite optimal BP control.

Adrenergic Crisis—Although pheochromocytoma is the classic example of a catecholamine excess–induced hypertensive emergency, markedly elevated catecholamines are more frequently seen with cocaine or amphetamine overdose, withdrawal from agents such as clonidine or β -blockers, or an interaction with tyramine-containing compounds and monoamine oxidase inhibitors. Excessive circulating catecholamines and severe hypertension are also associated with acute spinal cord injuries.

Phentolamine, with and without a β -blocker, can be used in initial management. In view of the hypertensive risk of unopposed α -adrenergic receptor stimulation in the setting of catecholamine excess, β -blockers should not be initiated until adequate α -blockade has been established. Sodium nitroprusside or labetalol are more easily titrated in the management of hypertensive emergencies caused by high circulating levels of catecholamines. Although increased experience with labetalol suggests that early reports of paradoxical hypertension may have been exaggerated, this risk must be considered.^{59,60} This response presumably relates to the fact that the β -blocking effects of labetalol tend to predominate in clinical usage. In cocaine-induced hypertensive crisis, the use of β -blockers may enhance cocaine-induced coronary vasoconstriction, further increase BP, and enhance the risk of both seizures and reduced survival. Furthermore, labetalol does not reverse cocaine-induced coronary vasoconstriction.⁶¹ In this condition, nicardipine, verapamil, or fenoldopam can be used.^{62,63}

Postoperative Hypertension—Early postoperative hypertension due to increased sympathetic tone and vascular resistance is common, particularly following vascular surgical procedures. Hypertension has been reported in upward of 30% to 50% of patients following coronary artery bypass graft surgery. The treatments of choice are nitroglycerin and sodium nitroprusside. Significant vascular bleeding postoperatively in a patient with uncontrolled hypertension may necessitate immediate lowering of BP. A number of easily titratable agents, including nitroprusside, labetalol, nicardipine, and possibly, fenoldopam, can be useful in this situation. Nicardipine, in particular, has shown efficacy in controlling postoperative hypertension in both cardiac and noncardiac surgical patients.⁶⁴ In one study, intravenous nicardipine was as effective as sodium nitroprusside and achieved BP control more rapidly and with fewer dose adjustments than sodium nitroprusside.³⁷

Preeclampsia and Eclampsia in Pregnancy—The syndrome of preeclampsia features the onset of hypertension after the twentieth week of pregnancy, edema, and proteinuria, and occurs almost exclusively during a first pregnancy. Preeclampsia must be differentiated from chronic hyperten-

sion that preceded the onset of pregnancy. An abrupt increase in BP at the onset of labor or during delivery may herald the onset of eclampsia, defined by the occurrence of seizures due to hypertensive encephalopathy.⁶⁵

Parenteral magnesium sulfate is the drug of choice for preventing eclamptic convulsions. Treatment should be continued for 12 to 24 hours postpartum because of the significant risk of seizures in the early postpartum period. For acutely lowering BP, hydralazine is the drug of choice. An initial dose of 5 mg intravenously can be followed by subsequent boluses of 5 to 10 mg at 20- to 30-minute intervals. Side effects include tachycardia and headache. For patients already in a hospital ICU, intravenous labetalol or nicardipine have also become preferred agents because of their effectiveness and ease of administration.^{66,67} Diazoxide, a potent vasodilator, previously recommended for women with hypertension refractory to hydralazine, is rarely used today. If using calcium channel blockers, keep in mind that magnesium sulfate may potentiate the effects of calcium channel blockers, resulting in precipitous and profound hypotension.⁶⁸ Oral or sublingual nifedipine is no longer recommended for the treatment of severe hypertension in pregnancy because of the risks of precipitous hypotension. Sodium nitroprusside is not recommended because of the potential risk of fatal cyanide poisoning, demonstrated primarily in animal models. Limited experience with intravenous prostacyclin has shown it to be as effective as hydralazine with less risk of tachycardia.⁶⁹

Careful attention must be paid to salt and water metabolism to minimize the risk of fluid overload or severe hyponatremia, which can precipitate cerebral edema. The clinical findings of severe preeclampsia or eclampsia can be expected to clear rapidly following delivery.

SUMMARY

Hypertensive emergencies and urgencies demand prompt recognition and management because they may represent a threat to organ function and life. Early triage in ED is necessary to identify the true hypertensive emergency for immediate admission and in-hospital management, whereas most hypertensive urgencies can be managed in ED followed by appropriate follow-up in the outpatient department. Initial evaluation of the hypertensive emergency should establish the degree of target organ damage, possibly identify any readily recognized secondary causes of hypertension, should facilitate selection of initial therapy, and determine the goal BP for treatment. Initial treatment should achieve a partial reduction in BP to a safer, noncritical level, although not necessarily to achieve normotension. Most hypertensive urgencies can be managed in the outpatient setting, if appropriate follow-up can be provided.

Aggressive Blood Pressure Targets: Developing Effective Algorithms

Myron H. Weinberger

INTRODUCTION

The decision of when and how to begin antihypertensive therapy is a complex one. Some of the factors influencing the “when” are discussed in Chapter 48 of this book. The reader is referred to that chapter and to the specific chapters dealing in detail with each of the lifestyle interventions for information concerning nonpharmacologic therapy when that is deemed the initial choice for a specific patient. After deciding that drug therapy is required because the blood pressure is above the “prehypertension” range or because of failure of nonpharmacologic approaches to reduce blood pressure adequately, the selection of the most appropriate agent(s) is a challenging one in view of the large number of drugs currently available and the massive amount of information available attesting to the efficacy of all of these agents. The results of numerous recent studies have led experts to recommend a variety of different drugs and different therapeutic approaches, all with scientific support. This has created a great deal of confusion and in many cases misinterpretation of study results and consternation in the minds of physicians regarding the optimal treatment approach for a given patient.

This chapter addresses the rationale for making this selection, alternative approaches, adverse effects associated with specific classes of drugs, and most importantly, the enhancement of efficacy obtained by combining different classes of agents. One of the fundamental precepts, bolstered by the results of virtually all of the outcome studies, is that hypertensive patients are not all the same. The mechanisms responsible for their blood pressure elevations, as well as their responses to specific classes of antihypertensive drugs are diverse. Hypertensive persons may have different comorbidities that influence the selection of antihypertensive therapy, and the effects of the drugs used to treat these concomitant conditions on blood pressure must be considered. Finally, the selection of antihypertensive drug regimens may have an impact on other cardiovascular risk factors that are often found in hypertensive patients. An extensive discussion of therapeutic approaches for those with secondary forms of hypertension is beyond the scope of this chapter and can be found in Chapters 73 through 76.

The choice of initial drug therapy is influenced by the level of blood pressure; comorbid risk factors; and diseases and issues related to feasibility of patient adherence to medication, such as insurance and related financial status, lifestyle effects, psychological factors, and the potential impact of minor or serious side effects of drugs. In addition, information is available that may provide a clue regarding the therapeutic approach most likely to be beneficial in a given patient. As mentioned in Chapter 48, the decision to begin drug therapy is usually made when the office blood pressure is above 140 mm Hg systolic and/or 90 mm Hg diastolic on several

measurements or when the average daytime ambulatory blood pressure exceeds 135 mm Hg systolic and/or 85 mm Hg diastolic and the nighttime average is greater than 120 mm Hg systolic and/or 75 mm Hg diastolic. The reason for dependence of these threshold values on time of day is related to the normal nocturnal decline in blood pressure that is often absent in those with hypertension. When the nocturnal decline is less than normal, this presents a greater pressure load on the cardiovascular system and has recently been shown to be related to an increased risk of cardiovascular events. In persons with diabetes mellitus, in whom the blood pressure goal recommended by the American Diabetes Association is below 130/80 mm Hg; in patients with renal disease, in whom the American Society of Nephrology recommends blood pressure levels of 125/75 mm Hg or lower to preserve renal function; or in those with congestive heart failure, in whom values lower than the traditional 140/90 mm Hg are usually preferred to reduce the workload of the heart, antihypertensive drug therapy is often begun at levels less than 140/90 mm Hg. Detailed information regarding preferred agents and approaches for each of these comorbidities is addressed in Chapters 24, 25, 52, 53, and 54. It is important to recognize that in virtually every study involving patients with these disorders, multiple drug therapy has been required to achieve the lower blood pressure goals. Indeed, even in uncomplicated hypertensive patients, multiple therapy is usually required to reach goals of less than 140/90 mm Hg.

The identification of an increased risk for cardiovascular disease in persons designated as “prehypertensive” (i.e., those having systolic pressures between 120 and 139 mm Hg and/or diastolic pressures between 80-89 mm Hg)¹ has raised an intriguing question regarding the potential benefit of drug therapy for this group. This issue remains to be addressed in the future. The recommendations in the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)^{2,3} have indicated that in individuals with blood pressure above 160/100 mm Hg, monotherapy does usually not suffice to achieve the blood pressure goals. Thus JNC 7 recommends beginning treatment with two drugs having differing mechanisms of action when the pressure is this high. This chapter does not deal with the severe, accelerated, or resistant forms of hypertension, because they are the topics of Chapters 59 and 78.

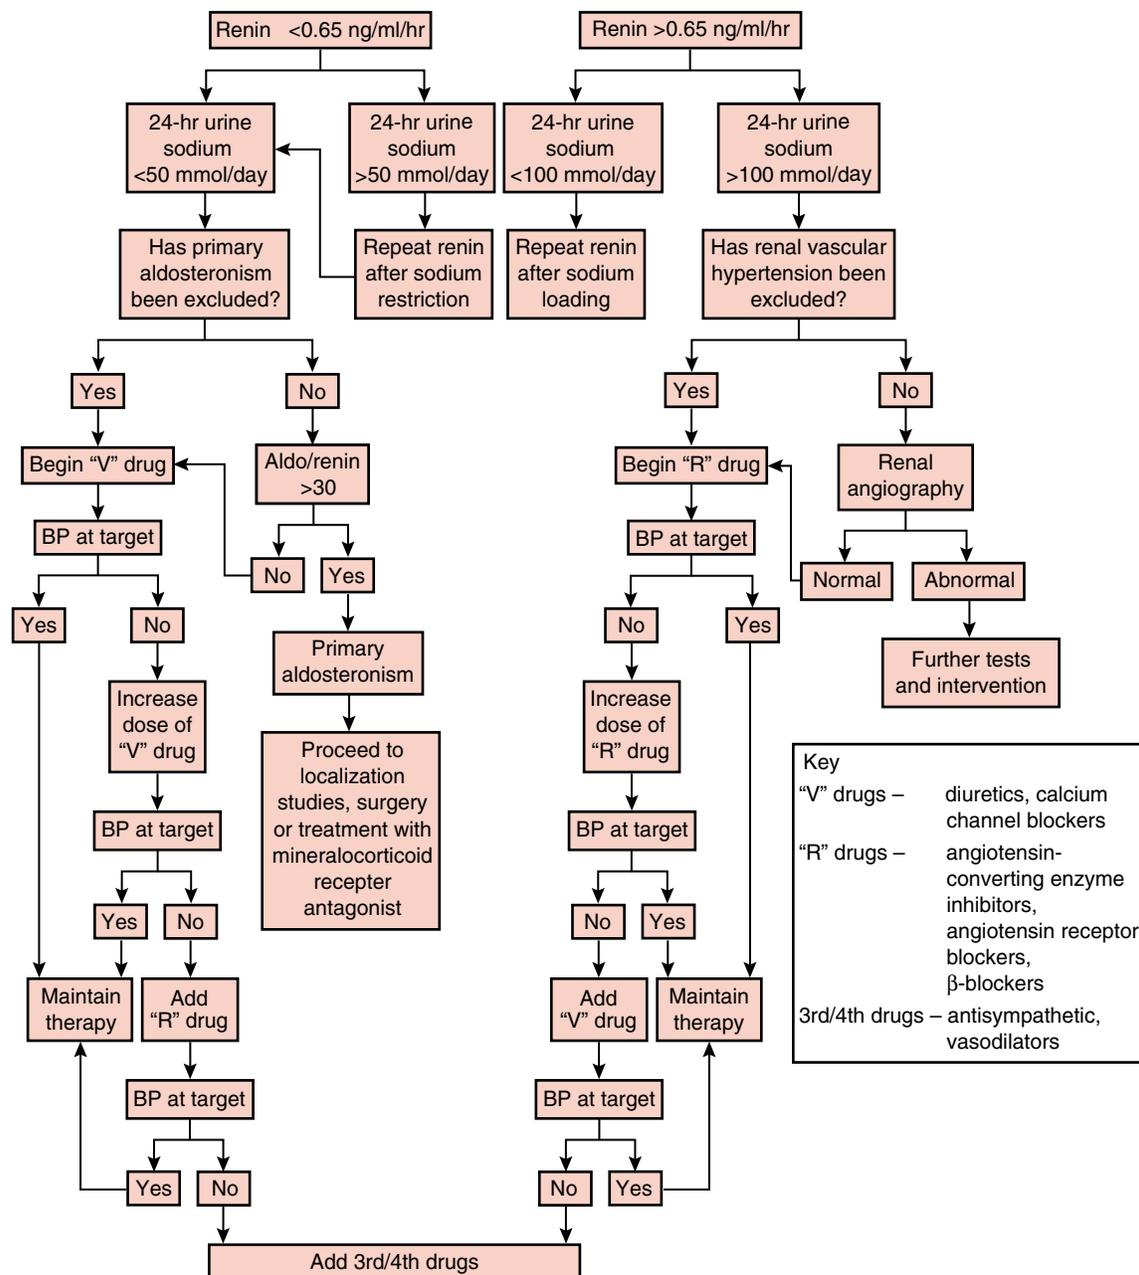

Patients may not always be as willing to wait for blood pressure reduction as their healthcare providers. It is important for the patient to realize that the decrease in blood pressure may be gradual and that it may be necessary to try several agents, alone or in combination, to achieve the target blood pressure with a minimum of side effects. The patient should be encouraged to report side effects when they occur and to understand the blood pressure goals and the time frame for achieving them.

THE USE OF PLASMA RENIN ACTIVITY TO GUIDE THERAPEUTIC CHOICES: THE "LARAGH" METHOD

Dr. John Laragh and his group working at the Cornell University Medical Center have been pioneers in elucidating the role of the renin-angiotensin-aldosterone system in human hypertension and its associated disorders. The results of their voluminous body of work have led to an approach to selecting antihypertensive therapy based on measurement of plasma renin activity (Figure 79-1).⁴ This group demonstrated more than 30 years ago the inverse relationship between plasma renin activity, measured by the production of angiotensin from endogenous renin substrate, and urinary sodium excretion, a

surrogate for dietary-sodium intake. They found that plasma renin activity was markedly reduced when dietary-sodium intake exceeded 150 to 200 mmol/day, the typical range for most free-living individuals. Plasma renin activity begins to rise at levels of dietary-sodium intake below 50 to 100 mmol/day.

The "Laragh" concept is based on measuring plasma renin activity to determine whether an individual has a blood pressure elevation that is primarily due to increased vasoconstriction from endogenous pressor agents (renin-dependent, "R," i.e. plasma renin activity >0.65 ng/ml/hr) or due to increased extracellular fluid volume ("V," sodium or salt dependent; plasma renin activity <0.65 ng/ml/hr).⁴ However, the accuracy of this measurement requires reduction of salt intake to levels below the threshold for the stimulation of renin (i.e., <50-100

Key
 "V" drugs – diuretics, calcium channel blockers
 "R" drugs – angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, β-blockers
 3rd/4th drugs – antisympathetic, vasodilators

Figure 79-1 Treatment algorithm based on plasma renin activity.

mmol/day to identify the “low-renin” or “V” individual). This requires collection of a 24-hour urine sample for measurement of sodium and creatinine to verify the completeness of the collection. Additional studies are required to rule out renin suppression as the result of primary aldosteronism or other mineralocorticoid excess syndromes. Similarly, when renin levels are >0.65 ng/ml/hr, the presence of renal vascular hypertension and other disorders of the kidney manifest by excessive renin release must be excluded by having the individual consume a high-sodium intake, verified by 24-hour urine measurement of sodium and creatinine. Even when these precautions are taken, about 20% of the patients will fail to reproduce their initial renin status on repeat examination. The logistics and expense involved in extra appointments for the measurements of renin and urinary sodium excretion and the cost for these laboratory tests must also be taken into consideration.

Initial antihypertensive therapy is selected on the basis of the apparent physiologic abnormality revealed by the renin measurements. Patients are then separated into “V” (volume and salt-dependent) or “R” (renin or vasoconstrictor-dependent) forms of hypertension, and drugs are selected on that basis. The “V” subjects, who comprise 30% to 60% of most hypertensive populations, have been shown to have the greatest initial blood pressure response to agents that reduce extracellular fluid volume, such as diuretics, aldosterone antagonists (spironolactone [Aldactone], eplerenone [Inspra]), and calcium channel entry blockers. For the “R” subgroup, typically comprising 10% to 30% of the essential hypertensive population, drugs that block the effects of vasoconstrictors such as β -adrenergic blocking agents, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, the experimental renin inhibitors, and sympatholytic agents are initially prescribed. A large segment, likely the majority, of the hypertensive population, based on the results of clinical trials, will not be controlled with a single agent,^{2,3} presumably because their blood pressure elevation is influenced by more than a single physiologic mechanism. These patients will require the addition of an agent from the “class” opposite that initially prescribed. When no response is noted to the initial drug and patient adherence to the prescribed medication is presumed to be likely, three options should be considered: (1) determining whether there is some interfering or confounding element, (2) deciding whether the renin measurement should be repeated, and (3) discontinuing the initial agent and substituting a drug from the opposite class. The “Laragh” method, despite its simplicity and sophisticated physiologic rationale, requires confirmation by other studies employing a larger number of subjects under conditions of ordinary office practice before widespread adoption is reasonable.

CHOOSING ANTIHYPERTENSIVE DRUG THERAPY BASED ON DEMOGRAPHIC FACTORS

A large number of studies have examined the blood pressure response to monotherapy as well as to multiple-drug approaches in many different hypertensive subpopulations. These studies have provided valuable information regarding blood pressure responses based on demographic characteristics as well as differences in the impact of specific therapeutic agents on cardiovascular events and the adverse effects of specific drugs. This

information has proven to be useful in the selection of initial and additive drugs (Figure 79–2).

AGE

Age is related to the prevalence of hypertension, mechanisms for blood pressure elevation, risk factors for cardiovascular disease, cardiovascular events, response to specific antihypertensive drug therapy, and side effects of these drugs. The prevalence of hypertension increases with age such that the majority of individuals over the age of 60 have an elevation of blood pressure. In the older population the systolic pressure is more likely to be elevated than the diastolic pressure. In younger persons both systolic and diastolic or occasionally, only diastolic pressure is elevated. The rise in systolic blood pressure with aging may be related to reduced arterial compliance and increased pulse wave velocity (see Chapters 15 and 22). In older individuals there are physiologic changes that also influence the response to blood pressure medication. Cardiac output decreases and β -adrenergic receptor and baroreceptor sensitivity are diminished. Thus β -adrenergic blocking drugs, which lower blood pressure primarily by reducing cardiac output, are less effective in older than in younger individuals, in whom there is often an enhancement of adrenergic responsiveness and a resting tachycardia, clues to the likelihood of response to β -adrenergic blocking drugs. The renin-angiotensin system appears to be more sluggish in responding to changes in sodium and volume in older compared with younger persons, and thus the blood pressure response to angiotensin-converting enzyme inhibitors and angiotensin receptor blockers is less in older compared with younger individuals when these agents are given alone. In older persons there is often a decrease in glomerular filtration rate and renal function, contributing to an expanded extracellular fluid volume. This is often manifest by relative suppression of renin and an increased blood pressure response to diuretic therapy. Because of the reduced sympathetic responsiveness in the elderly, protection against volume depletion is less vigorous than in younger individuals and thus orthostatic hypotension, falls, and even syncope are more likely, particularly when diuretics are given.

For this reason I favor using low doses of diuretics (6.25–12.5 mg/day of hydrochlorothiazide or its equivalent in other intermediate- to long-acting agents) in the older population if diuretics are chosen as initial therapy. The Systolic Hypertension in the Elderly Program (SHEP) trial demonstrated no reduction of cardiovascular events despite blood pressure reduction in older subjects receiving chlorthalidone in whom hypokalemia occurred.⁵ The popularity of furosemide as a diuretic agent because of its potency and its preferential selection in acute pulmonary edema and renal failure has led to its widespread and inappropriate use in uncomplicated hypertensives. Because of its short duration of action (4–5 hours) and potency, administration of furosemide causes a prompt and often precipitous diuresis and natriuresis, followed by marked stimulation of the renin-angiotensin-aldosterone system and resultant salt and water retention equal to that recently excreted until the next dose is given. Thus furosemide must be given three to four times daily if effective blood pressure control is desired. This requirement for frequent dosing is associated with markedly reduced

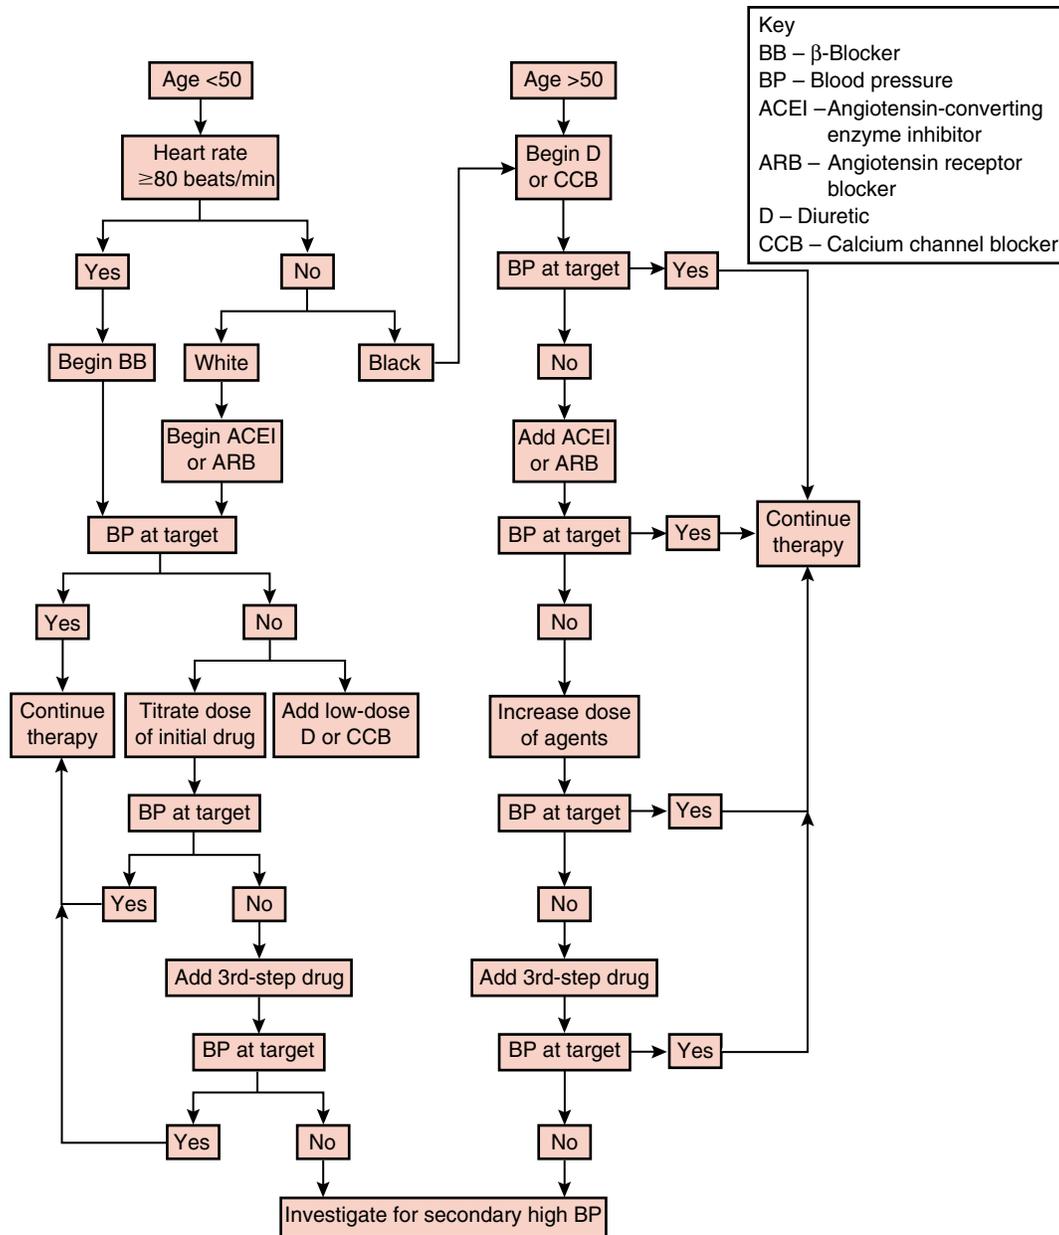

Figure 79-2 Treatment algorithm based on age and ethnicity.

patient adherence and a variety of metabolic complications for those able to maintain the schedule. For this reason, furosemide should be reserved for use in the complicated hypertensive patient (i.e., the patient with chronic kidney disease or heart failure).

In older persons, particularly women, diuretics may occasionally cause profound and life-threatening hyponatremia. The risk of this idiosyncratic reaction may be reduced by avoiding administration of diuretics to patients in whom serum sodium is low-normal at baseline and by monitoring the serum sodium levels soon after beginning diuretic therapy in these patients. Hyponatremia is not a dose-dependent adverse effect and may even occur with the first dose of the drug. Hypokalemia is a much more frequent concomitant of diuretic therapy and usually requires weeks or months of administration to become apparent. Diuretic-associated

potassium loss is dependent on sodium intake, because it is mediated by the aldosterone response to sodium and volume depletion and the resultant potassium-for-sodium exchange in the distal segment of the kidney. Therefore, it can be reduced or prevented by reducing sodium intake, which will also enhance the efficacy of diuretic therapy in lowering the blood pressure.

Alternatively, potassium-sparing agents can be combined with the diuretic. Several are currently available, most in combination form with hydrochlorothiazide. Triamterene is frequently prescribed in combination with hydrochlorothiazide (Dyazide, Maxzide), but this combination is less effective in preventing potassium loss than others because the potassium-conserving duration of action of the triamterene component is shorter than the potassium-losing duration of hydrochlorothiazide. Amiloride (Midamor) is a longer-acting potassium-

sparing agent that is usually combined with hydrochlorothiazide (Moduretic). It is available in the United States only in doses of 5 mg amiloride and 50 mg hydrochlorothiazide, which is a much higher diuretic dose than is preferable for most patients. Triamterene and amiloride are available as single agents but are relatively ineffective as diuretics when used without a thiazide or other more-effective diuretic. The oldest potassium-sparing agent, spironolactone (Aldactone), is the most-potent agent of this group in terms of both blood pressure reduction and potassium conservation. Its mechanism of action is different from those of the other potassium-sparing agents because spironolactone specifically antagonizes the effect of aldosterone at the level of the renal mineralocorticoid receptor. The appeal of spironolactone waned because of the frequent occurrence of sex-hormone-related side effects caused by its interaction with the estrogen receptor. This was manifest by impotence, gynecomastia, and breast tenderness in males and menstrual irregularities in females. Spironolactone is also available combined with hydrochlorothiazide (Aldactazide). A new and more selective mineralocorticoid receptor blocker, eplerenone⁶ (Inspra) has become available (see Chapters 12 and 70). This agent has virtually no sex-hormone-related side effects and appears to be better tolerated than spironolactone. It also will be available in combination form with hydrochlorothiazide.

A word of caution should be voiced regarding the use of potassium-sparing agents. In patients with renal impairment, in some elderly diabetics with hyporeninemic hypoaldosteronism, in some patients receiving nonsteroidal antiinflammatory drugs (NSAIDs), and occasionally, in patients when combined with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, these agents can cause problematic hyperkalemia. If a diuretic is selected as the initial choice for an older hypertensive, lower doses are prudent. In addition, monitoring for and correction of the commonly encountered metabolic side effects of diuretic therapy other than hypokalemia and hyponatremia—such as hyperuricemia and gout, hyperglycemia, and hyperlipidemia—is appropriate. While some have contended that these metabolic effects of diuretic therapy are trivial and transient, the results of the recent Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)⁷ suggest otherwise, because the group assigned to initial therapy with chlorthalidone, a thiazide-type diuretic, had a significantly greater incidence of new-onset diabetes mellitus at the end of the study as compared with the groups assigned to amlodipine or lisinopril. Furthermore, the changes in potassium, glucose, and lipids were found to persist at the end of 5 years of study, and thus are hardly transient.

Calcium channel entry blockers provide an alternative to diuretics for the older hypertensive, because these agents lower blood pressure by inducing a diuresis and natriuresis in addition to their vasodilator effect.⁸ This rarely recognized action of calcium channel blockers provides a dual mechanism of action for reducing blood pressure and probably accounts for the very broad spectrum of antihypertensive efficacy demonstrated by this class of drugs. The calcium channel blocker class can be separated on the basis of chemical structure and actions into three distinct groups: the benzothiazepines (diltiazem), phenylalkylamines (verapamil), and the dihydropyridines (amlodipine, felodipine, isradipine, nicardipine, nifedipine, and nisoldipine are currently available in the United States). For blood pressure reduction the dihydropyridines appear to be the most potent.

The antihypertensive dose of diltiazem is typically much higher than the antianginal dose. Early studies indicated that the average effective antihypertensive dose of diltiazem was more than 300 mg/day. Verapamil also requires an average dose of 240 to 480 mg/day for antihypertensive efficacy. The greatest use of the nordihydropyridine calcium channel blockers is in individuals in whom slowing of heart rate is desired, because they reduce heart rate by their effect on cardiac conduction. In addition, they are useful in the treatment of patients with atrial fibrillation, a not uncommon finding in older hypertensives. However, because of this negative chronotropic effect, they should be used cautiously in patients receiving β -adrenergic blocking drugs because of risk of profound, symptomatic bradycardia and heart block. Other side effects include edema (about which more will be said later), constipation, and skin rash.

The dihydropyridines are devoid of heart-rate slowing effects. In fact, the initial short-acting forms of these drugs, which are no longer widely used, caused reflex activation of the sympathetic nervous system as a result of their precipitous and rapid blood pressure-lowering effect. However, the current generations of these agents, generally sufficiently long-acting for once-daily administration, do not have any demonstrable effect on heart rate. The most commonly prescribed agent of the group, amlodipine (Norvasc), is frequently given for the treatment of angina as well as hypertension. The dihydropyridines are generally the most potent in reducing blood pressure but also may cause edema. The edema seen with calcium channel entry blockers appears to be somewhat paradoxical in view of the extensive documentation of their diuretic and natriuretic actions. The edema seems to be due to the potent vasodilation of the capillary bed, increasing the capillary pressure with leakage of fluid into the interstitial tissues and, by the effect of gravity, to pooling in the legs. This can typically be remedied by antigravitational maneuvers such as elevating the legs periodically, wearing support stockings, or if those techniques are not adequate, by the addition of small doses of an angiotensin-converting enzyme inhibitor or an angiotensin receptor antagonist, which appears to correct the increased capillary pressure responsible for the edema.

Cognitive decline and dementia of all forms are more frequent among older persons than younger and in hypertensives as compared with normotensives. In fact, elevated blood pressure has emerged as a major risk factor for the development of dementia. Importantly, trials in elderly hypertensives have demonstrated, prospectively, a reduction in the development of dementia in this susceptible group when systolic blood pressure is lowered with a dihydropyridine calcium channel entry blocker.⁹ It is likely that other agents will show a similar benefit, but no data on this issue are presently available.

When the initial agent chosen for the older hypertensive, typically a low-dose diuretic or a calcium channel entry blocker, does not reduce blood pressure to goal (systolic pressure below 140 mm Hg), the addition of an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker will usually produce a further decrease in pressure because of the additive effects of such agents to diuretics and calcium channel blockers. I prefer not to use β -blocking drugs in this population unless there is another compelling indication for their use (such as atrial fibrillation, angina, congestive heart failure, benign tremor, or migraine headaches) because of their low antihypertensive efficacy and their adverse effects on cardiac output and lipids.¹⁰

When essential hypertension is diagnosed at a younger age, typically less than 40 years, the etiology is more typically the result of an increase in vasoconstriction induced by catecholamines or angiotensin II via the renin system. In addition to the increase in blood pressure, a resting tachycardia or hyperdynamic chest wall may be observed. Such individuals are typically more responsive to β -adrenergic blocking agents, to which they may exhibit a reduction of blood pressure at relatively low doses, thus making dose-related side effects less likely, or to agents interfering with the renin-angiotensin system, such as angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers. When β -adrenergic blocking agents are prescribed, there is often concern regarding the occurrence of bradycardia. Because the main mechanism by which β -blockers reduce blood pressure is by reducing heart rate and thereby decreasing cardiac output, a reduction in heart rate is a good way to evaluate the efficacy of the agent. For this reason, asymptomatic bradycardia, even with pulse rates as low as 40 beats/min, should not necessarily be a reason for discontinuation of a β -blocker if the blood pressure is responsive and the patient does not exhibit other side effects. β -Adrenergic blocking agents are less effective in cigarette smokers, presumably because of the increase in catecholamine release in such individuals.

With angiotensin-converting enzyme inhibitor treatment, the major life-threatening side effect is angioedema. This is a relatively rare event but does appear to be more prevalent in Blacks, who generally are less responsive than Caucasians to monotherapy with angiotensin-converting enzyme inhibitors in terms of blood pressure reduction. This side effect does not seem to be dose-dependent and may occur at any time during treatment, not necessarily with the initial dose. Cough is another much more frequently encountered side effect of this drug class that, although not dose-dependent, appears to be duration-dependent, more likely to occur the longer the patient takes the drug. Cough also seems to be more prevalent among African American and Asian American hypertensives, as well as women and smokers. The incidence of both angioedema and cough with angiotensin II receptor blockers is much lower than that with angiotensin-converting enzyme inhibitors, providing a rationale for preferring the former in many patients.

ETHNIC BACKGROUND

A variety of studies have reported on differential responsiveness to antihypertensive agents among patients separated on the basis of ethnic background or race (see Chapter 56).^{7,11-13} One of the earliest such reports concerned the decreased responsiveness of Black hypertensives to treatment with β -adrenergic blocking drugs.¹² These studies failed to demonstrate a blood pressure response to 160 mg/day of propranolol but demonstrated that 640 mg/day did lower pressure in a small group of Black hypertensives. Similar observations have been made with angiotensin-converting enzyme inhibitors and angiotensin receptor blockers when used alone in this subgroup. On the other hand, diuretics and calcium channel entry blockers generally are effective in reducing pressure in Black hypertensives.^{11,12} Because the elevation of pressure in this population is often greater than in other subgroups, multiple medications are more frequently required. The addition

of angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers to initial therapy with diuretics¹³ or calcium channel entry blockers usually provides additional blood pressure reduction.

There have been a paucity of studies in the United States to provide information regarding the blood pressure responses of Hispanic Americans, Native Americans, or Asian Americans to different antihypertensive agents given as monotherapy. Some of the large “outcome” trials such as ALLHAT⁷ and the International Verapamil-Trandolapril Study (INVEST)¹⁴ can provide that information, because they had a very substantial representation of minority hypertensives.

GENDER

Despite a large number of studies that have included women as well as men as participants, there is no consistent evidence of gender differences in the response to antihypertensive drugs when other factors such as age and ethnicity are considered.^{2,3} Having said that, several gender-specific concerns may influence the choice of antihypertensive drug therapy in women. Because angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are contraindicated in pregnancy, they should probably be avoided in women with childbearing potential unless a very effective form of contraception is utilized. When hypertensive women are found to be taking oral contraceptives or hormone replacement therapy, a trial of several months of withdrawal of such agents may be rewarded by a reduction in blood pressure. Women appear to experience a cough with angiotensin-converting enzyme inhibitors, hypokalemia with diuretics, and edema with calcium channel entry blockers more frequently than do men.

WHAT TO DO WHEN INITIAL THERAPY IS NOT ENOUGH

Several large trials have provided evidence that the majority of uncomplicated hypertensives require more than two drugs to achieve the current blood pressure goal recommendations.^{2,3,7,14} As previously mentioned, the JNC 7 report advocates beginning with two agents when the blood pressure is above 160/100 mm Hg, because a single drug is not likely to achieve the targeted blood pressure reduction. In the “Laragh” method, when the initial “V” or “R” drug, chosen on the basis of the renin measurement, in full doses does not lower blood pressure sufficiently, a drug from the opposite class is recommended. When demographic characteristics are used as a clue to initial therapy, a similar approach of adding drugs with a differing mechanism of action from that initially prescribed is usually effective. It should be emphasized that when calcium channel blocking drugs are given initially, the addition of a diuretic is unlikely to produce a significant further blood pressure reduction, although the opposite sequence may demonstrate a further drop in pressure, presumably owing to the dual antihypertensive mechanisms of calcium channel entry blockers.¹⁵ Similarly, combining a β -blocker with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker, or combining the latter two agents, in the absence of a diuretic or calcium channel blocker, is not likely to produce an additive antihypertensive effect.

The very limited studies demonstrating the benefit of combining angiotensin-converting enzyme inhibitors with angiotensin receptor blockers, to date, have not compared the response to full or increased doses of either agent alone to satisfy the concern that the response to the combination simply reflects greater inhibition of the renin-angiotensin system. Such studies should be available in the future. When two agents, working by different mechanisms, fail to reduce blood pressure adequately, third-step agents—for example, sympatholytic drugs such as clonidine (Catapres), guanfacine (Tenex), guanabenz (Wytensin), methyl-dopa (Aldomet), doxazosin (Cardura), terazosin (Hytrin), prazosin (Minipress) or reserpine—may be appropriate. Alternatively, direct-acting vasodilators such as hydralazine (Apresoline), or rarely, minoxidil (Loniten), may be added.

SUMMARY

Given the large number of antihypertensive drugs available, it is often bewildering to decide how to begin treatment in a given individual. Essentially there are two rational approaches, one based on a cumbersome and sometimes inconsistent method of measuring plasma renin activity in relationship to 24-hour urinary sodium excretion, which often requires a manipulation of dietary-sodium intake to ensure accuracy, and another based on demographic characteristics. Neither of these approaches is fool-proof, nor have they been consistently and reproducibly subjected to rigorous randomized clinical trial examination to compare their relative costs, efficacies, advantages, and disadvantages. Nonetheless, both offer a way to begin drug treatment in specific patients, recognizing that the overwhelming majority of hypertensives will require more than a single drug to achieve adequate blood pressure control. The use of these algorithms should make the tough choices a little easier.

Appendix

Oral Antihypertensive Drugs

Class	Drug (trade name)	Usual Dose Range, mg/day	Usual Daily Frequency*
Thiazide diuretics	Chlorthalidone	12.5-25	1
	Hydrochlorothiazide	12.5-50	1
	Indapamide (Lozol [†])	1.25-2.5	1
	Metolazone (Mykrox)	0.5-1.0	1
	Metolazone (Zaroxolyn)	2.5-5	1
Other diuretics	Bumetanide (Bumex [†])	0.5-2	2
	Furosemide (Lasix [†])	20-80	2
	Torsemide (Demadex [†])	2.5-10	1
Aldosterone receptor blockers	Eplerenone (Inspra)	50-100	1
	Spirolactone (Aldactone [†])	25-50	1
β-Blockers	Atenolol (Tenormin [†])	25-100	1
	Betaxolol (Kerlone [†])	5-20	1
	Bisoprolol (Zebeta [†])	2.5-10	1
	Metoprolol	50-100	1-2
	Metoprolol extended release	50-100	1
	Nadolol (Corgard [†])	40-120	1
	Propranolol	40-160	2
	Propranolol long-acting (Inderal LA [†])	60-180	1
	Timolol (Blocadren [†])	20-40	2
β-Blockers with intrinsic sympathomimetic activity	Acebutolol (Sectral [†])	200-800	2
Combined α- and β-blockers	Carvedilol (Coreg)	12.5-50	2
	Labetalol (Normodyne, Trandate [†])	200-800	2
ACEIs	Benazepril (Lotensin [†])	10-40	1
	Captopril (Capoten [†])	25-100	2
	Enalapril (Vasotec [†])	5-40	1-2
	Fosinopril (Monopril)	10-40	1
	Lisinopril (Prinivil, Zestril [†])	10-40	1
	Moexipril (Univasc)	7.5-30	1
	Perindopril (Aceon)	4-8	1
	Quinapril (Accupril)	10-80	1
	Ramipril (Altace)	2.5-20	1
	Trandolapril (Mavik)	1-4	1
	Angiotensin II antagonists	Candesartan (Atacand)	8-32
Eprosartan (Teveten)		400-800	1-2
Irbesartan (Avapro)		150-300	1
Losartan (Cozaar)		25-100	1-2
Olmesartan (Benicar)		20-40	1
Telmisartan (Micardis)		20-80	1
Valsartan (Diovan)		80-320	1-2
CCBs—Nondihydropyridines	Diltiazem extended release (Cardizem CD, Dilacor XR, Tiazac [†])	180-420	1
	Diltiazem extended release (Cardizem LA)	120-540	1
	Verapamil immediate release (Calan, Isoptin [†])	80-320	2
	Verapamil long acting (Calan SR, Isoptin SR [†])	120-480	1-2
	Verapamil (Coer, Covera HS, Verelan PM)	120-360	1

Continued

Oral Antihypertensive Drugs—cont'd

Class	Drug (trade name)	Usual Dose Range, mg/day	Usual Daily Frequency*
CCBs—Dihydropyridines	Amlodipine (Norvasc)	2.5-10	1
	Felodipine (Plendil)	2.5-20	1
	Isradipine (Dynacirc CR)	2.5-10	2
	Nicardipine sustained release (Cardene SR)	60-120	2
	Nifedipine long-acting (Adalat CC, Procardia XL)	30-60	1
	Nisoldipine (Sular)	10-40	1
α_1 -Blockers	Doxazosin (Cardura)	1-16	1
	Prazosin (Minipress [†])	2-20	2-3
	Terazosin (Hytrin)	1-20	1-2
Central α_2 agonists and other centrally acting drugs	Clonidine (Catapres [†])	0.1-0.8	2
	Clonidine patch (Catapres-TTS)	0.1-0.3	1 weekly
	Reserpine (generic)	0.1-0.25	1
Direct vasodilators	Hydralazine (Apresoline [†])	25-100	2
	Minoxidil (Loniten [†])	2.5-80	1-2

From the National Heart, Lung, and Blood Institute (NHLBI). From Physicians' Desk Reference. 57th ed. Montvale, NJ: Thomson PDR; 2003.

ACEI, Angiotensin-converting enzyme inhibitors; CCBs, calcium channel blockers.

*In some patients treated once daily, the antihypertensive effect may diminish toward the end of the dosing interval (trough effect). BP should be measured just prior to dosing to determine if satisfactory BP control is obtained. Accordingly, an increase in dosage or frequency may need to be considered. These dosages may vary from those listed in the *Physician's Desk Reference*, 57th ed.

[†]Available now or soon to become available in generic preparations.

Combination Drugs for Hypertension

Combination Type	Fixed-Dose Combination, mg	Trade Name
ACEIs and CCBs	Amlodipine-benazepril hydrochloride (2.5/10, 5/10, 5/20, 10/20)	Lotrel
	Enalapril-felodipine (5/5)	Lexxel
	Trandolapril-verapamil (2/180, 1/240, 2/240, 4/240)	Tarka
ACEIs and diuretics	Benazepril-hydrochlorothiazide (5/6.25, 10/12.5, 20/12.5, 20/25)	Lotensin HCT
	Captopril-hydrochlorothiazide (25/15, 25/25, 50/15, 50/25)	Capozide
	Enalapril-hydrochlorothiazide (5/12.5, 10/25)	Vaseretic
	Fosinopril-hydrochlorothiazide (10/12.5, 20/12.5)	Monopril/HCT
	Lisinopril-hydrochlorothiazide (10/12.5, 20/12.5, 20/25)	Prinzide, Zestoretic
	Moexipril-hydrochlorothiazide (7.5/12.5, 15/25)	Uniretic
	Quinapril-hydrochlorothiazide (10/12.5, 20/12.5, 20/25)	Accuretic
	Candesartan-hydrochlorothiazide (16/12.5, 32/12.5)	Atacand HCT
ARBs and diuretics	Eprosartan-hydrochlorothiazide (600/12.5, 600/25)	Teveten-HCT
	Irbesartan-hydrochlorothiazide (150/12.5, 300/12.5)	Avalide
	Losartan-hydrochlorothiazide (50/12.5, 100/25)	Hyzaar
	Olmесartan medoxomil-hydrochlorothiazide (20/12.5, 40/12.5, 40/25)	Benicar HCT
	Telmisartan-hydrochlorothiazide (40/12.5, 80/12.5)	Micardis-HCT
	Valsartan-hydrochlorothiazide (80/12.5, 160/12.5, 160/25)	Diovan-HCT
	Atenolol-chlorthalidone (50/25, 100/25)	Tenoretic
β-Blockers and diuretics	Bisoprolol-hydrochlorothiazide (2.5/6.25, 5/6.25, 10/6.25)	Ziac
	Metoprolol-hydrochlorothiazide (50/25, 100/25)	Lopressor HCT
	Nadolol-bendroflumethiazide (40/5, 80/5)	Corzide
	Propranolol LA-hydrochlorothiazide (40/25, 80/25)	Inderide LA
	Timolol-hydrochlorothiazide (10/25)	Timolide
	Other combinations	Amiloride-hydrochlorothiazide (5/50)
	Spirolactone-hydrochlorothiazide (25/25, 50/50)	Aldactazide
	Triamterene-hydrochlorothiazide (37.5/25, 75/50)	Dyazide, Maxzide

From the National Heart, Lung, and Blood Institute (NHLBI). From Physicians' Desk Reference. 57th ed. Montvale, NJ, Thomson PDR; 2003.

ACEI, Angiotensin-converting enzyme inhibitors; CCBs, calcium channel blockers; ARBs, angiotensin receptor blockers.
