NOTICE

Medicine is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the editor assumes any liability for any injury and/or damage to persons or property arising from this publication.

Preface

Creating a comprehensive book on hypertension is a demanding task, particularly for the numerous contributors who provide chapters giving detailed descriptions of the most current information in their fields. For this reason, we were both highly gratified by the enthusiastic acceptance and wide distribution of the first edition of this book.

Now, 4 years later, the dedication and generosity of our professional colleagues have allowed us to produce this second edition. In some ways, it might have been tempting simply to add some updates to the original volume; after all, many of the chapters from the earlier edition remain highly relevant and contemporary. But, despite our earlier success, we have decided to entirely re-cast this publication. The last few years have seen not only the completion of a number of important and high-impact clinical trials in hypertension but also the emergence of new attitudes toward the scientific infrastructure and the clinical priorities of hypertension. We believe that the effort involved in creating this new book has been fully worthwhile.

Major trials that have been recently completed have been allocated chapters in this volume. These include two studies done in high-risk hypertensive patients, both comparing the relatively new angiotensin receptor blockers against older, more established drug classes. The Losartan Intervention For Endpoint Reduction (LIFE) trial compared the angiotensin receptor blocker, losartan, with the β -blocker, atenolol, and concluded that the angiotensin receptor blocker was significantly more efficacious in preventing strokes in hypertensive patients who are at high risk due to the presence of electrocardiographic evidence of left ventricular hypertrophy. The Valsartan Antihypertensive Long-term Use Evaluation (VALUE) trial compared the angiotensin receptor blocker, valsartan, with the calcium channel blocker, amlodipine. This study was confounded because the protocol resulted in achievement of somewhat unequal blood pressures in the two treatment groups. Importantly, VALUE emphasized that blood pressure control, perhaps more than any other factor, is the key to preventing major events and mortality in hypertension. Both the LIFE and VALUE trials also provided evidence that the angiotensin receptor blockers may have the added benefit of preventing or at least delaying the appearance of new-onset diabetes, an important attribute considering the worldwide epidemic of the triad of obesity, insulin resistance, and the cardio-metabolic syndrome.

Two trials, the Irbesartan Diabetic Nephropathy Trial (IDNT) and Reduction of Endpoints in Non-Insulin Dependent Diabetes Mellitus with the Angiotensin II Antagonist Losartan (RENAAL), were performed in patients with diabetic nephropathy and demonstrated that—for the same effects on blood pressure—angiotensin receptor blockers were more efficacious than other drug classes in preventing further deterioration of renal function and progression to end-stage renal disease. Apart from the importance of these results, and their implications for therapy, the studies have had the additional effect of focusing attention on the interaction of hypertension and diabetes.

One of the most noted events since the first edition was the publication of the Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Trial (ALLHAT). This large-scale trial, conducted primarily in the United States across a diverse population of high-risk hypertensive patients, compared the effects on fatal and nonfatal coronary events (as well as other relevant secondary endpoints) of treatments based on a thiazide-like diuretic, a dihydropyridine calcium channel blocker, and an angiotensin-converting enzyme (ACE) inhibitor. The three treatments had virtually identical effects on the primary coronary outcomes, but the diuretic had advantages with respect to some of the secondary endpoints, at least in some high-risk subgroups of patients.

The study was greeted with criticism from an array of experts who argued that its conclusions were influenced by artifacts of the study design that favored the diuretic, particularly in terms of achieving blood pressure control, and that there was no creditable basis for claiming superiority—or, for that matter, even economic advantage—for the thiazide when the full cost of therapy beyond drug acquisition was taken into account. This broad-based skepticism regarding the interpretation of ALLHAT has diluted its impact on hypertension practice, although it still remains a subject of much discussion and debate. A particularly interesting finding of ALLHAT was that the incidence of new-onset diabetes during the trial was significantly higher with the diuretic than with the other drugs, although during the relatively short-term follow-up of these patients there was no indication that having diabetes increased their risk of cardiovascular events. In this edition of our book, the authors of ALLHAT present their results as a chapter and provide an interesting discussion.

More than ever, hypertension is characterized by a wide array of issues at the molecular, physiologic, clinical, and population levels. A review of our contents will indicate that we have left very few stones unturned in our quest to provide a broad and contemporary view of hypertension. Right now, in the clinical arena, there is a particularly strong focus on the importance of blood pressure control. Although this goes back to the very origins of our understanding of hypertension as a clinical condition, compelling new data have made us more aware than ever that achieving aggressive target blood pressure levels during treatment may represent the single most important benefit that we can provide our patients. Throughout this book the message of blood pressure control across hypertension in its many clinical manifestations is addressed consistently by the authors.

Another contemporary issue in hypertension is the dramatically growing prevalence of the metabolic syndrome and its frequent outcome, type 2 diabetes mellitus. Even the lay public is now aware that there is a worldwide problem of obesity, perhaps exaggerated by the more physically passive and sedentary lifestyles that so many people have adopted. Most worrying, children even more than adults appear to have fallen victim to the dual problems of increased calories and decreased activity. A consequence of this is that not only is the

prevalence of hypertension increased, but also it is likely to be associated with concomitant problems of obesity, lipid disorders, and glucose intolerance. Our readers will find these issues addressed in several places throughout this book. We are working hard to understand the pathophysiology, clinical characteristics, and optimal management for this important and highly prevalent syndrome.

Diabetes mellitus, particularly type 2, is increasing dramatically in incidence and is frequently part of the hypertension story. It would be easy to blame this on the aging of our populations in North America and Western Europe, but the unfortunate fact is that children and young adults are also now prone to this disorder. Currently, we equate diabetes with the presence of cardiovascular disease; in fact, most of our colleagues in endocrinology simply regard type 2 diabetes as being equivalent to coronary disease in creating cardiovascular risk. A small consolation is that we are getting a better idea of how differing therapies and approaches to management might provide some measure of protection for our patients who have diabetes and certainly for those who have this condition in association with hypertension and renal involvement. Once more, several chapters in this edition will provide insights and recommendations for understanding and managing this all-too-common problem.

The sophisticated readers of a book of this type are already aware that creating guidelines for the management of hypertension or other medical conditions can be as much a political as a scientific process. Ultimately, their recommendations to some extent represent the compromises of a group of experts, with disparate interpretations of scientific, clinical, and practical issues, attempting to achieve a consensus. Despite the differences among the specific recommendations produced by organizations or agencies around the world, they all recognize that control of blood pressure in all countries is far from optimal and that aggressive reduction of blood pressure remains the primary objective of treatment. There is also a growing agreement among the guidelines that starting therapy with combination drug treatment—which previously had been regarded as an imprecise or even shot-gun approach to hypertension—may in fact be desirable as a means to more effectively and rapidly achieve blood pressure control in patients whose pretreatment blood pressures are excessively elevated.

A quick review of the chapters in this book will reveal the various categories or sections into which we have placed them. Section 1 provides interesting background information on hypertension: its history, chiefly from a clinical perspective, and the role of an official organization—the National High Blood Pressure Education Program—in disseminating information to the American public about the importance of diagnosing and treating hypertension; and, of course, there is a chapter on the epidemiology of this very common condition.

Given the wide variety of regulatory systems and structural factors that influence blood pressure, Section 2 describes pathophysiology and is relatively large and comprehensive. A number of chapters deal with the renin-angiotensin-aldosterone system, including renin itself, the various forms of angiotensin, angiotensin-converting enzyme, angiotensin receptors, aldosterone, and selective mineralocorticoid receptors. There is strong evidence that this system not only plays a major role in blood pressure control, but also contributes to several mechanisms that

appear to accelerate atherosclerosis and other forms of hypertension and related target organ damage. This information lays the ground work for later chapters that describe the growing role of drugs that interrupt the renin-angiotensin-aldosterone system in managing hypertension as well as other cardiovascular and renal diseases.

Complementary to the renin axis is the sympathetic nervous system, which clearly is also pivotal in governing blood pressure. Increased sympathetic activity appears to be a major mediator of the blood pressure effects of obesity and other metabolic disorders that predispose to the development of hypertension. Other important vasoactive mediators, including the natriuretic peptides, the vasodilator peptides and the kallikrein-kinin system are also discussed in detail. Our section on pathophysiology emphasizes the endothelium, and looks at the importance of early structural changes in the microcirculation, as well as the stiffness of larger arteries. A chapter on the metabolic syndrome lays the foundation for important clinical issues discussed elsewhere in the book.

The transition to these more clinical issues requires, first of all, an understanding of the concept of total risk, particularly as hypertension is just one of the contributors to cardiovascular events and mortality. There is little doubt, however, that hypertension is a major antecedent to coronary events and to heart failure. These relationships are discussed in Section 3, which deals with target organ damage and cardiovascular events. The connection between blood pressure and the kidney is particularly strong, and this Section contains an important chapter that delineates how preventing the progression of renal disease depends highly on blood pressure control as well as other strategies. It is fascinating how, even at this relatively advanced stage of our understanding of hypertension, we are still seeking better ways of interpreting the blood pressure itself: which component or derivative of the blood pressure is the most important prognostically, and which should be the primary target of treatment?

After Section 4 explores blood pressure both from a diagnostic and mechanistic point of view, Section 5 goes on to describe the general principles of treating hypertension. The early chapters in this Section report the findings of major clinical trials in hypertension and related areas, including those that were discussed above, and review major meta-analyses looking at the comparative effects of antihypertensive drugs on major cardiovascular outcomes. Commentaries on current prescribing practices in hypertension and some of the highlights and controversies arising from published hypertension guidelines are included, as well as discussion of some innovative approaches to managing hypertension, including nursing clinics and community outreach programs. Getting patients to take their medications, one of the hardest tasks in hypertension, is also dealt with here.

We have taken a broader view of hypertension treatment than consideration of drug therapy alone, and Section 6 contains detailed chapters on lifestyle modifications. These include discussions of micronutrients, special diets involving adjustments in macro- and micronutrients that appear to affect blood pressure, and thoughtful reviews of the mechanisms as well as the challenges of management of obesity in hypertension. Further chapters deal with the relationship between alcohol and hypertension, the role of physical activity in prevention and treatment, and a careful look at the common concomitant diagnosis of diabetes.

Section 7 considers some contemporary issues in the use of antihypertensive agents: how best to choose the initial drug for treating hypertension, the pharmacokinetics of the major antihypertensive drugs, the growing role of fixed combination antihypertensive agents, and the concept of chronotherapeutics in which drugs are designed to exert maximal effects during the early morning hours when patients may be at greatest risk of cardiovascular events.

Circumstances that can affect the selection of antihypertensive drugs, including the presence of concomitant conditions and the special needs of different populations, are discussed in Section 8. Particular focus is directed toward the special needs of patients with such conditions as diabetes or the metabolic syndrome, chronic kidney disease, and coronary heart disease. Optimal strategies for treating African American patients, the elderly and children, as well as the special requirements of treating hypertension in pregnancy are considered in depth. The challenges associated with treatment-resistant hypertension and orthostatic hypotension are also dealt with here.

There is always strong interest in the properties of individual drugs, and Section 9 gives detailed information regarding all the currently used antihypertensive drug classes. Potential new classes are also considered, including endothelin antagonists, vasopeptidase inhibitors and renin inhibitors. We have also included a chapter describing the process by which the United States Food and Drug Administration approves new antihypertensive agents.

The final part of the book, Section 10, deals with secondary hypertension and special circumstances that can affect the management of hypertension. Beyond the most important secondary forms of hypertension, including aldosterone excess, renovascular disease and pheochromocytoma, we have included chapters on obstructive sleep apnea and the special requirements of general anesthesia in hypertensive patients, as well as management of patients with hypertensive emergencies. In view of the ever more aggressive blood pressure targets recommended by contemporary guidelines, our final chapter offers strategies and treatment algorithms for achieving this ambitious goal.

Our most important task is to thank our many colleagues who labored so hard to write contemporary and incisive chapters for this book. Thanks to their efforts, readers will now have access to a comprehensive and detailed review of hypertension as we understand it today. We would also like to thank Susan Pioli and Kim Davis at our publisher, Elsevier, who have worked so closely with us in dealing with the time-consuming and complicated issues of producing a work of this magnitude. Finally, we are delighted to acknowledge Lorraine Wilson at the Downstate College of Medicine in Brooklyn, NY, and Carla Segars at the University of Alabama, Birmingham, for their outstanding administrative support and commitment in completing this task.

Suzanne Oparil, M.D.
Michael A. Weber, M.D.

Preface to the First Edition

Results of recent population surveys have underscored the enormity of the health problem posed by elevated blood pressure. With a prevalence of 20% of the adult population worldwide, high blood pressure increases the cardiovascular risk of billions of people. Careful analyses of cohort data have shown that this increased risk pertains not only to persons with frank hypertension by traditional definitions but also to those with blood pressures at the higher end of the “normal” range. The risk of cardiovascular disease is directly and linearly related to both systolic and diastolic blood pressure, although the slope of this relationship is steeper for systolic than for diastolic pressure. Recent analyses have shown that elevated pulse pressure may carry the worst prognosis of all, particularly among the elderly.

The risk of elevated blood pressure is clearly modifiable with appropriate and aggressive antihypertensive treatment. Results of recent randomized clinical trials have reinforced the concept that lowering blood pressure can prevent morbidity and mortality due to cardiovascular diseases, including stroke, congestive heart failure, myocardial infarction, and end-stage renal disease. Further, these studies have shown that lowering blood pressure to more aggressive target levels confers relatively greater benefit in those persons at highest risk, including diabetics and persons with renal insufficiency accompanied by proteinuria.

Despite the impressive successes of controlled clinical trials in preventing hypertension-related cardiovascular events, the incidence of heart failure and end-stage renal disease has increased dramatically since the early 1980s. A major contributor to this trend is inadequate control of blood pressure in the population. Hypertension control rates are disappointing (only 27% in the United States and much lower in other industrialized countries, for example, 6% in the United Kingdom) and have declined in recent years.

The challenge to the practicing physician, then, is to translate the promising results of clinical trials into everyday practice. Impediments to this effort include nonadherence to prescribed medical regimens by patients, failure to communicate the need for treatment by providers, the cost of care, failure to prescribe medications in adequate doses, and the requirement for multidrug regimens to achieve adequate control in most patients. Hope for the future lies in innovative health care delivery systems that utilize nurses, pharmacists, and other nonphysician providers, increased emphasis on adherence-enhancing measures, and reliance on referral to hypertension specialists for the care of complex and resistant patients. The team approach to care of hypertensive patients also facilitates implementation of lifestyle modification measures, including novel dietary programs, that can reduce blood pressure.

Broader recognition by health care providers of the need to treat to lower goal blood pressures and by the health care delivery system of the importance of successful antihypertensive treatment should yield immediate benefit. Results of randomized controlled trials currently in progress will yield

insights into whether specific antihypertensive drugs are more—or less—effective than others in preventing morbid and mortal cardiovascular events. These studies should provide definitive answers to the question of whether blood pressure reduction per se fully accounts for the benefits of antihypertensive treatment or whether the mechanism of action of antihypertensive drugs also has a bearing on outcomes.

Interesting questions and controversies remain. High blood pressure rarely exists as a solitary abnormality. Metabolic changes such as lipid disorders and insulin resistance, often associated with obesity, are common in hypertensive patients. In addition, cardiovascular findings, including changes in the structure and function of the left ventricle or stiffening of the arteries, as well as evidence for renal hyperfiltration, are also part of this syndrome. Since these findings can be detected in the apparently normotensive offspring of patients with hypertension, the issue of how and when to best evaluate those at risk of hypertension and its consequences becomes important. Another ongoing question: Although randomized clinical trials with hard endpoints are critical to hypertension guideline writers and policy makers, how can practicing physicians best judge the true effectiveness of treatment in their own individual patients? Can surrogate endpoints like regression of left ventricular hypertrophy, improvement in arterial compliance, or reduction in proteinuria be regarded as legitimate guideposts in patient management?

The science of vascular biology has become a critical part of hypertension. Changes in the endothelium and in the structure and function of the arterial wall are critical in determining the cardiovascular prognosis of patients with this condition. The renin-angiotensin-aldosterone system, together with the many other vasoactive peptides and substances with which it interacts, has become an important therapeutic target as well as a subject of basic scientific interest. There is now an active ongoing search for links between these vascular and clinical findings and the underlying genetic variations and abnormalities that are responsible for them.

It could be anticipated that application of knowledge gained from the human genome project and other studies of the inheritance of high blood pressure and related comorbid conditions will lead to better understanding of the pathophysiology of essential hypertension and to the selection of more effective, targeted antihypertensive therapy based on the genotype of the patient.

This entirely new book is intended to be a useful reference for clinicians who provide care for hypertensive patients, for scientists who are studying the pathobiology of blood pressure control and hypertension-related target organ disease, and for health care planners from academia, industry, and government. The volume begins with a brief history of clinical hypertension and an overview of the epidemiology of hypertension worldwide. Sections 2 and 3 emphasize contemporary issues in the pathophysiology of blood pressure

elevation and its cardiovascular complications and target organ damage, as well as common comorbid conditions, such as obesity and insulin resistance. A particularly novel aspect of these sections is the discussion of primary arterial pathology and arterial stiffness in the pathogenesis of hypertension, providing a mechanistic basis for the recent emphasis on pulse pressure as a predictor of cardiovascular morbidity and mortality in hypertensive subjects. Consideration of target organ damage and cardiovascular complications, as well as blood pressure level per se, as components of total cardiovascular risk is presented as a critical factor in deciding when and how aggressively to treat the patient with elevated blood pressure.

Section 4 on diagnosis emphasizes the importance of accurate blood pressure measurement, including the role of ambulatory and self-measurement of blood pressure in guiding antihypertensive therapy, as well as the complex issue of white-coat hypertension. Section 5 on general considerations in antihypertensive treatment focuses on a number of contemporary issues, including use of outcome data from recent clinical trials in making therapeutic decisions. A critical assessment of hypertension treatment guidelines and their impact on office practice is presented. Current prescribing practices, as well as the cost-effectiveness of antihypertensive therapy in a managed care setting, are discussed. Novel systems for delivering antihypertensive therapy, including nursing clinics and community outreach programs, and for optimizing compliance with antihypertensive medication occupy prominent positions in this section.

Section 6 deals with lifestyle modification in the prevention and treatment of hypertension. It discusses the value of a balanced diet rich in fruits, vegetables, and low-fat dairy products, for example, the Dietary Approaches to Stop Hypertension (DASH) diet, as well as weight reduction, increased physical activity, and moderation of alcohol consumption as primary or adjunctive therapy in hypertensive patients.

Section 7 outlines general considerations for the initial choice of antihypertensive drug treatment, including low-dose fixed-combination therapy, and the role of chronotherapeutics in treatment decisions. Special considerations in the treatment of hypertensive patients with comorbid conditions, particularly insulin resistance, diabetes, ischemic heart disease, and renal disease, as well as in special patient groups, including women, the elderly, and Blacks, are discussed in Section 8. Chapters on resistant hypertension and orthostatic hypotension round out this section.

The process of antihypertensive drug registration in the United States is described in Section 9, which also includes detailed consideration of antihypertensive drug actions by class. New antihypertensive drug classes, including endothelin antagonists, renin inhibitors, and the vasopeptidases, which combine neutral endopeptidase and angiotensin-converting enzyme-inhibiting properties, as well as the established classes, are discussed here.

Section 10 emphasizes recent advances in the diagnosis and treatment of secondary hypertension. Obstructive sleep apnea, a recently recognized and important cause of hypertension, is highlighted. Anesthesia in the hypertensive patient and the treatment of hypertensive emergencies, specialized areas that often baffle clinicians, are discussed in this section. The volume ends with a set of tables listing the antihypertensive drugs currently available in the United States.

We thank the contributing authors for their scholarly and extremely contemporary treatment of important topics in hypertension pathophysiology, diagnosis, and therapy. We also express our appreciation to Richard Zorab, Jennifer Shreiner, and the production staff at W.B. Saunders Company for their expertise and diligent attention to detail in the preparation of this text.

Background and History

Chapter 1

A History of Hypertension Treatment

Edward D. Freis

Much of the early history of hypertension was collected by Ruskin and presented in his book entitled *Classics in Arterial Hypertension*.¹ This book is the primary source of my review of the opinions of the ancient physicians. Prior to the twentieth century there were no clinical instruments for measuring blood pressure noninvasively. However, the presence of a high blood pressure had long been recognized by the degree of “hardness” of the pulses (difficulty in obliterating the pulse by manually compressing the radial artery).

The first known reference to increased tension within the arterial system was made in a Chinese book written about 2600 B.C. entitled *The Yellow Emperor’s Classic of Internal Medicine*.² The author stated “Nothing surpasses the examination of the pulse, for with it errors cannot be committed. In order to examine whether Yin or Yang predominates one must distinguish a gentle pulse and one of low tension from a hard and pounding pulse.” He further stated that “The heart influences the force which fills the pulse with blood. If too much salt is eaten in food, the pulse hardens.” He also described a syndrome closely resembling hypertensive cardiac failure, stating that “when the pulse is abundant but tense and hard like a cord there are dropsical swellings.”

A medical textbook from the Ashurbanipal Library at Nineveh (669–626 B.C.) advised that apoplexy be treated with venesection and cupping, which reduces blood pressure. The *Pulse Classic of Wang* (280 A.D.) stated that in apoplexy the pulse should be superficial and slow. If it is firm rapid and large there is danger.” Leeches were a popular treatment for apoplexy in ancient times. Some of the ancient Chinese texts recommended acupuncture or venesection for hardening of the pulse.¹

In Roman medicine, Cornelius Celsus³ wrote that increased rate and tension of the pulse occurs with exercise, passion, and even the doctor’s arrival (the Roman version of the “White Coat” phenomenon).

The Chinese and Arabic cultures considered that overeating and overexcitability were harmful. The Arabian textbook called *The Therapy* warned: “Nothing is more harmful to an aged person than to have a clever cook and a beautiful concubine.” Obesity was considered to be dangerous by Hippocrates, who stated it was associated with sudden death⁴ (metabolic syndrome). Hippocrates correctly believed that apoplexy caused paralysis and both resulted from plethora of the brain. He also was the first to find that head wounds of the brain caused paralysis on the opposite side of the body. He recommended

bleeding in patients with stroke, a treatment used until the eighteenth century.

Galen (131–201 A.D.) was the great medical authority until the eighteenth century. But he was often wrong. For example, he denied that stroke was associated with a hard pulse, that is, hypertension.⁵ He also failed to believe that blood circulates from arteries to veins. Autopsies were forbidden until the seventeenth century.⁶ This held back the growth of medical knowledge for hundreds of years.

MEDICAL ADVANCES DURING AND AFTER THE RENAISSANCE

Thomas Young, who lived in the early eighteenth century, was a scientific phenomenon, making important discoveries in diverse fields of science, including theories of light and visual accommodation, color vision, a partial translation of the Rosetta stone, and also became fluent in seven different languages.

Young’s studies on the arterial system were remarkable. In 1808, in his Croonian Lecture,⁷ he stated, “that pressure of the blood at the beginning of the great trunk of the aorta is kept up without noticeable loss down to the branches of the lower order”. In studies in dogs he discovered that the fall in systolic blood pressure from the aorta to arteries as small as 200 μm in diameter was approximately 16 mm Hg. Sugiura and Freis measured the systolic pressure drop in dogs using modern equipment.⁸ We found it to average 17 mm Hg, confirming Young’s finding of 1808.

Richard Bright in 1836 was the first to describe Bright’s disease, an inflammatory disease of the kidneys now known as acute glomerular nephritis, which he described as including inflammation and hardening of the kidneys, fullness and hardness of the pulse (hypertension), and albuminuria.⁹ Bright benefited from the contributions of previous investigators. Aetios in the sixth century A.D. described a sclerosis of the kidneys associated with oliguria, hematuria, and edema. Cotugo first described albuminuria in 1770.¹ Cardiac hypertrophy with widespread sclerosis of the arteries was described by Morgagni at autopsy.¹

Bright brought these and his own observations together and illustrated them with anecdotal case presentations. He later expanded these observations to include reduced specific gravity of the urine with increased urea, as well as apoplexy,

serositis, hypertrophy of the left ventricle, and stroke. Most importantly, he listed scarlatina as a possible cause of acute glomerulonephritis. He also noted thickening of the walls of small arteries in the kidneys and throughout the body in chronic glomerulonephritis.

In 1872 Gull and Sutton¹⁰ observed that chronic Bright's disease was due to a primary, generalized deposition of hyaline fibrosis of the arterioles and capillaries. These changes resulted in hypertrophy of the left ventricle and contracted kidneys. In 1874 Mahomed, also in England, was the first to indicate that generalized arteriolar disease frequently occurred without preceding renal disease.¹¹ In 1876 Gowers¹² described the constricted arterioles in the optic fundi of patients with generalized arteriolar disease using an ophthalmoscope invented by Helmholtz 25 years earlier.

Sir Clifford Allbutt popularized the concept of hypertensive disease. In 1895 he presented his views on "senile plethora and hyperpiesia" as a generalized disease of the small arteries, which was separate from glomerulonephritis.¹³ In addition, he separated hypertensive arteriolar disease from atherosclerosis of the large arteries. These could occur together or separately. In Germany, the generalized arteriolar disease was called *hypertensive essential* meaning *primary hypertension*.¹⁴ However, in English speaking countries it was translated to mean *essential hypertension*.¹⁵ The latter suggested that the term *essential* indicated that the elevation of blood pressure was a compensatory reaction of the cardiovascular system to overcome ischemia of the tissue caused by constricted arterioles. Misinterpretation helped to discourage any attempts to lower the blood pressure by developing anti-hypertensive drugs.

QUANTITATING BLOOD PRESSURE

Stephen Hales, an eighteenth century parson, is credited for being the first person to measure blood pressure in a living animal. To do so he tied a horse to a fallen-down wooden gate. He then inserted a sharpened brass tube into a carotid artery. Using the windpipe of a goose, he connected the brass tube to a vertical glass tube held aloft by an assistant.¹⁶ The pulsating column of blood rose to a height of 8 feet, 8 inches initially and then gradually declined to two feet, at which point the animal died.

Fifty years later Poiseuille¹⁷ introduced the mercury hydrometer, which greatly reduced the height of the column needed for measuring the blood pressure. Carl Ludwig¹⁸ in 1864 added a float to the top of the mercury column in Poiseuille's hydrometer, with a horizontal arm lightly touching a smoked drum. The pressure wave of the arterial pulse was then recorded on a slowly revolving smoked drum.

For clinical purposes, however, a simple noninvasive method for measuring blood pressure that could be used on humans was needed. Because hypertension usually has no symptoms, the only way to detect the disease and measure its severity is to use some kind of indirect method.

The early attempts were not very accurate and estimated the systolic blood pressure only. Von Basch¹⁹ used the mercury manometer attached to a rubber bulb placed on the radial artery. He then compressed the artery slowly with the bulb until the pulse was obliterated. Only the systolic pressure could be measured by this method (read off the mercury

manometer). In 1889 Von Hemholtz made some improvement on the Von Bosch instrument, which he used to first diagnose coarctation of the aorta by measuring the systolic blood pressure in the radial and temporal arteries compared with that in the dorsalis pedis artery.

An important advance was made by Riva-Rocci, who invented the inflatable rubber cuff to occlude the brachial artery in the upper arm.²⁰ He could only measure the systolic blood pressure, which he did by inflating and then slowly deflated the cuff until he could feel the first pulse detected at the radial artery. To obtain better accuracy, Von Recklinghausen increased the width of the cuff from 5 to 14 cm.²¹

The greatest advance was made by a Russian Army officer, Nikolai Sergeevich Korotkov²² in 1905. Using the inflatable rubber cuff, he listened with a stethoscope over the brachial artery. After he inflated the cuff to obliterate the pulse, he slowly deflated it while listening with the stethoscope over the brachial artery just below the cuff. He proved that the first sound heard was at the systolic blood pressure and the point where the sounds disappeared represented the diastolic blood pressure. It was not long before every doctor's office contained a blood pressure manometer.

THE TREATMENT OF HYPERTENSION—EARLY ATTEMPTS

In 1897 Tigerstedt and Bergman in Sweden discovered a pressor protein in the kidney, which they called renin.²³ This led in 1934 to another important discovery by Goldblatt²⁴: Constriction of a renal artery caused an increased secretion of renin, which resulted in hypertension. Six years later Page and Helmer²⁵ and Braun-Menendez²⁶ simultaneously discovered angiotensin, a polypeptide formed by the action of circulating renin. The active form of angiotensin is a powerful pressor substance. These fundamental discoveries had important clinical consequences, including the diagnosis and surgical treatment of renovascular hypertension and the development of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), pharmacologic agents of great importance in the treatment of cardiovascular diseases, including hypertension.

LOW-SODIUM DIETS

In 1905 two French medical students, Ambard and Beaujard²⁷ were the first to promote the concept that the cause of hypertension was salt in the diet. They thought the culprit was chloride rather than sodium. They claimed some success in reducing blood pressure by restricting salt.

In the 1940s Kempner demonstrated that a diet of plain rice, fruit and vitamin tablets was effective in reducing blood pressure in patients with severe or even malignant hypertension. All other foods, including salt, were forbidden. Kempner maintained 100% compliance by forcing the patients to live for 100 days confined to special dormitories. Kempner thought that the success of his diet was due to the lack of protein, but two other investigators, Watkin et al.²⁸ and Murphy,²⁹ both found that the effectiveness of Kempner's diet was due to its extremely low sodium content of only 20 to 30 mEq/day,³⁰ much lower than the moderate restriction that is used today to

approximately 80 mEq/day. The antihypertensive effectiveness of the lesser degree of sodium restriction is controversial.³¹⁻³⁶ The much greater sodium restriction in the Kempner diet reduced plasma and extracellular fluid volume by an amount similar to that produced by thiazide diuretics.^{37,38} This suggests that the antihypertensive effects of both the Kempner rice diet and thiazide diuretics are volume dependent. These observations also suggest that sodium restriction may not be very effective unless it is reduced to the point of lowering plasma and extracellular volume.^{28,29,38,39}

SURGICAL SYMPATHECTOMY

At the turn of the century it was already known that the excitation of the sympathetic nervous system caused a rise in blood pressure and, therefore, it was thought that removal of the sympathetic ganglia might control hypertension. The first operation to remove part of the sympathetic ganglia in order to treat hypertension was carried out in Germany by Bruening⁴⁰ in 1923. Sympathectomy was later carried out by American surgeons, especially Peet⁴¹ and Smithwick⁴² in the 1940s, but it was a major debilitating, painful operation only justified in severe hypertension. However, the operation stimulated the development of drugs that inhibited the sympathetic nervous system by blocking transmission of sympathetic nerve activity through the autonomic ganglia. These ganglion blocking agents, such as tetraethylammonium,⁴³ hexamethonium,⁴⁴ pentaquine,⁴⁵ and bretylium,⁴⁶ did reduce blood pressure and reversed signs and symptoms of malignant hypertension, but the side effects of autonomic blockade were too great to justify use of these drugs except in patients with severe hypertension. Nevertheless, these early studies demonstrated that antihypertensive drugs were beneficial and stimulated the search for agents that had fewer side effects.

EARLY ANTIHYPERTENSIVE DRUG TREATMENT

Sodium thiocyanate was introduced as a drug treatment for hypertension by Treupel and Edinger⁴⁷ in 1900 and later by Hines in 1946.⁴⁸ It was not very effective in reducing blood pressure and was potentially toxic.

The prevailing opinion of physicians during the period between 1920 and 1970 was that hypertension was a disease of the small arteries and the arterioles, resulting in restricted blood flow. They believed that in order to maintain a normal blood supply to the tissues, compensatory adjustments had to be made by the body to raise the blood pressure in order to restore normal blood flow through the narrowed channels.

P.D. White, perhaps the premier cardiologist of his day, wrote in 1931: "Hypertension may be an important compensatory mechanism which should not be tampered with even were it certain that we could control it." This opinion persisted⁴⁹ in leading medical centers until the early 1970s except for patients with malignant hypertension. The first effective drug treatment of patients with severe, including malignant, hypertension was suggested to me by James Shannon, then with Squibb Company Research in 1946. I gave the antimalarial drug pentaquine to 17 patients with severe hypertension, 3 of them in the malignant phase of the disease.⁴⁵ Because of dis-

turbing side effects, the drug was not acceptable for clinical use. However, it lowered blood pressure and reduced several of its complications, including neuroretinitis, congestive heart failure, and headache in the patients with malignant hypertension. There was no improvement in renal failure. Nevertheless, this study demonstrated that reduction of blood pressure with a drug could reduce organ damage. Therefore, it was a stimulus for developing antihypertensive drugs with fewer side effects. Page and Taylor⁵⁰ reported in 1949 that pyrogen treatment reduced blood pressure and improved signs and symptoms in malignant hypertension, but it had too many side effects for regular clinical use.

The ganglion blocking drugs were introduced by Acheson and Moe,⁵¹ who found that tetraethylammonium blocked autonomic nerve transmission in animals. In 1947 Lyons⁴³ used the drug in patients. While the drug reduced blood pressure, the effect was too short to be used in treatment, and intravenous administration was required. Hoobler⁵² found that tetraethylammonium abolished the skin temperature gradient from the foot to the umbilicus, as occurs in a sympathectomized extremity, thereby proving that the blood pressure effect was likely due to sympathetic nerve blockade.

Longer-acting ganglion blockers soon appeared, the prime example being hexamethonium.⁵³ In 1950 Restall and Smirk⁵⁴ published on the treatment of severe hypertension with two or three subcutaneous injections per day of hexamethonium. Despite orthostatic hypotension and a great number of other side effects, they reported regression of neuroretinitis, reduction of heart size, and clearing of the signs of heart failure.

RESERPINE, HYDRALAZINE, AND THIAZIDE DIURETICS

Reserpine is still a useful antihypertensive drug. Several Veterans Administration Cooperative studies^{55,56} demonstrated that the customary dose of 0.25 mg could be reduced to 0.1 mg per day without losing much if any antihypertensive effectiveness but with great reduction in side effects. Addition of a thiazide diuretic to reserpine in a 0.1 mg dose provided excellent blood pressure control with very few side effects. Because both drugs are inexpensive, they could be made available in third world countries as 1 tablet daily of either reserpine or a diuretic alone or in a fixed-dose combination tablet of reserpine with a thiazide diuretic. A fixed-dose combination of reserpine, hydralazine, and chlorothiazide with the brand name of "Ser-Ap-Es" was the most widely used treatment for hypertension in the 1960s to 1980 until other newer brand name drugs appeared.

Around 1980, a steady bombardment of U.S. physicians with questionable data about the toxicity of thiazide diuretics, especially deadly cardiac arrhythmias due to drug-induced hypokalemia, new onset diabetes, and increased serum cholesterol, convinced many physicians that thiazides are dangerous drugs. Sales of diuretics plummeted while sales of the new more expensive classes of drugs took over. Several physicians, including myself, wrote articles defending the diuretics, but to no avail until the early 1990s, when controlled clinical outcome trials in elderly patients demonstrated that diuretics are not toxic. Importantly, the ALLHAT study,⁵⁷ carried out in more than 42,000 older patients with hypertension plus at

least one other cardiovascular risk factor, demonstrated that thiazides are more effective than ACE inhibitors or calcium channel blockers in controlling blood pressure and reducing many of the cardiovascular complications of hypertension.

Chlorothiazide, the first thiazide diuretic, was discovered by Beyer and Sprague. It reduced extracellular volume to the same degrees as a strict low-salt diet, similar to a strict rice diet.³⁸ Thiazide diuretics were effective in controlling blood pressure in approximately 50% of patients, and also enhanced the antihypertensive effects of other drugs. This unique action has made possible the success of small-dose fixed dose combination drugs, one of the constituents being a diuretic.⁵⁸

When first administered, the thiazides reduce blood pressure by lowering cardiac output, but after several weeks of continued treatment, cardiac output returns to pretreatment levels and total peripheral resistance falls to maintain the reduction in blood pressure.⁵⁹ It is interesting that Ledingham,⁶⁰ Borst,⁶¹ and Guyton⁶² all observed the opposite effect during salt-loading hypertension. The early elevation of blood pressure with salt loading was due to an increased cardiac output, which after a month or more converted to a normal cardiac output, the hypertension being maintained by an increased total peripheral resistance. This has been called “delayed autoregulation” for the salt-loading hypertension⁶² and “reverse autoregulation”⁶³ in the response to the diuretics. The mechanism is unknown.

β-ADRENERGIC BLOCKING DRUGS

Prichard and Gilliam⁶³ were the first to demonstrate the effectiveness of β-blockers in reducing blood pressure and preventing its complications, as demonstrated in several controlled trials. β-Blockers were especially effective when combined with a diuretic. The various types of β-blockers are discussed in other chapters.

ACE INHIBITORS, ANGIOTENSIN RECEPTOR BLOCKERS, AND THE CALCIUM CHANNEL BLOCKERS

ACE inhibitors were developed in the late 1970s⁶⁴ and their close cousins, the angiotensin receptor blockers (ARBs), were developed about a decade later. They are major drug classes that block the actions of the renin-angiotensin system. These drugs and the calcium channel blockers are relatively recent important additions to the armamentarium of antihypertensive drugs and will be discussed in greater detail in other chapters.

CONTROLLED CLINICAL TRIALS

A most important advance with regard to prevention of cardiovascular complications in patients with hypertension was made possible by the new availability of methods for the prospective, unbiased evaluation of the efficacy and safety of antihypertensive drug treatment in preventing cardiovascular complications in patients with essential hypertension.

Until 1970 there were two schools of thought regarding antihypertensive treatment in patients with systolic/diastolic essential hypertension. The opinion of most, in part based on

autopsy evidence, was that hypertension was an adaptive response to provide adequate blood flow through the narrowed arteriolar channels in hypertension. Therefore, reducing the blood pressure would only make matters worse.⁴⁹ The opposing school, which was much smaller in numbers, believed that the constriction of the arterioles was due to unknown causes. It was further believed that it was the elevated blood pressure that caused the hyaline sclerosis of the arteriolar walls. This hypothesis further proposed that the complications of hypertension, such as accelerated atherosclerosis, were due to the elevated blood pressure. In fact, all of these complications such as myocardial infarction, heart failure, stroke, and renal damage, were consequences of the stresses induced by the hypertension. Isolated systolic hypertension was rightly considered to be caused by loss of distensibility of the elastic proximal aorta due to aging, but was not considered to be a subject of interest for antihypertensive drug treatment until some years later.

The first multiclinic prospective controlled double blind trial designed to determine unequivocally whether drug treatment was safe and effective was carried out by the Veterans Administration Cooperative Study Group. The results were reported in 1967 for the subgroup with severe hypertension (baseline diastolic blood pressures of 115 to 129 mm Hg)⁶⁵ and in 1970 for the patients with mostly moderate hypertension.⁶⁶ The prevention of morbidity and mortality was so great in the treated patients with severe hypertension compared with the placebo group that the study was discontinued in those severely hypertensive patients after approximately 1 year. The results for the patients with moderate (and a few with mild) hypertension, including those with pretreatment diastolic blood pressure between 90 and 114 mm Hg, were reported in 1970. The risk of developing a major cardiovascular complication over a 5-year period was significantly reduced with active treatment (combination of chlorothiazide, reserpine, and hydralazine) compared with placebo. The greatest reductions in the treated patients were in the incidence of stroke and heart failure. While the trend was favorable in the subgroup with mild hypertension, the sample size of the mild group (baseline diastolic blood pressure of 90/109 mm Hg) was too small to be statistically significant.

The Medical Research Council (MRC) trial⁶⁷ in 1985 and other trials^{68,69} were large enough and well enough controlled to determine that drug treatment is also effective in preventing complications in patients with mild hypertension. Subsequent trials have found that the further the blood pressure is reduced (to <140/90 mm Hg), the greater is the prevention of complications^{70,71} down to <130/80 mm Hg in patients with diabetes and chronic renal disease.

Other clinical trials, including the Systolic Hypertension in the Elderly Program (SHEP),⁷² demonstrated that antihypertensive treatment was equally or even more effective in preventing cardiovascular complications in elderly patients with isolated systolic hypertension as in middle-aged patients with both systolic and diastolic hypertension.

SUMMARY

It has been approximately 80 years since the Actuarial Society of America published their breakthrough book *Blood Pressure Study of 1925* that described the high mortality in

mild and moderate hypertension due to cardiovascular complications.⁷³

In 1905 Korotkov provided an instrument for making the measurement of blood pressure clinically possible. Hypertensive hormones and neurotransmitters such as renin, angiotensin, norepinephrine, epinephrine, and aldosterone, were discovered by 1950. Yet only a small fraction of patients had hypertension due to abnormalities in any of these mediators. Hypertension of unknown cause, so-called essential hypertension, is by far the most common form of hypertension occurring in humans.

Because autopsy studies showed that essential hypertension is associated with sclerotic thickening of the arteriolar walls, producing narrowed channels of the arterioles, it was formerly believed that elevated blood pressure was a compensatory reaction to provide normal blood flow through the narrowed arterial channels. Therefore, no attempts to reduce blood pressure were undertaken. However, controlled clinical trials beginning around 1970 proved that reduction of blood pressure with antihypertensive drugs significantly reduced cardiovascular complications.

In recent years it has been shown that the lower the blood pressure, the better, down to an optimal level of 120/80 mm Hg. The only way to accomplish this is to use combinations of antihypertensive drugs in adequate dosage. Currently doctors are being advised to be more aggressive even with those who have only mild hypertension and to use diet, exercise, and drugs such as statins to reduce the associated atherosclerosis.

We have come a long way during the past 100 years. We have learned to measure blood pressure, and recognize the risks for complications of hypertension and reduce them with antihypertensive drugs and other treatment.

The National High Blood Pressure Education Program

Edward J. Roccella

PROGRAM ORIGIN

Published in 1965, the Report of the Commission on Heart Disease, Cancer, and Stroke contains the recommendations of the subcommittee on hypertension. It calls for a nationwide increase in screening and treatment of high blood pressure.¹ Unfortunately, after publication of the report, no initiative was launched to address the problem, even though actuarial studies showed a clear relationship between rising blood pressure and increased chance of death, and several epidemiologic studies had reported a relatively high prevalence of hypertension in the U.S. population, with only a small percentage receiving adequate treatment.^{2,3} Although the report appeared to be ahead of its time, what was lacking was clear evidence regarding the benefits of lowering raised arterial pressure. That evidence soon came in a dramatic fashion with the 1967, 1970, and 1972 publications of the Veterans Administration Cooperative Study on the Treatment of Hypertension.⁴⁻⁶

LANDMARK MEETING

In April 1972, Elliott L. Richardson, then Secretary of the Department of Health, Education, and Welfare, met with Mrs. Mary Lasker, a longtime supporter of biomedical research and lobbyist for improving the nation's health; Mr. Michael Gorman, of the National Committee Against Mental Illness; Ms. Deeda Blair, a philanthropist associate of Mrs. Lasker; and Dr. Michael DeBakey, a noted cardiovascular surgeon. The purpose of their meeting was to convince Secretary Richardson that the moment had arrived for the federal government to take the initiative and begin a nationwide effort to reduce high blood pressure. During the meeting with the Secretary, Mrs. Lasker outlined the extraordinary findings of the soon-to-be-landmark Veterans Administration Cooperative Study on the Treatment of Hypertension, which was supported in part by the Lasker Foundation and conducted by Dr. Edward Freis. She emphasized that this science was not being applied in clinical practice and the nation was experiencing unprecedented rates of heart attack and stroke. Secretary Richardson was especially responsive to the suggestion to launch a national campaign to detect and treat hypertension. His father, a distinguished surgeon in Boston at the Massachusetts General Hospital, had suffered a career-ending stroke that was attributed to uncontrolled high blood pres-

sure and had spent the remaining 15 years of his life in a wheelchair. Secretary Richardson directed Dr. Theodore Cooper, Director of the then National Heart and Lung Institute (NHLI) to develop a national plan of action.

The fortunate temporal coincidence of a proven medical intervention, the active interest of major philanthropists and a noted cardiovascular surgeon, a favorable public policy position, and a personal interest of the key policymaker led to a rapid decision—the establishment of the National High Blood Pressure Education Program (NHBPEP), which was launched officially in July 1972. This education program was designed and implemented by the then NHLI staff to raise public awareness and stimulate blood pressure screening and treatment throughout the nation. Adding to the support for the NHBPEP was the enactment by Congress, on September 19, 1972, of the National Heart, Blood Vessel, Lung and Blood Act of 1972 (Public Law 92-423). This Act became the legislative basis for the NHBPEP by calling for expanded efforts in the areas of information dissemination and public and professional education, with special emphasis on certain areas, including hypertension.

Concurrently, Mrs. Lasker, Dr. DeBakey, and Dr. Malcolm Todd from the American Medical Association developed articles of incorporation to form Citizens for the Treatment of High Blood Pressure, a private-sector group that would work in tandem with the NHLI effort. Citizens would use its private-sector platform and join with the NHLI to focus its efforts on creating a national consciousness regarding high blood pressure as a medical problem. Early in 1973, Citizens encouraged Congress to enact legislation creating hypertension project grants for state health departments. Eventually passed in 1975, this legislation provided \$120 million to the states for hypertension screening and control over a period of a decade. Congress later gave large demonstration grants to seven states to test the research hypothesis that maximal screening and detection would reduce the prevalence of high blood pressure. Another important function of Citizens was to stimulate private-sector resources to address this large public health problem. The NHLI and other federal agencies could not provide all the funding needed to implement these initiatives. Armed with solid data regarding the significance of hypertension, Citizens and NHLI staff worked to push innovative programs, such as financial support from the life insurance industry for health education programs for high blood pressure detection and control. Demonstration programs on the cost-effectiveness of hypertension screening and control were conducted at worksites.^{7,8} The spirited collaboration of the people involved launched and then vitalized the NHBPEP program over the years, contributing immensely to advancement of the health of the American people.

The National High Blood Pressure Education Program by Edward J. Roccella, Ph.D., is in the Public Domain.

PROGRAM TENETS

Strong Science Base

From the inception of the NHBPEP, the program planners recognized the need to ground the program activities to a strong science base. The congressional act that established the program mandated the need to translate health information into positive action because research results were not being used to improve the public's health. Large-scale community-based education programs and messages would not go forward unless there was a scientific rationale and data to support them.

Achieving Consensus

It is reasonable to expect that different people might have different points of view regarding the interpretation of data generated in research studies. From the beginning, the opinions of professional and voluntary societies—such as the American College of Cardiology, the American Heart Association, the American Hospital Association, the American Medical Association, the American Osteopathic Association, the National Medical Association, and the National Kidney Foundation—were actively sought. All points of view would be heard. It became clear that differences of opinion needed to be resolved so that the health and medical professions could provide clear and consistent messages to the public, patients, and practicing physicians. To avoid confusion, the program needed to speak with one voice. For example, at the time, hypertension was defined in various ways. Some suggested that hypertension was defined as systolic blood pressure (SBP) of 100 mm Hg plus one's age, whereas others defined it as diastolic blood pressure (DBP) greater than 105 mm Hg. Thus, consensus became another critical program tenet.

To achieve consensus among the major scientific, professional, voluntary societies and federal agencies, the NHBPEP Coordinating Committee was formed to serve as a policymaking body.⁹ This committee has now grown to represent 39 professional and voluntary societies and 7 federal agencies. Its purpose is to review the scientific evidence, develop clear messages, agree on national priorities, and then develop and implement program activities. Each of the member organizations brings a different perspective to the hypertension arena. Some organizations have a clinical perspective; others have strong interests in subsets of the population, such as minorities, who experience an unusually high burden of the consequences of hypertension; and yet others have a population-wide or public health interest. The representatives participating in the Coordinating Committee are selected by their parent organizations, not by the NHBPEP. The intent of this approach is to increase the probability that consensus, once adopted, will have credibility and be widely implemented by the Coordinating Committee member organizations.

Evaluation

A third program tenet has been evaluation of activities. The approach of the NHBPEP always has been geared toward evaluation as an early step prior to implementation. Defining a problem before implementation—using outcome data to the extent that resources, opportunity, and the state-of-the-art

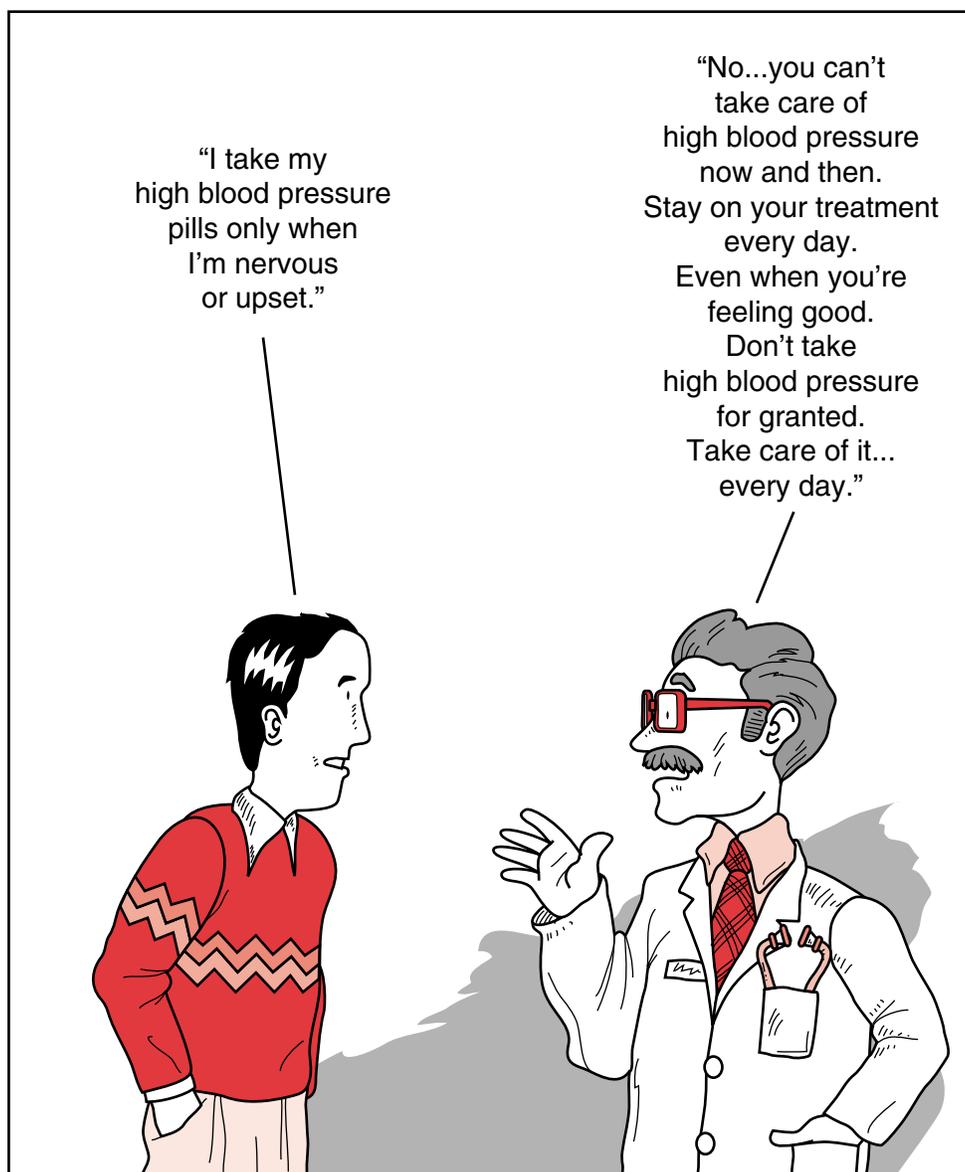

permit—is a core planning tenet for the program. Evaluation data include national baseline surveys of the public's knowledge, attitudes, and reported behavior; surveys of physicians' response to hypertension therapy selection and management; and data on prescribing patterns and patient visits. Other efforts include gathering and analyzing data on hypertension prevalence and control rates as well as trends in morbidity and mortality rates for stroke, coronary heart disease (CHD), heart failure, and end-stage renal disease (ESRD). This information helps track program progress and is useful in identifying program deficits and planning future direction and activities.

MASS MEDIA EFFORTS

To reach the many different people in the United States with high blood pressure, education messages require that the target audience be partitioned in various ways. The audience to be reached is divided into those who are unaware of their condition; those who are aware but are doing little, if anything, to control their blood pressure; those who are aware, treated, and controlled but who need reinforcement to stay on therapy; and those who are aware, were treated, but dropped out of care and require advice and motivation to reenter treatment. Those without hypertension are candidates for primary prevention messages, or they may reinforce needed action by friends or relatives who do have elevated blood pressure. The target audiences can be further segmented by sex, race, age, ethnicity, and other factors. For all these different groups, high blood pressure may have different meanings. Accordingly, the messages and skills required, as well as the channels of communication and even the language spoken, may be different. Figures 2-1 and 2-2 are examples of messages designed to reach different audiences.

Leveraging Program Resources

A multitude of communication channels and activities must be used to reach the many target populations with the NHBPEP's science- and consensus-based messages. Program partners are called upon to adapt existing materials and distribute them to their constituents. The American Medical Association, the American Heart Association, the National Kidney Foundation, the International Society of Hypertension in Blacks, and city, county, and state health departments have developed their own print, radio, and television high blood pressure education materials aimed at various target audiences. The National Heart, Lung, and Blood Institute (NHLBI) program staff developed a unique semi-preproduced television program on hypertension, called "Silent Killer," and successfully marketed it to a number of television and radio talk shows. The product was packaged as a kit and contained film clips and a script that could be used verbatim or as a guide for the local television host with questions and answers allowing dialog among the host and guests—usually local physicians and nurses. More than 5000 kits were distributed throughout the nation. In collaboration with Safeway grocery stores, a high blood pressure message was printed on grocery bags. More than 1 million shopping bags were distributed with messages encouraging Americans to control their hypertension.

Figure 2-1 A public service message on high blood pressure education and prevention targeting individuals with hypertension.

HIGH BLOOD PRESSURE EDUCATION MONTH

Another highly visible program strategy designed to stimulate community-based action and sustain interest in hypertension is High Blood Pressure Education Month, which is May of each year. Each year, a kit of program-planning materials is designed, produced, and distributed to state and local health departments, community hospitals, voluntary health organizations, and civic groups. The kit contains suggested print ads, camera-ready artwork, suggested newspaper articles, community activity ideas, and heart-healthy recipes. It also features proclamations to be signed by

governors, mayors, or local dignitaries declaring May as National High Blood Pressure Education Month and recommending that citizens get their blood pressure measured and, if needed, treated and controlled. Participating organizations are encouraged to put their names on the materials to increase their own visibility and to work harder to disseminate the message.

High Blood Pressure Education Month also encourages communities to conduct education and screening programs at churches.¹⁰ This forum became a successful way to reach African Americans, who have a high prevalence of hypertension and risk of cardiovascular disease. A program-planning guide was developed to provide direction for health

**HIGH BLOOD PRESSURE
Never helps higher profits**

Think about it. More than 29 million work days, (\$2 billion in earnings) are lost in the U.S. annually because of high blood pressure-related diseases, like heart attack, stroke and kidney disease.

Think about all those non-productive days it's cost you in sick leave, disability, and high insurance premiums.

Now think about paying for something that's going to pay off for you. A High Blood Pressure Control Program that's right for your company. A program that will help keep your employee's blood pressure down and your production up.

Think about it. Then write: Work Place Coordinator, National High Blood Pressure Education Program, 120/80 National Institutes of Health, Bethesda, MD 20205

**High Blood Pressure Control Programs
BETTER FOR BUSINESS**

professionals to reach out to religious congregations to implement programs to reduce the risk of cardiovascular disease.¹¹ In an effort to reach men, a planning guide was created to develop high blood pressure education and screening programs at sporting events.¹² Hypertension screening and education programs were conducted at professional baseball and hockey games, at high school football games, golf tournaments, and basketball games.

THE JOINT NATIONAL COMMITTEE REPORTS

When the U.S. Congress passed a law creating the NHLI (now the National Heart, Lung, and Blood Institute [NHLBI]) and directing its function—to improve the health of the people of the United States through the conduct of research, investigations, experiments, and demonstrations relating to the cause,

prevention, and methods of diagnosis and treatment of diseases of the heart and circulation—it also indicated that the obligation to the public would not be fulfilled even if and when every research project was completely successful. The Institute was directed to develop and implement methods of public and professional education in disease prevention and control. This directive is completely compatible with the responsibility of the NHBPEP. The translation of research results into practice is a natural complement to the research program, and the NHBPEP facilitates this process.

One important tool that the NHBPEP has fostered is the development of clinical guidelines and working group reports.¹³⁻³⁵ These guidelines are developed in partnership with the Coordinating Committee member organizations. The first clinical guideline was titled the Joint National Committee (JNC) on the Detection, Evaluation, and Treatment of High Blood Pressure, which published its report in 1977.²⁹ The JNC report was designed to bring order to a then-chaotic situation regarding hypertension management. At that time many clinicians were of the opinion that elevated blood pressure was needed to perfuse the organs of the body and there was little reason to lower blood pressure. Thus, the important findings of Freis and colleagues were not being applied to practice. In addition, there was confusion regarding whether to use the fourth or fifth Korotkoff sound to measure DBP and regarding which drug to use as the initial therapy for treating hypertension. The first JNC document provided consensus regarding key hypertension detection and control issues, with clinical recommendations based on the available scientific evidence. In making their recommendations, the JNC reports have evolved to address difficult questions, such as the cutpoints to be used to define hypertension, which antihypertensive drugs should be used first and why, and careful assessment of absolute versus relative risk of cardiovascular disease and what this means to the responsible physician. Through the years, the program produced seven JNC reports at approximately 4- to 5-year intervals, each report building on the evidence and making recommendations to the practicing community.²⁹⁻³⁵ The JNC reports have been a critical component of the NHBPEP. The intent has always been to synthesize the available scientific evidence and then to unify the positions of member organizations and send one clear message. One challenge has been to achieve consensus among the many organizations on the Coordinating Committee. Having the many organizations on the Coordinating Committee agree on strategies to prevent and manage hypertension and to speak with one voice helps to bring clear messages and guidance to the health professionals. The JNC documents demonstrate that different disciplines can agree when the focus is on the common good.

RESULTS OF THE NATIONAL HIGH BLOOD PRESSURE EDUCATION PROGRAM

A variety of methods have been used to measure program impact. Process measures employed included the number of health education activities, materials produced and distributed, news articles written, people having their blood pressure measured, antihypertensive drug sales, and reported changes in behavior. In the early days of the NHBPEP, the evaluation process was rudimentary at best. With insight and gradual maturing overtime, it became clear that what really mattered were changes leading to improvement in health status and outcome.

Table 2-1 shows the changes in hypertension prevalence during the last 40 years. In the first three-point estimates, the age-adjusted hypertension prevalence remained fairly stable, with approximately 40% of the population reporting blood pressures >140/90 mm Hg or taking antihypertensive medication. Then, during the 1980s, the prevalence of hypertension declined. While the reason for this reduction is subject to discussion, some of this decline is associated with activities that encouraged the American public to take action, such as increasing fruit and vegetable consumption and decreasing sodium intake. The increase in the prevalence of hypertension from 1999 to 2000 may be attributed in part to the national obesity epidemic.³⁶ Figure 2-3 describes changes in mean arterial blood pressure associated with NHBPEP activities. It is clear that the average blood pressure for the nation has declined. This decline is associated with a reduction in mortality. Table 2-2 describes trends in the public's awareness of hypertension as reported in the National Health and Nutrition Examination Survey for adults ages 18 to 74. Awareness rates have substantially improved from half to nearly three fourths of the hypertensive population.

In addition to increasing the public's awareness about hypertension, the NHBPEP also appears to have interested scientists and clinical investigators to seek more information about the condition and has stimulated interest in hypertension research. Figure 2-4 shows the number of reported citations from the National Library of Medicine's PubMed database accessed by using the search terms *hypertension* and *clinical trials*, indicating that high blood pressure research and subsequent publications have grown steadily.

Table 2-2 shows that high blood pressure treatment and control rates have improved rather remarkably in the years since creation of the NHBPEP. Blood pressure was controlled

in more than 34% of the hypertensive population in 1999 to 2000. Because hypertension is the primary antecedent of congestive heart failure, the decrease in prevalence, reduction in mean arterial pressures, and improvement of hypertension control rates suggest that the prevalence of heart failure should also decrease. Figure 2-5 shows the age-adjusted prevalence of heart failure by race and sex for persons ages 25 to 74 over the years since the NHBPEP began. The prevalence of heart failure in this population has declined in both races and in both sexes. Because hypertension is also associated with ESRD, the decline in average blood pressure and improvement in the hypertension control rate should also decrease the incidence of ESRD. While ESRD has been increasing, Figure 2-6, which shows the incidence rates by primary diagnosis, indi-

cates that hypertension is no longer as great a contributor to this condition as diabetes.

Large-scale clinical trials have shown that controlling hypertension will reduce CHD and stroke regardless of race or gender. Figures 2-7 and 2-8 show 60% and 50% declines in age-adjusted mortality for stroke and CHD, respectively, during the last 30 years. These declines are seen in both genders and races. It should be noted that the decline in CHD and stroke preceded the advent of the NHBPEP. Figure 2-9 shows age-adjusted stroke mortality rates beginning with 1960. If a regression line is plotted for the years 1960 to 1971 and then cast forward, the expected rates of stroke mortality can be plotted. However, beginning at the point of NHBPEP inception, the observed rates were much lower than expected and many more people who were projected to die of stroke were alive. The precise contribution of the NHBPEP to improving this disease outcome will never be known, but it is hoped the steady decline in deaths from stroke and CHD will continue in synchrony with the efforts of the NHBPEP. The NHBPEP is clearly the dividend of a very worthwhile investment promulgated by Mrs. Lasker and colleagues. The nation owes its gratitude to these

Epidemiology of Hypertension

Nathan D. Wong, Stanley S. Franklin

Approximately 50 million individuals in the United States and 1 billion worldwide are affected by hypertension.¹ There are, however, important differences in prevalence between populations and ethnic groups.²⁻⁴ Although there is a dramatic age-related increase in the prevalence of hypertension, several important cardiovascular risk factors, particularly obesity, nutrient intake, physical activity, and diabetes also relate to the likelihood of hypertension. The Framingham Heart Study has estimated that individuals normotensive at age 55 years have a 90% lifetime risk of developing hypertension.⁵ Hypertension represents a potent risk factor for cardiovascular, peripheral vascular, and renal disease⁶⁻¹⁰ (Figure 3-1). The higher the blood pressure, the greater is the likelihood of myocardial infarction, heart failure, stroke, and kidney disease. This chapter reviews the prevalence and natural history of hypertension, the risk factors associated with the development of hypertension, the cardiovascular risks associated with hypertension, and the extent of treatment and control of hypertension.

CLASSIFICATION OF HYPERTENSION

Blood pressure (BP) is continuously distributed with a skewed normal distribution and without distinct separation between normotensive and hypertensive values. It has been suggested that the cutpoint for hypertension is best defined as the level of arterial BP at which the benefits of intervention exceed those of inaction. Over the decades the classification of hypertension has changed as a result of (1) the decrease in severity of hypertension over the past half century, (2) the improvement in the efficacy and side effect profile of antihypertensive medications, and (3) the recognition of the continuum of cardiovascular risk across all levels of BP. This has resulted in a gradual reduction in the lower limits of target BP for therapeutic intervention.

The most recent definition of hypertension as released by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)¹ is a systolic blood pressure (SBP) ≥ 140 mm Hg or diastolic blood pressure (DBP) ≥ 90 mm Hg, which simplifies hypertension classification by including only stage 1 (SBP 140-159 mm Hg or DBP 90-99 mm Hg) or stage 2 (SBP 160 mm Hg or higher or DBP 100 mm Hg or higher) (Table 3-1). Perhaps the most important change is the new classification of “prehypertension” (SBP 120-139 mm Hg or DBP 80-89 mm Hg), which combines the normal and high-normal categories of the previous JNC VI report, in recognition of the fact that even these levels of BP confer an increased risk of the development of hypertension¹¹ and future cardiovascular events.¹² Individuals with prehypertension may require health-promoting lifestyle modification to prevent the development of future hypertension and cardiovascular disease.

PREVALENCE OF HYPERTENSION

The Fourth National Health and Nutrition Examination Survey⁴ (NHANES IV) showed an overall prevalence of hypertension (140 mm Hg SBP or greater or 90 mm Hg DBP or greater, or on antihypertensive medication) of 28.7% in 1999-2000, which varied from 7.2% in those aged 18 to 39 years to 65.4% in those aged 60 years and older, and which was greater in women (30.1%) than in men (27.1%). Noteworthy is the fact that since 1988-1991 the prevalence of hypertension has increased significantly in women and in all age groups, although most dramatically in those aged 60 and older, who experienced an increase in prevalence from 57.9% in 1988-1991 to 65.4% in 1999-2000 (Figure 3-2). Moreover, in the United States, prevalence of hypertension is greatest among non-Hispanic Blacks and least among Mexican Americans⁴ (Figure 3-3).

Compared with the United States, data primarily from the past decade have shown that the prevalence of hypertension is similar in Canada, but is markedly higher in European countries (44% overall, 55% in Germany)³ (Figure 3-4). The specific reasons for such substantial geographic variation in hypertension prevalence are not entirely clear, but differences in nutrient intake, obesity, physical activity, alcohol intake, environmental toxins, psychosocial stressors, and genetic susceptibility have been suggested.¹³

CHARACTERISTICS OF HYPERTENSION AS A RISK FACTOR

Numerous epidemiologic studies have consistently shown a relation of increased BP to risk of cardiovascular disease. The relationship is *strong, continuous, and graded* without any distinct threshold level; it is present both in men and in women, in younger and older adults, and in those with and without known coronary heart disease (CHD); it is present in different countries and in different ethnic and racial groups. As with other risk factors, there is evidence of *tracking of BP*, which refers to the stability of BP over time in an individual in relation to his or her peers. Of note, however, there is evidence of *disparate rather than parallel tracking of BP*, whereby an individual in the upper quintile or decile of BP will have a much steeper age-BP relationship than one in the lower quintile or decile of BP. Although the lability of BP is directly related to age and severity of hypertension, suggesting that it may also relate to cardiovascular risk, when other risk factors are accounted for by multivariate analysis, risk is largely unaffected by lability of BP. It is the average BP over the day and night cycle, not lability, that determines cardiovascular risk.

CARDIOVASCULAR COMPLICATIONS OF HYPERTENSION

Early reports by the Framingham Heart Study demonstrated that hypertension, SBP, and DBP are risk factors for CHD,^{9,10} helping dispel a longstanding belief that the common variety of hypertension was a benign condition essential for ade-

quate perfusion of peripheral tissues. A 36-year follow-up from the Framingham Heart Study showed that hypertension is associated with twofold to fourfold increases in risk for the development of CHD, stroke, peripheral artery disease, cardiac failure, and overall cardiovascular events in both men and women.¹⁴ The Seven Countries Study provided strong ecologic study evidence demonstrating a direct relation of SBP and DBP within 16 communities to CHD death rates, showing a doubling in risk for every increment of 10 mm Hg in the population's median SBP.⁶ Among middle-aged men screened in the Multiple Risk Factor Intervention Trial (MRFIT), a direct relation of increasing SBP and DBP with CHD mortality over 11.6 years was shown.⁷ Moreover, a pooling of results from 418,343 persons initially free of CHD showed CHD mortality to begin increasing at levels of DBP above 73 mm Hg and to increase more than fivefold between levels of 73 and 105 mm Hg.¹⁵ A meta-analysis has further emphasized the importance of increasing risk above normotensive levels, showing that starting at an SBP/DBP of 115/75 mm Hg, cardiovascular mortality doubles with each increment of 20/10 mm Hg throughout the BP range.¹⁶ In the Framingham Heart Study, more than a third of those with high-normal BP (130-139 mm Hg SBP or 85-89 mm Hg DBP) developed hypertension in the next 4 years (Figure 3-5).¹¹ Compared with those with "optimal" BP of <120 mm Hg SBP and <80 mm Hg DBP, those with high-normal BP also had nearly a threefold greater incidence of developing major cardiovascular events in the next 12 years (Figure 3-6).¹²

Left ventricular hypertrophy (LVH) is a particularly important independent risk factor for cardiovascular disease, and is the response of the heart to chronic pressure and/or volume overload. Hypertension often precedes the development of LVH. The Framingham Heart Study has demonstrated the highest (versus lowest) quartile of left ventricular mass to be associated with a fourfold increased risk of cardiovascular events in women and a threefold increased risk of events in

men.^{17,18} It has been well demonstrated that aggressive control of hypertension can prevent the development or induce regression of LVH.¹⁹

The incidence of stroke and peripheral arterial disease also increases dramatically with increasing BP, particularly SBP. Stroke incidence is approximately three times greater in persons with stage 2 systolic hypertension (160 mm Hg or greater) and 50% higher in those with stage 1 systolic hypertension (140-159 mm Hg) compared with those with BP below these levels. From a 50-year follow-up of the Framingham Heart Study, elevated midlife BP during the prior 10 years is associated with a significant 1.7-fold increase in the risk of stroke per standard deviation increment in women and a 1.9-fold increase in risk per standard deviation increment in men at age 60.²⁰ Of those experiencing stroke, 30% have stage 1 hypertension and 40% stage 2 hypertension (with half of this latter group having SBP of 180 mm Hg or

greater). Framingham has also shown peripheral arterial disease (intermittent claudication) risk to increase dramatically by approximately threefold in men and more than fourfold in women from the first through fifth quintiles of SBP, and approximately twofold across quintiles of DBP.²¹

Finally, the relation of increasing BP levels to incidence of end-stage renal disease (ESRD) is well documented. MRFIT showed the multivariate-adjusted relative risk of ESRD to be 1.7 in men for every 16 mm Hg increment in SBP. Baseline SBPs of >140 mm Hg were associated with a fivefold to sixfold greater risk for the development of ESRD compared with SBPs below 117 mm Hg.²² Risk of developing ESRD is graded and continuous throughout the entire distribution of BP above optimal. Even persons with high-normal BP have approximately a twofold greater risk of developing ESRD and those with stage 2 hypertension have a sixfold or greater risk of developing ESRD compared with those with optimal BP.²²

AGE-RELATED INFLUENCES ON BLOOD PRESSURE AND RELATION TO CORONARY HEART DISEASE RISK

Approximately 25% of persons with hypertension are younger than 50 years old, with the remaining 75% 50 years old or older; 45% of all persons with hypertension are 50 to 69 years of age.²³ Application of JNC 7 BP categories to recently released 1999-2000 data from NHANES IV shows that among adults younger than the age of 50, nearly 30% are prehypertensive. Prevalence of hypertension (SBP \geq 140 mm Hg or DBP \geq 90 mm Hg or reporting hypertension medication use) increases dramatically by age, accounting for 7% of subjects aged 18 to 29, 16.6% of those aged 30 to 39, 33% of those aged 40 to 49, and 54% of those aged 50 to 59 years. By the seventh decade of life, approximately 70% are hypertensive, increasing to more than 80% in those aged 80 and older. After age 60, less than 20% of persons have BP in the normal range (<120 mm Hg SBP and >80 mm Hg DBP) (Figure 3-7).

Of particular interest is the transition of hypertension subtype with increasing age among those untreated for hypertension. From NHANES 1999-2000 data, the predominant

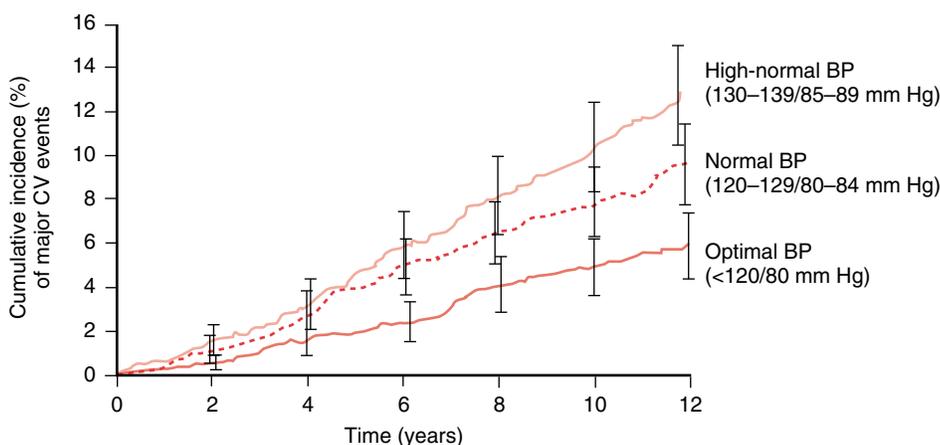

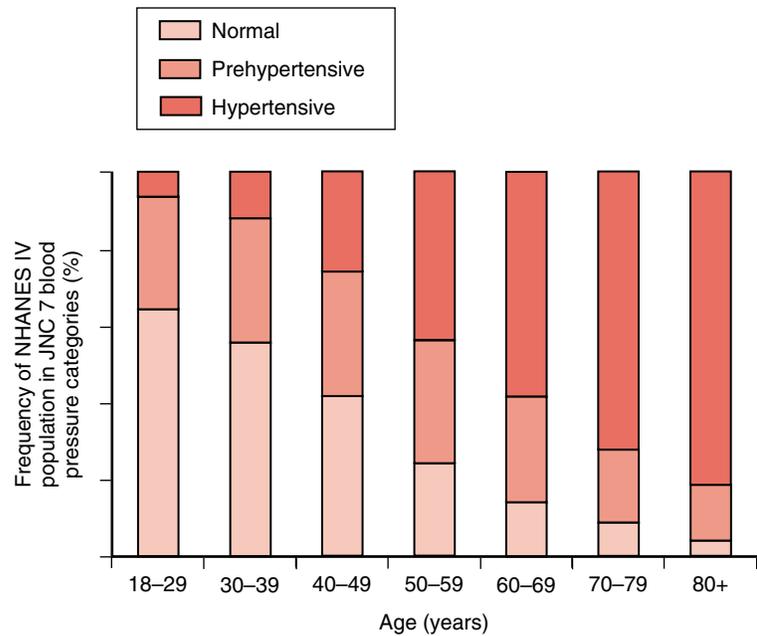

Figure 3-6 Impact of high-normal BP on risk of major cardiovascular events in men. These events are defined as death resulting from cardiovascular disease: recognized myocardial infarction (MI), stroke, or congestive heart failure. Adapted from Vasan RS, Larson MG, Leip EP, et al. Impact of high-normal blood pressure on the risk of cardiovascular disease. *N Engl J Med* 345:1291-1297, 2001.

Figure 3-7 Distribution of blood pressure categories in the JNC 7 guidelines among population in NHANES 1999-2000 by age.

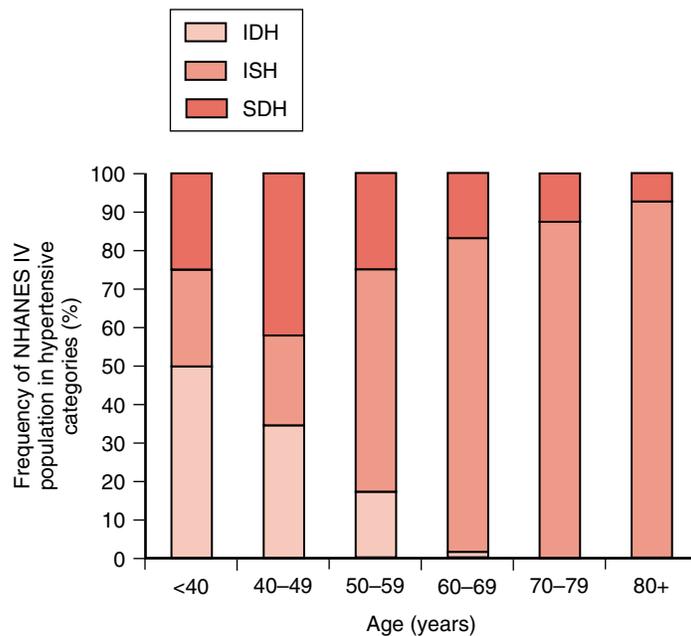

$p < .0001$ comparing distribution of blood pressure categories across age groups

form of hypertension among those younger than 40 years old is isolated diastolic hypertension (IDH) (SBP <140 mm Hg and DBP \geq 90 mm Hg), which accounts for 60% of those with hypertension in this age group (Figure 3-8). During ages 40 to 49 there are roughly equal proportions of IDH (SBP <140 mm Hg and DBP \geq 90 mm Hg) and systolic-diastolic hypertension (SDH) (SBP \geq 140 mm Hg and DBP \geq 90 mm Hg), which together account for three fourths of persons with hypertension. Beginning at age 50, the most predominant form of hypertension is isolated systolic hypertension (ISH), accounting for more than 75% of those with hypertension aged 50 to 59, approximately 80% of hypertension in those aged 60 to 69,

and approximately 90% of those with hypertension aged 70 years or older (see Figure 3-8). Thus, ISH is the most common subtype of hypertension and SBP is less likely to be under control than DBP.²⁴ Because guidelines classify hypertension on the basis of which component (SBP or DBP) is in the higher category, the majority of persons with hypertension can be defined based on (or “upstaged” by) SBP, leading to a 94% accurate classification of BP by assessment of SBP alone. In contrast, among those aged 18 to 49 years, 65% of individuals with untreated hypertension in the NHANES III population were upstaged by DBP alone.²⁴ This indicates SBP is the more important overall determinant of upstaging of untreated

Figure 3-8 Distribution of hypertension subtype in the untreated hypertensive population in NHANES 1999-2000 by age.

$p < .0001$ comparing distribution of hypertension groups across age categories

hypertension and hence eligibility for therapy in the population, because the great majority of individuals with untreated or inadequately treated hypertension are 50 years of age or older, with an 80% prevalence of ISH.²⁴

Both cross-sectional²⁵ and longitudinal population studies²⁶ demonstrate that SBP rises from adolescence through most of adulthood, whereas DBP initially increases with age, but levels off at ages 50 to 55 and decreases after ages 60 to 65. Thus pulse pressure (PP), defined by the difference between peak SBP and end-diastolic BP, increases after ages 50 to 55, a change that is accelerated from the ages of 60 to 65 and older. The rise in SBP and DBP up to ages 50 to 55 can best be explained by the dominance of peripheral vascular resistance. In contrast, after the sixth decade of life (1) increasing PP and decreasing DBP are surrogate measurements for central elastic artery stiffness; (2) central arterial stiffness overrides increased systemic vascular resistance and becomes the dominant hemodynamic factor in both normotensive and hypertensive individuals, as manifested by an increase in SBP, a decrease in DBP, and hence, a rise in PP; and (3) hypertension, left untreated, may accelerate stiffening of elastic arteries, which, in turn, may set up a vicious cycle of worsening hypertension and further increases in elastic artery stiffness.²⁶

BLOOD PRESSURE COMPONENTS AS PREDICTORS OF RISK

An increased SBP alone has been well documented to be associated with increased risks of CHD, myocardial infarction, kidney failure, stroke, heart failure, and peripheral vascular disease (Table 3-2).^{22,27-30} In the MRFIT study, whereas those with the highest SBP had the highest risk of CHD mortality, a

particularly increased risk was observed for those with the highest SBP (>160 mm Hg) in conjunction with the lowest diastolic BP (<70 mm Hg) and, therefore, the highest PP (Figure 3-9).²⁷

Moreover, in the Framingham cohort, future CHD risk in those ages 50 and older and free of clinical cardiovascular disease was inversely correlated with DBP at any level of SBP ≥ 120 mm Hg, suggesting that PP was an important component of risk.³¹ This suggests that PP may be useful as an adjunct to SBP in predicting risk. A strong independent association of higher levels of SBP and lower levels of DBP with thoracic aortic calcium, an indicator of atherosclerosis, is evidence of the significance of increased PP in the etiology of arterial stiffness and atherosclerosis.³² Numerous other reports have also shown that at a given level of SBP, there is an inverse relation of CHD risk with DBP, indicating PP as superior to the reference SBP in predicting total and cardiovascular mortality and CHD risk.³³⁻³⁷

Additional information relating BP indices to CHD risk emerged from the Framingham Heart Study when individuals younger than 50 years of age were examined.³⁸ In this younger group, DBP was a more powerful predictor of CHD risk than SBP; PP was not predictive. With increasing age there was a continuous, graded shift from DBP to SBP and eventually to PP as predictors of CHD risk. From age 60 and older, when considered with SBP,³⁸ DBP was negatively related to CHD risk, so PP emerged as the best predictor. The bias in favoring DBP over SBP as a risk factor by earlier generations of physicians may, in part, be due to the emphasis on hypertension as a young person's condition. However, with the aging of the population over the past half-century, hypertension has become largely a condition affecting older persons with ISH.

Table 3-2 Relative Risks of Cardiovascular and Renal Diseases Associated with Elevated Systolic Blood Pressure

Disease	Relative Risk
Kidney failure (ESRD)	≥ 2.8
Stroke	≥ 2.7
Heart failure	≥ 1.5
Peripheral vascular disease	≥ 1.8
Myocardial infarction*	= 1.6
Coronary artery disease	≥ 1.5

IMPACT OF OTHER CARDIOVASCULAR RISK FACTORS AND TARGET ORGAN DAMAGE

Hypertension is usually accompanied by other cardiovascular risk factors and is metabolically linked to dyslipidemia, glucose intolerance, abdominal obesity, and hyperinsulinemia. Only about 20% of the time does hypertension occur in isolation. About half of the persons with hypertension have two or more other accompanying risk factors. The clustering of other CHD risk factors adds to the importance of hypertension as a risk factor. For example, in a hypothetical 55-year-old adult with hypertension, the estimated 10-year risk of CHD is expected to increase fourfold to fivefold from the additional impact of several other CHD risk factors.¹⁴ Both traditional and new cardiovascular risk factors from JNC 7, as well as examples of target organ damage, are listed in Box 3–1.¹ The following have been added to the traditional risk factors of age, family history of hypertension, cigarette smoking, diabetes mellitus, and dyslipidemia: (1) obesity (body mass index ≥ 30 kg/m²), (2) physical inactivity, and (3) microalbuminuria (50–300 mg of urinary albumin/24 hours). The European Society of Hypertension³⁹ has added elevated high-sensitivity C-reactive protein (>3 mg/L) as a risk factor. The presence of one or more of these risk factors greatly increases the rationale for more intensive treatment to BP goal levels, as well as consideration of therapy at lower cutpoints. This is demonstrated well by data from the Multiple Risk Factor Intervention trial, showing a substantial additive impact of type 2 diabetes on the risk of CHD conferred by increasing SBP levels (Figure 3–10).⁴⁰

Box 3–1 Cardiovascular Risk Factors and Target Organ Damage

Major Risk Factors

- Hypertension*
- Cigarette smoking
- Obesity (BMI ≥ 30 kg/m²)*
- Physical inactivity
- Dyslipidemia*
- Diabetes mellitus*
- Microalbuminuria or estimated GFR <60 ml/min
- Age (>55 years for men, >65 years for women)
- Family history of premature cardiovascular disease (men <55 years or women <65 years)

Target Organ Damage

- Heart (left ventricular hypertrophy, angina or prior myocardial infarction, prior coronary revascularization, or heart failure)
- Brain (stroke or transient ischemic attack)
- Chronic kidney disease
- Peripheral arterial disease
- Retinopathy

Adapted from Chobanian AV, Bakris GL, Black HR, et al. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. The JNC 7 Report. JAMA 289:2560-2572, 2003.

*Components of the metabolic syndrome.

BMI, body mass index; GFR, glomerular filtration rate.

SIGNIFICANCE OF HYPERTENSION IN THE METABOLIC SYNDROME

There is general agreement that people with the metabolic syndrome are at increased risk of developing cardiovascular disease and diabetes (see Chapter 13).⁴¹ Indeed, the cluster of abnormalities associated with the metabolic syndrome are probably more important than any single risk factor in predisposing to CHD. According to the Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (ATP III),⁴¹ the metabolic syndrome is defined as consisting of three or more of the following abnormalities: waist circumference >102 cm in men and >88 cm in women (abdominal obesity); serum triglycerides level ≥ 150 mg/dl (1.69 mmol/L); high-density lipoprotein (HDL) cholesterol level <40 mg/dl (1.04 mmol/L) in men and <50 mg/dl (1.29 mmol/L) in women; BP $\geq 130/85$ mm Hg or being treated for hypertension; and a fasting serum glucose level of 110 mg/dl (6.1 mmol/L) or higher. (Some experts recommend separating diabetes from this definition, because specific treatment goals for BP and hypercholesterolemia exist for diabetics who should be treated as having a CHD risk equivalent.) (See Table 3–3.)

One study of U.S. adults with the metabolic syndrome reported that more than 80% of those satisfying these criteria (excluding those with diabetes who are universally considered high risk, warranting aggressive clinical management) had elevated triglycerides, low HDL cholesterol, and elevated BP. In this sample, 83% of men and 87% of women with the metabolic syndrome had elevated BP (SBP/DBP of 130/85 mm Hg or higher, or on treatment) consistent with the ATP III criteria (Figure 3–11).⁴² Approximately one fourth of U.S. adults have the metabolic syndrome (including those with diabetes), although this varies dramatically with age, with prevalence increasing to near 40% in older age groups.⁴³ There is also great variation in risk among those with the metabolic syndrome; most women are at low or intermediate risk, whereas most men are at intermediate or high global risk ($>20\%$ calculated risk of CHD in the next 10 years), the latter of which would constitute a CHD risk-equivalent by ATP III standards.⁴² Moreover, projections have estimated that BP control, ideally to optimal levels, and preferably combined (lipid and BP) risk factor management, can prevent the vast majority of CHD events.⁴²

RELATIVE VERSUS ABSOLUTE RISK ASSESSMENT AND PROJECTION OF TREATMENT BENEFIT

Over the past several decades, there has been a gradual evolution from the use of *relative risk* to *absolute risk* as the basis of deciding whom and when to treat. Relative risk quantifies the likelihood of future cardiovascular events in a “hypertensive” population in comparison with a “normotensive” reference population, with impact most frequently expressed as a risk ratio (RR). In contrast, absolute risk imparts information as to the expected absolute incidence of cardiovascular deaths or morbid events. In calculating absolute risk, one must not only include hypertension as a risk factor, but also age, gender, and all other major cardiovascular risk factors that commonly cluster with hypertension^{1,43} (see Chapter

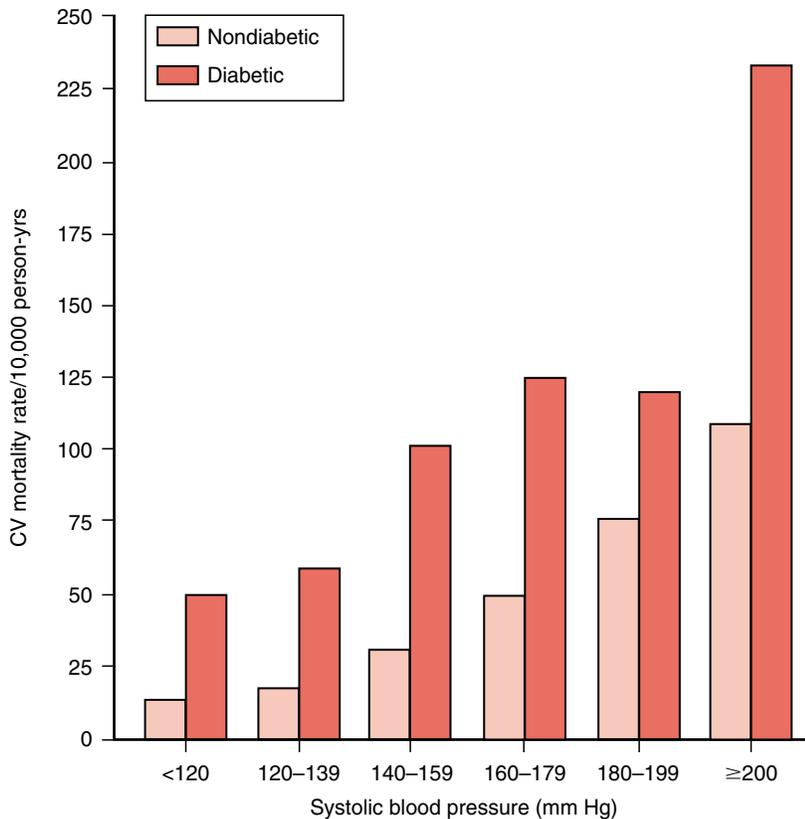

Figure 3-10 MRFIT: Association between systolic blood pressure and cardiovascular (CV) death in type 2 diabetes. Adapted from Stamler J et al. Diabetes, other risk factors, and 12-yr cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. *Diabetes Care* 16:434-444, 1993.

21). Over the past decade there have been many national and international guidelines for antihypertensive therapy that have used absolute risk in varying degrees to assist physicians in decision making.

Table 3-3 Criteria for the Metabolic Syndrome (without diabetes)*

Risk Factor	Defining Level
Abdominal obesity [†]	
Waist circumference [‡]	
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglyceride	≥150 mg/dl
High-density lipoprotein cholesterol	
Men	<40 mg/dl
Women	<50 mg/dl
Blood pressure	≥130/≥85 mm Hg or treated
Fasting glucose [§]	≥110 mg/dl

Modified from the executive summary of the third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *JAMA* 285:2486-2497, 2001.

*Diagnosis is established when three or more of these risk factors are present.

[†]Abdominal obesity is more highly correlated with metabolic risk factors than is ↑ body mass index.

[‡]Some men develop metabolic risk factors when circumference is only marginally increased.

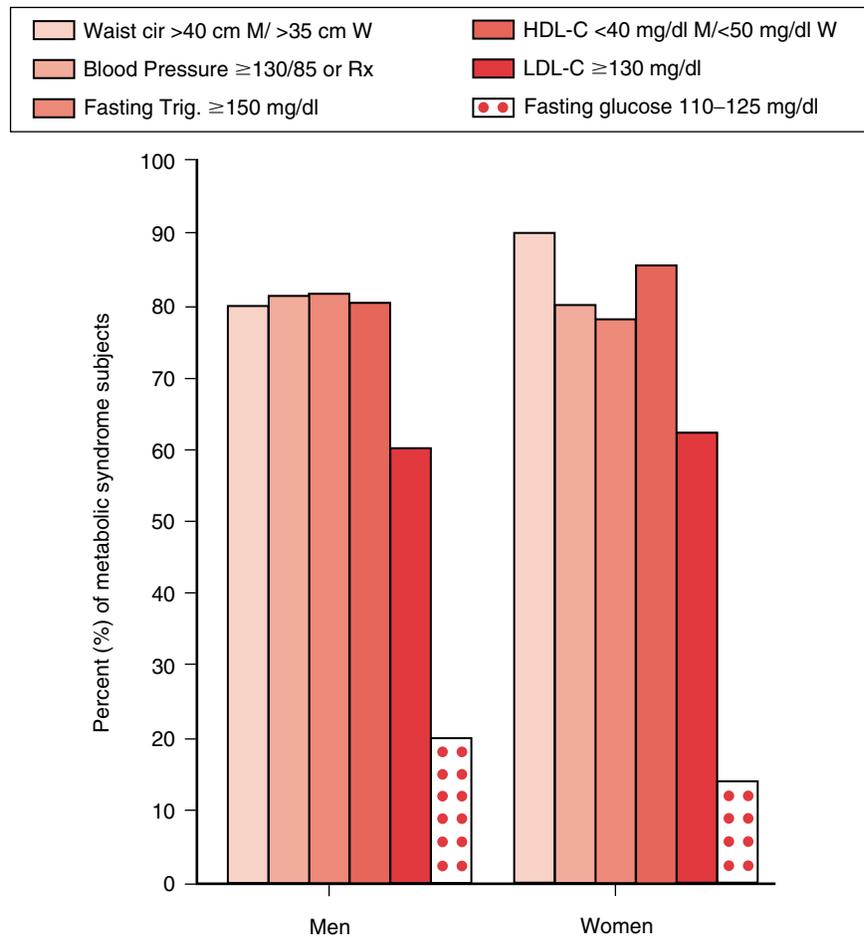

[§]Some experts recommend separating out those with diabetes, those with a fasting glucose of 126 mg/dl, because clear guidelines for these persons exist.

In trying to estimate absolute benefit in terms of preventable CHD events from control of hypertension, one can apply absolute risk estimates obtained from Framingham algorithms to the general U.S. population of adults with hypertension.⁴⁴ This calculation suggests that treatment of the U.S. population with hypertension (30-74 years of age) to a nominal goal of <140 mm Hg SBP and <90 mm Hg DBP could prevent approximately 19% of CHD events in men and 31% of CHD events in women in the next 10 years. Treatment to an idealized goal of <120 mm Hg SBP and <80 mm Hg DBP could prevent 37% and 56% of CHD events, respectively.⁴⁴ The long-term value of sustained antihypertensive treatment has also been estimated from a secular trend study from Framingham involving three successive cohorts between the ages of 50 and 59 years in 1950, 1960, and 1970.⁴⁵ After adjusting for risk factors, there was as much as a 60% reduction in cardiovascular mortality in those receiving antihypertensive therapy for 20 years compared with their untreated counterparts.

GLOBAL RISK STRATIFICATION

Based on the results of considerable outcome data, there is consensus that antihypertensive medications should be used as part of therapy in all high-risk patients.^{1,39} These would include individuals with persistent stage 2 hypertension BP (≥160/100 mm Hg) and those with stage 1 hypertension BP (≥140-159/90-99 mm Hg) or prehypertension BP (≥120-139/80-89 mm Hg) with associated risk factors or cardiovascular disease. The latter two BP categories encompass those individuals with (1) hypertensive target organ involvement (LVH, microalbuminuria [50-300 mg albuminuria/24 hours], mild increase in serum creatinine [1.3-1.5 mg/dl in men and

Figure 3-11 Prevalence of selected risk factors in U.S. adults with the metabolic syndrome (without diabetes). Adapted from Wong ND, Pio J, Franklin SS, L'Italien GJ, Kamath T, Williams R. Preventing heart disease by nominal and optimal control of blood pressure and lipids in persons with the metabolic syndrome. *Am J Cardiol* 91:1421-1426, 2003.

1.2-1.4 mg/dl in women], and grade 3 or 4 retinopathy [retinal hemorrhages/exudates and papilledema, respectively]); (2) associated clinical conditions (CHD, heart failure, stroke, renal impairment [serum creatinine of >1.5 mg/dl in men and >1.4 mg/dl in women], peripheral vascular disease); or (3) diabetes with or without vascular complications.

On the other hand, there is considerable disagreement about when to supplement lifestyle treatment measures with antihypertensive therapy in individuals with stage 1 hypertension (140-159/90-99 mm Hg) without associated risk factors or cardiovascular disease. To date, there have been no definitive trials to assess the benefit of treatment in this group, which represents the largest single category within the hypertensive population: Ogden et al.⁴⁶ found that in the NHANES III adult hypertensive population, 20.7% had complicated hypertension, 31.3% had uncomplicated but stage 2 hypertension, 5% had stage 1 hypertension without additional risk factors, and 43% had uncomplicated stage 1 hypertension with at least one or more additional risk factors.

ACCURACY OF CURRENT RISK ASSESSMENT FOR UNCOMPLICATED MILD HYPERTENSION

JNC 7 guidelines¹ suggest that every individual with uncomplicated stage 1 hypertension who does not respond to lifestyle modification promptly be started on antihypertensive therapy.

In contrast, the European Society of Hypertension guidelines³⁹ stress the importance of assessing global risk and then complementing lifestyle modification with drug therapy in the presence of moderate to high risk. This type of assessment requires that the number and severity of risk factors in an individual be used to calculate the likelihood of future CHD events by multivariate assessment, similar to that based on the Framingham risk equations. According to these criteria, in the presence of a 10-year risk of hard CHD events of >20%, based on Framingham risk equations and designated a CHD risk equivalent by the Third Adult Treatment Panel of the National Cholesterol Education Program,⁴¹ therapeutic intervention should be considered for those with SBP of 130 to 159 mm Hg and DBP of 80 to 89 mm Hg as it is for others in this range with diabetes or target organ damage. In the presence of an intermediate risk (e.g., 10-year 6%-20% risk), consideration can be given for using noninvasive screening tests for the detection of subclinical cardiovascular disease to further stratify risk.⁴⁷

Data from NHANES adults surveyed in 1999-2000 show that a substantial proportion of persons with hypertension is at intermediate risk (6%-20% estimated 10-year risk of CHD). By the sixth decade of life, more than 40% are at high risk (>20% 10-year risk of CHD, including those with known CHD, stroke, or peripheral vascular disease); by the eighth decade of life this rises to more than 60% of persons with hypertension (Figure 3-12). Approximately 60% of males and 40% of females with hypertension are at high risk of CHD based on these estimates.

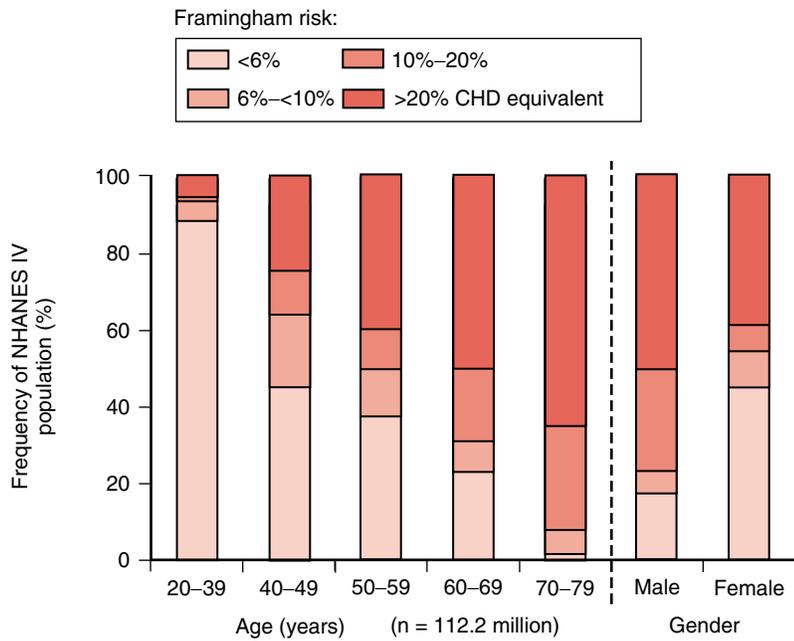

Figure 3–12 Distribution of Framingham Risk in the NHANES 1999-2000 Hypertensive Population by Age and Gender. People with diabetes, prior cardiovascular disease (CHD, MI, stroke, CHF), or peripheral vascular disease (PVD) were treated as CHD equivalents.

Noninvasive subclinical disease measures, including carotid artery intimal medial thickness (IMT) measured by ultrasound, ankle brachial index, coronary artery calcium, echocardiographic left ventricular mass, and left ventricular global systolic function (ejection fraction), have been shown to have reasonable sensitivity and reproducibility in detecting subclinical atherosclerotic disease and also show predictive value over and above standard assessment of risk factors. If evidence of significant subclinical disease is revealed (e.g., coronary calcium score >400, ankle brachial index <0.90, or carotid artery IMT ≥ 1 mm), one can make the case for stratification of treatment to the next highest level (e.g., as a CHD risk equivalent), warranting lower cutpoints for treatment initiation or BP goal.⁴⁷ For example, the Assessment of Prognostic Risk Observational Survey (APROS) study⁴⁸ found that 53% of patients previously classified as mild or medium risk by the World Health Organization/ International Society of Hypertension were reclassified as high risk (10-year risk $\geq 20\%$) after LVH was found on echocardiography and/or significant increased diffuse or focal carotid artery IMT was found by ultrasound examination.

However, the prognostic utility and cost-benefit considerations of using noninvasive screening tests in selected intermediate-risk population groups have yet to be determined, and no consensus regarding such screening currently exists for the general population of hypertensives. Therefore, clinical judgment based on a thorough office-based examination and global risk assessment remains the primary basis on which to decide when antihypertensive therapy should be added to lifestyle measures in uncomplicated prehypertension and stage 1 hypertension.

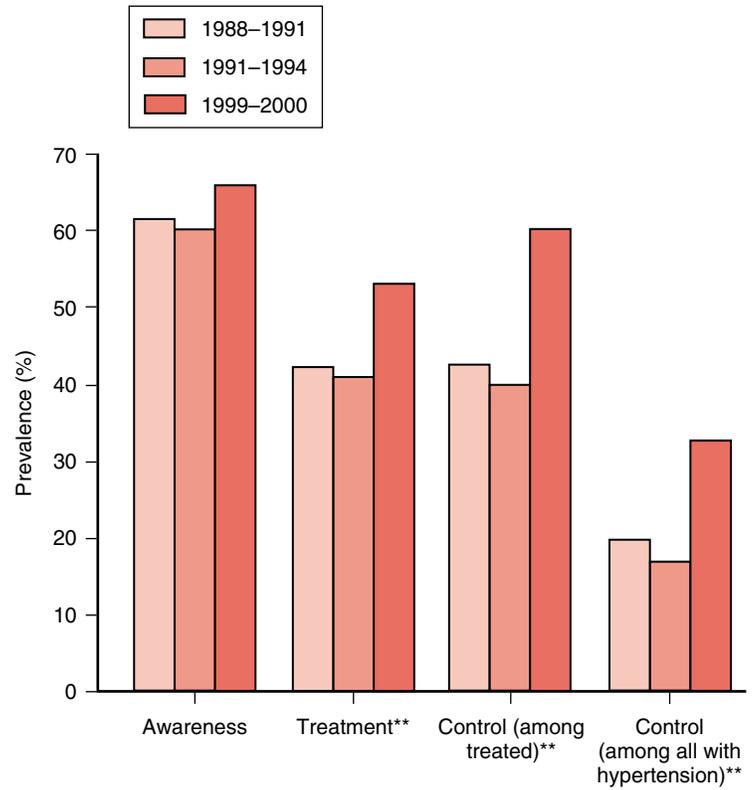

HYPERTENSION AWARENESS, TREATMENT, AND CONTROL RATES

Since 1988-1991, there have been no significant improvements in awareness of hypertension in men (from 63% in 1988-1991 to 66% in 1999-2000) and actually a trend toward lesser awareness in women (from 75% in 1998-1991 to 71% in 1999-2000).⁴ Although a trend toward improvements in awareness among Mexican Americans has been noted, no significant improvements were seen in any other ethnic group.

Treatment rates, however, have improved from 52.4% to 58.4% ($p = .007$) overall due to improvements in treatment rates in men (44.5%-54.3%, $p < .001$) but not in women (60.1%-62.0%, $p = .24$) (Figures 3–13 and 3–14).⁴ Rates of treatment have improved significantly in non-Hispanic whites and non-Hispanic Blacks, but only marginally in Mexican Americans, during this time period.

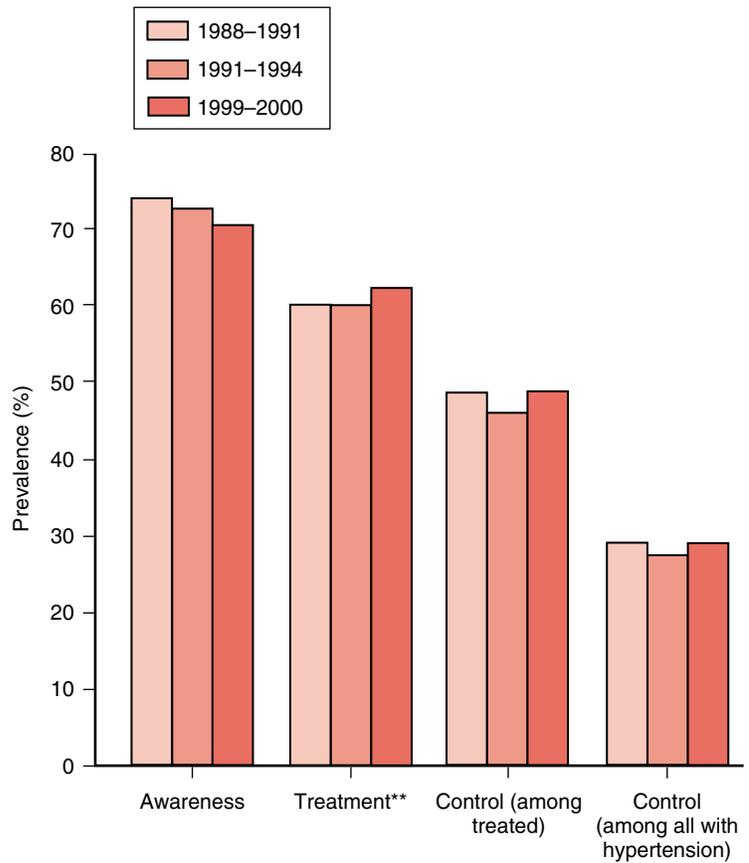

Significant improvement in control of hypertension, both among those treated and among all with hypertension, have also been seen in men, but not in women during this time period. In 1999-2000, approximately 60% of men being treated had their hypertension controlled to <140/90 mm Hg compared with less than 50% of women (see Figures 3–13 and 3–14). Women, older persons, and Mexican Americans tended to have the lowest rates of hypertension control. The improvement in control rates for men exclusively resulted from substantial improvements in control in non-Hispanic white men (from 20.7% in 1988-1991 to 36.5% in 1999-2000), without any significant change in men of other race/ethnic groups.⁴ The reasons for the poorer treatment and control rates in women are not well understood. The poorer control

**No significant changes in awareness, treatment, or control from 1988 to 2000

rates in older persons, despite universal health insurance (Medicare) for those aged 65 and older, may in part be a reflection of greater severity of their hypertension, particularly ISH. It has been noted that improving hypertension treatment and control in women, the elderly, Mexican Americans, and persons with diabetes will have a significant impact on overall control rates, and unless hypertension control rates improve, the 50% target for hypertension control by 2010 will not be met.⁴

Although hypertension treatment rates are far from optimal in the United States (52.5%), they are substantially higher than in European countries (26.8%) (see Figure 3–4). This has been attributed to lower thresholds for treatment in the United States, increasing the numbers of treated cases, and lowering the mean BP in the population.³

POPULATION VERSUS HIGH-RISK APPROACHES FOR PREVENTION

Prevention of complications of hypertension requires concerted efforts of both population and high-risk approaches.⁴⁹ The former involves efforts of public health education, the media, communitywide alliances, and legislation promoting healthful policies, in an effort to gradually reduce morbidity and mortality in the population from shifting the population distribution of BPs downward (or prevent their upward trends). The latter requires intensive one-on-one clinical management of patients with preexisting hypertension to reduce individual risks of cardiovascular, renal, and other complications. Efforts of governmental, community, and healthcare providers cooperating together are vital to successfully prevent and manage hypertension and its consequences.

SUMMARY

Hypertension is associated with a twofold to fourfold increased risk of CHD, stroke, peripheral vascular disease, and renal disease. Increased SBP is strongly associated with increases in risk, even when diastolic pressure is normal; a high PP further increases risk. An increase in risk of developing of hypertension and cardiovascular events begins among persons in the prehypertension range of BP. Three out of four persons with hypertension are age 50 or older, and by the age of 80, more than 65% of the population will have hypertension, as currently defined. Over the past 15 years, prevalence has increased among women and older persons, but treatment and control have improved only among men. ISH is the predominant form of hypertension after the sixth decade of life, whereas diastolic hypertension is the most common form before the age of 50. Hypertension is seldom a lone cardiovascular risk factor; it tends to cluster with additional risk factors as part of the metabolic syndrome. Appropriate risk stratification of persons with hypertension involves a combined approach of an office-based examination and global risk assessment. In intermediate-risk persons with hypertension, subclinical disease screening may be useful to identify candidates for more intensive treatment. For both primary and secondary prevention, treatment of all significant risk factors, as opposed to treating only hypertension, will result in the largest reduction in cardiovascular risk.

Pathophysiology

Chapter 4

Pathophysiology of Hypertension

Maria Carolina Delgado, Alan B. Weder

Regulation of blood pressure is one of the most complex of physiologic functions, dependent on the integrated actions of cardiovascular, renal, neural, and endocrine systems. Hypertension is a disorder of the average level about which blood pressure is regulated, and although it is of clinical importance because chronically elevated blood pressure damages the heart, blood vessels, and kidneys, at least in its early stages hypertension does not cause obvious disturbances of cardiovascular function. Most of the functional cardiovascular derangements of hypertension arise from the compensatory mechanisms elevated blood pressure provokes (e.g., vascular and ventricular hypertrophy) or from its contribution to vascular damage (e.g., atherosclerosis and nephrosclerosis). Investigating the pathophysiology of hypertension therefore means understanding the mechanisms of normal blood pressure control and seeking evidence of subtle abnormalities that precede (or at least coincide with) the rise of blood pressure to hypertensive levels.

Because hypertension represents a quantitative dysfunction of the highly interactive elements of the cardiovascular system, traditional reductionist research modes are unlikely to yield more than fragments of the answer to the question of what causes hypertension.¹⁻³ Pathophysiologic thinking is one such reductionist approach. Essentially mechanistic and concerned largely with the immediate or proximate causes of disease, such research seeks to identify the structures and functions that result in elevated blood pressure. Pathophysiologic studies have been of great value in describing the underlying causes of differences between hypertensives and normotensives but less successful in identifying root causes of hypertension. To address causality, findings gathered in the physiologic investigation of cardiovascular control systems will need to be integrated into broader frameworks: The value of evolutionary research for organizing the findings derived from pathophysiologic research has been pointed out before.⁴ The goal of evolutionary thinking is to understand how heritable traits affect reproductive success, and ultimately to describe not only the fundamental genetic complement underpinning hypertension but also the environmental factors necessary for expression of the phenotype and the physiologic processes mediating the interaction of genes and environment. Each such complement of genes, each set of environmental exposures, and each history of their interaction will be unique, so that a truly comprehensive description of the pathophysiology of hypertension will probably never be possible. But by integrating broad frames such as evolution into our

pathophysiologic thinking, we are likely to get a better understanding of ultimate causation.

This introduction attempts to lay out some of the broad principles of cardiovascular regulation that are relevant to a consideration of the pathophysiology of essential hypertension. We do not aim to summarize the mechanisms to be explored in detail by experts in the succeeding chapters of this volume but rather to demonstrate how complex the task of formulating an integrated pathophysiologic picture of hypertension is likely to be. We begin by emphasizing three fundamental features of blood pressure control:

1. Blood pressure regulation is flexible and responsive to local organ perfusion requirements.
2. Blood pressure regulation is integrated into overall cardiovascular-renal function to serve total-body homeostasis.
3. The level at which blood pressure is regulated changes throughout a patient's life history.

BLOOD PRESSURE CONTROL AND LOCAL NEEDS

At its most basic level, blood pressure provides the driving force that moves blood through the vascular system. Because maintenance of this function is absolutely critical to life, it is not surprising that natural selection has favored organisms that have evolved mechanisms that contribute to blood pressure stability. Nor is it unexpected that such mechanisms are powerful and highly redundant, providing ample "backup" to cope with changes in environmental factors, including electrolyte intake, physical activity, threats, and trauma. Indeed, it would be remarkable if the situation were otherwise.

All mammals have fundamentally the same circulatory system, so blood pressure control systems are likely to be highly evolutionarily conserved across species, and it may therefore not seem surprising that mean arterial blood pressure in the aortic root is essentially constant in mammals, about 100 mm Hg.⁵ This constancy is in contrast to many anatomic features (e.g., heart weight) and physiologic functions (e.g., heart rate) that are scaled to average body mass across a wide range of species sizes.⁶ In many cases, unscaled variables (i.e., those not related to body size) are constrained by fundamental and invariant physical or chemical features important to life, such as diffusion distances. Because several

other critical aspects of circulatory function are similarly unscaled, notably capillary and red blood cell diameters, it seems plausible to assume that blood pressure is part of a system finely adapted in many ways to ensure optimal delivery of metabolic substrates at the tissue level. The level of blood pressure characteristic of mammals as an adaptation of their particular body plan is evidenced by the differing average blood pressure levels found in other animals. Birds, for example, operate at a higher average blood pressure level than do mammals, and the reasons for the difference are not clear.⁶

Whereas the constancy of blood pressure in mammals might seem to imply rigidity of function, nothing could be further from the truth. An example of naturally elevated blood pressure in a nonhuman mammalian species is instructive in demonstrating how flexible blood pressure regulation can be. Giraffes have evolved to occupy an ecologic niche of arboreal feeding by means of selection for an extreme elongation of the neck (selection pressure may have been multifunctional [e.g., male-male competition]). Although closely related to the other ruminants, where blood pressure averages the expected value of about 100 mm Hg mean, giraffes demonstrate extraordinarily high blood pressures at the level of the heart, with estimates of resting blood pressure of 180 mm Hg⁷ to greater than 300 mm Hg.⁸

Elevated blood pressure in these animals serves to maintain blood flow to the brain, so that blood pressure level at the base of the skull is about 100 mm Hg. The cardiovascular system has accommodated the particular structural adaptations of giraffe anatomy by altering force generation at the left ventricle and thus aortic root pressure to provide precisely the energy necessary to drive blood to the brain. It is theoretically possible for natural selection to have altered the structural plan of the giraffe body to one in which the brain migrated to a more central body location and therefore could operate at a “normal” systemic blood pressure. However, such an adaptation would involve wrenching changes in the established body plan and ontologic course of vertebrate development that would undoubtedly be difficult to fashion. Nature usually shapes its adaptations conservatively. The giraffe’s neck, for instance, although markedly different in appearance from that of the taxonomically related cow, nonetheless contains the same seven cervical vertebrae. In meeting the cardiovascular demand imposed by its anatomic adaptation, rather than redesigning the system, it is more efficient to draw on built-in features of the cardiovascular repertoire—notably the ability to regulate average blood pressure level—and to use those features to match the specific circulatory demands imposed by neck elongation. Thus although generally fixed within a narrow range in mammals, when necessary, blood pressure can be maintained indefinitely at a markedly increased level when critical local needs require it.

The giraffe illustrates an important principle of blood pressure control: Blood pressure level is flexible and responsive to important physiologic needs (e.g., brain perfusion). From the viewpoint of the fitness of the organism in terms of natural selection, this functional trade-off of high blood pressure for optimal brain perfusion is perfectly reasonable, even if some adverse consequences flow from the compromise. The adaptationist paradigm holds that, in general, natural selection favors any individual or suite of novel features (in the case of

the giraffe, a long neck and the attendant elevated blood pressure) when the net impact of such changes is favorable in terms of reproductive success of the affected individual’s genes. Importantly, not every preserved element need be in itself adaptive. Thus, whereas employing high blood pressure as a way of matching circulatory function to an unusual anatomic situation is an elegant solution to an adaptive challenge, it does not imply that giraffes do not pay a price for maintaining high aortic root pressures. They evidence a large number of pathologic effects of high blood pressure, including massive left ventricular hypertrophy (LVH) and extraordinary arterial vascular smooth muscle hypertrophy in the limbs.^{9,10} It seems likely that such cardiovascular adaptations are potentially deleterious, but any such adverse consequences are more than balanced by the advantages of a long neck on overall fitness.

BLOOD PRESSURE CONTROL AND INTEGRATED CARDIOVASCULAR-RENAL FUNCTION

In addition to providing perfusion to the brain, blood pressure plays a key role in the optimization of other organ and whole-body functions. Starling recognized as long ago as 1909 that total-body sodium and water balance is regulated in part by renal arterial perfusion pressure.¹¹ This concept was further characterized by subsequent investigators, most notably by Guyton et al., who proposed that blood pressure and sodium homeostasis are related through the mechanism of pressure natriuresis: When perfusion pressure increases, renal sodium output increases and extracellular fluid and blood volumes contract by an amount sufficient to return arterial blood pressure to its baseline.^{12,13} Guyton characterized the relationship between natriuresis and mean arterial blood pressure by a pressure-natriuresis curve characteristic of each individual, which is shifted to a higher value on the pressure axis when hypertension is chronically sustained.¹³

In most normotensives, that curve is very steep, because blood pressure differs very little at extremes of sodium intake. In some normotensives and in a greater proportion of hypertensives, the slope of the curve is diminished, meaning that blood pressure varies continuously with differences in salt intake. Such individuals are said to be “salt-sensitive.”¹⁴

Although the phenomenon of salt-sensitivity is often characterized as a primary isolated defect in pressure-natriuresis and while that deficiency surely underlies the volume responsiveness of blood pressure in patients with advanced renal insufficiency, more subtle renal dysfunctions also may be important.¹⁵ One such physiologic mechanism recently proposed as contributing to renal physiologic and structural changes causing salt-sensitivity is a resetting of the set-point of tubuloglomerular feedback.¹⁶

Mammalian kidneys accurately match glomerular filtration to tubular sodium excretion by regulating afferent and efferent glomerular arteriolar resistance in response to distal tubular chloride load (Figure 4–1). Responses of glomerular filtration rate over a wide range of distal tubular load are described by a nonlinear function referred to as the tubuloglomerular function (TGF) curve.¹⁷ TGF is a classic negative feedback loop, serving to control whole-body homeostasis. Thus, when the macula densa senses a decrease in sodium (NaCl) delivery to

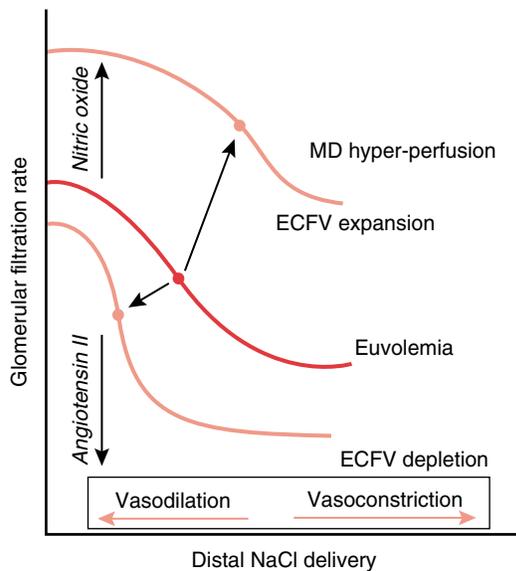

Figure 4-1 The relation between the GFR and the distal sodium (NaCl) delivery, as expressed in tubular glomerular feedback (TGF). A resetting of the operating point downward and to the left occurs in depletion of the extracellular fluid volume (ECFV) (i.e., dehydration). A resetting of the operating point upward and to the right occurs in expansion of the ECFV or in a sustained increase in the delivery of NaCl to the distal tubules (i.e., tubular hyperperfusion of the macula densa [MD]), under euolemic condition. The vascular tone (vasodilation or vasoconstriction) of the afferent arterioles is the main mechanism of the change in the GFR. Resetting of the TGF operating point is largely dependent on the balance between the levels of angiotensin II, extracellular adenosine, and nitric oxide in the vicinity of the glomerular arterioles. Resetting of the set-point has been proposed to result in chronically elevated glomerular filtration and promote renal damage. (From Aviv A, Hollenberg NK, Weder A. Sodium glomerulopathy: Tubuloglomerular feedback and renal injury in African Americans. *Kidney Int* 65(2): 361-368, 2004.)

the distal tubule, a signal is relayed to the afferent arteriole to dilate, resulting in increased glomerular capillary hydrostatic pressure and increased glomerular filtration rate. If as hypothesized, the TGF curve is displaced such that at a given distal tubular load a higher glomerular filtration rate is required to maintain normal whole-body sodium homeostasis, the chronic increase in glomerular capillary pressure could result in renal damage, which could in turn further depress pressure natriuresis and lead to a cycle of increasing salt-sensitivity of blood pressure and progressive renal injury. Such a sequence is consistent with the results of the African American Study of Kidney Disease and Hypertension, in which angiotensin-converting enzyme inhibitors and β -blockers, drugs that affect renin-dependent mechanisms, presumably including afferent arteriolar resistance and thus glomerular capillary pressure, slowed the progression of renal disease more effectively than a calcium channel blocker.¹⁸ Interestingly, more aggressive control of systemic hypertension did not significantly affect the progression of renal damage and TGF, suggesting that local intrarenal hemodynamic factors are more important than systemic blood pressure as a cause of renal damage in this population. TGF

resetting, by triggering a pathophysiologic cascade compromising whole-body sodium metabolism, may necessitate increased reliance on a flexible compensatory system, blood pressure, resulting in a salt-sensitive pressure–natriuresis curve. Salt-sensitivity of blood pressure thus serves a critical biologic need, the maintenance of sodium balance in the face of a disorder of another important physiologic regulator of sodium balance, TGF. The point to be remembered is that cardiovascular-renal homeostatic mechanisms are highly integrated and redundant.

CHANGING THE SET-POINT: GROWTH, DEVELOPMENT, AND HYPERTENSION

As pointed out in 1978 by Sir George Pickering, *hypertension* is defined by an arbitrary division in the continuous blood pressure distribution.¹⁹ Two sets of definitions are commonly used, one for adults and one for children and adolescents. Adult levels exceeding a threshold of usually 140 mm Hg systolic or 90 mm Hg diastolic in the United States are defined as being *hypertensive*. Such cut-points are based largely on tradition rather than on any biologic significance of the values. In childhood, hypertension is defined as a blood pressure exceeding the 95th percentile for age,²⁰ another arbitrary division that results in a constantly changing threshold for hypertension during development. Such definitions are of heuristic value in identifying individuals on whom medical attention should be focused. But perhaps the real message of the different definitions is that they acknowledge an important feature of blood pressure during postnatal development: Blood pressure rises with age. Long ignored, the significance of the childhood, and indeed even prenatal, antecedents of hypertension are receiving increasing attention.^{4,21}

The rise of blood pressure during childhood and adolescence follows a very stereotypical course, with a rapid increase during the first few weeks of life, a gradual increase throughout childhood, and a dramatic rise during puberty.²⁰ Blood pressure then remains relatively constant in most individuals throughout the remainder of the second and well into third decade, after which it again begins to rise.⁴ It is during this period that most diastolic hypertension develops (i.e., blood pressures finally exceed 90 mm Hg diastolic). However, it has long been recognized that adult blood pressures are related to adolescent levels: Serial measures of blood pressure within individuals are correlated, and the coefficient of correlation becomes increasingly strong with aging.²¹ As a consequence, adolescents with the highest relative rank of blood pressure have the highest risk of future hypertension. So where does hypertension begin? Is it when the blood pressure is established in the upper rank, as certainly can be determined during adolescence? Or alternatively, must we wait until middle age to diagnose hypertension? Because the pattern of high blood pressure is established early in life, hypertension may have its roots in early developmental events. Events contributing to high blood pressure in youth may result in pathophysiologic changes that cannot be subsequently reprogrammed or that set the stage so that events affecting blood pressure later in life have an enhanced hypertension-promoting effect.

Although the precise mechanisms affected early in development are unknown, several schema incorporating the general principle of early events conditioning later responses have been proposed:

1. *Vascular remodeling.* Observations by Folkow²² and Sivertsson²³ that hypertensive vessels undergo adaptation by structural remodeling, which increases the wall:lumen ratio, identified an important mechanism that maintains chronically increased vascular resistance in established hypertension. Although partially reversible by long-term antihypertensive therapy, this structural adaptation persists to a degree even in effectively treated patients and progresses in uncontrolled hypertension.²⁴ Because structural changes are present even in borderline hypertension, it is likely that this adaptation begins early in the course of the blood pressure rise, probably before the hypertensive range is reached.^{25,26}
2. *Hyperkinetic borderline hypertension.* Julius et al. described serial changes in cardiovascular function that result in a transition in the hemodynamics of blood pressure control from a state of increased cardiac output, largely sustained by the autonomic nervous system, to one of a sustained elevation of blood pressure dependent on increased vascular resistance and unrelated to increased autonomic tone.^{27,28} The initiating factor for the early hyperkinetic circulatory state, increased sympathetic and decreased parasympathetic tone, is postulated to cause β_1 -receptor down-regulation in the heart that, perhaps in concert with changes in myocardial function,²⁹ results in a regression of cardiac output to normal values. At the same time, structural enhancement of vascular resistance (increased wall:lumen ratio), induced by high blood pressure and sympathetic overactivity, results in a progressive increase in vascular tone even as sympathetic drive falls. The net effect of these adaptations is a transition from a state of increased cardiac output to one of increased vascular resistance.^{30,31} Because the transition occurs over decades, serial longitudinal hemodynamic studies have been difficult to organize, but Lund-Johansen and Omvik documented the transition in a small group of subjects who presented with hyperkinetic borderline hypertension in youth and ended with typical high-resistance essential hypertension 20 years later.³²
3. *Allometric dysfunction.* Weder and Schork proposed a schema in which the coordinated programs matching somatic and renal growth could be disrupted by an excessively vigorous growth pattern in youth and adolescence.⁴ They postulated that the vigorous growth associated with modern childhood and adolescence, coupled with compression of the period of active growth by earlier puberty, might result in a fixed mismatch of some critical growth-related renal function and somatic metabolic demands. Such a mismatch might be compensated for by increased blood pressure, and since the fundamental defect could not be corrected after the cessation of growth at puberty, this fixed defect could promote hypertension throughout life. Although the precise nature of the renal defect leading to such a situation is unknown, underdevelopment of the medullary microcirculation or cortical afferent arterioles³³ appear to be important aspects of renal structure affecting sodium handling.³⁴ Aspects of this schema are pertinent to the subsequent discussion of how modernity causes hypertension.
4. *Synchronicity.* Schork et al. noted that in inbred animal strains, there is a temporal coupling of growth and blood pressure such that growth spurts regularly precede rises in blood pressure.³⁵ Similar findings have been reported for humans when serial changes in body size and blood pressure have been examined.³⁶ The vigor of the rise in blood

pressure after a growth spurt appeared to be greater in genetically hypertensive rats compared with a genetically normotensive strain, suggesting that genetic programs controlling the coupling function could be responsible for initiating states of increasing blood pressure initially triggered by normal growth processes.

5. *Telomere shortening.* Aviv and Aviv proposed the interesting hypothesis that telomere shortening, a phenomenon accompanying normal aging, might contribute to hypertension.³⁷ There is considerable evidence that essential hypertension is closely linked to the growth, development, and aging of human beings. One biologic indicator of growth and aging that could provide a better understanding of the etiology of essential hypertension is the age-dependent telomere attrition rate in somatic cells, which registers the replicative history of somatic cells. Telomere attrition rate records the growth that results from the replication of somatic cells and their turnover—a process that is strongly linked to inflammation and oxidative stress, which are key factors in the biology of human aging.³⁸
6. *Birth weight and hypertension.* Largely through the work of Barker, a relationship between low birth weight, increased placental weight, and increased risk of adult hypertension has been established.^{39,40} These observations suggest that in utero events can condition, or in Barker's terminology, *program*, an infant to a phenotype characterized by insulin resistance and a tendency toward the development of hypertension and diabetes.³⁹ Barker argues that in utero growth retardation sets the stage for a thrifty phenotype that manifests itself as disease late in life.

The mechanism of such programming has been further investigated by Seckl, who has provided evidence that placental 11 β -hydroxysteroid dehydrogenase activity may play a key role in such programming.⁴¹ This enzyme converts physiologic glucocorticoids such as cortisol to inactive metabolites, thus decreasing the transfer of maternal steroids to the fetus. Experimental studies show that steroid exposure inhibits fetal growth but increases placental weight, the pattern identified by Barker as predisposing to hypertension.³⁹ Seckl demonstrated that in rats, in utero exposure to steroids increases the blood pressure of offspring,⁴² suggesting that factors that control fetal steroid exposure, especially 11 β -hydroxysteroid dehydrogenase activity, could play a role in promoting hypertension.

All these mechanisms share a common theme: Events at one point in development have consequences for the blood pressure level at a later stage. In searching for causal events, then, we would be well advised to look at the times at which such events are operative.

HYPERTENSION: PROXIMATE AND ULTIMATE CAUSATION

Having stressed the importance to research in hypertension of the essential functions of the circulatory system, the integrated nature of cardiovascular-renal homeostasis and the importance of the temporal evolution of the level of blood pressure, let us turn to a consideration of why humans get hypertension.

No one can say with absolute certainty when hypertension first appeared in human history, but it is generally accepted to

be a relatively modern disease of civilization. The emphasis on the importance of the acculturated environment somewhat undervalues the role of genes, and the term *syndrome of impaired genetic homeostasis* has been suggested as a better characterization of the problem.⁴³ The strongest support for the view that hypertension results from a fundamental mismatch between our ancient genes and our modern environment comes from observations of blood pressure in populations of modern-day hunter-gatherers.⁴⁴ Individuals in many of these societies pursue a lifestyle probably quite like that of the Neolithic period and do not develop hypertension or the progressive rise in systolic and mean blood pressure that is universally observed in individuals living in Westernized societies. Because adult hunter-gatherers have typical mammalian blood pressures (i.e., mean arterial blood pressures of about 100 mm Hg), elevated blood pressures in Westernized societies may reflect a response to some physiologic need imposed by our acculturation. Although we do not have an adaptive problem as obvious as the giraffe's long neck, modern environmental novelty apparently activates the flexible, powerful, highly evolutionarily preserved systems that alter the set-point of blood pressure control to a higher level in some individuals. Unlike the giraffe, we do not seem to "need" high blood pressure, for in general, there is no obvious physiologic dysfunction induced by lowering blood pressure through antihypertensive treatment. Furthermore, clinical trials show that the adverse consequences of sustained high blood pressure are ameliorated by such treatment.

Yet the indisputable fact that genes contribute to human hypertension implies an adaptive role for those genes.⁴⁵ We are unaware of any data suggesting an adaptive advantage or disadvantage for hypertension itself. Except for the relatively rare event of fatal malignant hypertension in youth, which could obviously affect reproductive potential, diseases arising from or aggravated by essential hypertension generally occur during postreproductive years. Thus, when considering high blood pressure in an evolutionary context, it is important to focus on issues other than high blood pressure, because that is not a trait likely to be related to reproductive success. It is reasonable to view hypertension as a pleiotropic effect of a genetic suite that subserves some important function other than blood pressure regulation.^{1,35} The keys to hypertension are likely to reside in genetic-environmental interactions, with the genes involved those of our ancient hunter-gatherer-adapted genome and the environment that of our new human-created world: Hypertension is a response to environmental novelty.

What is it that Westernized society does to our bodies that causes high blood pressure? The increased dietary sodium intake of acculturated societies has been extensively studied, and the Intersalt trial has provided good evidence that in populations with minimal sodium intake, the prevalence of hypertension is very low.⁴⁶ However, other factors may also be important, as exemplified by the Kuna of Panama, some of whom follow a traditional lifestyle yet consume sodium at levels typical of Westernized societies and do not evidence hypertension.⁴⁷ Others have suggested that the ratio of sodium:potassium intake may be critical and have identified the weight gain associated with migration from rural to urban settings as a factor associated with the development of hypertension.⁴⁸ The most obvious features of Westernized lifestyle are calorie intake in excess of need and calorie expenditure far below that of our early ancestors. Hunting and gathering

involved nomadic foraging and persistent pursuit of game, both of which required vigorous physical exertion. Even as agriculture arose, life remained strenuous, and not until industrialization did humans begin to escape a lifestyle of obligatory physical activity. Such a lifestyle required considerable energy throughput, and the estimated daily energy expenditure of adult members of hunter-gatherer and traditional (nonmechanized) agricultural societies was on the order of 3000 kcal/day,^{49,50} whereas individuals in our modern industrialized societies expend about 2000 kcal/day or less.

This shift is almost entirely the result of mechanization, as illustrated by estimates of the effect of mechanized farming in Japan, which reduced daily work expenditure for the average farmer by more than 50%.⁵¹ The shift from a balanced energy throughput, characterized by high intake but equally high expenditure, to one of intake in excess of expenditure resulted in an altered body habitus with an increase in body fat and a loss of muscle mass.^{52,53} Even recently studied hunter-gatherers, who have already been somewhat affected by the modern world, have skinfold thicknesses half those of Westernized North Americans.⁵² The experience of the Inuit of the Northwestern Territories of Canada during the period when hunting by dog sled and kayak was superseded by travel on snowmobiles, all-terrain vehicles, and power boats is particularly powerful and instructive, as the effect of modernization occurred quickly and resulted in dramatic changes in body composition within a generation.⁵³ Eaton noted that for 20- to 29-year-old males, lean body mass declined 10.1% and body fat (estimated from skinfold thicknesses) increased 88.7% over one 20-year period; for women in the same age category, lean body mass fell 12.1% while body fat rose 40.1%.⁴³ Along with the observed changes in body habitus, which seem to inevitably follow Westernization, comes hypertension. It is reasonable to think that the effects on body habitus and blood pressure are related: The question is, how?

The most logical place to search for the causes of hypertension is in normal blood pressure regulatory systems, and the optimal time is before blood pressure rises to pathologic levels. In order to carry out such studies, we need to examine further how blood pressure changes during normal growth and development. Blood pressure rises in several reasonably stereotypical spurts, most notably during adolescence. This adolescent spurt is probably part of our fundamental human biology, as it appears in hunter-gatherer adolescents as well as in Westernized individuals.⁵⁴ However, hunter-gatherers do not go on to develop hypertension later in life, whereas we do. Most interest has traditionally focused on the period during which hypertension actually develops—adulthood. However, increasing attention is being paid to childhood and adolescence as evidence accumulates that the forces driving the blood pressure up may already be in play by that time. An alteration in the natural history of the adolescent growth spurt may be important in the pathophysiology of adult hypertension.

Schorck et al. observed that the rise in blood pressure in young rats that corresponds to the adolescent blood pressure spurt in humans is coupled to a growth spurt: Rapid growth precedes a rise in blood pressure in a regular manner.³⁵ More recently, longitudinal observations in humans demonstrated the same sequence with the adolescent blood pressure spurt trailing the onset of the growth spurt by about 1 to 2 years.³⁶ The appearance of this sequence in both humans and rats suggests that blood pressure rises to serve some need imposed by

growth, presumably as part of maintenance of overall homeostasis.⁵⁵ In humans, secular trends in growth and development suggest that the overall program of maturation may be greatly accelerated by modern life.⁵⁵ Interestingly, evidence suggests that human ancestors were quite tall, probably on average as tall as the upper 15% of the modern population,^{56,57} so the amount of linear growth itself may not be the problem.

Historical data show a progressive compression of the period of active growth and development in children and adolescents,⁵⁸ such that the growth of contemporary adolescents is probably near its biologic limits for both the final height achieved and the rate at which linear growth proceeds.⁵⁹ Coupled with vigorous linear growth is a tendency to adiposity that results in a high average body mass index in the tallest adolescents. In addition, sexual maturity is now probably achieved almost as early as biologically possible,⁵⁵ and the relative obesity of adolescents may again play an important role. It has been suggested that a critical fat mass is a trigger of menarche (perhaps mediated by increasing leptin levels),⁶⁰ presumably because sufficient fat accumulation increases the potential for successful pregnancy and childbearing.⁶¹ The earlier and greater accumulation of body fat by acculturated children may be part of the reason that sexual development is now much more rapid than in earlier times. We have previously proposed that this compression of growth and development has affected growth programs preserved during evolution and adapted for a more leisurely pace, resulting in mismatches between structure and function, perhaps at the level of the kidney.⁴ If this hypothesis is correct, a rise in blood pressure to high levels in adolescents who grow rapidly to a large size and mature early is simply a mechanism by which the body maintains overall homeostasis. Because those adolescents who are driven by rapid and vigorous growth to develop high blood pressure are predisposed to adult hypertension, it may be that the effects of modern civilization are mediated in part by a disruption of normal (i.e., Paleolithic) growth patterns.

An important distinction between hunter-gatherers and us is lack of an adult rise in blood pressure in non-Westernized people. It is during this adult phase that hypertension actually develops. Hypertension has at least two developmental phases, an early phase (childhood and adolescence), during which the stage is set for future hypertension, and a later phase, during which progressively rising blood pressure finally achieves hypertensive levels. It seems likely that the later phase of hypertension development is a product of the same environmental influences that affected early growth and development, but in adulthood, where linear growth is no longer possible, the result of caloric excess is progressive adiposity, which ultimately promotes a rise in blood pressure and the development of hypertension. Some support for this view comes from an intriguing observation reported in the Framingham cohort that lean young hypertensives go on to develop obesity in adulthood, suggesting that factors that promote hypertension in youth may predispose to adiposity in adults.⁶² As described previously, Barker et al. suggested that this tendency toward hypertension and obesity may actually be set during in utero development.⁶³ A pathophysiologic schema by which obesity may promote hypertension has been proposed by Landsberg.⁶⁴

Our Paleolithic genes are affected by modern lifestyle factors with the result that we achieve less than optimal muscularity and a considerable excess of body fat, yet we grow linearly at an accelerated rate and achieve sexual maturity at a

young age. These alterations in human natural history appear to provoke a rise in blood pressure through mechanisms not yet well described: Physiologists still have much to contribute to reveal the detailed mechanisms by which the set-point of blood pressure regulation is altered.

GENETICS OF HYPERTENSION

Identifying genes predisposing to hypertension is a daunting challenge. Mutations have been described for several rare Mendelian hypertensive diseases with distinctive pathophysiologic features, and it is of interest that most relate to renal sodium handling, reinforcing the concept that the kidney has an overriding influence on blood pressure regulation.⁶⁵ These variants are not important causes of high blood pressure in the general population.

That genes contribute to hypertension is well established from twin and family studies. The diathesis for hypertension appears to be multigenic and to account for some 30% to 40% of total variation in blood pressure level. The number of “hypertension genes” transmitted to an at-risk individual is important: The relative risk of developing hypertension for offspring of hypertensive parents is higher if both parents are hypertensive and if the disease has had earlier onset in the parent(s).⁶⁶

It is important to recognize that while estimates of heritability apportion part of the population variance of blood pressure to genetic factors, all blood pressure variance represents a gene-by-environment interaction. There are no “genes for hypertension,” there are only genes predisposing to hypertension in our current environment. Most if not all the genetic component of hypertension is expressed only in a permissive environment, so-called context-dependency.^{2,67} Defining what environmental factors promote and modify the expression of the genetic component of hypertension is at least as difficult as identifying genes for hypertension, and most clues from cross-cultural or case-control studies are not carefully measured when population-based genetic epidemiologic studies are performed. Effects may be very subtle and in part be determined by an individual’s life history. Even in a population of completely inbred animal models maintained under standardized conditions, blood pressure is normally distributed with a surprisingly large range.

Hypertension is a prototypical genetically complex disease; investigators seeking to identify individual genes for such diseases face many barriers (Figure 4–2):

1. *Diseases such as hypertension are not discrete.* Unlike Mendelian diseases with distinctive phenotypes, common diseases are often quantitative disorders, and definitions are based on arbitrary cut-points. Phenotypes employed for genetic studies are therefore somewhat poorly defined and probably etiologically heterogeneous. One of the clearest lessons from the secondary hypertension is that there are many ways to sustain elevated blood pressure chronically. In addition, characterizing blood pressure is difficult; blood pressure itself is very labile, and there is no agreement as to what is the “right” blood pressure for analysis. Reducing variation by arbitrarily dichotomizing the population distribution into hypertensive and normotensive groups probably increases the problem of phenocopies.

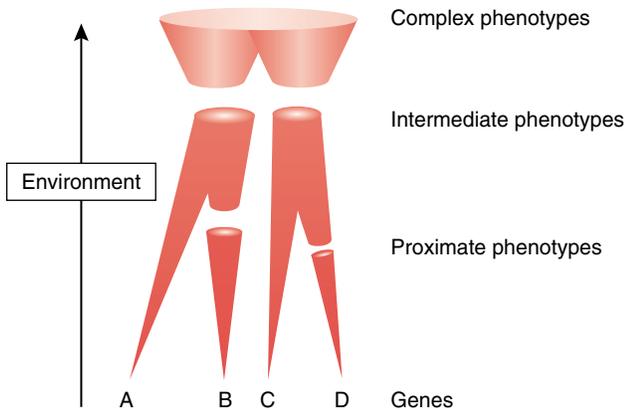

Figure 4–2 Complex disease phenotypes arise from multiple genes. Proximate phenotypes (e.g., direct measurements of gene products) can identify discrete subtypes of complex diseases. Intermediate and complex phenotypes result from multiple gene-gene and gene-environment interactions, and identification of genes contributing to final phenotypes such as hypertension is increasingly difficult.

One promising approach accepts the premise that hypertension is not an isolated disorder of the regulation of the set-point of blood pressure control but rather reflects a complex disorder of multiple systems (e.g., those relating to the metabolic syndrome). Cluster analysis, a method for empirically identifying phenotypic features that form distinctive phenotypes, may advance the identification of intermediate phenotypes more proximate to genetic disorders than blood pressure itself.⁶⁸ Other intermediate phenotypes based on physiologic (e.g., nonmodulation)⁶⁹ or biochemical (e.g., increased red blood cell sodium-lithium countertransport activity)^{70,71} also hold promise.

2. *Hypertension is a disease of middle age.* Although as a group, offspring of hypertensives have higher blood pressures in youth than offspring of normotensives, the differences are modest, and subsequent tracking of blood pressure sufficiently variable to render reliable identification of normotensive individuals destined for future hypertension impossible. Families identified through hypertensive parental probands can therefore be studied only in populations for which hypertension status is known for at least two adult generations. Classical segregation analyses that track the vertical transmission of genetic markers in individuals with and without a disease are therefore of limited utility in hypertension except in studies of Mendelian hypertensions in which distinctive features can be identified early in life or by medical history.

Because of the great difficulties inherent in extended-family studies, alternative nonparametric approaches have recently been favored. Foremost among these is the affected sibling pair approach, in which genetic variants more common in hypertensive than nonhypertensive siblings are sought. Increasingly sophisticated analyses of the genetic transmission of such variants in nuclear families are slowly yielding clues to candidate genomic regions and genes. Such methods are less likely to be affected by problems of population stratification that can produce false positive findings in simple association studies.⁷²

3. *Methodologic shortcomings constitute a third barrier to investigation of the genetics of hypertension.* While genetic linkage approaches have successfully identified genes causing Mendelian forms, application to essential hypertension has been less successful. By studying individuals with severe hypertension (defined either as a very high blood pressure level, early onset, or a requirement for multidrug therapy), the angiotensinogen gene was identified by linkage as a candidate for essential hypertension.^{73,74} In truth, however, this gene would have been studied as a logical candidate anyway, and certainly its identification by linkage was greatly facilitated by prior knowledge of its physiologic role. More typically genomic regions identified by genetic linkage encompass broad chromosomal regions comprising a significant fraction of the genome and containing tens or hundreds of candidate genes, many with known or potential roles in cardiovascular function. It is not currently possible to sequence all such genes to look for functional variants, and prior characterization of hypertension-related physiologic or biochemical disorders potentially arising from differences in candidate genes is therefore still required to narrow the search. Unfortunately, relying upon what is already known probably risks missing new candidates, confounding the potential for gene discovery that is one of the appeals of the linkage approach.

Incorporating genomic structure via haplotype analysis may advance the understanding of which segments of genes harbor functional variants. Current efforts to build a genome-wide haplotype map will result in a framework that should facilitate gene discovery work in complex diseases, including hypertension. Haplotype analyses will still be complicated by the limitations noted above.

4. *Is hypertension the result of many relatively uncommon genetic variants or of common alleles?* Although still somewhat unsettled, the latter is favored.⁷⁵ In either case, in addition to phenotypic heterogeneity, genotypic heterogeneity is likely important in hypertension, complicating the search for genes. Furthermore, it is unlikely that most common single nucleotide polymorphisms are nonsynonymous, causing simple changes of the primary amino acid sequence of encoded proteins.⁷⁶ More likely, as is thought to be the case for the A(-6) allele of the angiotensinogen gene, common allelic variants will affect functions like gene expression or regulation or perhaps mRNA splicing. Single lesions may not be causal in themselves: Another of the lessons from animal models is that the genetic background upon which a variant is expressed may dramatically affect its phenotypic impact. Because such effects of gene-gene interactions are subtle, defining the functional consequences of genetic variation defined by linkage or association studies will be challenging. Here animal models, particularly those employing gene knockout or directed mutagenesis techniques, promise to be instructive.
5. *Race remains a vexing issue in the study of the genetics of hypertension.* There is a history of hypertension research on racial differences in physiologic and biochemical characteristics, which leads many to assume that there are unique genetic determinants of blood pressure in the races. At the same time, there is considerable debate as to whether genetic characterization of race is possible or desirable.^{77,78} Given that there are certainly differences in allelic frequencies

between individuals whose ancestors spread from Africa to populate the world,⁷⁹ apparent genetic differences between hypertensives and normotensives may arise from population stratification or admixture. Because many differences in population-specific allelic frequencies arise from random genetic drift or other adaptively neutral processes, the conclusion that allelic frequency differences contribute to differences in the prevalence of hypertension in different populations must be viewed skeptically. We are all humans, and the mechanisms underlying blood pressure are likely to be quite similar in all of us.

Although challenging, identifying genes has proven not to be impossible. As noted previously, the angiotensinogen gene is thought to contribute to hypertension, although not all studies support the particular polymorphism originally described. A structural membrane protein, α -adducin, first identified in the Milan Hypertensive Rat model, has been associated with blood pressure salt-sensitivity and diuretic responsiveness.⁸⁰ Several other polymorphisms including ones in the genes encoding the β subunit of the G-protein complex⁸¹ and the β_2 -adrenergic receptor⁸² are associated with hypertension. With genotyping becoming ever more efficient and increasingly affordable, more extensive surveys of candidate genes, including whole genome surveys using hundreds of thousands of single nucleotide polymorphisms will soon be feasible. Such intensive characterization should allow us to begin to define which genes are related to subtypes of essential hypertension as defined by intermediate phenotypes such as salt-sensitivity, nonmodulator status, or membrane transport abnormalities.

There are a huge number of additional issues to be addressed at every organizational level to answer the question of what causes hypertension. How we ask the question frames the answer we will get. Let us hope that we are clever enough to ask the right question.

Blood Pressure Genetics

Stephen B. Harrap

Attempts to determine the genetic basis of blood pressure have encompassed a variety of approaches. These range from studies of blood pressure correlations between relatives,¹⁻³ to more direct analyses of associations between blood pressure and DNA variation. The potential of identifying the causative DNA variants has been reinforced by the release and refinement of the draft sequence of the human genome.⁴⁻⁶ Beyond scientific curiosity, the impetus is a fundamental understanding of mechanisms to provide the basis for new means of detecting, preventing, and treating high blood pressure and allied cardiovascular disease.

The successful discovery of the molecular origins of rare familial Mendelian diseases that affect blood pressure⁷ engendered optimism for genetic discovery in more common conditions such as clinical essential hypertension. However, the elucidation of genetic explanations of normal blood pressure variation and clinical hypertension are proving much more difficult.

ASSUMPTIONS AND MODELS

Important to both the discovery and application of genetics of high blood pressure is a clear understanding of the epidemiologic characteristics of blood pressure and its relevance as a risk factor. In particular, the clinical concept of hypertension and the relationships with cardiovascular disease deserve scrutiny.

Blood Pressure and Cardiovascular Disease

Much interest on the genetics of blood pressure has focused on hypertension, but the rationale owes more to clinical medicine than it does to the population burden of cardiovascular endpoints or the underlying biology of blood pressure.

Hypertension Is an Arbitrarily Defined Risk Factor, Not a Disease

For individuals, the greatest relative cardiovascular risk is associated with the highest blood pressures.⁸ This correlation justifies the medical approach of screening blood pressure and treating hypertensive subjects to reduce individual risk.

However, the population distribution of blood pressure is unimodal (Figure 5-1) and the definition of hypertension is operational.^{9,10} Classifications such as hypertensive and normotensive are constantly changing^{11,12} and do not necessarily differentiate individuals into meaningful biologic and, therefore, genetic groups.

There Exists a Continuous Relationship between Blood Pressure and Cardiovascular Risk

Epidemiologic analyses indicate that the relationship between blood pressure and risk of cardiovascular disease is continuous.⁸ In other words, across the entire population distribution an increment in pressure is associated with higher risk (Figure 5-2). However, such representations of individual risk reveal little of the impact of blood pressure in a population.

Much Cardiovascular Disease Attributable to Blood Pressure Occurs in Normotensives

When the number of people exposed to a certain level of blood pressure is multiplied by the relevant relative risk, a different picture emerges.¹³ For example, population attributable risk of blood pressure from the MRFIT study of 347,987 men (aged 35 to 57 years) is shown in Figure 5-3 as “excess deaths” from coronary heart disease (CHD) in relation to systolic blood pressure levels¹⁴ after accounting for age, race, serum cholesterol, cigarettes per day, use of medication for diabetes, and income. Thirty-two percent of CHD deaths attributable to systolic blood pressure (SBP) occurred in men with a systolic pressure of less than 140 mm Hg, compared with 24% of excess CHD deaths attributable to SBP in subjects with pressures greater than 160 mm Hg.

The Genetics of Higher Blood Pressure, Not Just Hypertension, Is Important

Although the individual burden rests with those with the highest pressures, the population burden is attributable to “average” pressures. Therefore, genetic explanations of the full range blood pressures are relevant to both individuals and to the entire community.

THE RELATIVE IMPORTANCE OF GENES AND ENVIRONMENT

What is the evidence that human genes affect blood pressure and how can such effects be understood in relation to the influences of the environment?

The Family Perspective

Biometric analyses are used to model blood pressure patterns within families and infer explanations based on genetic or environmental causation.^{1-3,15}

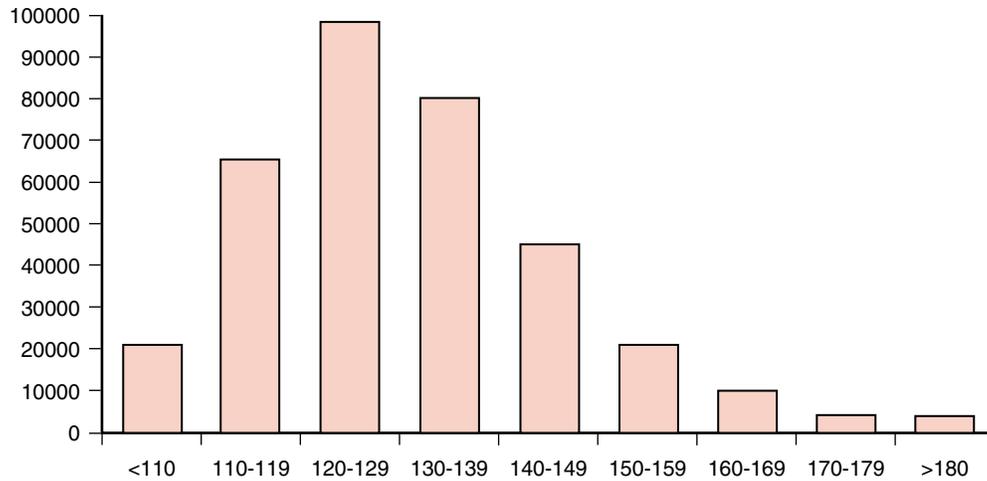

Figure 5-1 Systolic blood pressure (SBP) distribution in 347,987 men aged 35 to 57 years screened for the Multiple Risk Factor Interventions Trial (MRFIT). These data have a unimodal distribution with a skew towards upper values. (Data from Stamler J, Stamler R, Neaton JD. Blood pressure, systolic and diastolic, and cardiovascular risks. US population data. Arch Intern Med 153:598-615, 1993.)

Shared Genes

Genetic influence is suggested by the observation that the closer the genetic relatedness, the more similar the blood pressure. For example, the correlation coefficient for blood pressure between monozygotic twins (whose genetic similarity is 100%) is 0.78, while nontwin siblings (whose genetic similarity is 50% on average) show correlation coefficients of about 0.23.

Shared Environment

The influence of shared environment is revealed by discrepancies in blood pressure correlations between relatives despite the same degree of genetic similarity. For example, with genetic relatedness of 50%, dizygotic twins, nontwin siblings, and parents and offspring show decreasing levels of blood pressure correlation.¹⁵ Such differences can be ascribed only

to variation in the nature and extent of shared environmental factors such as diet and lifestyle.

Careful research design can provide interesting insights into such environmental effects. For example, the fact that the blood pressure correlation of adult offspring living apart exceeds that between those adult offspring and their parents suggests the persistent influence of environmental factors shared by offspring when they were living together in the family home.³ It also suggests that the influence of such factors is more potent within a generation than it is across a generation, a manifestation of the generation gap. The importance of the shared family environment is also seen in the blood pressure correlations during childhood between genetically unrelated adopted siblings.¹ The higher blood pressure correlation between dizygotic twins than between nontwin siblings suggests possible additional environmental exposures.³ In this respect the early life environment might be important.¹⁶

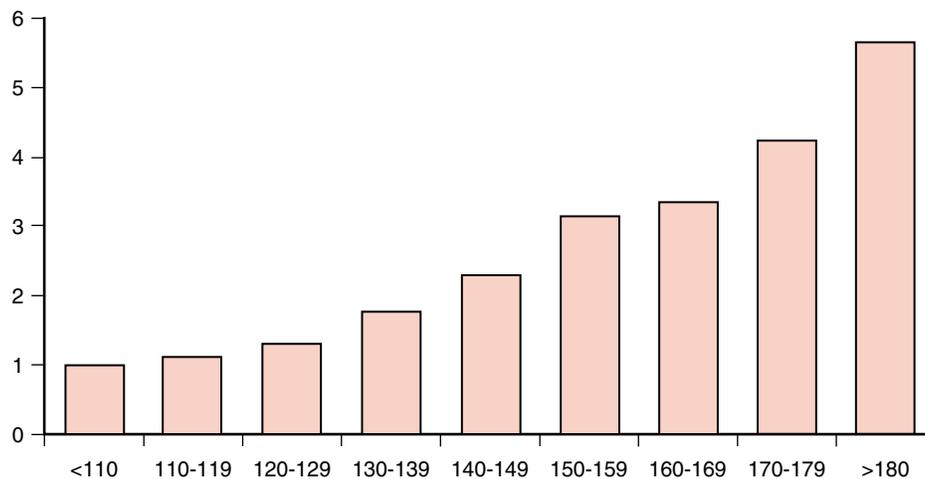

Figure 5-2 Rate of deaths from coronary heart disease (CHD) (adjusted for age, race, serum cholesterol, cigarettes per day, diabetes, and income) relative to the group with the lowest SBP in 347,987 men aged 35 to 57 years from Multiple Risk Factor Interventions Trial (MRFIT). These data show a stepwise increase in relative risk for each increment in SBP. (Data from Stamler J, Stamler R, Neaton JD. Blood pressure, systolic and diastolic, and cardiovascular risks. US population data. Arch Intern Med 153:598-615, 1993.)

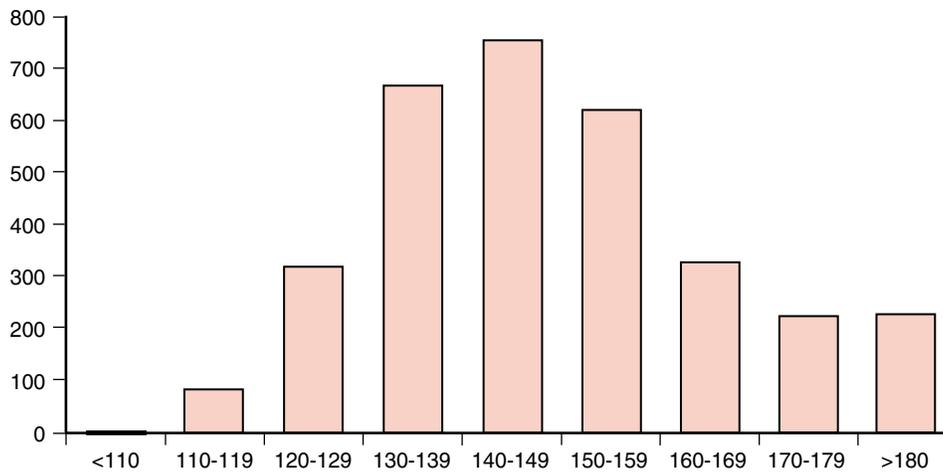

Figure 5-3 Number of “excess deaths” from CHD attributable to SBP relative to the group with the lowest SBP in 347,987 mean aged 35 to 57 years from Multiple Risk Factor Interventions Trial (MRFIT). See text for details. These show a large number of people exposed to a modest risk (average blood pressure) account for many cases of cardiovascular death in a population. (Data from Stamler J, Stamler R, Neaton JD. Blood pressure, systolic and diastolic, and cardiovascular risks. US population data. Arch Intern Med 153:598-615, 1993.)

In adulthood the influence of shared environment is less apparent. The blood pressure correlation coefficient between parents is often of the order of 0.13¹⁻³ and does not increase significantly as the period of shared environment increases.¹⁷

Defining the Balance between Genes and Environment

Sophisticated mathematical modelling and statistical analyses of family blood pressure patterns can partition variation of blood pressure into genetic and environmental compartments. The exact estimates depend on the research design and specific modelling parameters. Studies based on classical twin analyses tend to inflate the genetic component because the inherent assumption that the degree of shared environment is the same between monozygotic and dizygotic twins is usually violated.^{18,19} Blood pressure heritability (the proportion of variance attributable to genes) estimates from twin-only studies can be as high as 80%.²⁰ Comprehensive familial analyses that include other relatives in addition to twins offer more reliable estimates. Such studies suggest that genetic factors account for 40% to 50% of blood pressure variance, while shared environment accounts for about 10% to 30% of variance.¹⁻³

The Population Perspective

Evidence of genetic and environmental effects from families is obtained from relatively stable groups over short time frames. A different perspective, particularly in terms of environmental effects, is obtained by the studies of populations subject to mass change over longer periods.

Population Environment—Migration and Secular Trends

Blood pressures change significantly following migration.²¹⁻²⁴ Indeed, there appears to be a shift in the population mean blood pressures (Figure 5-4), such that there are changes at every level of the distribution.²⁵ These movements must be due to changes in the population environment because genes remain stable. In this context, “environment” encompasses economic, social, psychologic, and biologic elements. Furthermore, average blood pressures in geographically stable Western societies have been falling.²⁶⁻²⁹ In the absence of major changes in the genetic constitution, such effects reflect the influence of subtle but cumulative transformation of the environment of the population as a whole.

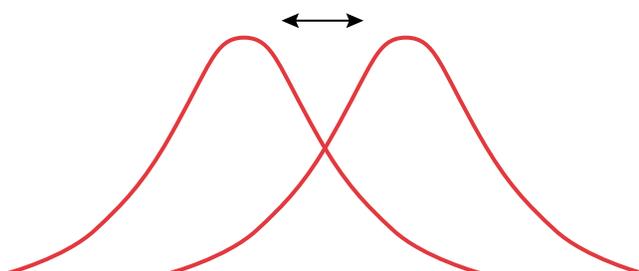

Figure 5-4 Changes in the population environment with migration over time tend to shift the distribution of blood pressure as a whole.

Attempts to define the responsible environmental factors are very difficult indeed. Changes in blood pressure are often associated with increases in body weight, but there are inconsistencies. In migration, blood pressure and body weight tend to move in the same direction while recent secular declines in blood pressures in Western societies seem to be coinciding with increased levels of obesity.³⁰ Sometimes differences exist in simple comparisons between populations, as in urinary electrolyte excretion. However, attempts to define the causative nature of such differences are confounded by intercorrelated environmental characteristics, many of which are unmeasured.³¹ Additionally, the influence of specific factors such as sodium is difficult to demonstrate between individuals within populations. Nevertheless, grouping of environmental exposures that are defined by socioeconomic status appear important correlations of blood pressure within populations.³²

Population Genetics

Within populations, individuals vary extensively across the genome, most commonly in the form of single nucleotide polymorphisms (see the section “Genetic Markers”). In general, the DNA sequence variation is greater within populations than it is between populations. Some estimates suggest that populations worldwide share 93% of the variation at individual genetic loci and 7% is unique to local populations.³³ Population-specific DNA variants tend to be younger and less frequent than the older, more frequent, global variants (Figure 5–5).³⁴ The unanswered question is to what extent population differences in blood pressure can be explained on population-specific differences.³⁵

The Individual Perspective

Gene-Environment Combination

Individual blood pressure can be understood as the result of two underlying influences.³⁶ One, genotype, would determine an individual’s rank within the population distribution (Figure 5–6). The other, population environment, would determine the mean for the population. Therefore, the final blood pressure would be the sum of these two influences and in this way depends on both genes and environment.

Gene-Environment Interaction

It is possible that certain genotypes predispose to larger changes in blood pressure for a given change in the population environment. This phenomenon might explain the skewed distribution of blood pressure in Western societies. Migration studies have identified subgroups of individuals who appear to have exaggerated blood pressure responses to migration.³⁷ These clusters are often familial, although not explained by simple genetic inheritance.³⁷

MOLECULAR GENETICS

The limelight in genetic research has fallen on the molecular biologic laboratory and statistical genetic analysis. As it does so, something of the complex, underlying genetic architecture is revealed. The concept that specific variants in DNA

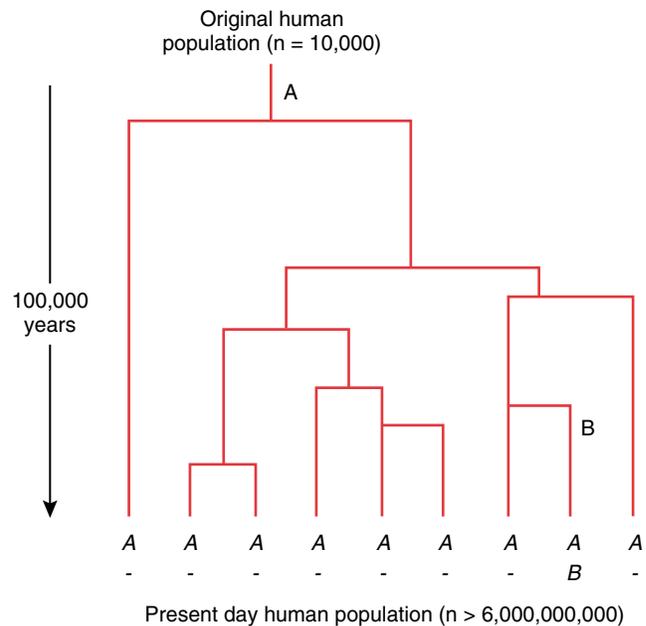

Figure 5–5 A schematic representation of the migration, expansion, and diversification of *Homo sapiens* from an ancient original population in West Africa to the present day. Allele **A** appeared over 100,000 years ago and is represented globally. Allele **B** appeared recently and is found in only one population. (From Harrap SB. Where are all the blood pressure genes? *Lancet* 361:2149-2151, 2003.)

sequence—known as alleles—in and around key genes might affect blood pressure has been proven by the discoveries relevant to monogenetic disease (discussed in the sections that follow). However, the number and nature of genetic variants that determine the physiologic variation in blood pressure and/or clinical hypertension remain largely mysterious. What seems certain is that the situation is not simple.

Blood Pressure Polygenes

It is important to note that the similarity of blood pressure between blood relatives is not limited to high blood pressure. Low, middle, and high blood pressure levels are heritable. Herein lie clues to the genetic architecture underlying blood

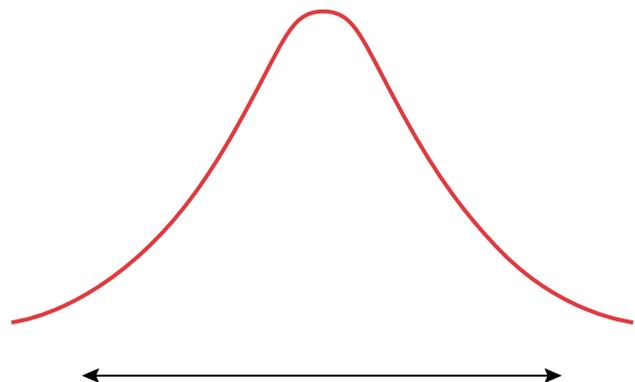

Figure 5–6 Blood pressure differences within a population are likely to be explained by genetic differences between individuals.

pressure; as “hypertension genes” alone could not explain such patterns. Instead it is believed that a number of genes (polygenes) exist. Certain alleles at each polygene could exert incremental effects on blood pressure and in combination with other alleles at other polygenes could account for the quantitative variation and familial correlations of blood pressure (Figure 5–7). More direct evidence of polygenes has been obtained from molecular genome analyses (see “Genomic Discovery and Blood Pressure”).

Lessons from Mendelian Disease

The important question for both research and its application is how many blood pressure alleles might exist in a population. It has emerged that many “monogenic” diseases are in fact syndromes, comprising often hundreds of specific allelic forms. Similar clinical phenotypes can be caused by any one of several genes, for each of which one of many possible causative alleles is sufficient.⁷

If such genetic and allelic heterogeneity characterize “simple” monogenic disease, what are the prospects for complex conditions? Some theorists propose that the forces governing genetic architecture for rare and common conditions are different and as a result the allelic spectrum for conditions such as blood pressure might be simpler rather than more complex.³⁸ As things stand, two schools exist.

Common Disease/Common Variants

According to the common disease/common variant (CD/CV) hypothesis,^{39–41} there will exist a few key alleles in a population. Such alleles would be relatively common in genetic terms (population frequency >1%) and each would exert a moderate incremental effect on blood pressure. Related examples include the APOE4 allele in Alzheimer disease⁴² or factor V^{Leiden} in deep venous thrombosis.⁴³

Common Disease/Rare Alleles

In contrast, the common disease/rare allele (CD/RA) hypothesis postulates that allelic heterogeneity will be high with large numbers of uncommon alleles.^{44,45} A large number of rare alleles would be difficult to detect in population-based studies⁴⁶ and

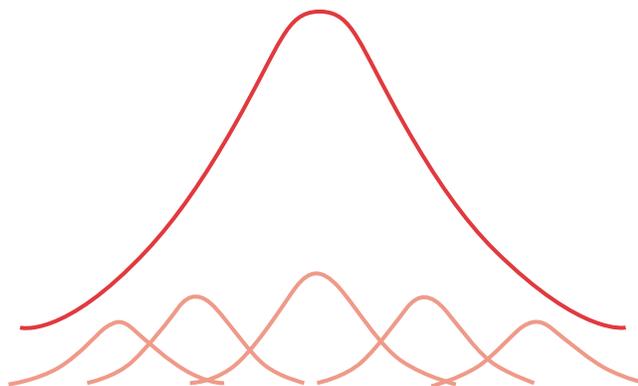

Figure 5–7 The unimodal population distribution of blood pressure could be explained by many genetically distinct subpopulations defined by a number of polygenes.

because rare alleles tend to be younger and population-specific³⁴ they might be lost in studies of heterogeneous populations.⁴⁷

For polygenic traits such as blood pressure both hypotheses might be relevant, with some polygenes fitting the CD/CV model and others fitting the CD/RA model.

GENOMIC DISCOVERY AND BLOOD PRESSURE

Genetic Markers

It has been estimated that one genome differs from another on average at 1 in every 1250 nucleotides. This allelic variation provides useful genetic markers. There are three major types of genetic markers: insertions and deletions of stretches of DNA (e.g., ACE I/D polymorphism^{48,49}), variation in the number of times a characteristic DNA sequence is repeated (e.g., microsatellite short tandem nucleotide repeats⁵⁰), and single nucleotide substitutions (known as single nucleotide polymorphisms [SNPs]).⁵¹

The most useful markers should be abundant and evenly distributed across the genome and they should be measurable easily and accurately. These criteria apply to microsatellites but especially to SNPs. Of the microsatellites, repeats of the dinucleotide CA(GT) are the most common and spread across the genome.⁵² The number of repeats at any site is often highly variable (polymorphic), reducing the likelihood that they will be the same in any two individuals—a useful characteristic when tracing the inheritance of blood pressure in family linkage analyses (see “Linkage Studies”).

Single Nucleotide Polymorphisms

Of the estimated 15 million SNPs that dwell in the genomes of modern *Homo sapiens*, between 50,000 and 100,000 SNPs are in or around genes and are well placed to alter gene function and protein expression.⁵³ More than 1.4 million SNPs have been identified,⁵¹ the most common being transitions between G↔A and C↔T.⁵⁴ For the typical gene one can expect to find 12 SNPs with a mean population frequency of 11% for the less common (i.e., the younger) allele at each SNP. About one half of SNPs are in coding sequences and one half of these alter protein sequence.⁵⁵ A survey of 75 genes of relevance to blood pressure homeostasis³⁵ found 874 SNPs, 209 of which changed the amino acid sequence. No association with blood pressure could be demonstrated in this relatively small analysis, but these protein-altering SNPs had the hallmarks of evolutionary youth, in that they each tended to be infrequent and in specific populations.

Alleles, Markers, and Haplotypes

Both marker SNPs and SNPs that are functional alleles can be associated on stretches of DNA known as haplotypes. Consider an ancient chromosome in the original human population of 10,000 in West Africa 100,000 years ago.⁵⁵ On this chromosome exists an ancestral haplotype—a stretch of DNA with a series of nonfunctional specific SNP alleles (Figure 5–8). Within this haplotype a mutation appears and results in a new functional allele that causes an increment of blood pressure. At each subsequent generation, the process of recombination during meiosis (formation of eggs and

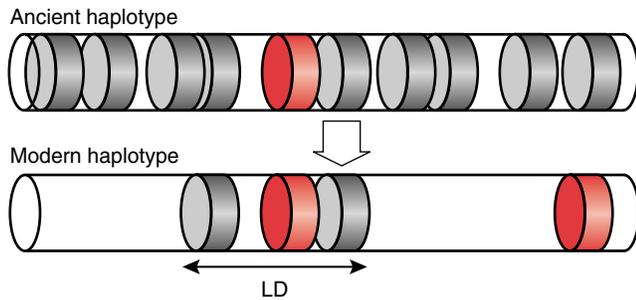

Figure 5–8 Diagrammatic representation of a stretch of ancient chromosome and a haplotype comprising a group of specific markers (gray cylinders) around a new DNA variant (red cylinder) that causes an increment in blood pressure. Over the generations, recombination whittles away at markers surrounding the mutation so that those with high blood pressure as a result of the variant will have only close remnants of the ancient haplotype. The markers that have survived to the modern haplotype are said to be in linkage disequilibrium (LD) with the variant. Therefore, the specific markers would be associated with high blood pressure. The red marker more distant from the variant would be in linkage with the variant if the chance of recombination over a few generations were low.

sperm) tends to swap pieces of the chromosome with the equivalent region of its pair. In this way the association between the blood pressure and surrounding the marker alleles tends to be lost. The chance of such recombination depends on a variety of factors including the distance between the blood pressure and the marker alleles⁵⁶ (the farther away, the greater the likelihood of recombination) and the number of generations (i.e., opportunities to recombine).

Linkage Disequilibrium

Specific SNP markers on remnants of the ancestral haplotype will lead by association to the blood pressure allele (see Figure 5–8). Such original marker alleles very close to the blood pressure allele will be preserved and are described as being in linkage disequilibrium (LD). The distance over which LD is preserved is typically less than 5000 nucleotides but varies in different parts of the genome from a few thousand nucleotides to more than 100,000 nucleotides.⁵⁷ Shorter distances of LD often occur in so-called recombination “hot spots.”^{56,58} Given the relative opportunities to recombine, ancient blood pressure alleles would be surrounded by shorter distances of LD than blood pressure alleles that emerged more recently.

Linkage

Just outside the stretch of LD will be a variety of marker alleles that have been imported by recombination (see Figure 5–8). The precise nature of these new marker alleles might vary between families, but within families they will be co-inherited with the blood pressure allele, provided they avoid being separated by recombination over a handful of generations. This situation is described as linkage between the blood pressure and marker alleles when they are inherited together. Linkage extends over much greater distances on either side of a blood pressure allele than LD.

Discovery Strategies

From the starting point of the human genome, the first step is to focus on the likely or “candidate” region in which blood pressure alleles might exist. This focus is achieved either conceptually by simply nominating a candidate gene on the basis of physiologic plausibility or experimentally with a genome-wide scan. The former is potentially efficient, but blinkered. The latter is burdensome, but without prejudice and more likely to reveal novel causes.

A contemporary strategy for discovery involves the following steps:

- Step 1. Genome-wide mapping to identify the candidate chromosomal region.
- Step 2. Fine-mapping study to replicate and refine the localization.
- Step 3. Allelic searches in and around genes within the candidate region, with priority given to those of known and relevant function.
- Step 4. Identification of candidate alleles with likely functional implications.
- Step 5. Testing of candidate alleles in living systems by physiologic genomic methods.
- Step 6. Determination of the contribution by candidate alleles to population blood pressure variation.

Linkage Studies

Studies based on linkage are used for genome-wide (step 1) and fine mapping (step 2). They necessarily involve families and test for coinheritance of blood pressure and adjacent marker alleles. The most informative linkage markers are highly polymorphic, so that the specific marker linked with a blood pressure allele in a particular family would be unlikely in other relatives by chance alone.

Genome Maps

For genome scans, maps of 450 or so microsatellite markers, spaced on average 10,000 nucleotides apart, are generally used. For fine mapping, microsatellite markers more closely spaced across the candidate region are employed.

Linkage Study Design

Linkage information is gathered family by family and the exact nature of the polymorphic marker linked with a certain blood pressure locus might vary between families. The minimum family unit for linkage studies comprises two relatives, often a pair of siblings.^{59,60} Indeed, pairs of dizygotic twins can be especially useful because they have less environmental variability and a potentially sharper genetic signal.⁶¹ Importantly, the sib-pair design is a pragmatic choice for conditions of middle age such as hypertension, in which parents might be dead and offspring difficult to classify. Both qualitative (hypertension, normotension, high, low) and quantitative (measured pressures) data can be used for sib-pair linkage studies.^{62,63}

In linkage approaches, the selection of siblings with discordant phenotypes has been proposed.^{64,65} Although there may be a theoretical argument for selecting from the extremes of

the blood pressure distribution to increase statistical power^{65,66} there are potential difficulties. The first is logistic. The more extreme the criteria, the fewer the eligible individuals and sibling pairs. Large screening phases are needed that can involve hundreds of thousands of individuals.⁶⁷ The second is etiologic. Pickering showed that familial correlation appeared to decline at very high levels of pressure and interpreted this as the result of inclusion of nonfamilial secondary forms of hypertension.⁶⁸ It can be difficult to effectively exclude nongenetic causes (sometimes transient) of very high or very low blood pressure in large scale screening programs. Finally doubt regarding the representativeness of individuals with extreme blood pressure will always remain, especially in relation to the genetic causes of middling levels of blood pressure around which most of the pressure-related complications occur.

Association Studies

In association studies, the “family” is the population. Cases with high blood pressure who share common ancestors will also share the remains of the ancestral haplotype in which a blood pressure allele arose (see previous section “Alleles, Markers, and Haplotypes”). By inference, specific ancestral haplotype marker alleles in LD with a blood pressure allele will be found more frequently in cases (i.e., associated) with high blood pressure than in controls. Simple chi-square tests are used to determine the statistical significance of differences in proportion of marker alleles.

Association can be tested using individual SNPs one at a time. However, there might also be merit in testing association with combinations of SNPs in the region of interest. At each gene there are on average approximately 14 different SNP haplotypes.⁵⁴ One potential advantage of using SNP haplotypes is that the phenotypic effect might depend on the molecular interaction between a particular combination of SNPs. Examples exist of phenotypes that are associated with the whole SNP haplotype, but not with the individual SNP components.⁶⁹ Moreover, it might be possible to identify “tag SNPs” that distinguish certain haplotypes without the need for genotyping all SNPs in the haplotypes.⁷⁰

Association Study Design

The usual comparison in association studies is between hypertensive and normotensive subjects, who sit either side of an arbitrary line drawn in the population distribution (Figure 5–9). Theoretically, selecting from the top and bottom of the distribution should enhance genetic contrast and the power to detect association (Figure 5–10).^{71,72} One practical example is the Four Corners Approach devised by Watt selects from the upper and lower ends of the blood pressure distribution using measured pressures from two generations.⁷³

As LD extends over shorter distances than linkage (see previous section “Linkage Disequilibrium”), association studies have higher resolution especially when using closely spaced SNPs as markers for fine-mapping (step 2) and allelic searches (step 3). Indeed, SNPs might also be useful for LD mapping of the entire genome⁴⁶ (step 1). Although initial success in cardiovascular disease has been reported,⁷⁴ there is debate about the general utility of this approach^{45,75,76} in which maps might require more than 1 million SNPs and high throughput methods to cope analytically.⁷⁷

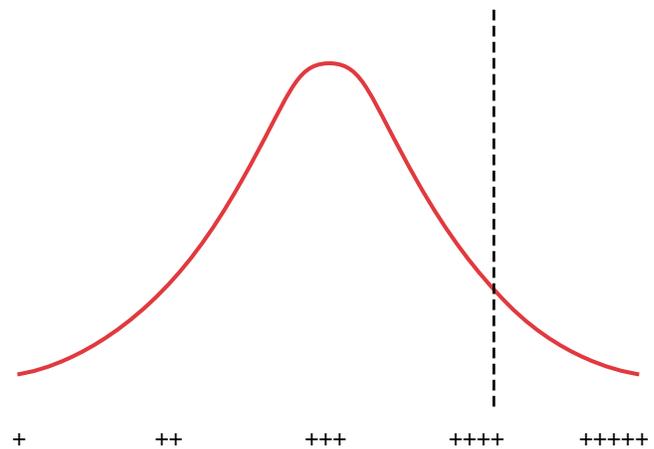

Figure 5–9 Assuming that blood pressure rank is the result of the individual “dose” of polygenes, the genetic contrast between hypertensives (to the right of the dashed line) and normotensives (to the left of the dashed line) is not especially large.

Single Nucleotide Polymorphism Discovery

Detailed allelic searches (step 3) demand a comprehensive catalog of SNPs in the region. This necessitates reference to global SNP databases combined with a phase of SNP discovery and verification in the relevant local population.^{35,54} The gold standard is direct sequencing in and around candidate genes, at minimum covering the exons (coding regions, 5′ untranslated region, 3′ untranslated region), up to 100 nucleotides into the introns from the exon-intron boundaries and the 5′ upstream genomic region.⁵⁴

Potential Difficulties

SNP LD mapping should be successful if blood pressure is influenced by relatively old mutations that are at high frequency. However, should the CD/RA model pertain, the utility

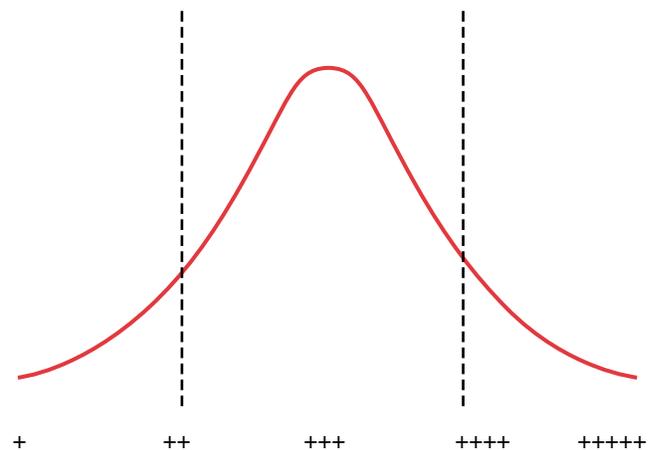

Figure 5–10 Assuming that blood pressure rank is the result of the individual “dose” of polygenes, the genetic contrast between subjects with high (to the right of the upper dashed line) and low (to the left of the lower dashed line) blood pressure is greater than with the dichotomous strategy (see Figure 5–9).

of LD mapping will be limited with the existing statistical methods.^{45,75} Indeed, any methods that depend on LD will struggle if high levels of allelic heterogeneity underpin blood pressure, simply because of the complexity imposed in detecting numerous and infrequent alleles. Under such circumstances, linkage methods that detect all blood pressure haplotypes in a chromosomal region might be better.

Bias

For any discovery based on association studies, the possibility of false positives as a result of population stratification must be considered,⁷⁸ although the magnitude of the problem is debated.⁷⁹ Stratification arises when bias is introduced (often unwittingly) during the selection of cases and controls.⁸⁰ One important example is unrecognized racial or ethnic heterogeneity confounding analyses.⁸¹ Where a racial or ethnic group is more prone to a disease (therefore, included more frequently as cases) any genetic variant characteristic of or more common in that group (even if not causative) will be mistakenly associated with the condition. Sometimes the causes of bias may be far more subtle and difficult to identify.

One approach has been to use independent markers at other loci to detect systemic genetic differences between cases and controls.⁸² However, the preferred solution lies in combining approaches and performing association tests within families. Analyses such as the transmission disequilibrium test (TDT)⁸³ are not susceptible to population stratification and have an important role in confirming positive associations of putative causative DNA variants.

GENETICS OF BLOOD PRESSURE DISEASES

Among the triumphs of molecular biology stand the definitions of genetic causes of rare Mendelian forms of blood pressure deviation.⁷ Table 5–1 summarizes these discoveries.

One important lesson for essential hypertension from these Mendelian syndromes is that even blood pressure effects of major mutations are not guaranteed,¹⁰² presumably as a result of interactions with other genes and the environment.

GENETICS OF COMMON BLOOD PRESSURE VARIATION

Candidate Genes

Before the advent of genomic maps, much of the early work analyzed associations between polymorphisms in candidate genes and clinical essential hypertension. The choice of candidates is directed by a variety of considerations.

Candidates from Rare Mendelian Diseases

Although major mutations in genes responsible for Mendelian blood pressure diseases do not explain common hypertension,^{103,104} other DNA variants in the same candidate genes with more subtle effects on gene expression or function might be relevant.

For example, the *SCNN1B* and *SCNN1G* genes encoding the β - and γ -subunits of the epithelial sodium channel that have been implicated in Liddle syndrome^{86,87} make logical candidates and these genes have been linked with variation of SBP in the general population.¹⁰⁵ Causative DNA variation in these genes has yet to be identified for common hypertension, but these findings illustrate the potential relevance of rare syndromes to defining candidates for population genetic analyses. Other genetic loci from Table 5–1 are also worthy candidates.

Candidates from Physiologic Plausibility

Careful physiologic study of blood pressure, and in particular the predisposition to high blood pressure, provides important clues to genes worthy of investigation. In contrast to the rare Mendelian syndromes, the pathophysiology is not predominantly renal and includes other neuronal and metabolic abnormalities.^{106–110}

Candidates with Functional Polymorphisms

Given the complex physiologic determination of blood pressure, the list of candidate genes is potentially enormous. However, those candidates for which functional DNA variation has been identified attract greater priority, especially if the variants are relatively common. For example, the simple I/D polymorphism of the ACE gene has been associated with differences in ACE enzyme activity^{111,112} and variants of the angiotensinogen gene are associated with differences in plasma angiotensinogen levels.¹¹⁸ A common polymorphism of the glucocorticoid receptor gene¹⁰⁸ has been related to tissue-specific differences in steroid sensitivity¹¹³ and polymorphisms of the gene encoding the β_2 -adrenergic receptor have been associated with changes in vascular reactivity.¹¹⁴ SNPs of the natriuretic peptide A receptor also have functional effects on receptor mRNA levels.¹¹⁵

Candidates from Linkage Mapping

The advent of genome-wide mapping offers an important means of selecting candidates that are located within chromosomal regions linked with blood pressure (see next paragraph). This approach will become increasingly important as linked loci are replicated to achieve confirmed status (see “Genome Scans” section).

Candidate Association Analyses

Polymorphisms in and around a large range of candidates have been associated with blood pressure, including genes encoding ACE,^{116,117} angiotensinogen,¹¹⁸ glucocorticoid receptor,¹⁰⁸ insulin receptor,¹¹⁹ complement C3F,¹²⁰ β_2 -adrenergic receptor,^{121,122} lipoprotein lipase,¹²³ type 1A dopamine receptor,¹²⁴ alpha-adducin,¹²⁵ α_{1B} -adrenergic receptor,¹²⁴ endothelial nitric oxide synthase,¹²⁶ pancreatic phospholipase A2,¹²⁷ α_2 -adrenergic receptor,¹²⁸ SA gene,¹²⁹ angiotensin II type 1 receptor,¹³⁰ G-protein β_3 subunit,¹³¹ 6-phosphogluconate dehydrogenase,¹³² prostacyclin synthase,¹³³ growth hormone,¹³⁴ Na,K,2Cl-cotransporter,¹³⁵ alpha(1)-Na,K-ATPase,¹³⁵ and GPR10.¹³⁶ However, almost every published positive result has been followed by a negative result.^{137–149} Aspects of research design and analysis provide some possible

Table 5-1 Rare Mendelian Forms of Blood Pressure Deviation

Disease	Phenotype	Genetic Cause
Glucocorticoid remediable hyperaldosteronism ⁸⁴	Autosomal dominant, hypertension, variable hyperaldosteronism	Chimeric 11 β -hydroxylase/aldosterone synthase gene
Syndrome of apparent mineralocorticoid excess ⁸⁵	Autosomal recessive, volume expansion, hypokalemia, low renin and aldosterone	Mutations in the 11 β -hydroxysteroid dehydrogenase gene
Liddle syndrome ^{86,87}	Autosomal dominant, hypertension, volume expansion, hypokalemia, low renin and aldosterone	Mutation subunits of the epithelial sodium channel <i>SCNN1B</i> and <i>SCNN1G</i> genes
Pseudohypoaldosteronism type II (Gordon's syndrome) ⁸⁸	Autosomal dominant, hypertension, hyperkalemia, volume expansion, normal glomerular filtration rate	Linkage to chromosomes 1q31-q42 and 17p11-q21
Gitelman's syndrome ⁸⁹	Autosomal recessive, low blood pressure, hypokalemic alkalosis, hypocalciuria	Mutations in the Na, Cl cotransporter <i>NCCT</i> gene
Bartter's syndrome ^{90,91}	Autosomal recessive, low blood pressure, hypokalemic alkalosis, hypercalciuria	Mutations in the Na, K, 2Cl cotransporter <i>NKCC2</i> gene or mutations in the K channel <i>ROMK</i> gene
Bartter's syndrome type III ⁹²	Autosomal recessive, low blood pressure, hypokalemic alkalosis, hypercalciuria without nephrocalcinosis	Mutations in the chloride channel <i>CLCNKB</i> gene
Pseudohypoaldosteronism type I—severe ⁹³	Autosomal recessive, low blood pressure, renal salt wasting, hyperkalemia and metabolic acidosis, elevated aldosterone levels	Mutation subunits of the epithelial sodium channel <i>SCNN1B</i> and <i>SCNN1G</i> genes
Pseudohypoaldosteronism type I—mild ⁹⁴	Autosomal dominant, low blood pressure, renal salt wasting, hyperkalemia and metabolic acidosis, elevated aldosterone levels that remit with age	Mutations in mineralocorticoid receptor gene
Polycystic kidney disease ⁹⁵	Autosomal dominant, renal cysts, hypertension and renal failure, liver cysts, cerebral aneurysms, valvular heart disease	Mutations in the <i>PKD1</i> and <i>PKD2</i> genes
Pheochromocytoma ^{96,97}	(a) Multiple endocrine neoplasia type 2A: autosomal dominant, medullary thyroid carcinoma, pheochromocytoma, hyperparathyroidism (b) von Hippel-Lindau disease: autosomal dominant, retinal angiomas, hemangioblastomas of the cerebellum and spinal cord, renal cell carcinomas, adrenal pheochromocytomas ⁹⁸ (c) Neurofibromatosis type 1: autosomal dominant, multiple neurofibromas, café au lait spots, Lisch nodules of the iris and pheochromocytomas ⁹⁹ (d) Nonsyndromic pheochromocytomas	(a) Mutations in the <i>RET</i> protooncogene (b) Mutations in the <i>VHL</i> tumour suppressor gene (c) Mutations in the <i>NF1</i> tumour suppressor gene (d) Mutations in <i>RET</i> , <i>VHL</i> , <i>SDHB</i> , <i>SDHD</i> genes ¹⁰⁰
Hypertension exacerbated in pregnancy ¹⁰¹	Autosomal dominant, early onset, severe hypertension with low aldosterone levels, exacerbated in pregnancy	Missense mutation resulting in substitution of leucine for serine at codon 810 (<i>MR</i> _{LB10})

explanations for inconsistencies. However, the combination of chance and editorial bias¹⁵⁰ explains why certain positive results have not stood the test of time.

Genome Scans

Figure 5–11 shows the results of a typical genome-wide scan, in this case a multipoint quantitative sib-pair analysis of SBP.¹⁵¹ Each panel represents a probability plot (expressed as Z scores) along the length of each of the 22 autosomes and the

X chromosome. The Y chromosome is not included in linkage analyses because, other than at the very tips, the vast majority of the Y chromosome does not recombine and is, therefore, uninformative for linkage.

Genome-Wide Significance

Evidence of linkage is derived from the magnitude of the probability and the likely location of the blood pressure locus is identified by the position along the chromosome

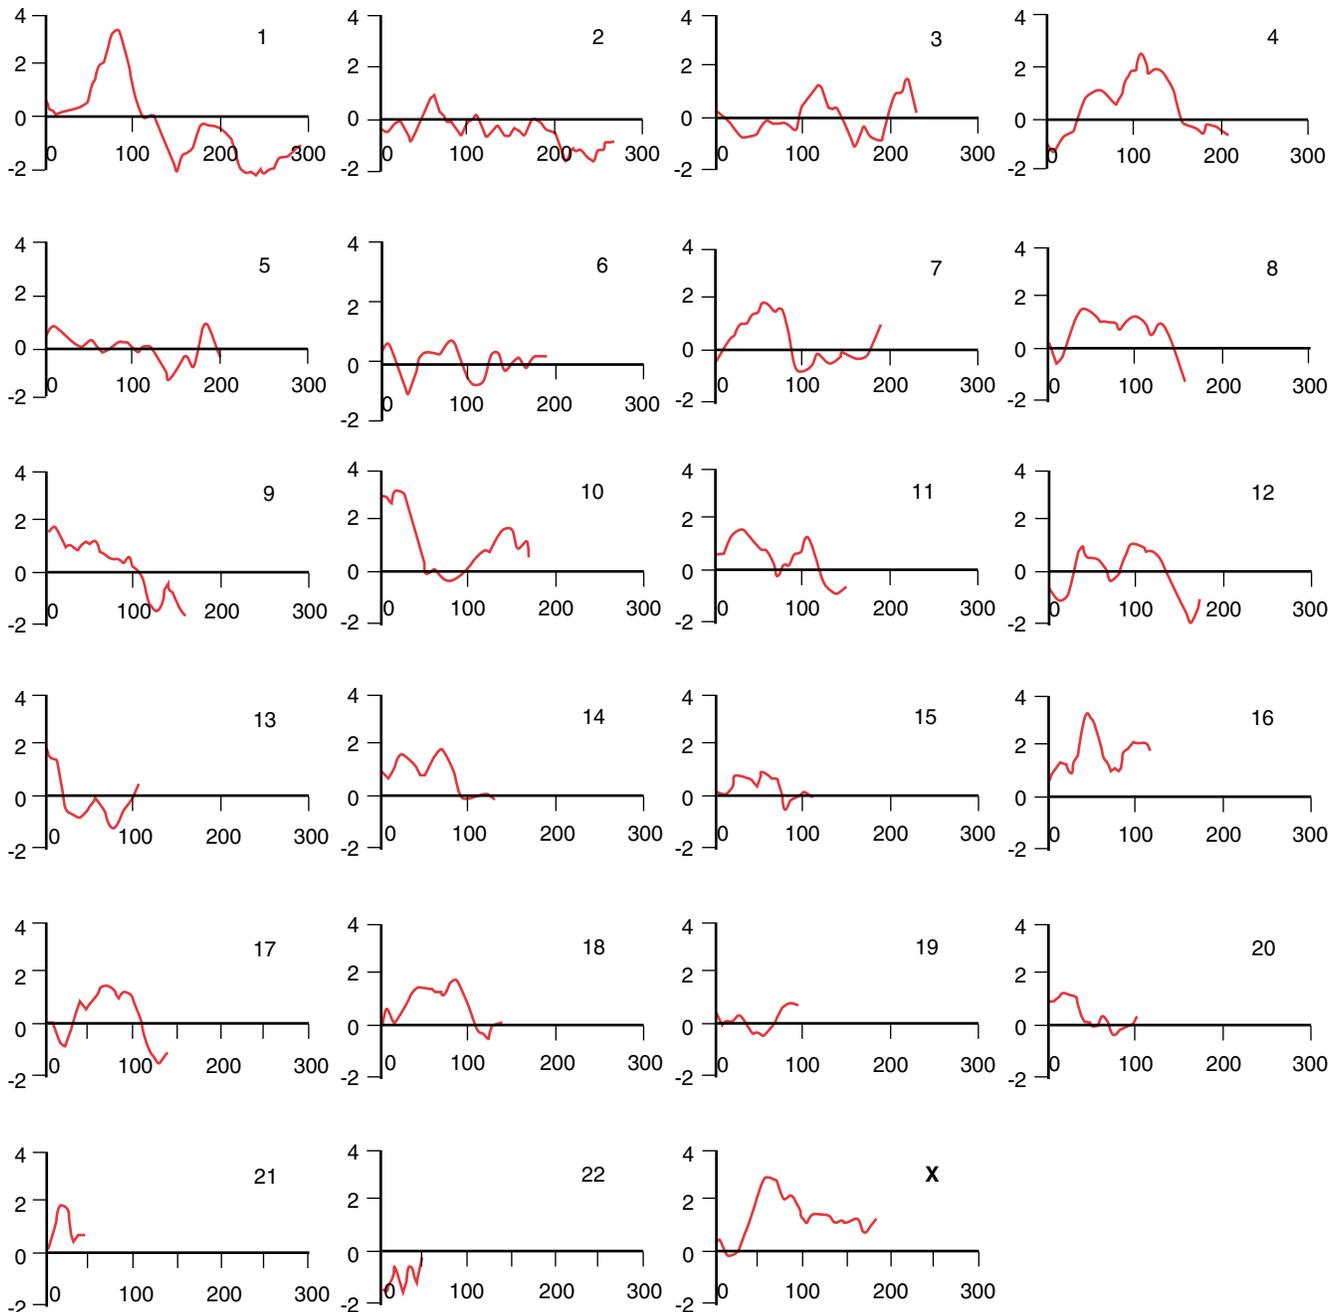

Figure 5–11 Genome-wide probability plots for evidence of linkage with SBP. Each panel shows a chromosome (22 autosomes and X) with genetic distance in centiMorgans along the x-axis and probability (Z) along the y-axis. On chromosomes 1, 4, 16, and X, Z exceeds the evidence for suggestive linkage. (From Harrap SB, Wong ZY, Stebbing M, et al. Blood pressure QTLs identified by genome-wide linkage analysis and dependence on associated phenotypes. *Physiol Genomics* 8:99-105, 2002.)

(expressed for example as a genetic distance in centiMorgans from the p telomere) at which peak probability occurs. Because multiple markers (around 450 microsatellites per first pass scan) increase the likelihood of false positives, Lander and Kruglyak¹⁵² proposed guidelines for accepting genome-wide significance with a series of gradings including “suggestive,” “significant,” and “highly significant.” These correspond to the likelihoods of false positive being 1.00, 0.05, and 0.001, respectively, per genome-wide scan. These stringent guidelines have been questioned¹⁵³ as they may risk discarding important results in cases of inadequate statistical power. Many investigators use lower thresholds and the category of “promising” has been adopted with probabilities below “suggestive.” Nevertheless, more important than arbitrary probability thresholds is the replication of linkage in independent populations. This essential step toward formal proof is central to the concept of a “confirmed” locus.¹⁵²

Table 5–2 summarizes these results from genome-wide scans for blood pressure or hypertension that have reported chromosomal loci for which multipoint analyses reveal linkage evidence that exceeds the “promising” threshold. The summary has been restricted to multipoint analyses (using adjacent groups of markers simultaneously) as they increase the power to detect true linkages, they decrease the false-positive rate, and when linkage is detected, they provide localization and confidence intervals.¹⁵⁴

Mixed Success

One is struck immediately by the differences in the number, location, and statistical significance of blood pressure loci between the studies. Evidence of genome-wide suggestive linkage was reported for between 0 and 4 loci per study. Given that one suggestive locus is expected by chance, this leaves only nine studies with results that might be considered less likely to be false positives. This group includes six studies reporting more than one suggestive locus^{67,158–161} and three others reporting a single locus at which linkage probability exceeded the “significant” threshold ($\log\text{-of-the-odds [LOD]} > 3.6$).^{155–157}

Where Are the Blood Pressure Polygenes?

The sparsity of linked loci might lead one to question the veracity of the polygenic model. But it is more likely that methodological problems impair the ability to detect the polygenes in linkage studies, especially if there are many of small individual effect.¹⁷⁴ If nothing else, the genome scans offer an attempt to define empirically the research designs that appear to provide the greatest success. This necessary process of trial and error will help chart the size and nature of further studies. The following identifies issues of potential relevance to both association and linkage analyses.

Maximizing Success in Genetic Discovery

Quantitative Versus Qualitative Phenotypes

Most of the nine “successful” genome-wide studies used quantitative methods (see Table 5–2). In qualitative analyses, clinical hypertension is most often used as the defining phenotype. However, the range of recorded pressures from any group of

hypertensives is very broad.¹⁷⁵ The qualitative assumption that all hypertensives are genetically similar is unlikely to be true and lumping together such genetic heterogeneity obscures valuable quantitative information that reflects to locus-specific effects that might be peculiar to certain families in linkage studies. Given the simple approaches for adjusting for the effects of antihypertensive treatments, quantitative analyses in treated subjects are feasible and worthwhile.¹⁷⁵

Different Pressure Phenotypes

Blood pressure can be measured as systolic, diastolic, mean, or pulse pressure in lying, sitting, standing, or ambulatory situations. Is any one better than another? From the genome scans, it appears that loci linked with SBP were reported more frequently than those with diastolic blood pressure (DBP) (see Table 5–2). However, this may simply be a function of the relatively high degree of individual-specific variation such as measurement error of DBP.¹⁵

The relationship between blood pressure and the underlying genotype might be complex or simple. If complex, a heterogeneous group of genes might influence blood pressure at any one of the numerous points of physiologic control (see Figure 5–7). By inference such alleles might be discovered when heterogeneity is minimized by subgrouping blood pressure according to underlying physiologic intermediate phenotypes.^{176–181} Few genomic analyses have used this approach because detailed phenotypic characterizations in large numbers of subjects is very difficult. Nevertheless, simple dissection of blood pressure in large-scale studies is feasible. For example, analyses of postural changes^{182,183} have the potential to reveal genetic factors related to the sympathetic nervous control of blood pressure. In hypertensive subjects the immediate blood pressure change on standing shows suggestive evidence of linkage to chromosome 18.¹⁸² However this locus was not linked with the postural blood pressure change after 2 minutes standing,¹⁸² suggesting genotypic heterogeneity even for the postural phenotypes.

If simple, there might exist DNA variants with pleiotropic effects (i.e., influencing all pressure phenotypes). Indeed, some evidence suggests that SBP and DBP,¹⁵ lying and standing SBP,¹⁸³ and SBP and pulse pressure¹⁸⁴ share genetic determinants. For pleiotropic genes, the most appropriate phenotype would be 24-hour ambulatory recordings¹⁸⁵ with the added advantages of repeated measures and reduced measurement error. Ambulatory recordings would also allow analyses of blood pressures for genes whose effects are more obvious at one time of the day than another.¹⁸⁶

Whether DNA variants are pleiotropic or highly specific in phenotypic effects, it is important that genetic analyses of blood pressure are precise and explicit in the selection of phenotypes. Furthermore, so that the measurements reflect the underlying genotype as reliably as possible,¹⁸⁷ measurement error must be minimized by careful standardization of techniques, training observers, and making repeated measures.

Study Size

All other things being equal, the bigger the study size the greater the statistical power. However, meaningful power calculation for linkage is a difficult task without knowledge of the underlying genetic architecture and the potency of

Table 5-2 Details of Genome-Wide Scans for Blood Pressure*

*Results are from multipoint linkage analyses only. Study samples comprise families (F) or sibling pairs (S) and analyses are either quantitative (QT) or qualitative (QL). Ethnicity and race of subjects were black (B), Chinese (C), Hispanic (H), Japanese (J), or white (W). After Lander and Krulyak⁵² the following linkage probabilities were defined: for sibling pair studies, significant-log-of-the-odds (LOD) >3.6 (Z >4.07), suggestive-LOD >2.2 (Z >3.18) and promising-LOD >1.5 (Z >2.63); for family studies: significant-LOD >3.3 (Z >3.90), suggestive-LOD >1.9 (Z >2.96) and promising-LOD >1.5 (Z >2.63). The position of loci is quoted as centiMorgans (cM) from the p telomere. The following abbreviations apply for phenotypes: DP, diastolic pressure; SP, systolic pressure; LC, low concordant; ED, extreme discordant; HC, high concordant; B, Black; W, white; M, male; HT, hypertension; BMI, body mass index; DZ, dizygotic.

individual DNA variants. Variants of small effect will be difficult to detect by any means, but in general association studies are expected to be more powerful than linkage studies, unless the variants are rare in which case even association studies struggle.¹⁸⁸ The theoretical estimates of the required numbers of families for linkage studies range from several hundred to a few million.⁴⁶ A review of genome-wide scans, each comprising 20 to 1783 individuals (1 to 580 families) found that successful scans had on average twice as many subjects as unsuccessful scans.¹⁸⁹ Strangely, the same trend is not especially obvious for blood pressure (see Table 5–2) where some of the bigger searches were less successful. However, factors other than numerical size are relevant to study power.

Population, Racial, and Ethnic Issues

The majority of genome-wide analyses have been based in outbred populations that have been sampled in a representative fashion^{151,155,163,171} or with certain restrictions or selection criteria.* The nature of the selection criteria varied considerably and comprised enrichment or exclusion of obesity,^{158,160,164} diabetes,^{156,158,164} and hyperlipidemia.¹⁶¹ The impact of ascertainment and selection on the genetic characteristics is unknown.

Four studies have been based in relatively isolated populations,^{156,157,159,164,168} in which genetic heterogeneity and environmental variation are expected to be relatively low. However, the theoretical advantages of genetic isolates such as Finland¹⁶⁴ and Sardinia¹⁶⁸ for linkage mapping have been questioned.¹⁹⁰ For blood pressure, genetic isolates reported single loci, often at relatively high probability.^{156,157} Nonetheless, these loci were not reproduced in other studies. Indeed, results were not found to be consistent between different genetic isolates within Finland itself,¹⁶⁴ raising questions (other things being equal) about the general inferences that might be obtained from genetically isolated populations.

The problem of population stratification (see previous section “Bias”) is relevant not only for association studies but also for genome scans. If blood pressure alleles are ancient and predate the divergence of the human populations, they would be found globally and one might expect consistent findings between genomic analyses in different geographic, racial, and ethnic groups (see Figure 5–5).⁴⁷ However, little consistency exists for blood pressure genome scans (see Table 5–2).

One might infer, therefore, that in terms of its genetic causation, hypertension is a modern condition resulting from recently derived alleles that are population-specific. However, it is not possible to exclude the existence of ubiquitous ancient blood pressure alleles that are obscured in particular populations by environmental milieus that might constrain their expression.^{191,192} Population differences, whether genetic or environmental will confound genetic studies that combine diverse populations.^{193,194}

Nevertheless, not all evidence favors population-specific modern blood pressure alleles as some regions on chromosomes 2^{158,159,164,169} and 16^{67,151} have been identified in different populations. The locus at 16q13 was reported as suggestive in two quantitative analyses, one of the full range of SBPs in white subjects,¹⁵¹ the other of low SBP in Chinese.⁶⁷ In addition, two other studies found evidence of promising linkage in this vicinity.^{162,171} This locus is attractive because it encompasses a

number of plausible candidate genes including the *SCNN1B* and *SCNN1G* genes that encode the β - and γ -subunits, respectively, of the amiloride-sensitive epithelial sodium channel and *SLC12A3* that encodes the thiazide-sensitive NaCl cotransporter. These candidates have been proven relevant in genetic blood pressure diseases (see previous section “Candidates from Rare Mendelian Diseases”) and it is conceivable that other DNA variants in and around these genes might have less dramatic but more common blood pressure effects.

Dealing with Covariates

It is important to identify and, if necessary, control important sources of variation. However, in doing so, care must be taken not to jettison covariate effects that might share genetic origins with blood pressure. For example, blood pressures are often adjusted by regression methods for well-recognized sources of variation such as age and sex. However, removing the components of blood pressure variation associated with these covariates will obscure the phenotypic effects of genes whose effects might be age- or sex-dependent.^{195,196}

Age

In adulthood there is a positive correlation between age and blood pressure and many linkage studies* adjust pressure for age prior to analysis (see Table 5–2). However, some studies include adolescents^{67,159,166} in whom the substantial effects of growth on blood pressure distort blood pressure ranking and correlations between blood pressure and age.¹⁹⁷ Indeed, genes for blood pressure found in growing adolescents might relate more to genes that determine the rate and timing of growth than to blood pressure per se.

Sex

Sex is relevant to blood pressure genetics in a number of ways. First, blood pressure alleles might be on sex chromosomes. To date only one genome scan has included the X chromosome and reported suggestive evidence for a blood pressure locus.¹⁵¹ Variation in the nonrecombining region of the Y chromosome has also been associated with significant blood pressure differences.^{198,199} Second, the sexual phenotype and its hormonal milieu can influence gene expression. Dependence of expression on sex might explain why evidence of linkage¹⁶⁴ or association¹⁹⁶ with blood pressure is demonstrable in one but not the other sex.

Few studies make formal tests of the possible influence of sex, and simple mathematical adjustments will not necessarily help reveal loci whose phenotypic expression depends on the sexual phenotype. Unfortunately dividing studies into subgroups of single sexes reduces statistical power and novel statistical methods are needed for identifying sex-dependent genetic effects from entire data sets.

Body Mass Index

Some analyses adjust blood pressures for variation in body mass index (BMI)^{151,163} or exclude subjects with high BMI levels.^{158,164} The rationale is to avoid the secondary nongenetic effects of BMI per se on blood pressure. However, there also appear to

*References 67, 160–162, 165–170, 172, 173.

*References 67, 151, 155, 162, 163, 171.

exist genetic factors that determine both blood pressure and BMI¹⁵ that will be missed when adjustments for BMI are made. Genes that influence several related cardiovascular risk factors in such a way might be the most important to identify because of their multiplicative implications for coronary risk including conditions such as the metabolic syndrome. At least one genome scan has addressed this issue by comparing the linkage results for systolic pressure unadjusted and adjusted for BMI.¹⁵¹ Three of the four suggestive loci were relatively unaffected by adjustment for BMI, but one locus showed a substantial reduction in linkage probability following adjustment of systolic pressure BMI.

Antihypertensive Treatments

In quantitative analyses, problems can arise with pressures measured in subjects taking antihypertensive medication.¹⁷⁵ Measured pressures in treated subjects represent a biased distortion in a quantitative analysis because treatment lowers blood pressure and is usually applied to those with the highest values. For this reason, some studies have excluded treated individuals, but not only is important information lost from subjects most likely to have a genetic predisposition, but overall statistical power is weakened.¹⁶³ Relatively simple methods have been proposed to adjust for treatment in ways that maximize genetic information and statistical power.¹⁷⁵

Genotyping Errors

The benefits of reliable measures of appropriate phenotypes can be undermined if the same rigorous standards are not applied to genotyping itself. Small error rates of 1% to 2% can have serious repercussions for linkage results²⁰⁰ and the rates of error are likely to increase with the use of extensive SNP maps and high-throughput technologies. It is possible to check for Mendelian transmission of marker alleles, but this method is not infallible, especially for small families and SNPs, and more comprehensive methods must be employed.²⁰¹ However, newer statistical methods are being developed to account for genotyping errors, even without actually correcting or deleting suspect genotypes.²⁰²

THE FUTURE

There is still a long distance to travel before genetic mutations of significance to blood pressure are confirmed²⁰³ and even further until they have an impact in everyday life. At the present stage we can claim to have made significant attempts at genome mapping (step 1 in the discovery strategy). However, there has been little reported evidence of the results of fine-mapping (step 2). As a result of thoughtful candidate gene selection there are well-documented alleles shown to be in linkage disequilibrium with functional variants (step 4) although their association with blood pressure is less certain.

In any case we can look ahead to the future where the genetics of blood pressure can be envisaged in terms of potential benefits for individuals and for populations.

Individual Benefit

Genetic discovery might be utilized to predict our personal risks, to suggest the most appropriate antihypertensive treatments and even to design gene therapy.

Genetic Diagnosis

Some hope that DNA analyses will identify genetic predisposition to high blood pressure and its complications. Such a possibility is predicated on reliable DNA tests that can be used to detect tangible and meaningful increases in risk. These possibilities will be hard to realize unless markers or variants conform to the CD/CV model. Vast numbers of infrequent alleles with small individual effects that typify the CD/RA paradigm will be difficult to locate and catalog in any comprehensive way. Even if discovered, they will not be useful individually for predictive screening because of their small effects.

In any case, genetic tests for complex human multifactorial disease might only ever provide an indication of predisposition and not predestination because of the modifying influence of other relevant genetic and environmental factors. Indeed, the true value of genetic markers of high blood pressure will not be known until large-scale epidemiologic studies demonstrate and quantify their predictive competency for major cardiovascular endpoints. Such evidence must not only achieve overall statistical significance but must also provide acceptably low rates of false positive and false negative results for individuals to avoid unnecessary anxiety or a false sense of security.

Tailored Treatments

Pharmacogenomics is a growing discipline in which genomic information is used, amongst other things, to inform treatment choices.²⁰⁴ DNA variants might be used to identify individuals who respond best to a certain class of antihypertensive drug treatment or to avoid certain treatments in particular patients in whom side effects are more likely to occur. Indeed, it might be that such DNA variants have no direct association with blood pressure but instead are relevant to drug pharmacokinetics or other physiologic control systems with which drugs might interact. Many large prospective clinical trials are incorporating genetic analyses in an attempt to identify variants that might be of use.²⁰⁵

Gene Therapy

Beyond pharmacotherapy for hypertension, the possibility of gene therapy has been raised.²⁰⁶⁻²¹¹ Some approaches are simply clever means of offering “symptomatic” treatment to achieve physiologic changes that can otherwise be achieved by pharmacologic treatment. Others might attempt to modulate a fundamental genetic defect. However, effective, safe, and cheap therapies exist to treat blood pressure and at this stage the difficulties and doubts about the long-term safety of gene therapy make it unattractive.

Population Benefit: Common Disease/Common Mechanism

Genetics might never contribute to personalized diagnosis of common diseases simply because of the underlying complexities. But that does not diminish the far greater potential of genetics for prevention and treatment. It is not necessary to accumulate comprehensive catalogs of every blood pressure allele to discover novel and tractable biologic mechanisms of high blood pressure.

Physiologic Convergence

We know from Mendelian cardiovascular diseases such as hypertrophic cardiomyopathy, that such phenotypes can be the common point upon which converge the effects of diverse alleles.²¹² This physiologic distillation of molecular diversity provides unique targets for preventive and treatment strategies.²¹³ The CD/RA hypothesis does not sound the death knell for genetics if there is a common disease/common mechanism (CD/CM) paradigm toward which we can direct our attention.

Instead of genetic searches for the whereabouts of every blood pressure allele, we should search for molecular clues to the points of physiologic convergence. In theory a single allele could lead from a polygene to a subclinical phenotype for common hypertension in the way that such discoveries have been made in Mendelian hypertension. The physiologic intersection of a variety of genes provides an ideal target for developing methods to thwart the actions of several different genes simultaneously.

Public Health Strategies

The identification of points of physiologic convergence facilitates tests of environmental variation on genetically determined mechanisms. Specific lifestyle or behavioral factors might be revealed as triggers of genetic predisposition and new strategies could be devised to minimize the impact of such mechanisms. If the behavioral or dietary modification is cheap and safe, then it could be (simply for consistency) implemented communitywide, even if the target genetic mechanism is not ubiquitous. Such an outcome might be the greatest contribution that genetics might make to blood pressure and cardiovascular disease.

The Sympathetic Nervous System in Acute and Chronic Blood Pressure Elevation

Joseph L. Izzo, Jr.

It has been almost 150 years since Claude Bernard proposed the concept of “sympathetic function,” by which he meant an organized patterned response of an animal to its external environment. In his vision, vasomotor nerves helped preserve the “internal milieu” in an overall normative process later called homeostasis. We now know that there is a wide spectrum of responses of the sympathetic nervous system (SNS) that ranges from mild to massive and from acute to chronic. With respect to cardiovascular regulation, the SNS is the only system in the body capable of both momentary (seconds to minutes) and sustained (days to years) regulation of blood pressure (BP).^{1,2} The SNS also plays a key role in extracellular volume regulation, metabolism, and thermoregulation. Because there is basal activity of the SNS at all times, it is logical to question whether hypertension and its associated metabolic abnormalities are related to SNS dysregulation. Such questions have been raised for more than a century but never satisfactorily resolved due to many factors, including the intrinsic complexity of the SNS; the cumbersome, expensive, and limited techniques required to study it; the complexity of the syndromes in which the SNS must be evaluated; the relative lack of direct clinical applications; and the failure of research agencies to fund investigations involving complex physiologic integrative science. Nevertheless, the conclusion that the SNS is intimately involved with all forms of hypertension is the inescapable theme of this chapter. Included are discussions of the organization of the SNS; links of sympathetic function with obesity, insulin resistance, and volume dysregulation; the complex effects of aging on SNS function; and the role of the SNS in secondary forms of hypertension.

ORGANIZATION AND FUNCTION OF THE SYMPATHETIC NERVOUS SYSTEM

For the purposes of this discussion, the SNS will be considered to include the vasomotor control centers within the central nervous system (CNS), the peripheral afferent and efferent sympathetic nerves, and the adrenal medulla. The arborized, multilayered, cross-linked organizational pattern of the central and peripheral SNS provides numerous mechanisms by which the SNS can affect BP. A review of these mechanisms and selected animal studies provides an important backdrop for understanding the potential role of the SNS in human hypertension.

Central Neuroanatomy and Sympathetic Nervous System Outflow Control

Much of our neuroanatomic understanding derives from the elegant studies of the late Donald Reis and others who identified the functional role of several CNS nuclei in acute and chronic BP regulation³⁻⁶ (Figure 6-1). Reflex and behavioral

control of arterial pressure is integrated in the rostral ventrolateral nucleus of the medulla oblongata (RVLM), which is sometimes called the vasomotor control center.^{3,5} Cell bodies of efferent SNS cardiovascular stimulatory neurons lie in the C₁ subregion, which also receives and sends neural projections to and from many other CNS centers.^{4,7} The most critical RVLM input comes from the adjacent nucleus tractus solitarius (NTS), which receives afferent fibers from stretch-sensitive mechanoreceptors in the carotid sinus and aortic arch (aortocarotid baroreflexes), and the cardiac atria and ventricles (cardiopulmonary baroreflexes).⁶⁻⁸ Signals from the NTS *inhibit* RVLM sympathetic outflow and tend to buffer acute BP changes.^{6,9} In parallel, the NTS receives signals from *stimulatory* chemoreceptors in the kidneys and skeletal muscle.⁶ The NTS integrates a variety of signals from stimulatory and inhibitory centers in the brain stem, basal ganglia, and cortex, including the overlying area postrema (AP) located in the floor of the fourth ventricle.¹⁰ The NTS is also controlled by signals from the overlying AP, which does not have a blood-brain barrier.¹¹ The AP is exquisitely sensitive to circulating angiotensin II (Ang II), which acts to blunt the inhibitory effect of the NTS, thereby increasing RVLM-dependent SNS outflow.¹¹⁻¹⁴ The NTS-RVLM complex also receives sensory input from excitatory peripheral chemoreceptor afferent neurons in the kidneys and skeletal muscle that act to enhance or sustain RVLM-dependent SNS outflow.^{6,7}

The Brain Stem in Hypertensive Models

CNS centers that modulate or control SNS outflow clearly affect acute and chronic BP levels in animal models of hypertension. In spontaneously hypertensive rats (SHR), sympathectomy prevents the development of hypertension.¹⁵ Brain stem regions in particular seem to participate in all forms of experimental hypertension. Ablation of the NTS in normal rats causes increased SNS outflow and either severe BP lability⁹ or severe chronic hypertension with organ damage,¹⁶ which can be abolished by simultaneous lesions of the RVLM.¹⁷ Lesions in the AP lower BP in rats with genetic¹⁷ and steroid-induced hypertension,^{13,18} while stimulation of the AP by Ang II sustains genetic and steroid-induced hypertension.^{11,13,14,18}

Role of the Hypothalamus in Integration of Behavioral and Cardiovascular Responses

Stress, emotions, and drugs affect SNS function through a variety of CNS centers. Different patterns of stress responses are initiated by unique activation patterns of participating hypothalamic subregions, with each pattern driving a linked hemodynamic redistribution that optimizes the organisms' response to the environmental stimulus that is present. The

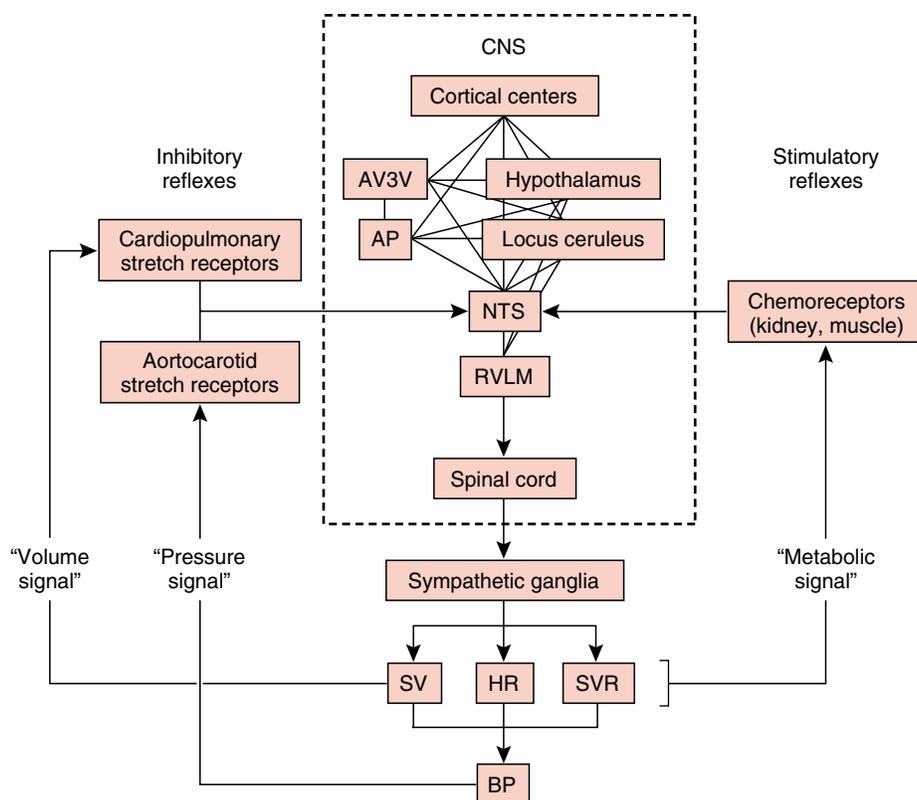

Figure 6-1 CNS control of sympathetic outflow. Efferent SNS output is the result of integrated actions of several CNS centers, including many areas of the cortex as well as lower centers in the hypothalamus, basal ganglia (especially the locus ceruleus), and circumventricular regions, including the area postrema (AP) and the AV3V region. The critical integrator region is the nucleus tractus solitarius (NTS), which lies in the medulla oblongata. The NTS receives inhibitory afferent signals from the baroreflexes (volume and pressure signals) and stimulatory afferent signals from renal and muscular chemoreceptors (metabolic signals). SNS outflow is ultimately dependent on stimulation of the rostral ventrolateral medulla (the RVLM or vasomotor control center), which is tonically inhibited by the adjacent NTS. Circumventricular regions such as the AP are of particular interest because they have no blood-brain barrier; stimulation of the AP by circulating angiotensin II (Ang II) blunts the inhibitory effects of the NTS. Ultimately, RVLM stimulation sends signals via the spinal cord and sympathetic ganglia to regulate heart rate, cardiac stroke volume (SV), and systemic vascular resistance (SVR), which together determine momentary and chronic blood pressure (BP) levels.

posterolateral hypothalamus mediates defense reactions such as the global “fight or flight” response, which induces massive RVLM activation, with increased heart rate and BP and vasodilation in skeletal muscle.^{19,20} Brody et al. identified the anteroventral third ventricular (AV3V) region as a region capable of modulating baroreflex function and SNS outflow in a complex pattern.²¹⁻²³ The median preoptic nucleus in this region serves to integrate water balance and thirst-sensing mechanisms with cardiovascular signals and may mediate organ-specific responses such as skeletal muscle vasodilation.²³ Thus, an interplay of CNS influences affects SNS outflow and these phenomena may also be involved in the heterogeneous syndrome of human essential hypertension.

Many other CNS nuclei have been found to modulate SNS outflow but a full discussion is beyond the limits of this work. For example, epinephrine release during exercise is blunted by benzodiazepine therapy.²⁴ The specificity of benzodiazepines for GABA-ergic neurons in the locus ceruleus strongly suggests a participatory role of that region of the basal ganglia in epinephrine-mediated hemodynamic responses.²⁵ Various other integrated hemodynamic response patterns are also necessary to meet different emotional and physiologic demands. For exam-

ple, an individual can experience different patterns of hemodynamic stimulation that are dependent on the individual’s state-of-mind. Stimuli perceived as challenging or manageable are characterized by SNS-mediated increases in cardiac output, whereas stimuli perceived as threatening or outside the individual’s range of control are associated with systemic vasoconstriction.^{26,27} These differential hemodynamic responses are not genetically determined because they are not predicted by family history of hypertension and because both threat and challenge patterns can be seen in the same individual.²⁶ In extreme situations such as vagal syncope, bradycardia is the result of a general parasympathetic override of SNS outflow that involves the nucleus ambiguus and other hypothalamic centers.

The Hypothalamus in Hypertensive Models

In addition to acute changes in BP, the hypothalamus may affect long-term BP control as well. Ablation of the posterior hypothalamus reduces BP in steroid-induced, genetic, and renal hypertension.²⁸ Lesions of the anterior hypothalamus dramatically increase BP via massive adrenomedullary stimulation in

normotensive rats, whereas electrical stimulation of this region causes hypotension.^{16,29} Ablation of the paraventricular nucleus prevents the development of hypertension in SHR.³⁰

The Spinal Cord and Peripheral Neurons

The SNS efferent impulses generated by cell bodies in the RVLM-C₁ region are conducted through efferent axons that run in the intermediolateral columns of the spinal cord and outward to the sympathetic ganglia. The pattern of neuronal arborization that is created allows an extremely small number of RVLM cell bodies to amplify the overall signal while allowing an extremely diverse system of linked organ-specific responses. Further amplification of the SNS signal occurs at the level of individual peripheral sympathetic neurons because each axon contains a series of norepinephrine (NE)-containing varicosities arranged like a string of beads that release NE in response to RVLM activation. Thus, the interlinked arborized organization of the SNS allows a spectrum of graded hemodynamic responses that range from subtle changes in regional blood flow to massive stimulation during fight or flight responses or in response to such major stimuli as severe hemorrhage, hypotension, hypoglycemia, or hypothermia.

Peripheral Hyperinnervation in Hypertensive Models

A series of studies suggests that SHR are anatomically hyperinnervated, as reflected in the increased number,³¹ axonal volume,³² and granular NE content³³ of peripheral sympathetic nerves in these animals. In addition, the NE content³⁴ and expression of mRNA for nerve growth factor (NGF) in caudal and mesenteric arteries and kidney³⁵ are increased during development in these rats, and early treatment with antibody to NGF prevents this hyperinnervation and the accompanying vascular hypertrophy and lowers BP.³³ A pattern of accelerated growth of renal sympathetic innervation has also been described in SHR.³⁶

Adrenal Medulla

The adrenal medulla is a specialized postganglionic sympathetic organ that is responsible for the secretion of epinephrine and NE into the circulation in response to cardiovascular and metabolic stimuli. The adrenal medulla is dually controlled by the locus ceruleus and the RVLM area of the brain stem, as already noted.^{24,37} Generally speaking, stimuli that cause substantial adrenomedullary responses are relatively major in magnitude, such as hypoglycemia, strenuous exercise beyond the anaerobic threshold, or hemorrhage. Whether the small increases in adrenal epinephrine secretion that occur during less intensive stimuli (postural change or mild mental stress) play a significant role in cardiovascular homeostasis is less clear.³⁷

Intrasynaptic Neuromodulation

The release of NE from storage granules in peripheral sympathetic varicosities is an exocytotic process dependent on intracellular calcium release.³⁸ Neuronally released NE faces one of three fates within the synapse: Reuptake (uptake 1) into the

presynaptic noradrenergic varicosity removes about 80% of the NE released into the synapse; uptake and metabolism by postsynaptic cells (uptake 2) releases O-methylated metabolites in urine or plasma; diffusion (spillover) from the synaptic cleft releases NE into the extracellular fluid.³⁹ Speculation about reduced catecholamine uptake in states of SNS excess has not been clearly substantiated, however. A variety of substances act at specific receptors on postganglionic presynaptic membranes to modify local neurotransmission, either reducing or augmenting the amount of NE released with each electrical nerve impulse.⁴⁰⁻⁴² The most important of these presynaptic receptors is the α_2 receptor, which is usually occupied by NE. α_2 Receptors act as conservators of peripheral neurotransmission by signaling the noradrenergic neuron that NE is already present in the synaptic cleft and that subsequent nerve impulses need not release the same amount of NE as the immediately previous ones. This system thus provides a check and balance to excessive SNS discharge. Presynaptic α_2 receptors are probably the main site of action of central sympatholytics such as clonidine, guanfacine, guanadrel, methyl-dopa, and rilmenidine, which compete with NE at α_2 or imidazoline receptors to exert their effects. In direct opposition to these inhibitory presynaptic receptors are stimulatory presynaptic receptors such as β_2 receptors and Ang II receptors^{42,43} that augment the amount of NE released per nerve impulse. Rand⁴² first postulated that epinephrine facilitates SNS neurotransmission by functioning as a cotransmitter with NE. Under chronic stress, epinephrine initially released from the adrenal medulla is subsequently taken up into postganglionic neurons in parallel with NE. Subsequent SNS nerve impulses then cause the release of both epinephrine and NE from noradrenergic nerve terminals. If stress is protracted, the stimulatory effect of intrasynaptic epinephrine on presynaptic β_2 receptors counterbalances the inhibitory effects of intrasynaptic NE on α_2 receptors. The clinical importance of this mechanism is not yet clear with respect to chronic hypertension, but studies suggest that the antihypertensive effect of nonselective β -blockers is related partly to blockade of intrasynaptic β_2 receptors.^{40,44,45}

Reinforcing Interactions of the Sympathetic Nervous System and Renin-Angiotensin-Aldosterone System

The body's two main BP defense mechanisms, the SNS and renin-angiotensin-aldosterone system (RAAS), have a unique set of mutually reinforcing actions that combine to raise BP acutely and chronically. A major impact of SNS activation is β_1 receptor-mediated release of renin from the kidney.⁴⁶ Renin in turn increases circulating Ang II, which acts at four or more levels to enhance further SNS outflow. First, circulating Ang II acts on CNS nuclei such as the AP, which does not have a blood-brain barrier, to enhance sympathetic outflow.^{47,48} Second, Ang II acts on stimulatory presynaptic receptors in CNS and peripheral synapses to enhance the amount of NE (or epinephrine) released by each nerve impulse,⁴⁸ similar to the function of presynaptic β receptors. Third, Ang II facilitates the effects of NE by virtue of its unique mechanism of inositol-dependent potentiation of calcium influx.⁴⁹ A fourth mechanism is the probable blunting of baroreflex suppression of SNS outflow.¹¹⁻¹⁴ In addition, Ang II has potent direct vasoconstrictive effects, principally via stimulation of AT₁ receptors, as well

as stimulation of other physiologic responses that indirectly raise BP, including increased thirst, secretion of aldosterone from the adrenal cortex, and secretion of vasopressin (antidiuretic hormone) from the posterior pituitary.⁴⁹ Ang II acts together with catecholamines to promote structural changes such as hypertrophy of cardiac⁵⁰ and vascular smooth muscle.^{51,52} Finally, Ang II promotes inappropriately high renal nerve activity, which directly promotes excessive salt and water retention and the phenotype of salt sensitivity.^{53,54}

Other Neuromodulators

A wide variety of other neurohormones, autacoids, and paracrine factors modify SNS activity centrally and peripherally. Nitric oxide (NO) has significant neuroinhibitory features, as demonstrated by increased SNS nerve traffic after NO synthase blockade.^{55,56} Either neuronal NO deficiency or baroreflex desensitization⁵⁶ secondary to reduced NO availability has been postulated to contribute to chronic hypertension. Gamma amino butyric acid (GABA) is another neurodepressant, as evidenced by the ability of valproate or muscimol to lower BP in hypertensive rats.²⁵ Calcitonin gene-related peptide (CGRP) suppresses NE release from the brain stem in normotensive rats but not SHR.⁵⁷ The CNS effects of opiates,^{58,59} atriopeptins,⁶⁰ and probably numerous other substances, are complex and dependent on the individual nuclei affected. Endogenous neurostimulatory substances also exist. SHR demonstrate augmented SNS responses due to activation of glutamate-sensitive neurons in the RVLM.⁶¹ Ouabain also mediates increased RVLM-SNS outflow, but this effect depends to a degree on the presence of Ang II because the prohypertensive effects of ouabain are diminished by AT₁ receptor blockade.^{62,63} Ouabain-Ang II interactions appear to exert their effects through altered cardiopulmonary baroreflex sensitivity.^{63,64}

Postsynaptic Adrenergic Receptors

α_1 -Adrenergic receptors tend to be found within adrenergic synapses, particularly on postsynaptic membranes on the adventitial side of the smooth muscle layer of blood vessels and their stimulation causes vasoconstriction, predominantly under the influence of NE. In addition to their intrasynaptic role, α_2 receptors are found on endothelium, platelets, white blood cells, and fibroblasts. β_1 Receptors are found predominantly in the heart and kidneys, whereas β_2 receptors are found in smooth muscle, endothelium, formed blood elements, and presynaptic neural membranes. Stimulation of β_2 receptors, which are preferentially occupied by epinephrine, tends to vasodilate directly and to increase cardiac output indirectly.

Effects of Circulating Catecholamines

Contrary to their relatively weak effects on metabolic parameters,⁶⁵ physiologic-range elevations of circulating NE can increase plasma renin activity and diastolic blood pressure (DBP).^{66,67} Thus, circulating NE should most properly be considered to be a cardiovascular hormone.^{66,67} Other effects of physiologic increases in circulating NE include increased platelet and leukocyte number⁶⁸ and increased platelet aggregation.⁶⁹ Hypertensives have greater platelet aggregability than normotensives.⁷⁰

Cardiac Chromaffin Cells

The mammalian heart possesses unique perivascular catecholamine-producing cells that are not innervated by postganglionic sympathetic neurons and do not respond to SNS activation.⁷¹ These cells have the potential to regulate a variety of physiologic processes, including growth and development,⁷² but their clinical significance is unknown.

INTEGRATED CARDIOVASCULAR, VOLUME, AND METABOLIC REGULATION

The richness and complexity of the physiologic responses mediated by the SNS is the basis for the complex patterns observed in physiologic and behavioral responses to environmental stimuli.

Hemodynamic Regulation

The simplified physical equation describing BP (the product of cardiac output and systemic vascular resistance [SVR]) is shown in Figure 6–2, along with the proximal neurohumoral and receptor-mediated efferent factors that acutely control BP. It can be seen from Figure 6–2 that the SNS directly and indirectly affects many different parameters that directly control cardiac output (the product of heart rate and stroke volume) and SVR, which together determine the BP at the moment.

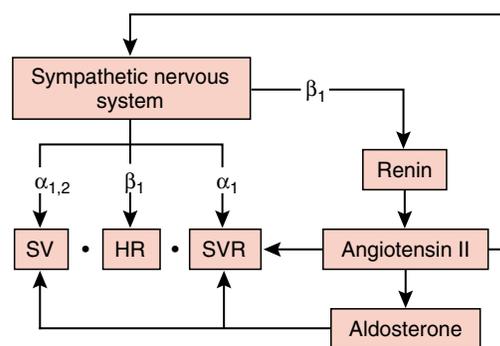

Figure 6–2 Central position of the sympathetic nervous system (SNS) in blood pressure (BP) regulation. Changes in BP are directly effected by acute or chronic alterations in SNS activity. Hemodynamically, these changes depend on alterations of systemic vascular resistance (SVR) or cardiac output, which is the product of heart rate (HR) and stroke volume (SV). Cardiac β_1 receptor stimulation directly increases HR and SV, while renal β_1 receptor stimulation indirectly increases extracellular fluid volume and cardiac filling pressure (preload). Preload is increased by stimulation of renal nerve–dependent renin release and subsequent production of Ang II and aldosterone. In addition, α_1 receptor–mediated peripheral venoconstriction centralizes blood volume, while renal tubular α_2 receptor stimulation enhances tubular sodium reabsorption. SVR is dependent on tonic arteriolar constriction that is affected by vascular α_1 and Ang II receptors. Circulating Ang II exerts a *positive* feedback on CNS centers, increasing or sustaining SNS outflow.

Cardiac output is highly dependent on ventricular distension during diastole (preload); ventricular preload is in turn dependent on SNS-mediated peripheral venoconstriction and venous volume. Ventricular performance is diminished by factors that increase impedance to ventricular emptying, mainly increased systolic blood pressure (SBP) and central arterial stiffness. Under resting conditions, cardiac output and SVR counterregulate each other so that BP remains relatively constant. Maintenance of a relatively constant central BP in response to common physiologic stimuli is thus dependent on simultaneous matching of flow and resistance.^{2,73,74} BP itself is only a loosely regulated physiologic variable that is directly influenced by the activity of the SNS. For example, during postural adaptation, venous return is limited by gravitational pooling of blood and cardiac output is about 20% to 25% less than that of the supine position. During dynamic exercise, cardiac output can increase by as much as fourfold and hypertensives exhibit a slightly greater increase in cardiac output with reduced exercise-induced systemic vasodilation.⁷⁵ Teleologically, it is probable that SNS-mediated central vasoregulation conferred adaptive advantages by allowing effective adjustments to upright posture but also aided in times of significant hemorrhage or dehydration.

The traditional view that hypertension is caused by an isolated increase in SVR is a gross oversimplification but the simplified hemodynamic model remains useful for instructional purposes. SVR measured under supine resting conditions in hypertensive subjects tends to be elevated, but the overlap with the normal range is extremely broad and the differences between normotensives and hypertensives are only modestly statistically significant. The dynamic physiologic variation in SVR is also extremely wide within and between individuals.⁷⁶⁻⁷⁸ Accordingly, over the range of conditions experienced daily, hypertensives exhibit features of both inappropriately high cardiac output and inappropriately high SVR. The fact that hemodynamic differences between normotensives and hypertensives are both instantaneous and chronic provides a clue that the SNS participates in the pathogenesis of hypertension, at least in a permissive fashion; no other system in the body is capable of such rapid and dynamic responses.²

High-Pressure (Aortic Carotid) Baroreceptors and Pressure Regulation

Two distinct inhibitory baroreflex sensor systems exist: One responds to changes in arterial pressure (aortic carotid baroreflexes), the other to changes in cardiac volume and filling (cardiopulmonary baroreflexes). In general these two systems work in tandem to defend systemic perfusion pressure and blood flow. Arterial pressure increases are immediately counterregulated by the aortic carotid baroreflex arc, which begins with stretch receptors within the walls of large arteries (the pressure signal). Baroreceptor loading during acute increases in arterial pressure initiates negative afferent signals that act via the NTS to limit subsequent efferent RVLM-SNS outflow. Reductions in arterial pressure “unload” the aortic carotid baroreflexes, which send afferent signals via the NTS to activate efferent SNS outflow, thereby resulting in increased heart rate, enhanced myocardial contractility, and constriction of arteriolar and venous smooth muscle. The arterial baroreflex system can also respond to metabolic signals generated by the carotid sinus endothelium.⁶ Aortic carotid baroreceptors are sensitized by

prostanoids⁷⁹ and respond to other factors that alter cellular ion transport.^{80,81} Whether baroreflex feedback mechanisms continue to function appropriately in hypertension or whether they permit excessive BP variability⁸² or inappropriately elevated SNS activity⁸³⁻⁸⁹ remains a central issue in understanding the hemodynamic abnormalities in hypertension.

Cardiopulmonary Baroreceptors and Volume Regulation

Operating in tandem with the arterial system are the low pressure stretch receptors in the heart and great veins (cardiopulmonary baroreflexes) that sense changes in cardiac stretch and central blood volume (cardiac preload). Decreases in preload, usually caused by loss of blood volume or severe salt depletion, lead to SNS activation; conversely, salt loading or extracellular volume expansion leads to suppression of SNS activity (the volume signal).^{90,91} Thames et al. demonstrated that renal sympathetic nerve traffic was normally suppressed by volume loading even after ablation of afferent aortic carotid nerves,^{92,93} demonstrating the intimate relationship between cardiac filling and renal nerve activity. In humans, cardiopulmonary baroreflexes can be stimulated separately by lower body negative pressure (LBNP), which increases muscle sympathetic nerve activity, renal vascular resistance, renal overflow of NE, glomerular filtration rate, plasma renin activity, and plasma Ang II, while reducing forearm and splanchnic blood flow.⁹⁴⁻⁹⁷ Postural adaptation studies in humans also reveal the close relationship between cardiac filling and SNS activity; across both supine and upright postures, plasma NE correlates more strongly with reduced cardiac stroke volume and increased SVR than with central arterial pressure.⁹⁸ These integrated physiologic responses can occur independent of any changes in aortic carotid baroreflex activity,⁹⁷ although it is clear that the two baroreflex systems also have extensive interactions.^{99,100} The net impact of cardiopulmonary baroreflex stimulation can thus supersede that of the aortic carotid system in controlling SNS and RAAS activity, especially during postural adaptation or other conditions that affect central blood volume in dogs^{92,93,101} or humans.⁹⁸

Renal Nerves

Afferent and efferent renal sympathetic nerves are extremely important as direct controllers of renal hemodynamics and volume homeostasis. Renal nerve stimulation causes renal vasoconstriction^{102,103} and also regulates renin release.¹⁰⁴⁻¹⁰⁶ There are collateral synapses of RVLM-C₁ axons on noradrenergic cell bodies in the spinal cord that offer the opportunity for regional modulation of SNS responses.⁴ The most relevant of these regional modulating influences is probably the reno-renal reflex that modifies contralateral renal hemodynamics in response to changes in ipsilateral flow and function.^{107,108} Juxtaglomerular cells release renin primarily via activation of membrane β_1 adrenoceptors¹⁰⁹ but α_1 adrenoceptors also stimulate renin release,^{102,103} probably via altering tubular sodium content or macula densa function.¹⁰⁴ Given these interrelationships between the SNS and the RAAS, a permissive role of the SNS in renovascular hypertension could be anticipated. The physiologic importance of renal nerves is further demonstrated by experimental denervation of the kidney, which leads to a salt-wasting state.¹¹⁰

Relative salt wasting also occurs after pharmacologic sympathectomy with guanethidine in humans^{111,112} and in autonomic insufficiency.¹¹³ Renal salt wasting is a major reason why individuals with autonomic insufficiency have abnormally low blood volume and orthostatic hypotension. Renal nerves also mediate the hypertension caused by NO synthase inhibition in rats because renal denervation prevents the BP increases.¹¹⁴

Baroreflex Abnormalities with Aging and Hypertension

Arterial baroreceptors exert an important permissive influence in chronic hypertension because they can never fully return BP or heart rate to normal if there is sufficient acute or chronic SNS stimulation. Two factors can be identified in the limitation of baroreflex activity, baroreflex resetting, and baroreflex blunting. Resetting of arterial baroreceptors is necessary in order for the baroreflex to continue to respond to acute changes in pressure, even when BP is mildly elevated.¹¹⁵ Thus the SNS can never be completely suppressed by the baroreflex.^{85,115-118} Although there remains an inverse correlation between resting plasma NE and arterial baroreflex sensitivity in chronic hypertension,⁸⁴ it can be argued that the apparent normal levels of SNS outflow are still inappropriately elevated. Chronic arterial baroreflex blunting also occurs with long-standing hypertension, where the relative ability of a given pressure increase to reduce SNS outflow is also diminished. Baroreflex blunting is associated with aging^{116,118} and with conditions such as chronic hypertension⁸⁴ or renal failure,¹¹⁹ in all of which there is increased arterial stiffness and presumably, reduced arterial mechanoreceptor distensibility.¹¹⁸ Arterial baroreflex dysfunction in the setting of age-related arterial stiffness is an attractive explanation for the positive interrelationships among age, SNS activity, and BP.^{87,88,120}

Altered sensitivity of cardiopulmonary baroreflexes may also play a significant role in permitting chronic increases in SNS activity with aging and hypertension. Hajduczuk demonstrated that impaired cardiopulmonary baroreflexes contribute to the age-related increases in SNS activity.⁸⁶ When cardiac filling is reduced equally, borderline hypertensives exhibit augmented muscle sympathetic activation compared with normotensives.^{97,121-123} In volume loading experiments in dogs with renal failure and hypertension, blunting of both cardiopulmonary and aortocarotid baroreflexes was found.^{92,93} CNS ouabain and Ang II may play a role in cardiopulmonary baroreflex blunting because the slope of the curve in hypertensives is normalized by digitalis.^{62,64}

Metabolic Regulation and Thermoregulation

The SNS controls intermediary metabolism and body temperature by several interrelated mechanisms. Maintenance of peripheral metabolic homeostasis is generally blood flow dependent, and low-flow situations or conditions of high muscular energy expenditure decrease tissue pH and alter local redox potential, which stimulates peripheral chemoreceptors to enhance CNS sympathetic output in an effort to increase tissue blood flow (the metabolic signal).⁶ The significance of these reflexes in hypertension has not been established. Thermoregulation is influenced by cutaneous blood flow reg-

ulation and sweating, which is mediated by acetylcholine rather than NE. Cold exposure creates the need for SNS activation to constrict blood flow to the extremities and the skin, reducing convective heat loss. Body temperature is also potentially influenced by the catabolic effects of catecholamines on adipose tissue, which can increase caloric availability and subsequent heat generation. In rodents, the metabolism of brown adipose tissue is regulated directly by catecholamines and adrenergic receptors.^{124,125} Speculation exists that visceral fat in man is the rough equivalent of brown fat in rats.

The role of the SNS in the regulation of body temperature involves selective cutaneous vasoconstriction. A link exists to energy combustion because vascular sensitivity to NE is increased by free fatty acids, which are liberated by the action of catecholamines on adipose tissue.¹²⁵ Young and Landsberg demonstrated that sucrose overfeeding increases SNS activity, as manifested by increased cardiac NE turnover in rats.¹²⁶ In contrast, starvation decreases SNS activity in rats and humans.¹²⁶⁻¹²⁸ The SNS also plays a major role in glucose homeostasis, providing an early line of defense against hypoglycemia.¹²⁶

Both NE and epinephrine have diabetogenic properties and infusion of catecholamines causes a rise in blood glucose similar to that found in pheochromocytoma.¹²⁹ Increased SNS activity promotes hyperglycemia by a variety of mechanisms, including epinephrine-induced glucose biosynthesis from lactate and amino acids,^{128,129} and β receptor-mediated decreases in glycogen synthase activity. The effects of NE in vivo on insulin and glucagon release are complicated by the influences of glucose, potassium, calcium, and growth hormone.¹³⁰ Stimulation of α -adrenergic receptors by catecholamines inhibits insulin secretion by pancreatic cells.¹³¹ In contrast, pancreatic islet cells pretreated with NE show enhanced glucose-mediated secretion of insulin.¹²⁶

Microcirculatory Protective Effects of Sympathetic Nerves

Although excessive SNS activity may be globally harmful, catecholamines and sympathetic nerves may also have organ protective effects via reflex arteriolar constriction, which may protect the capillaries of the brain and kidney from surges in SBP. A baroprotective role of cerebral sympathetic nerves was uncovered by Heistad et al., who unilaterally denervated the cerebral vasculature in stroke-prone rats and found that fatal stroke occurred rapidly in the hemisphere ipsilateral to the sympathetic denervation.¹³²⁻¹³⁴ In the syndrome of malignant hypertension, cerebral edema is worsened by sympathectomy, which causes increased cerebral blood flow.¹³⁴ In rats made acutely hypertensive by stellate ganglion stimulation, cerebral sympathetic nerve stimulation limits hyperemia.¹³⁵ In the kidney, afferent arteriolar constriction may slow the progression of glomerulosclerosis.¹³⁶ Presumably, sufficient lowering of systemic pressure in hypertensives reduces the need for precapillary arteriolar protection of the microcirculation.

ENVIRONMENTAL STRESS AND BLOOD PRESSURE

The relatively loose regulation of BP is most apparent during times of physiologic stress, especially pain, exercise, and mental

stress. The role of environmental and psychosocial stress in hypertensives is reviewed extensively in Chapter 7.

Acute Mental Stress and Blood Pressure

The SNS stimulation that occurs repeatedly throughout the day as a result of mental stress and activity causes transitory increases in NE production and BP. Among the most important of these stimuli is physical activity. Although exercise raises BP, physical conditioning overrides this stimulatory effect and leads to effective reduction in basal and stimulated SNS activity and BP,^{137,138} as well as cardiovascular risk.¹³⁹ Another important SNS stimulant is cigarette smoking.¹⁴⁰ Even though the effects of smoking are transient and BP is only increased for a short time, the repetitive nature of smoking causes an increase in average daily BP. Major stressors that cause acute hypertension are burns, brain injury, surgical interventions such as cardiopulmonary bypass, and general anesthesia, each of which results in marked SNS activation.¹⁴⁰ Exposure to cold and withdrawal from drugs such as opiates and central sympatholytics also acutely activate the SNS. Such episodes are transient, however, and are not associated with chronic hypertension.

Chronic Stress, Personality Factors, and Blood Pressure

Among the most provocative simple observations about the effects of chronic stress on BP is that BPs are lower in primitive societies than complex societies. Lower socioeconomic groups within complex societies, who lead more stressful lives, have increased rates of hypertension.¹⁴¹ Because of the difficulty in quantitating stress, however, large trials have generally ignored stress as a cardiovascular risk factor. When diary recordings have been combined with ambulatory BP monitoring, correlations have been found among stressful daily events, increased BP,¹⁴²⁻¹⁴⁵ and increased left ventricular mass.^{145,147} A major component of workplace BP elevation is stressful interpersonal relationships, particularly with one's immediate supervisor.¹⁴⁷ Specific personality subtypes also appear to predispose to hypertension and cardiovascular disease, but the original description that anxiety-prone individuals with "type A" personalities are at increased risk is no longer generally accepted. Rather, a personality pattern of suppressed hostility or "anger-in,"¹⁴⁸ with controlled, guilt-prone, and submissive characteristics has been found to be associated with hypertension. This personality pattern correlates with elevated plasma NE and increased plasma renin activity¹⁴⁹ and with increased cardiovascular morbidity and mortality.¹⁵⁰

Volume Regulation during Stress

Exaggerated stress-induced systemic and renal vasoconstriction contribute to increased SVR, reduced renal blood flow, and blunted natriuresis. Abnormally high renal sympathetic nerve tone thus is an important potential consideration in the pathogenesis of essential hypertension because excess salt and water retention during times of psychologic or physiologic stress contributes to high cardiac output. Delayed natriuresis due to renal vasoconstriction would also be important in sustaining the transient increase in extracellular volume and cardiac output for an extended period of time. If the frequency of significant stressors were sufficiently high, excessive volume

retention would result.^{107,151-154} Dibona et al. used an air jet stress paradigm to study renal nerves and salt and water excretion in SHR, which exhibited exaggerated renal vasoconstriction and excess salt and water retention during stress.¹⁵⁵ Other studies identified the importance of α_2 receptors in CNS control centers in mediating this pattern.¹⁵¹ In humans, Hollenberg et al. directly measured changes in renal blood flow during mental stress in normotensives with no parental history of hypertension, normotensives with a parental history of hypertension, and borderline hypertensives.¹⁵⁶ In borderline hypertensives there is decreased renal blood flow with mental stress.^{156,157} Blunted natriuretic responses during stress would be further exacerbated by the blunting of cardiopulmonary baroreflex suppression of renal sympathetic nerve activity.⁹² SNS activation also causes modifiable activation of the RAAS during mental stress,¹⁵⁸ an additional feature promoting impaired salt-water excretion.

Circadian and Seasonal Variation in Sympathetic Nervous System Activity

The circadian rhythm of BP follows the circadian rhythm of the SNS, which decreases during sleep and then peaks in the morning hours in parallel with plasma renin activity, blood volume, cortisol secretion, cardiac output, body temperature, and other variables. Panza et al. used plethysmographic techniques to demonstrate that the basal vasomotor tone of the peripheral vasculature has a diurnal rhythm that is dependent on α -receptor stimulation.¹⁵⁹ SNS activity decreases at night or during sleep along with BP, heart rate, cardiac output, and plasma catecholamines.¹⁶⁰ Superimposed on this circadian pattern are other daily SNS stimuli. Daytime BP is determined principally by daily activities rather than diurnal rhythms,^{161,162} as shown most clearly in shift workers.¹⁶³ In addition to these high frequency and circadian patterns, seasonal and other ultradian variations in SNS activity have also been reported. During winter months, plasma and urinary catecholamine levels are increased¹⁶⁴⁻¹⁶⁶ and there is increased systemic vasoconstriction, decreased blood volume and cardiac output, and in some cases, seasonal hypertension. Morbidity and mortality patterns also follow the patterns of SNS activation. The morning peaks of myocardial infarction and sudden cardiac death^{167,168} and ischemic stroke¹⁶⁹ parallel the morning peak of SNS activity and platelet aggregability. This diurnal pattern is abolished by β -blockers.¹⁶⁷ A seasonal influence on coronary and cerebrovascular disease also exists with higher incidence of angina, heart failure, and mortality rates during winter months.¹⁷⁰⁻¹⁷²

SYMPATHETIC NERVOUS SYSTEM HYPERACTIVITY IN ESSENTIAL HYPERTENSION

General Considerations

The foregoing discussion has served to underscore the central position of the SNS in physiologic BP regulation and leads directly to the hypothesis that the SNS plays a major pathogenic role in chronic human hypertension. At least five major questions arise in considering the role of the SNS in hypertension.

1. *Is the SNS only a trigger mechanism or a sustaining influence in hypertension?* The answer to this question is important for several reasons, including optimal therapy for the condition.
2. *What level of SNS activity is normal in the setting of chronic hypertension?* It can be argued that appropriate SNS outflow should be low in hypertension, not normal.
3. *What are the effects of aging or obesity on SNS outflow?* Age, weight, SNS activity, and BP all tend to increase together, so the question of causality or interaction is complex.
4. *If the SNS responds to so many cardiovascular and metabolic signals, can these influences be adequately controlled among individuals?* Assessment of SNS activation ideally requires control of time of day, body temperature, central blood volume, blood glucose, degree of emotional excitation, posture, and degree of physical activity to name several.
5. *Have appropriate study techniques been employed?* None of the current techniques is fully applicable to all forms of investigation.

Genetic Markers

At present there are no genetic markers for increased SNS activity, but in SHR, the Y-chromosome confers higher BP and SNS activity but not increased pressor responses to physiologic or social stress.¹⁷³ The mechanism for this effect is not known but may be related to the stimulatory effects of testosterone on the rate-limiting catecholamine synthetic enzyme tyrosine hydroxylase.¹⁷⁴ Another catecholamine synthetic enzyme, dopamine beta hydroxylase (DBH) and its regulatory genes have been found to be deficient in certain patients with autonomic failure.¹⁷⁵

Family History Studies

Family history studies worldwide consistently reveal weak correlations between genetics and various indices of SNS overactivity. In a cross-sectional study of 557 Japanese, high plasma NE was found to predict future hypertension but was not closely related to family history of hypertension.¹⁷⁶⁻¹⁷⁸ These investigators also found that family history of hypertension correlated with supranormal responses of NE and insulin to glucose loading.¹⁷⁶⁻¹⁷⁸ In two smaller American studies, no relationship was found between family history of hypertension and plasma NE, urinary NE,¹⁷⁹ or plasma chromogranin A at rest or after mental stress.¹⁸⁰ A Swedish study, on the other hand, found that family history of hypertension predicted exaggerated responses of urinary catecholamines and heart rate to mental stress.¹⁸¹ Similar findings, including an association with exaggerated BP responses were observed in an Italian study of children with hypertensive parents,¹⁸² while an Australian study found that normotensives with a parental history of hypertension had elevated plasma NE and increased NE spillover.¹⁸³ In a small Swiss study¹⁸⁴ and in African Americans,¹⁸⁵ family history of hypertension was associated with exaggerated responses of muscle sympathetic activity to mental stress. A Canadian study demonstrated that the abnormal heart rate and forearm blood flow responses to mental stress in normotensives with a family history of hypertension could be abolished by α - β -blockade.¹⁸⁶ At the same time, arterial baroreflex sensitivity appears to be inherited separately from hypertension in humans.¹⁸⁷ In all these studies, the overlap between those

with and without a family history of hypertension was substantial and the presence of a positive family history explained no more than 20% to 30% of the intergroup differences. Thus increased SNS activity and hypertension appear to be related more to environmental or acquired characteristics than to a strong genetic predetermination.

Prehypertension and Early Hypertension

The first clinical evidence of SNS overactivity in prehypertensives was the observation that military recruits who later developed hypertension exhibited higher heart rates than those who remained normotensive.¹⁸⁸ Louis was the first to report elevated plasma catecholamines in hypertension, also observing that the abnormal catecholamines and hypertension could be proportionally reduced by the administration of ganglionic blockers.¹⁸⁹ Goldstein reviewed 78 studies published by 1982¹⁹⁰ and concluded that the majority of studies demonstrated elevated plasma NE values in young borderline hypertensives. Urinary catecholamines have been less consistently elevated in early hypertension.¹⁹¹⁻¹⁹³ In the Tecumseh study, 37% of borderline hypertensives were found to have elevated plasma NE along with increased heart rate, cardiac index, and forearm blood flow.¹⁹⁴ This pattern persisted from ages 5 to 23 and was also associated with a parental history of hypertension. More recently, a prospective 10-year follow-up study in initially normotensive Japanese found higher initial plasma NE values in those normotensives whose BPs subsequently increased than in those who remained normotensive,^{177,178} clearly suggesting a role for the SNS in the initiation of hypertension. Elevated plasma epinephrine values have been reported to be elevated in early essential hypertensives,¹⁹⁵ who also have evidence of decreased β receptor responsiveness.¹⁹⁶ It has been suggested that increased circulating epinephrine could act as a cotransmitter with NE release that acts to “prime the pump” for sustained elevation of SNS outflow. Another SNS biochemical marker, plasma chromogranin A, is elevated in hypertension.¹⁸⁰

In the hope of improving upon the relatively low sensitivity of plasma NE for detecting small changes in SNS activity, Esler et al. pioneered the use of steady-state radio-labeled NE infusion techniques to measure NE spillover and found increased whole-body NE spillover in early hypertension, corroborating the conclusions based on studies of plasma NE.¹⁹⁷⁻¹⁹⁹ Kinetic techniques have also yielded data to suggest increased organ-specific NE spillover from the heart, kidney, and jugular vein of hypertensive subjects.^{197,200} Despite the intuitive appeal of the kinetic approach, there are discrepancies with respect to data derived from direct muscle sympathetic nerve recordings. For example, kinetic techniques do not reveal increased skeletal muscle SNS traffic in hypertension, a finding consistently demonstrated by venous plasma NE values and by muscle sympathetic nerve recordings.^{201,202} Curiously, muscle sympathetic activity has been reported to correlate with renal NE spillover.²⁰³ Furthermore, obese individuals demonstrate reduced cardiac and increased renal NE spillover,²⁰⁴ data that seem at odds with studies showing increased muscle sympathetic nervous activity in obesity.^{205,206} These technical discrepancies should be interpreted in the context of the totality of evidence demonstrating increased SNS activity in early hypertension.

The Metabolic Syndrome

Central obesity, hypertension, glucose intolerance, and dyslipidemia compose the metabolic syndrome because they coexist in individuals at prevalence rates greater than would be predicted by chance alone^{207,208} (see Chapter 13). The central feature of the metabolic syndrome is probably central adiposity, which is strongly and positively correlated with hypertension at all ages, regardless of gender or race.²⁰⁹⁻²¹¹ In the Tecumseh study, obesity, insulin resistance, and sympathetic hyperactivity were highly correlated¹⁹⁴; thus, increased SNS activity appears to be an under-recognized feature of the metabolic syndrome. Increased muscle sympathetic activity has been found in obese individuals^{205,206} and there is growing realization of the potential role of the SNS in obesity-related hypertension.²¹²⁻²¹⁴ There is thus a well-documented three-way association among increased SNS activity, obesity, and insulin resistance.²¹²⁻²¹⁵ Not only does increased SNS activity cause insulin resistance but hyperinsulinemia clearly increases SNS activity²¹⁶ and probably favors weight gain. Thus, the vicious cycle of increased SNS activity; hyperinsulinemia may be a major pathophysiologic linkage between obesity and hypertension. Insulin-sensitizing drugs such as metformin²¹⁷ have been found to decrease SNS activity and BP. Given the diabetogenic actions of catecholamines, it is likely that increased SNS activity itself causes insulin resistance.¹²⁹ This hypothesis is consistent with studies showing that when the SNS is activated by lower body negative pressure, human forearm insulin resistance increases²¹⁸ and with the ability of the central sympatholytic drug clonidine to lower SNS output and plasma catecholamines while increasing insulin sensitivity in obese dogs.²¹⁹ Salt sensitivity is a lesser known association with the metabolic syndrome, as is “nondipping” status of overnight BP.²²⁰

Sympathetic Nervous System-Renin-Angiotensin-Aldosterone System Interactions in Hypertension

Given the close relationship between SNS activity and RAAS activity, it would be logical to examine their interactions in essential hypertension. Esler found higher heart rates and cardiac indices among the high-renin hypertensives who also had isolated systolic hypertension.²²¹ In contrast, the normal-renin hypertensive group had normal heart rates and cardiac indices but elevated peripheral resistance. In addition, the degree of BP lowering following β -blockade was significant only in the high renin subgroup, suggesting that these individuals had neurogenic hypertension.²²² Other studies demonstrated a direct correlation between plasma renin activity and plasma NE in these younger individuals.^{223,224} In essential hypertensives, Luft et al. found that mental stress caused exaggerated increases in glomerular filtration and plasma Ang II that were fully blocked by ACE inhibition.²²⁵ Increased RAAS activity may play a role in insulin resistance as well, and insulin resistance may also stimulate Ang II production, because the insulin sensitizer troglitazone has been found to suppress Ang II along with insulin signaling in vascular smooth muscle cells.²²⁶ Thus similar to the pattern observed for insulin resistance and SNS activity, bidirectional reinforcement may also exist for Ang II and insulin resistance.

Sympathetic Nervous System Activity in Aging and Chronic Hypertension

The presence of multiple confounders in the assessment of appropriateness of SNS outflow has already been emphasized. The most important confounder of assessment of sympathetic activity in chronic hypertension is the close interrelationship among aging, increased SNS activity, and hypertension. Despite the prevalent view that SNS activation is present only in the early phases of hypertension, a more careful review of available information suggests that increased SNS activity remains a major pathogenetic component of essential hypertension at all stages of the disorder. Because body mass increases with age, it can at least be argued that a common thread linking aging, obesity, and hypertension is increased SNS activity. What remains to be identified are the precise mechanisms by which SNS activity increases with aging.

The prevalent view about the effects of aging on circulating catecholamines has been that age adjustment eliminates differences in SNS activity between hypertensives and normotensives. Upon closer scrutiny, however, this dogma appears to be incorrect. Messerli et al.⁷⁸ and Izzo et al.¹²⁰ found a significant positive correlation among age, plasma NE, and BP in hypertensives. After adjustment for age, a strong residual correlation between plasma NE and SVR remained.¹²⁰ Closely related to this pattern is the age-related decrease in β -adrenergic receptors that may explain in part the observed age-related decline in cardiac output.^{227,228} In the Normative Aging Study,²²⁹ one of the strongest residual relationships among the various parameters tested as determinants of BP was the age-independent relationship between urinary NE excretion and BP. Plasma epinephrine has also been reported to remain elevated in hypertensives beyond age 60, suggesting a continuing role in sustaining inappropriate SNS activity.²³⁰ Although age-related increases in plasma NE were once believed to be reflections of reduced clearance rather than increased release,²³¹ this finding is probably explained by technical artifacts introduced by the use of tracer infusion techniques. Clear-cut age-related increases have been documented in muscular sympathetic nerve traffic in normotensives and hypertensives²³²⁻²³⁴ and specifically in the resistance arterioles within these tissues.²³³ In addition, positron imaging techniques have demonstrated increased cardiac sympathetic activity with advancing age.²³⁵ On balance, it is highly likely that increased SNS activity is a central feature of the age-related increase in BP.

Antihypertensive Therapy and Sympathetic Nervous System Activity in Sustained Hypertension

In the early twentieth century, the notion that vasomotor nerves contributed to vasoconstriction led to the variably successful practice of surgical sympathectomy of the lower extremities to treat hypertension. Pharmacologic studies were the first techniques used to corroborate increased SNS activity in hypertension. The first class of oral antihypertensive drugs developed were the ganglionic blocking drugs, which lowered BP but caused significant postural hypotension.²³⁶ These agents were found to cause proportional falls in BP and plasma NE in people with longstanding, severe hypertension.¹⁸⁹ Julius et al. concluded that because elevated cardiac

outputs in borderline hypertensives were not normalized by β -blockade without atropine, there was a combination of sympathetic hyperactivity and parasympathetic dysfunction.^{237,238} Goldstein found that hypertensive individuals with high resting plasma NE values exhibited a proportional fall in both BP and plasma NE after administration of the central α_2 -agonist clonidine,²³⁹ confirming results with guanethidine.¹⁸⁹ Similar findings have been demonstrated in patients with kidney failure, another state of increased SNS activity.^{240,241} Goldstein demonstrated that the α_2 antagonist yohimbine increased SNS outflow and plasma NE to a greater degree in hypertensives than normals.²⁴² Similarly, Izzo et al. found that when BP was lowered by α_1 -blockade or nonspecific vasodilation, plasma NE doubled in hypertensive subjects,²⁴³ while ACE inhibitors had no effect on plasma NE. The vasodilator studies of Goldstein and Izzo suggest that baroreflex suppression of SNS outflow masks the intrinsically increased SNS activity in chronic hypertension and, furthermore, that the RAAS plays a role in baroreflex blunting.²⁴³ General clinical experience confirms the general utility of the central sympatholytic agents in hypertension, a finding that supports the concept of inappropriate SNS activity in all forms of chronic hypertension.

α -Adrenergic Hyperresponsiveness

NE-induced vasoconstriction may be enhanced in hypertension.²⁴⁴ Egan et al. found increased basal forearm vascular resistance in established hypertensives that could be normalized by α -blockade.⁷³ Phillip et al.²⁴⁵ and Kiowski²⁴⁶ examined the relative contributions of increased plasma NE and increased α -adrenergic vascular responsiveness in established hypertension. After stratification for BP, Phillip found a series of hyperbolic relationships between plasma NE concentration and α -adrenergic responsiveness; those with high plasma NE had low α -adrenergic responsiveness, whereas those with low plasma NE had high α -adrenergic responsiveness.²⁴⁵ Thus, the impact of the SNS on BP is a combined effect of the amount of agonist and the tissue sensitivity to that agonist. Differential genetic expression of α -adrenergic receptors has been found in different vascular beds, and α_1 gene expression increases with age, at least in the internal mammary artery.²⁴⁸ Racial differences in α -adrenergic responsiveness have been described as well; Black children have higher BPs with lower urinary catecholamines.²⁴⁸ Egan et al. have reported that α -adrenergic hyperresponsiveness is caused by increased endothelial fatty acid uptake, suggesting another link between metabolism and hypertension.²⁴⁹ Vascular responses to SNS activation are generally attenuated by aging²⁵⁰⁻²⁵² and in diabetes.²⁵⁰ The significance of this finding in age-related BP increases and hypertension has not been fully evaluated.

SECONDARY HYPERTENSION

There is clear evidence that inappropriate SNS activity occurs in all forms of secondary hypertension.

Steroid-induced Hypertension

A significant misconception exists that steroid-induced hypertension is simply volume-dependent hypertension. Substantial evidence in animals and humans suggests that

steroid-induced hypertension is neurogenic in nature and is most clearly understood as a disturbance of the equilibrium between volume and SNS-mediated vasoconstriction. Normally, volume loading leads to a suppression of SNS outflow.^{90,91} In steroid-induced hypertension, there is elevated or unsuppressable SNS outflow. Although rats implanted with deoxycorticosterone acetate (DOCA) develop hypertension with minimal elevations of catecholamines, their SNS outflow is accentuated by hemorrhage,²⁵³ and pharmacologic interruption of neurotransmission results in BP normalization.²⁵⁴ Zambraski et al. demonstrated that miniature swine implanted with DOCA, which do not require additional salt loading to manifest hypertension, exhibit increased plasma catecholamines that are normalized by pharmacologic sympathectomy.^{255,256} In DOCA-salt rats, adrenalectomy significantly lowers BP and blunts NE release by a reduced cotransmitter effect on presynaptic β_2 receptors.²⁵⁷ Although the mechanisms by which steroid excess engenders increased SNS outflow are not fully known, brain stem epinephrine synthesis increases during chronic steroid administration through induction of the epinephrine-synthesizing enzyme phenylethanolamine-*N*-methyl transferase (PNMT).^{258,259} Local epinephrine exerts an excitatory effect on the RVLM to increase SNS outflow, which may interact with impaired cardiopulmonary baroreflexes²⁵⁹ to sustain the hypertension.

Renovascular Hypertension

Given the tight interrelationship between the SNS and the RAAS, a permissive role of the SNS in renovascular hypertension should be expected. Renal nerves participate in the maintenance of 2-kidney and 1-kidney renovascular hypertension in the rat because renal denervation substantially lowers BP in these animals.^{260,261} In the 1-kidney renovascular model, Katholi et al. found that renal denervation reduced the abnormal hypothalamic NE metabolism that was found^{262,263} and corrected the SNS overactivity.^{263,264} In these animals, the development of hypertension could be prevented by posterior hypothalamic lesions, chemical sympathectomy, or thoracolumbar dorsal rhizotomy, which selectively ablates afferent renal nerves.²⁶⁵⁻²⁶⁷ Thus, renal afferent nerves are important promoters of SNS overactivity, which contributes to the genesis and maintenance of renovascular hypertension.

Renal Parenchymal Hypertension

Hypertension in renal failure may be simply an extension of essential hypertension, a subject that has recently been extensively reviewed.²⁶⁸ Plasma catecholamines are elevated in chronic renal failure^{240,269} in parallel with elevations in whole-body NE turnover²⁶⁹ and BP. In uremic humans, hypertension is associated with increased muscle sympathetic nerve traffic.²⁷⁰ Central sympatholytic drugs such as clonidine are extremely effective in uremic hypertension, causing proportional falls in plasma NE and BP.^{240,241} Widespread clinical experience dictates that combined α - β -blockers are also extremely effective in treating hypertension in renal patients. The mechanisms for increased sympathetic discharge in uremia include cardiopulmonary baroreflex failure,^{92,93} but it is also likely that abnormal afferent signals from renal nerves contribute to inappropriately high SNS outflow.²⁷¹

Pheochromocytoma

The paradigm of catecholamine hypertension is the naturally occurring model of pheochromocytoma. In this situation, excessive production of catecholamines directly causes hypertension and the removal of the autonomous catecholamine-secreting tissue cures the hypertension. In pheochromocytoma, plasma catecholamine levels are generally much higher than those observed in essential hypertension.²⁷² This argument has been used in the past to indicate that catecholamines play no role in essential hypertension. Because about 80% of NE released is immediately taken back up into that nerve terminal, however, the concentration of NE at the postsynaptic membrane in essential hypertension may be similar to that observed in pheochromocytoma.

Preeclampsia

Microneurographic studies have demonstrated that the syndrome of preeclampsia is associated with marked increases in SNS activity, which was shown to return to normal as BP normalized after delivery.²⁷³ Although this syndrome has features similar to profound volume depletion, the degree of SNS activation is higher than would be expected to occur from a compensatory response to hypovolemia.

SUMMARY

The SNS is a diverse physiologic regulatory system that modulates normal cardiovascular, renal, and metabolic function in response to existing environmental conditions. Experimental evidence in animals and humans indicates that inappropriately high SNS activity is a feature of all stages and all forms of hypertension. Thus, the SNS participates at least as a facilitator of chronic hypertension and may be a primary etiologic factor in many situations.

Environmental and Psychosocial Stress in Hypertension Onset and Progression

Kathleen C. Light

Life events that evoke negative emotions such as anger, fear, and sadness have long been known to produce temporary elevations in blood pressure (BP).^{1,2} Since the application of standardized laboratory experimental methods has become widely used to assess cardiovascular and neuroendocrine responses (psychophysiological stress testing), a large body of evidence has shown that many other experiences also lead to short-term pressor responses. These experiences range from cognitive to physical challenges and from positive to negative emotional states. These laboratory studies have also shown that different adrenergic and hemodynamic patterns are involved during different types of stressors. Challenging tasks involving active coping and mental effort typically elicit a state involving increased β -adrenergic receptor activity characterized by increased heart rate, cardiac output, cardiac contractile force (frequently indicated by decreased pre-ejection period) and vasodilation in skeletal muscle.³⁻⁵ This state is similar to the pattern originally identified through studies in animal models as “preparation for fight or flight” or the defense reaction, which is characterized by enhanced activity of the sympathetic adrenomedullary system.^{6,7} Events that incorporate aspects of frustration, passive coping, loss of control, or helplessness tend to evoke less β -adrenergic activity and less cardiac activation but instead result in greater vasoconstriction, presumably owing to α -adrenergic activity.³⁻⁵ This pattern resembles the “defeat reaction” of animal models, which is characterized by overactivity of the hypothalamic-pituitary-adrenocortical (HPAC) system.^{6,7}

These psychophysiological stress studies have also shown that even when the stressors themselves are highly standardized, individuals differ greatly in the magnitude that the BP increase evoked.³ Those individuals who demonstrate BP increases that place them in the top 25% of those studied are often labeled *high stress reactors*. An active hypothesis guiding considerable research has focused on these hyperresponsive persons as a group that may be at increased risk of developing hypertension.⁸ Studies have also shown that healthy normotensive men and women differ in their stress responses, with men showing greater systolic BP (SBP) increases, greater vasodilation during stressors evoking β -adrenergic activation, and greater vasoconstriction during stressors evoking α -adrenergic activation.^{5,9} Men also show slower return of BP to prestress levels (slow recovery) after the stressful event has ended.⁹ These gender differences are enhanced when women are tested in the phase of their menstrual cycle when female reproductive hormones, particularly estrogen and progesterone, are higher than when these are low. Estrogen has vasodilator effects, which may underlie both this observation and other findings suggesting that postmenopausal women have enhanced stress-induced BP increases compared with premenopausal women.^{10,11} Ethnic differences in cardiovascular stress responses have also been shown in both nor-

motensive and hypertensive adults, with African Americans demonstrating greater vasoconstriction during stress and sometimes greater BP increases than European Americans.^{4,12,13} African Americans more frequently demonstrate another potentially maladaptive response to short-term stress exposure—increased sodium retention. This response, like exaggerated BP increases during stress, has been shown to occur more frequently in persons with risk factors for hypertension, including borderline hypertension and positive family history of hypertension.¹⁴⁻¹⁶

Laboratory stress studies in normotensive and hypertensive humans can be very informative about patterns of cardiovascular responses. They can also document the stability of high and low reactivity in a variety of cardiovascular measures. Stability at acceptable levels has been documented over periods ranging from weeks to months to as long as 10 years.^{3,8,17} However, such studies cannot establish the long-term predictive significance of stress or of stress reactivity in the onset or progression of hypertension. This critical issue has been addressed in several other ways. This review summarizes recent findings in the following areas: (1) animal models involving stress showing progression to hypertension; (2) human studies showing relationship of environmental factors or personality or behavioral patterns to the development of hypertension; (3) prospective long-term follow-up studies of normotensive individuals characterized as high and low stress reactors; and (4) evidence that stress buffers and stress-management interventions are related to lower BP.

ANIMAL MODELS OF STRESS-RELATED HYPERTENSION

One of the most influential leaders in the field of stress exposure, patterns of response, and health consequences was James P. Henry.⁷ His model of stress-related hypertension in mice induced by social environments that increase territorial confrontations provided some of the strongest evidence to date that chronic stress exposure can indeed be a key precipitating factor in the pathogenesis of hypertension. The development of sustained hypertension was evident in dominant males (mean BP levels of 145 mm Hg) and was worsened in subdominant males (those just below the dominant ones in social status; mean levels of 160 mm Hg) but not in the truly subordinate males (mean levels of 125 mm Hg). The elevation was greater when the colony members were changed frequently versus when stable dominance hierarchies were allowed to remain intact. According to the interpretation of Henry and Stephens, dominant males showed a classic defense reaction with sympathetic activation as they exerted themselves but maintained control. Subdominant animals showed a more extreme defense reaction associated with striving but

incomplete control. Subordinate animals showed a defeat reaction with enhanced corticosterone and HPAC activity.¹⁸ In keeping with this as the era of genetic and molecular biology, it is important to emphasize that even in this model of social environmental hypertension, genetic influences are critical.

When Henry extended his work on social stress from mice to rats, he compared chronic social stress effects in rat strains that normally do not develop hypertension in standard laboratory environments.^{7,19} Wistar-Kyoto hyperactive rats, classified as very peaceable, showed no BP rise with chronic unstable social environments, whereas the moderately peaceable Sprague-Dawley animals showed some rise in BP, and the aggressive Long-Evans rats showed much larger increases in BP, with rise in BP positively correlated with number of scars from aggressive encounters. This research was later expanded by Mormede, who reports that among six rat strains, both behavioral and adrenal and heart weight evidence can be used to identify those strains more vulnerable to social stress.²⁰ However, even strains showing high social stress sensitivity must also have related target organ vulnerability (renal, cardiac, or vascular) before the excess sympathetic adreno-medullary activity evoked by chronic social instability results in sustained BP increases.^{20,21}

A second prominent model of stress-related hypertension is the borderline hypertensive rat (BHR) as developed and studied by Lawler et al.²²⁻²⁶ This first-generation backcross of a spontaneously hypertensive rat (SHR) with a normotensive Wistar-Kyoto rat typically develops only high-normal or borderline hypertension in the usual laboratory environment. With daily exposure to a brief period of a shock avoidance conflict task for 16 weeks, the BHRs develop hypertension with

target organ damage that persists even if the stress exposure is terminated. This stress-induced hypertension is blunted if the animals receive daily swimming exercise as well as the conflict task (Figure 7-1).²⁵ Hypertension also develops in BHRs if they are placed on a high intake of salt, and the combination of high salt and stress leads to greater adverse cardiovascular effects than either environmental factor individually.

A primary role for renal involvement in the hypertension resulting from either high stress or high salt is suggested by the observation that renal denervation delays onset of the rise in pressure. Work by DiBona et al. has shown that stress induces greater increases in sodium retention in SHRs and BHRs than in normotensive rat strains, and that this effect of stress can be prevented by renal denervation or reduction in central sympathetic outflow owing to administration of sympathetically active agents into the ventricles of the brain.²⁷⁻²⁹ Lawler et al. have reported that in the early period of stress exposure plus high salt, norepinephrine content decreases in nuclei of the hypothalamus that are known to be involved in the classic defense reaction.²⁴

A third animal model of stress-related hypertension described by Anderson et al. is the mongrel dog exposed to daily shock avoidance while on increased salt and low potassium intake.³⁰⁻³² This model requires both stress exposure and high salt intake to induce hypertension; neither factor alone is sufficient. The reversible hypertension that results involves retention of sodium, and either renal denervation or potassium supplementation is sufficient to prevent or reverse hypertension in this model. Thus, even in animals lacking clear genetic predisposition, a reversible form of hypertension may arise when three adverse environmental factors are present: excessive salt, potassium deficiency, and regular stress exposure.

Figure 7-1 Stress-induced hypertension in borderline hypertensive rats (BHR) is attenuated by concurrent swim training. Mean (\pm SEM) tail cuff systolic blood pressure (SBP) for each 2-week period before the stress manipulations (*Pre*), during the 2 weeks when the stress was being progressively lengthened (*Training*), and during the 12 weeks of daily swim or tail shock, or both (*Stress*), in rats exposed to daily shock plus swim training (*triangles*), shock only (*circles*), or neither intervention (*squares*). (From Cox RH, Hubbard JW, Lawler JE, et al. Exercise training attenuates stress-induced hypertension in the rat. Hypertension 7:747-751, 1985.)

In animal models, early life and even prenatal exposure to stress have also been shown to affect BP and stress responses throughout the life span.³³ In animals as well as humans, early loss of a parent or prolonged maternal separation has particularly profound effects including increased BP and corticosterone levels as an adult.³³⁻³⁵ Conversely, early exposure to stress buffers such as enhanced maternal contact and stroking (known to increase central oxytocin activity), or multiday exogenous oxytocin administration, leads to decreased BP, corticosterone, and anxiety behavior into adolescence and adulthood.³⁶⁻³⁷ Oxytocin, a mammalian neuropeptide/hormone linked to social bonding as well as maternal behavior, appears to decrease BP through alterations in central α -adrenergic activity, as well as stimulating release of atrial natriuretic peptide and affecting cardiovascular function peripherally.³⁸

These animal models provide the most definitive evidence to date that chronic life stress exposure can contribute to the development of hypertension in individuals with genetic susceptibility and/or when combined with other adverse environmental factors such as a high-salt/low-potassium diet. Also, the importance of early exposure to stress and/or stress buffers is highlighted. These observations lay the foundation for studies of environmental stress in humans, which cannot provide such direct and definitive evidence but do show important associations with parallels to the animal models.

ENVIRONMENTAL STRESS EXPOSURE: CHRONIC JOB OR HOME LIFE STRESS AND ACUTE TRAUMATIC STRESS

Observations of people who move from stable, rural, traditional societies to unstable, urban, Westernized environments have indicated that contemporary urban conditions contribute to increases in BP over the life span.³⁹ For example, the nomadic Samburo warriors of Kenya show no BP increase with age in their traditional environment, yet when they join the Kenyan military, they show BP increases similar to those of recruits from more urban areas.^{40,41} The principal factors that change with such a move and are believed to contribute to the pressure rise include (1) diet, (2) physical activity, (3) increased obesity, (4) reduction of supportive ties to the family and larger community, and (5) increased mental effort and active coping to perform work and home life activities under time pressure and competition. Waldron et al., after examining BP data from 84 different cultures and social groups, concluded that BP increases were independent of changes in salt intake and obesity (in men), and that the remaining factors, particularly economic competition and loss of family ties, appear to be the more universal contributing causes.⁴²

Among Westernized societies, both urban and rural, people with less education, lower-status occupations, less total household income, and generally lower socioeconomic status (SES) have higher BP.⁴³ Although African Americans have on average fewer educational and economic resources and higher BP than age-matched European Americans, ethnic differences do not account for these differences in BP between lower and higher SES groups. Clear BP differences are seen between lower and higher SES African Americans, as between lower and higher SES whites and members of other ethnic minorities. Sources of these group differences have been reviewed by

Anderson et al.^{44,45} All explanations involve multiple contributing factors, including *chronic stress*, defined as increased frequency of threats to the well-being of the individual and her or his close family and friends. This definition of chronic stress is so general that it leaves completely open which specific elements that differ between SES groups are most critical in their impact on BP. However, its generality is also one of its strengths in that it spans both the objective and the more individualized subjective perception of actual and anticipated life experiences as components of the stress exposure. Thus, it leaves room for individual differences in response to the same experience and for multiple models focusing on specific dimensions of low SES, such as economic insecurity or lack of control at work or at home.

One specific model that grew from the observed SES differences in BP is Dressler's model of lifestyle incongruity.⁴⁶ This model associates increased chronic stress and sympathetic nervous system (SNS) activity with the extent to which the individual's material acquisitions are higher than average for his or her occupation and income level (i.e., living beyond one's means). High lifestyle incongruity has been associated with increased BP levels. Dressler's current model also addresses incongruity in regard to noneconomic issues that are related to expectations about behavior and multiple roles or status within the family and community. Both economic and social incongruity appear to act, in part, through another important factor—reduction in social support from family and other sources.

Low occupational status and low control within the workplace are associated with lower SES, and both have been associated with increased job stress. Ever since early work by Rose et al. on air traffic controllers,⁴⁷ the hypothesis that daily stress exposure on the job may contribute to hypertension has been gaining support. Karasek et al.'s model of "job strain" was developed to formalize the study of stress on the job across a variety of occupations.⁴⁸ Job strain focuses on two dimensions of work stress: (1) psychological demands (i.e., how hard and how fast the worker perceives she or he must work) and (2) job decision latitude (i.e., the level of control over the nature and pace of the work). *Job strain* is defined as occurring when high psychological demand occurs together with low decision latitude.

Research on job strain as a contributing stress exposure factor in the onset and exacerbation of elevated BP has included more than 14 studies since the late 1980s. As summarized by Pickering, the method of BP assessment is critical.³⁹ Clinic assessments of BP are more time-efficient, but ambulatory BP obtained at intervals of every few minutes throughout a normal weekday spent at work and at home has distinct advantages for assessing response to daily work life demands at work and as they spill over to influence responses after work. Of seven studies using clinic assessments only, none has found a relationship between job strain and increased BP. Of another seven studies that employed ambulatory monitoring, all but one have observed a positive relationship for men. The most definitive work has come from Schnall et al., who have shown that job strain is related to higher BP at work and also at home and during sleep, to increased left ventricular mass, and to hypertensive status in a case-control study in 196 men.^{49,50} They have also reported that job strain interacts with age such that the increase in BP with age is greater for high-job strain men, and that the combination of high job strain and increased alcohol use is

related to greater increases in BP. Furthermore, in a 3-year follow-up study, this research team found that increases in pressure over time are greater for high–job strain than low–job strain men, controlling for BP at study entry.

High work demand and low control on the job have been related to increased urinary epinephrine but not cortisol,⁵¹ suggesting that enhanced adrenergic receptor activity may contribute to the BP increase in high–job strain individuals. It is worth noting that research reported by Pickering³⁹ and another study by Light et al.⁵² have observed no increase in work BP in women reporting job strain, although men in the same study showed the predicted relationship. This observation is consistent with recent work by Lundberg⁵³ and by Luecken et al.⁵⁴ suggesting that stress related to child care and other family duties is a greater influence than job-related stress on the mental and physical well-being of working women.

PERSONALITY AND BEHAVIORAL PATTERNS ASSOCIATED WITH ELEVATED BLOOD PRESSURE

A number of psychological characteristics have been related to higher BP levels and/or increased prevalence of hypertension. Several of these traits are of relevance because they are presumed to act, in part, by increasing the individual's exposure to stress or perception of stress (e.g., cynical hostility) or because they themselves may be a consequence and thus a marker of excessive stress exposure (e.g., hopelessness and depressive symptoms).

Type A or the coronary-prone behavior pattern is associated with increased risk of atherosclerosis and coronary morbidity.⁵⁵ This pattern includes three semi-independent component traits: hostile outlook, competitiveness, and time urgency.⁵⁶ Of these traits, hostile outlook was the primary predictive factor in most studies that examined relationships of the individual factors. Additional research on hostility by Barefoot et al. has confirmed that this trait is stable over time and predicted both cardiovascular and all-cause mortality, in part through its relationship to increased BP.^{56,59} Hostile outlook, described as a combination of angerability and cynical mistrust, leads to increased BP, vasoconstriction, and plasma cortisol and testosterone responses to laboratory stressors, as well as higher 24-hour urinary cortisol and ambulatory BP levels in normotensive and hypertensive individuals.^{60–63} Some experts have interpreted such findings as evidence that hostile individuals demonstrate greater and more frequent stress reactions in daily life because they perceive more situations as threatening and because they provoke more conflicts and negative interpersonal interactions. Some studies have found no excessive BP responses to stress in high-hostility men and women during purely cognitive tasks such as mental arithmetic or the Stroop color-word task^{64,65}; but other investigations in which the stressors involved interpersonal interactions, including efforts to control or dominate others or harassment and frustration by others, have consistently found greater pressor responses in high-hostility persons.⁶⁶ High-hostile young men reporting greater frequency and longer duration of angry episodes in their lives also demonstrate adrenergic receptor down-regulation, suggesting greater chronic SNS activity.⁶³

Some studies have reported an apparently paradoxical association between low rather than high self-reports of hostility and higher BP. Work by Shapiro and Jamner et al. has suggested that these persons are not truly low in hostility, but instead they employ a defensive coping style, characterized by reluctance to admit to anger, anxiety, or other socially undesirable thoughts or feelings.^{67,68} Defensive copers among paramedics and nurses showed higher ambulatory BP on the job, particularly under more stressful conditions. Defensive coping, like hostility, is more consistently related to high stress reactivity in men than in women, possibly because of differences in social expectations about expression of emotion between genders.^{69,70} These observations indicate that it is not appropriate to conclude that there is a simple, unidirectional relationship between high scores on a hostility scale and risk of hypertension. Furthermore, several large-scale investigations have found that hostility scores decrease with increasing education and income.^{71,72} Thus, it is important to separate the effects of social class from hostility by matching groups for education and economic resources or controlling statistically for group differences in these variables.

Anger-arousing experiences have long been known to raise BP and increase vasoconstriction.^{1,2} One way in which hostile outlook may influence cardiovascular risk is through frequent bouts of anger. Three patterns of anger coping—high anger-out (hair trigger and explosive verbal and physical expression of anger), low anger-out (inability or unwillingness to show or express anger even when appropriate and justified), and high anger-in (denial of angry feelings toward others with unjustified self-blame)—have been hypothesized to lead to increased BP reactivity to stress and to hypertension.^{73,74} The original research by Harburg et al. on African Americans living in high-crime areas of Detroit suggested that anger suppression or low anger-out was directly related to elevated BP in these stress-vulnerable people.⁷⁵ This pattern has been related to increased BP and heart rate during role play of conflicts and harassment in the laboratory, as well as to increased BP in wives after discussion of conflicts with their husbands.^{59,76–80} Anger suppression, like hostility with its association of high-anger expression, has been related to down-regulation of β -adrenergic receptors, suggesting a stable pattern of sympathetic overactivity.^{63,81,82} Engebretson et al. originally suggested that high cardiovascular reactivity was more frequent in both high–anger-in and high–anger-out persons if the stressor involved some provocation of angry feelings.⁷⁷ A recent prospective analysis of middle-aged men from the Kuopio, Finland study indicated that subjects who were at the extreme ends of the distribution for either anger-in or anger-out had a significantly higher risk of developing hypertension over the next 5 years.⁸³ These results confirm that extremes in either expressing or suppressing angry feelings are maladaptive and that moderation is the lowest-risk solution.

Another psychological factor related to increased BP is the desire to dominate and impress others, termed *power motivation*. McClelland found that inhibited power motivation in men predicted hypertension-related pathology in a 20-year study,⁸⁴ but few studies have confirmed an association between power motivation and either high reactivity or increased BP levels. Furthermore, a number of negative studies exist. The parallel of this pattern to Henry et al.'s psychosocial model of hypertension in rats and mice^{7,18} is compelling and may provide a basis for integrating the

contradictory results. Dominant and subdominant rats develop hypertension only if they are members of a strain that is vulnerable to stress-induced hypertension, and the BP increase occurs when aggressive contacts are high. In the truly dominant males, this occurs only when the social group members change, so that frequent bouts of aggression are required to assert dominance. In humans, the appropriate parallel might be that inhibited power motivation may lead to hypertension only when the individual's work and home environments are also unstable and the individual's social dominance is repeatedly threatened.

A related characteristic is the preference for active coping, or "John Henryism."⁸⁵⁻⁹⁰ This trait is defined by the belief in individual control and that hard work and persistence despite obstacles will lead to future success. The theory regarding the active coping behavior pattern states specifically that it will not be related to increased sympathetic activity and BP if the environment is supportive and has adequate resources. Only if the individual's environment is deficient in some way, thus leading to excessive effort and sympathetic overactivity, will hypertension develop. James et al. showed that high John Henryism was associated with increased BP in lower-social class rural African Americans, whose environment offered little opportunity for success.^{85,86} African American and white adolescents with the combination of high John Henryism and lower social class had increased BP and higher vascular resistance.⁹⁰ In another study in which the sample was limited to well-educated and employed African American and white adults, Light et al. observed that ambulatory BP at work was increased in women and African Americans with high-status professional and managerial jobs who scored high in this preference for active coping.⁸⁹ This effect was not seen among white male professionals and managers, and this was interpreted as evidence that this role is more threatening and less supportive for women and African Americans because of lack of peers in these jobs.

Attention has also focused on depressive symptoms and their relation to hypertension and cardiovascular risk.^{91,92} Depression is different from previous psychological factors because it is assumed to be an impermanent mood state (characterized by sadness and loss of interest in work, hobbies, family, and friends) rather than a stable trait. However, longitudinal studies indicate that depressive states tend to recur and that past history of depression is a primary predictor of subsequent depressive states. Although fewer reports have supported a link between depression and hypertension versus a link between depression and cardiovascular or total mortality, the overall consistency of the pattern is compelling. Depression (as well as its correlated measure of distress, anxiety) is linked prospectively to onset of hypertension in both men and women, and in African American as well as white samples.⁹³ In elderly patients with established hypertension, men and women with higher depression scores show greater hypertension-related disease progression and increased incidence of stroke.^{94,95} Depressive symptoms are predictive of more severe cardiac events. In patients with confirmed coronary heart disease (CHD), depressive symptoms are linked to increased myocardial infarction (MI), stroke, surgical intervention, and cardiac death; to decreased heart rate variability; and to increased cardiac activation and myocardial ischemia during Holter monitoring or mental stress in the laboratory.^{91,96-100}

Depression can develop in susceptible persons as a reaction pattern to life stress, including stresses associated with health crises such as MI and other serious cardiovascular diagnoses.^{96,97} In young healthy women, depressive symptoms were related to increased cardiac adrenergic tone and enhanced norepinephrine increases during a speech stressor.¹⁰¹ In a larger subsequent study involving a biracial sample of both men and women, depressive symptoms were linked to increased ambulatory BP in persons with a genetic susceptibility to hypertension (i.e., those with hypertensive parents), but not in those with no susceptibility.¹⁰² Stressful life events may contribute to worsening of depressive symptoms, and depression may in turn worsen sympathetic and cardiovascular responses to stress, producing a vicious circle effect. Frasure-Smith et al. have confirmed that in patients with a recent MI, depression predicts premature death due to recurrent MI, arrhythmic events, and congestive heart failure (CHF) at 6, 12, and 18 months' follow-up; risk was further increased in those whose post-MI depression was not their first depressive episode.^{91,96,97} The effects of depression are strongest in the subgroup with premature ventricular complexes, a group especially vulnerable to arrhythmia and sudden death associated with alterations in cardiac autonomic activity, such as may be induced by severe acute life stress.

Hopelessness and pessimism are common among depressed and vitally exhausted individuals, but these can also occur without the severe sadness or loss of interest in life that are the true hallmarks of depression.¹⁰³ Unlike depression, which is more common in women than in men and less common in African Americans than in other ethnic groups, hopelessness is reported equally in both genders, and it may be equally or more common in minorities and those from lower social classes.¹⁰⁴ In the Kuopio Ischemic Heart Disease study, men with moderate to high hopelessness at baseline were 2.5 to 4 times more likely than men with lower levels of hopelessness to die of cardiovascular causes over a 6-year follow-up period, even after controlling for baseline BP, smoking, and other traditional cardiovascular risk factors.¹⁰⁵ Hopelessness also predicted all-cause mortality in this group of 2428 middle-aged men and carotid atherosclerotic lesion progression in the 942 men showing some carotid plaque at initial testing.^{105,106} *The effect of persistent hopelessness was equivalent to that of smoking 2.5 packs of cigarettes daily.* Pessimism before coronary bypass surgery is also linked to increased likelihood of having a perioperative MI.^{107,108} Less research has focused on the linkage of hopelessness and pessimism to hypertension, but the few studies reported to date support this relationship.¹⁰⁹ For example, in postmenopausal women, those who both had low SES and used a stable pessimistic attributional style (believing that bad events are permanent and cannot be controlled or improved) had increased ambulatory BP.¹¹⁰ Helplessness and pessimism, like depression, are seen as both consequences of previous life stress and states that enhance the adverse cardiovascular effects of subsequent stress exposure.¹¹¹ Additional work on these important factors, which appear to parallel the defeat and helplessness state in animal models,^{6,7} is currently in progress.

Altogether, there is substantial and growing evidence to support the association of hypertension and cardiac events with a number of psychological factors that involve stress as a causal factor in initiating the psychological condition or in contributing to its adverse cardiovascular consequences. Psychological

states such as hostility, depression, anxiety, and hopelessness are thus ripe for serving as risk identifiers and as focal points for interventions to reduce risk. In two clinical trials, the Sadheart trial of pharmacotherapy for depression and the Enhanced Recovery in Coronary Heart Disease Patients (ENRICH) trial of cognitive-behavioral therapy for clinical depression and/or social isolation, the addition of treatments for depression to standard medical care in patients with recent MI have alleviated psychological symptoms but did not further reduce cardiovascular morbidity and mortality.¹¹²⁻¹¹⁴ Thus, it appears at this time that such psychological measures are best used as markers of additional risk that might be employed in an equation identifying persons for whom traditional medical interventions are even more vital to implement.¹⁰²

HIGH CARDIOVASCULAR RESPONSE TO STRESS IN PREDICTION OF LATER BLOOD PRESSURE ELEVATION

The hypothesis that those individuals who show exaggerated BP, heart rate, or other cardiovascular responses to behavioral stressors have increased risk of becoming hypertensive has generated considerable research and much debate since the late 1970s.^{8,115} Indirect evidence supporting this hypothesis included observations that persons with borderline hypertension or those with hypertensive parents showed increased BP responses to stress in many studies, although not in all. Other evidence indicated that high response to stress was a stable characteristic of certain people, documented by highly correlated response levels when compared across stressors or on retesting after intervals as long as 1 to 10 years. Notably, response levels showed greater stability than did reactivity scores (calculated as increases from resting baseline levels).^{3,17} More direct support for this hypothesis has been derived from several longitudinal studies. A number of these have employed a single stressor, often the cold pressor test, which elicits a BP increase via α -adrenergically mediated vasoconstriction. These investigations have not always yielded positive findings,¹¹⁵ but the two largest investigations with the longest follow-up interval have supported the reactivity hypothesis by showing that individuals with the greatest BP increases to painful cold later developed hypertension at a higher rate than those with lesser BP increases.^{116,117}

Several smaller-scale studies, particularly those focusing on young borderline-hypertensive individuals, have shown that high reactivity to active coping stressors like mental arithmetic that evoke BP increases through β -adrenergic activity and increased heart rate and cardiac output is predictive of later sustained hypertension.^{118,119} Similar studies with active coping stressors using normotensive subjects have generated both positive and negative findings after partitioning out effects related to higher prestress BP, which is associated with high stress reactivity and later hypertension.¹²⁰⁻¹²² BP increases during *anticipation of upcoming physical or mental stress* and during *recovery after stress* are added effects of stress reactivity; increases in these measures are strongly predictive of later hypertension.^{118,119,123}

Two prospective studies that included women as well as men in the sample have examined responses to multiple stressors. In the study by Matthews et al. involving parents and their children, high pressor reactivity to active coping stressors was related to increased BP after 6.5 years; the effects were

more consistent for men and boys than for women and girls.¹²⁴ In the much larger Coronary Artery Risk Development in Young Adults (CARDIA) study involving more than 3300 African American and white young adults,¹²⁵ results after 5 years of follow-up indicated that high SBP reactivity to the active coping task, but not to the passive cold pressor test, was predictive of greater BP elevations and increased incidence of hypertension in African American and white men, even after controlling for baseline BP levels and other key covariates. In women regardless of race, neither task was effective in predicting later BP (Table 7-1).¹²⁵ The gender difference seen in the latter studies may have been related, in part, to the fact that women tend to develop hypertension at a later age, perhaps related to protective effects of female reproductive hormones during the ages under study. Another possibility is that video games may differentially engage higher active coping effort in men than in women.

Prior work by our group has supported the interpretation by the CARDIA investigators that individuals showing enhanced cardiac responses due to β -adrenergic activity during active coping stressors have a greater likelihood of demonstrating BP increases as young adults. In our investigation, the sample under study was small, but the follow-up testing involved more than 60 measures of BP from each subject obtained through ambulatory monitoring on a regular workday, providing greater confidence in the outcome measures.¹²⁰ Both high heart rate reactors and high BP responders to an active coping reaction time task demonstrated increased BP at work and at home as well as in the clinic 10 years later. The predictive effect of high heart rate reactivity most directly points to mediation via β -adrenergic activity, because our laboratory has confirmed through use of β -antagonists that heart rate and SBP elevations in response to active coping reaction time tasks primarily reflect such activity.^{4,5}

More recently, our group has completed a second 10-year follow-up study using ambulatory BP monitoring.¹²⁶ This study reconfirmed that initially normotensive young men

Table 7-1 Odds Ratios of Having Significant Blood Pressure Increase (8 mm Hg) Over 5-Year Follow-Up Function of Gender and Systolic Reactivity to Video Game: The CARDIA Study*

[†]Reference group = 10 mm Hg.

who were high heart rate and SBP responders to stress showed greater BP increases and a high incidence of borderline hypertension 10 years later. The results also showed that prediction of later development of borderline to stage 1 hypertension was strongest for the men who had hypertensive parents as well as high stress responsivity (Figure 7–2).¹²⁶ Finally, the study indicated that the stress exposure and stress buffers in the person's home and work environments could influence the predictive effect of high cardiovascular responsivity to stress. Clinic pressure was higher in high stress responders who reported high scores on the Daily Stress Inventory, but not for those reporting low daily stress. Similarly, ambulatory pressure at work was greater in high stress responders reporting low support from their work supervisor and greater during leisure at home from those reporting low overall social support, but not in high responders who had greater support in their lives. These findings encourage reconsideration of the reactivity hypothesis, expanding it to take into account genetic factors (e.g., parental hypertension); differences across individuals in chronic stress exposure, which affects expression of the predisposition to high heart rate and BP responses; and differences in exposure to stress buffers like social support.

In sum, these investigations provide cautious encouragement for continued research addressing high reactivity to stress as a potential risk factor for hypertension. Future research should avoid some of the oversimplified approaches of the past and utilize available opportunities to examine stress-response patterns in association with information about family history and factors relating to chronic stress level.

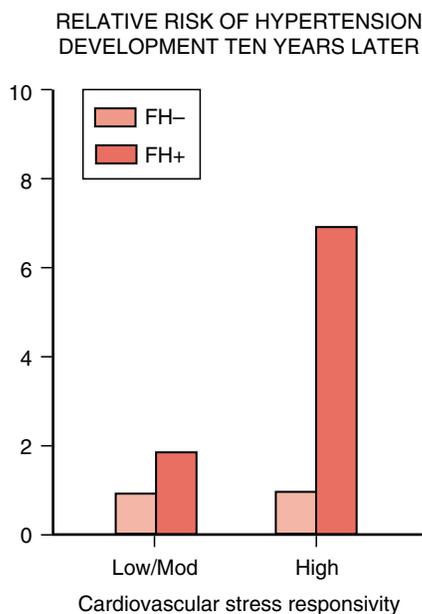

Figure 7–2 High cardiovascular stress response predicts future hypertension in men with positive (*FH+*) but not negative family history of hypertension (*FH-*) (Adapted from Light KC, Girdler SS, Sherwood A, et al. High stress responsivity predicts later blood pressure only in combination with positive family history and high life stress. *Hypertension* 33:1458-1464, 1999.)

STRESS BUFFERS AND STRESS-REDUCTION INTERVENTIONS

As one of the spokesmen for models of stress and disease in humans, Cohen has incorporated a category of factors labeled *stress buffers* in his model.¹²⁷ Stress buffers include any factor that reduces perceived level of distress in individuals exposed to stress, that limits exposure to stressors, or that decreases adverse physiologic reactions to stress. The best-documented stress buffer is social support. Social isolation has been associated with high rates of premature death from cardiovascular disease and all causes combined.¹²⁸⁻¹³¹ In patients with MI, increased emotional social support was related to decreased mortality, even after controlling for age, Killip class, and other cardiovascular risk factors.¹³¹ Laboratory studies have shown that BP and other cardiovascular responses to mental challenges are less when a supportive and nonevaluative person is present.¹³²⁻¹³⁴ Similarly, even support from a pet dog or cat has been shown to reduce stress responses.¹³⁵ In contrast, when the supportive person may be evaluating the test subject based on her or his performance, or when support may increase the intensity of effort (such as arguing against racial discrimination in the presence of another person advocating the same position), cardiovascular responses can actually be increased rather than decreased when the supporter is present.¹³⁴⁻¹³⁶ Support provided by a marital partner can be especially beneficial in reducing stress responses. In a recent study by Grewen et al., *BP and heart rate increases to a speech task were reduced by almost 50% in 100 men and women tested immediately after a 10-minute period of warm contact with their partner (including hand-holding and a hug) versus 89 persons tested after solitary rest (Figure 7–3).*¹³⁷

In studies involving ambulatory BP monitoring, high perceived support is related to lower BP.¹³⁸⁻¹⁴¹ Again marital support is especially important. Persons reporting a more supportive relationship with their spouse/partner had lower ambulatory BP than those with no partner, but others who were married with a poor partner relationship had higher BP than those with no partner.¹⁴⁰ In a 3-year prospective study of hypertensive patients, more supportive marital relationships were prospectively associated with an 8% decrease, whereas poorer marital relationships were associated with a 6% increase in left ventricular mass.¹⁴¹ In another study, Brownley et al. reported that high social support did not act by itself to lower BP in 129 healthy African American and white men and women, but it did interact with another factor that might increase stress and BP: a hostile outlook on life. In this sample, high-hostile persons lacking support had higher ambulatory BP, whereas high-hostile persons with social support showed no BP increase relative to low-hostile persons.¹³⁹ A similar interaction was seen in a prospective study of Swedish men, in which type A men lacking social support had increased mortality but other type A men reporting more support had no increase in risk relative to type B men.¹⁴² Additional work addressing the potential stress-buffering effect of social support is needed, however. In particular, interactions of support with anger-coping styles and other psychological factors, with high stress reactivity, and with environmental stressors like job strain have clear potential to reveal important relationships.

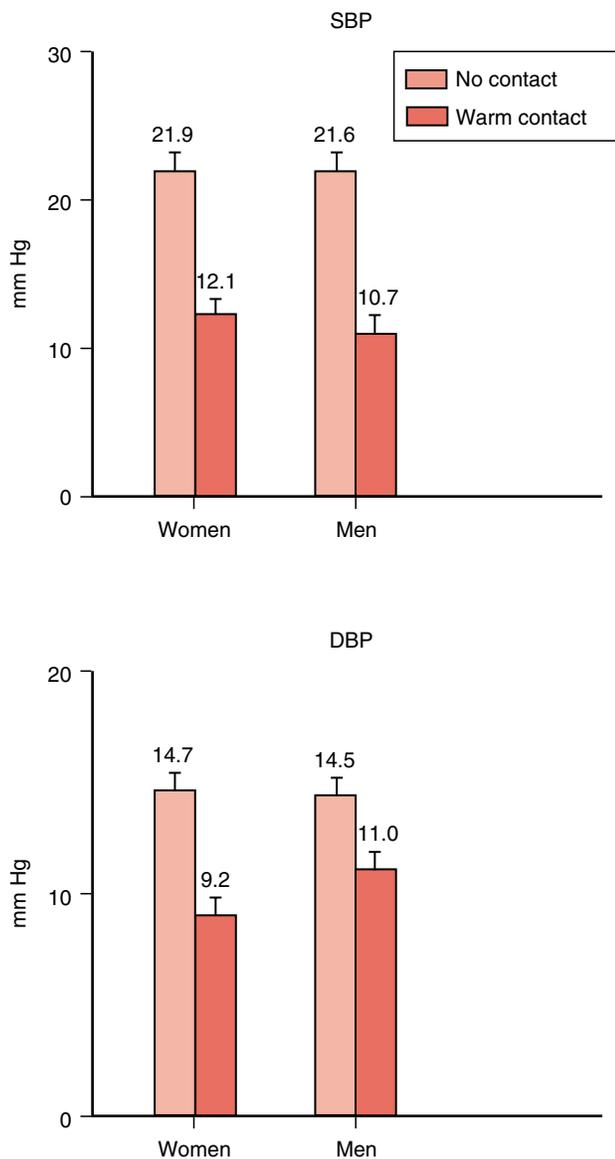

Figure 7-3 Warm contact with spouse/partner prior to stress reduces systolic blood pressure (SBP) and diastolic blood pressure (DBP) increases to an anger-recall speech task. (Adapted from Grewen K, Anderson B, Girdler S, et al. Warm partner contact is related to lower cardiovascular reactivity. *Behav Med* 2003; 29:123-130.)

Another potential stress buffer is aerobic exercise. A number of studies have compared cardiovascular responses to stress after a period of exercise versus those following a control condition.¹⁴³⁻¹⁴⁸ Some of these studies showed no differences, whereas others supported the hypothesis that stress responses are reduced after exercise.¹⁴⁸ Two factors that may influence the outcome of such studies are whether the subject is a high reactor to stress and whether his or her BP is elevated. Research in our laboratory has suggested that moderate aerobic exercise for only 20 to 30 minutes can evoke a reduction in vascular resistance in most individuals, but that BP will not decrease in all subjects.^{144,147} BP responses during stress appear to be blunted after exercise in high stress reactors. This makes sense, because it is hard to reduce a response that is

already minimal. Also, ambulatory BP levels have been shown to be reduced at work for up to 5 or more hours after exercise in borderline-hypertensive persons, whereas normotensive subjects typically show no reduction in BP, although they do show potentially beneficial decreases in total vascular resistance.^{147,149} This appears to be related to homeostatic influences, such as baroreceptor activity, that elicit compensatory adjustments in circulatory control systems to prevent a fall in BP in normotensive individuals. Other research has indicated that reduced efferent SNS activity and lower circulating catecholamine levels contribute to the lower vascular resistance in the postexercise period.^{150,151}

These studies addressed the effects of only a single bout of exercise on responses during the postexercise period. Other investigations have examined the effects of increased aerobic fitness level due to weeks of physical training on stress responses. These studies have similarly suggested that stress responses are reduced after aerobic training in some but not all persons, with hypertensive individuals being most likely to benefit. More rapid recovery of cardiovascular responses after stress has been observed as a more general benefit of training.¹⁴⁸ For this reason, regular exercise is strongly recommended both as adjunctive treatment and as a preventive intervention for hypertension.^{109,151-153}

Stress-reduction interventions, including biofeedback, relaxation training, and cognitive behavioral therapies, have been extensively studied as potential ways to lower BP, with mixed success.¹⁵⁴⁻¹⁵⁷ McGrady and Higgins attempted to develop a profile of hypertensive patients most likely to lower their BP through biofeedback. They found that young women with higher anxiety and tension levels and higher initial heart rates are the most successful in using this method.¹⁵⁵ Other studies have indicated that relaxation therapy is more effective with individuals whose daytime ambulatory BP is elevated versus those with lower daytime pressures.¹⁵⁴ Although some studies employing a “habituation control phase” have observed no changes with stress-reduction treatment,¹⁵⁷ falls in BP during both habituation and treatment have been seen in other well-designed investigations.¹⁵⁶

There has been substantial rekindling of interest in stress-reduction interventions after the reports by Ornish et al.¹⁵⁸ and by Blumenthal et al.¹⁵⁹ that stress management can be part of a lifestyle intervention program that can reduce risk and even partially reverse vascular pathology in CHD patients. The former study employed stress management only in combination with other established methods, such as low-fat diet, exercise, and weight reduction, whereas the latter used stress management as a solitary intervention and compared its benefits with an exercise training group as well as to a usual care group. Patients given a combination of relaxation, biofeedback, and cognitive therapies to help them recognize and manage stress, anger, and depression demonstrated greater reduction in risk of subsequent cardiac events or interventions compared with patients given exercise training or usual care.¹⁵⁹ Although more studies are clearly needed, the overall pattern suggests that stress-management techniques are effective in reducing cardiovascular risks in some individuals. Benefits are more likely with interventions using cognitive therapy as well as simpler relaxation or biofeedback approaches and in patient groups with more cardiovascular and psychological risk factors. It is expected that more research on this topic will be forthcoming.

SUMMARY

The preponderance of animal and human research shows that environmental and psychosocial stress have a clear impact on BP levels over the short term, and these may have a role in the onset and progression of hypertension in individuals with genetic or environmentally enhanced susceptibility (such as a high-salt, low-potassium diet). Increased SNS activity is a mediator of the effect of stress on BP, although other factors are also involved. Certain personality and behavioral patterns are associated with high stress responses and greater risk of hypertension and cardiovascular disease, and certain environmentally stressful conditions (ranging from the broadest, such as low SES, to the more specific, such as high job strain) are potential risk factors for hypertension. Buffers available to reduce the adverse effects of stress on BP include social support, exercise, and stress-management therapies. Since modern life in Western societies appears to make stress exposure unavoidable, more research on strategies to reduce the effects of stress exposure is needed.

Renin

Timothy L. Reudelhuber

More than 100 years ago Tiegerstadt and Bergmann first noticed that extracts of rabbit kidney had the ability to raise blood pressure (BP). It eventually became clear that the active ingredient in this extract was a protease that would later be named *renin* (derived from *renal*), which plays a key role in the generation of the angiotensin vasoactive peptides (for a historical review see Hall¹). Over the last century, the work of a host of laboratories across the world has led to our current understanding of the renin-angiotensin system (RAS; Figure 8–1). In humans, renin is coded for by a single gene located on chromosome 1. Although rats also have a single renin gene, most strains of laboratory and wild mice have two renin genes, both of which contribute to circulating renin.²

Renin is an aspartyl protease that is first synthesized as an enzymatically inactive precursor, prorenin. Although it is possible to activate prorenin by prolonged exposure to cold or acidic conditions in the laboratory, the primary mechanism for prorenin activation *in vivo* is the proteolytic removal of a 43 amino acid prosegment from its amino terminus. This proteolytic activation is not autocatalytic, and although several proteases have been shown to convert prorenin to renin *in vitro*, the most likely physiologically relevant proteases to date are cathepsin B, and the prohormone convertases 1 and 5 (PC1, PC5).^{3–5}

The vast majority of the renin in the circulation originates in the juxtaglomerular (JG) cells surrounding the renal afferent arterioles (Figure 8–2, A). Removal of the prosegment occurs within the secretory pathway, after prorenin is targeted to immature secretory granules.⁶ Once activated, renin is stored in these secretory granules until the cells receive a signal for its release. It has been estimated that JG cells divert roughly 20% of the prorenin they produce to secretory granules for activation,⁷ while the remainder of the prorenin is secreted unmodified and constitutively. In humans, there is from 5 to 10 times more prorenin than renin in the plasma,^{8,9} and there is no evidence to date that circulating prorenin contributes to the activity of the circulating RAS.

There have been some interesting variations proposed for the cell biology of renin, including the suggestion that active renin can be formed within the cytoplasm of cells (reviewed in Re¹⁰), and the finding of renin receptors,^{11,12} at least one of which appears to generate an intracellular signal when bound to renin.¹³ The importance of these phenomena to the biology of the RAS remains unclear, however.

RENIN BIOLOGY AND ITS IMPORTANCE IN MEDICINE

Tissue Origin and Activating Enzymes

The mechanism of activation of prorenin has received a lot of attention in recent years because organs other than the kidney, including the brain, pituitary, and adrenal glands; testes;

uterus; and placenta, have been shown to express the renin gene (reviewed in Lavoie and Sigmund¹⁴). In fact, after nephrectomy renin virtually disappears from the circulation while prorenin persists,¹⁵ demonstrating that nonrenal organs not only make prorenin but can also secrete it into the circulation. Other organs, such as the heart, are capable of taking up renin and prorenin from the circulation.^{16,17} Because many of these tissues also make other components of the RAS, including angiotensinogen, angiotensin-converting enzyme (ACE), and angiotensin receptors, it has been suggested that *tissue RAS* could exist and be biologically important. The key question that remains is whether these tissues can activate prorenin to catalyze the first reaction in the RAS. Evidence supporting this possibility comes from three findings: First, enzymes are present in nonrenal tissues that can activate prorenin in the secretory pathway and lead to renin storage in secretory granules.⁵ Second, prorenin with its prosegment still attached appears to display some enzymatic activity within tissues in transgenic mouse models.¹⁸ Third, prorenin taken up from the circulation can be cleaved to active renin after uptake in certain cells.¹⁹ Thus, while active renin in the circulation has been the primary focus for most physiologic studies and pharmacologic interventions, there is substantial experimental evidence suggesting that a tissue RAS could contribute to the local production and action of angiotensins.

Control of Circulating Renin Levels

The primary mechanism by which the RAS contributes to acute changes in fluid and pressure homeostasis is by regulating renin levels in the circulation. This is accomplished in large part by modulating the release of renin-containing secretory granules from JG cells. The afferent arterioles contain baroreceptors and release renin in response to a perceived drop in BP or interstitial pressure. In addition, nerve terminals that make connections to the JG cells cause a release of renin in response to sympathetic nervous system activation. The JG cells also express angiotensin II type 1 (AT₁) receptors and decreases in circulating angiotensin II (Ang II) or inhibition of signaling through the AT₁ receptor (e.g., by pharmacologic blockade) stimulate renin release. In fact, chronic inhibition of the RAS actually causes the recruitment (or reactivation) of new JG cells (see Figure 8–2, B), leading to a further increase in renin secretion. Finally, the macula densa relays a signal to the JG cells to increase renin release when a drop in sodium is detected in the distal tubule. Renin secretion can also be inhibited by the converse of these same signals. For example, increases in BP, β -adrenergic blockade, increases in circulating Ang II, and a high urinary sodium concentration will all result in a decrease in renin secretion in an attempt to balance their effects on BP. These considerations are clinically important when tailoring therapy for hypertension, as the most common interventions (diuretics, β -blockers, ACE inhibitors, angiotensin receptor blockers [ARBs], low-sodium

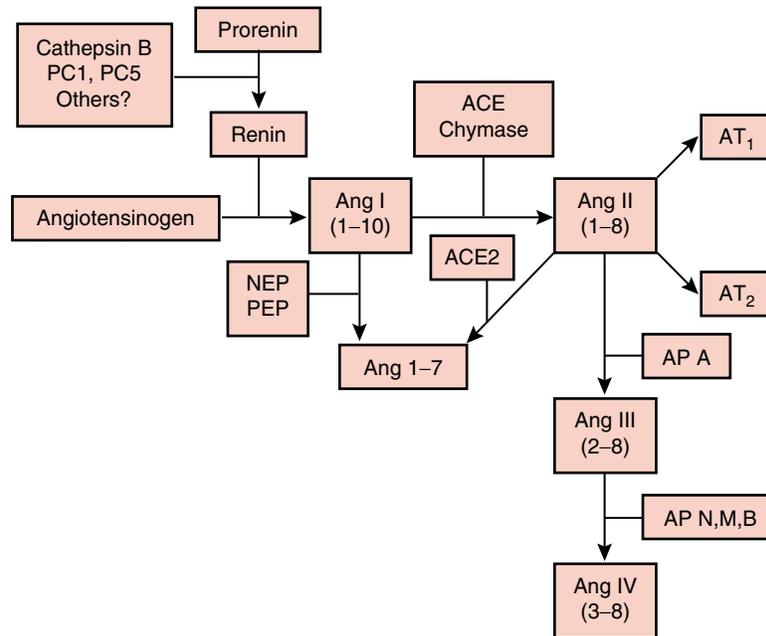

Figure 8-1 Schematic representation of the renin-angiotensin system (RAS). The heavy arrows indicate the enzymes that catalyze the corresponding step. ACE, angiotensin-converting enzyme; Ang, angiotensin (Roman numerals refer to the nomenclature for the peptide; numbers in parentheses refer to the amino acid positions in the peptide relative to Ang I (10 amino acids)); NEP, neutral endopeptidase; AT₁, angiotensin II type 1; AT₂, angiotensin II type 2; PC1, prohormone convertase 1; PC 5, prohormone convertase 5; PEP, prolyl endopeptidase; AP, aminopeptidase.

diet) will cause a resetting in the activity of the circulating RAS that often requires a further adjustment in medication dosage.

Renin as a Limiting Factor in the Renin-Angiotensin System

Laboratory measurements for renin are most commonly expressed as the capacity of plasma to generate angiotensin I (Ang I) when incubated either directly (plasma renin activity or PRA) or in the presence of excess angiotensinogen (plasma renin concentration or PRC). Thus, PRA reflects not only the amount of renin in the circulation, but also the amount of substrate angiotensinogen and is therefore the best measure of RAS activity *in vivo*. In most cases, PRC will parallel PRA, with the exception of patients with heart or liver failure, or other conditions that lead to increases in angiotensinogen.²⁰ The fact that PRA can be affected by changes in the levels of either angiotensinogen or renin is explained by the biochemistry of the RAS: In humans, the concentration of plasma angiotensinogen is close to the affinity constant (K_m) of renin for angiotensinogen.²¹ In practical terms, this means that the amount of angiotensin peptide generated in the plasma is a direct reflection of the concentrations of angiotensinogen and renin, because ACE is in over-abundance in the vascular wall. In general, this provides for rapid increases in activity of the RAS through the acute release of renin-containing granules from JG cells and more long-term regulation of the RAS by modulation of expression of the genes coding for both angiotensinogen and renin. Interestingly, in laboratory mice renin appears to be in excess and angiotensinogen is limiting for the activity of the RAS.²

RENIN AS A RISK FACTOR AND DIAGNOSTIC TOOL

Plasma Renin as a Predictor of Cardiovascular Complications

In a study involving 1717 hypertensive patients, Alderman et al. found that those with a high PRA (adjusted for urinary sodium content) were at significantly higher risk of suffering a myocardial infarction independent of other risk factors, including BP, race, sex, age, serum cholesterol, smoking, ECG evidence of left ventricular hypertrophy (LVH), history of cardiovascular disease, body mass index (BMI), and use of β -blockers.²² This very striking result was the first indication that circulating renin might act via a mechanism other than by regulating BP and it provided a boost to those who championed the importance of tissue RAS. This association was later refuted in a study by Meade et al.,²³ who found that myocardial infarction correlated best with BP. Attempts to sort out the differences between these studies²⁴ have not been very fruitful, and the unfortunate conclusion has been that renin-sodium profiling may not be a good indicator of future cardiovascular complications.

Renin Gene Mutations for Genetic Diagnosis and Prognosis

Because physiologic modulation of the activity of the RAS plays such a crucial role in fluid and pressure homeostasis, it is a natural extension to postulate that mutations in the genes coding for components of the RAS might result in activation of the system and therefore explain some forms of hypertension.

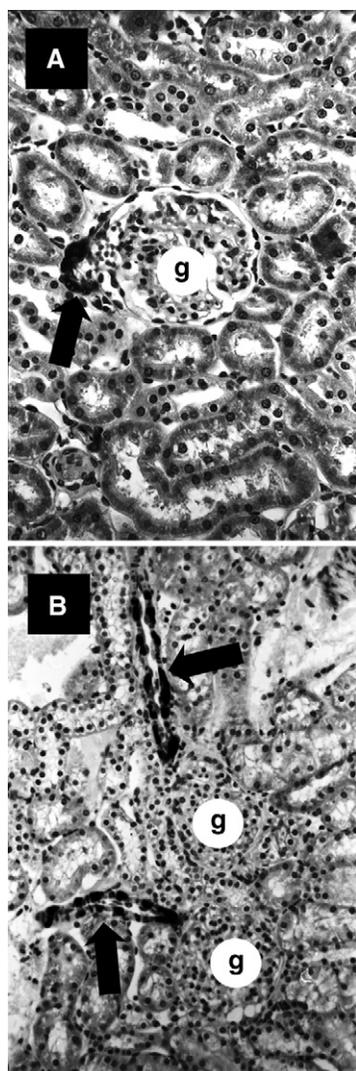

Figure 8-2 Immunodetection of renin-producing cell in the juxtaglomerular (JG) apparatus (*dark arrows*) of rats either untreated (**A**) or after 2 weeks of treatment with the ACE inhibitor captopril (**B**). g, glomeruli.

Early evidence suggesting a link between genetic variations in the angiotensinogen gene and hypertension²⁵ fueled an intense search for variations in the genes of the remaining components of the RAS, including renin. However, there have been many conflicting results over the years, with some suggesting a link between the renin gene and hypertension (see for example, Zhu et al.²⁶), while others found no link (see for example, Jeunemaitre et al.²⁷). This is a surprising result, because several rare forms of hypertension are associated with mutations in genes that code for downstream effectors of the RAS, including salt transport in the kidney.²⁸ The variable results in most association studies might be due to the small size of the patient populations or difficulty in defining the appropriate target group. Another possibility, suggested in a whole-genome scan study for hypertension-related genes, may be the fact that “BP regulation is most likely governed by multiple genetic loci, each with a relatively weak effect on BP in the population at large.”²⁹

Alternatively, the genes of the RAS may be “protected” from mutation because of their importance for some aspect of human survival. This possibility is supported by the finding that pharmacologic inhibition of the RAS during pregnancy in humans is fetotoxic, resulting in spontaneous abortion with severe defects of the fetus, including hypoplas-

tic organs and multiple defects of the kidney and urinary tract.³⁰ Hydronephrosis, defects in development of the urinary tract, and high neonatal mortality are also seen in laboratory mice in which the gene coding for renin,³¹ as well as those coding for any of the other components of the RAS, including angiotensinogen, ACE, or the AT₁ receptor are inactivated (see Gurley et al.³² for a review). These results probably explain why there has never been a report of a human mutation that completely inactivates the RAS because such a mutation would probably be lethal. Therefore, even though mutations in the renin gene have not been shown to cause hypertension to date, data on the consequences of blocking the RAS during development raise the possibility that such mutations may eventually explain some of the congenital abnormalities of the kidney and urinary tract (CAKUT).³³

Measurement of Renin to Tailor Therapy

The many physiologic, pharmacologic (discussed previously), and pathophysiologic (discussed in the following paragraphs) factors that can cause changes in circulating renin levels make the measurement of renin a capricious indicator of therapeutic potential. Studies have confirmed that PRA varies widely in

hypertensives.^{34,35} In a study involving more than 4000 hypertensive patients,³⁵ Alderman et al. divided their patient population into those with low renin (PRA <0.65 ng/ml/hr; 30% of the patients); medium renin, (PRA 0.66 to 4.5 ng/ml/hr; 60% of patients); or high renin, (PRA >4.5 ng/ml/hr; 10% of patients). They found that PRA varied according to sex, ethnicity, and age, but demographics alone could not predict the renin levels for any given patient group because of high interindividual variability. In spite of this complication, Laragh has proposed that hypertensive patients can be rationally subdivided into three groups to tailor therapy³⁶: (1) “R” patients who have too much renin and who will respond best to interventions (β -blockers, ACE inhibitors, ARBs) that will block the RAS. (2) Hypertensive patients who have low renin levels and who will not respond well to this regimen. (3) “V” patients who have a predominantly volume and salt-dependent hypertension that will respond best to diuretics. Renin status as a guide for tailoring therapy remains hypothetical and the choice of drug class for the treatment of hypertension by most primary care physicians continues to be largely empirical.

CONDITIONS OF RENIN EXCESS

With the key role that renin plays in the activity of the RAS in humans, it is not surprising that disorders of renin secretion would have deleterious effects on cardiovascular health. In fact, there are two clinical syndromes that are associated with renin-dependent hypertension. Diagnosis of these uncommon types of hypertension is made more difficult by the overwhelming prevalence of essential hypertension.

Renovascular Hypertension

Obstruction of the renal artery leads to a drop in perfusion pressure in the JG apparatus, which reacts by increasing renin secretion. The relationship between renal artery stenosis and hypertension was elegantly demonstrated by the work of Goldblatt et al.,³⁷ who placed unilateral clips on the renal artery in rats and showed that the resulting increase in BP was initially due to a massive increase in renin production by the “clipped” kidney. Interestingly, as hypertension progresses in this model, it becomes less renin-dependent and may actually be fueled by a vicious cycle of secondary organ damage.³⁸

The identification of patients with renovascular hypertension is important because they are more likely to progress to severe hypertension and to suffer from ischemic kidney injury. On the other hand, early diagnosis and treatment holds hope for reversal of the stenosis and resulting pathologies.

There are two major causes of renal artery stenosis, which are not seen with equal frequency in men and women. The most common cause of renovascular hypertension is atherosclerotic renal artery stenosis (ARAS; for a review see Safian³⁹ and Chapter 74). ARAS occurs more frequently in men than women, although gender differences tend to disappear in elderly individuals. Disease progression in these patients generally mirrors the development of atherosclerosis throughout the rest of the body and the vast majority of patients with ARAS have other clinical manifestations of atherosclerosis.

Fibromuscular dysplasia, in contrast, is restricted to the renal arteries. Although far less common overall than ARAS, fibromuscular dysplasia is the most common cause of renovascular hypertension in women younger than 50 years of age.^{39,40}

The common clinical hallmarks of hypertension due to renal artery stenosis include the appearance of hypertension in young (<30 years) or old (>60 years) patients, the rapid progression of previously mild or controlled hypertension and/or the presence of an abdominal bruit. Associated clinical findings include unexplained acute or chronic azotemia. Although elevated renin is at the root of the problem, measurement of circulating renin either at rest, after ACE inhibitor “stimulation,” or in the renal veins has not proven to be of great use because of the confounding effects of hypertension and antihypertensive medications on renin levels.^{39,40}

Treatment of renovascular hypertension, particularly in the early phases, includes inhibition of the RAS including β -blockers, ACE inhibitors, and/or ARBs. In ARAS, aggressive risk reduction and use of lipid-lowering drugs are also recommended. In case of primary treatment failure, revascularization with angioplasty and/or stent placement is sometimes necessary. The diagnosis and treatment of renovascular hypertension are covered in more detail in Chapter 74.

Renin-secreting Tumors

Renin-producing tumors represent the purest, albeit very rare, form of primary reninism resulting from unregulated secretion of renin, because the tumors have escaped the hemodynamic and hormonal control of the afferent arteriole. Two very thorough and informative reviews on renin-producing tumors have been published^{41,42} and, because of the rarity of these cases, will likely remain excellent sources of information and reference for the interested reader for the foreseeable future. Renin-secreting tumors can be roughly divided into renal and nonrenal tumors, including lung cancers, hepatoblastomas, paragangliomas, pancreatic carcinomas, adenocarcinoma of the colon, adrenal carcinomas, and various types of ovarian and fallopian tube tumors. Production of renin by these tumor types is rare and unexpected and likely to be due to the particular chromosomal mutations or rearrangements undergone by the cancer cells. Treatment of hypertension in these cases has focused on the use of RAS inhibitors and tumor ablation, although hypertension is likely to reappear with new tumor growth or metastasis.

In the kidney, hypersecretion of renin is infrequently associated with renal carcinomas and quite frequently (>50% of cases) with Wilms’ tumors. Although renal masses can cause compression-induced hypertrophy of the JG apparatus, leading to increased renin secretion, it is now clear that Wilms’ tumor cells themselves secrete renin. Another exceedingly rare type of tumor associated with renin-dependent hypertension is the JG cell tumor, sometimes referred to as reninoma. These tumors are benign neoplasms that are most often clinically detected as causes of hypertension associated with severe hypokalemia in very young patients. The first report of such a tumor appeared in 1967, and to date the English literature contains less than 100 reports of such tumors.

Patients with renin-producing tumors are invariably hyperreninemic, resulting in hyperaldosteronemia and hypokalemia. Increased plasma renin activity (PRA) is not

always apparent in these patients, however, and diagnosis by PRA is complicated in patients being treated for hypertension with medications that lead to increased renin secretion, such as ARBs and ACE inhibitors. Increased circulating renin is also seen in other conditions, including renovascular hypertension and renal failure, making the interpretation of increased PRA more equivocal. The best evidence in the diagnosis of a JG cell reninoma is the appearance of significant hypertension associated with hypokalemia in relatively young patients without other apparent risk factors.⁴¹ In analyzing previously reported cases, Martin et al.⁴² noted that the mean age at diagnosis was 26.8 years with less than one fourth of patients being diagnosed after 40 years of age. Many of these patients display hypertension that becomes increasingly difficult to control with standard therapy over time. If left untreated, patients may present with complaints commonly associated with severe hypertension, including headache, vomiting, polyuria, nocturia, and dizziness.

Three clinical tests have been used with limited success to provide support for the diagnosis of a reninoma. First, treatment with an ACE inhibitor or ARB, which normally results in a rise in renin secretion in patients with essential hypertension, will sometimes fail to elicit increased renin secretion in a patient with a reninoma, since the tumor cells may have escaped the normal feedback regulation of renin secretion. The hormonal response of these tumors is not uniform or entirely predictable, however.⁴¹ It may also be impractical to administer such tests, as most suspect cases will already be dependent on RAS-targeted antihypertensive therapy to control their BP. Second, renal vein PRA measurements have been used to test for lateralization of renin secretion from the tumor-bearing kidney, because the healthy kidney suppresses renin secretion in response to the hypertension. Renin secretion from the tumor-bearing kidney is not always increased, however,^{43,44} perhaps due to alternate vascularization of the tumor or to direct generation Ang II within some of the tumors. Patients with unilateral artery stenosis may lateralize renin secretion to the ischemic kidney, limiting the specificity of this diagnostic test. Finally, renal arteriograms may be used to detect larger tumors and in some cases to rule out stenosis as a cause of the hyperreninism. However, most reninomas are less than 4 cm in diameter^{41,42} and may not appear on an arteriogram. A careful analysis of imaging studies of the kidneys will be the best adjunct when a reninoma is suspected, as it should have the necessary resolution to detect even small tumors, which can be clinically significant even at sizes under 1 cm in diameter. Importantly, there is no obvious correlation between the severity of hypertension and the size of the responsible reninoma.⁴²

Treatment of hypertension associated with renin-secreting tumor of any sort consists of RAS-targeted antihypertensive therapy and may become more difficult with time as the tumor grows or metastasizes.⁴⁵ However, the ultimate correction of this problem is by ablation of the tumor. Patients harboring a JG cell reninoma have a particularly good prognosis. In greater than 90% of cases, reninoma-associated hypertension is smoothly and completely reversed by surgical resection of the tumor. In most of the remaining cases, only mild hypertension persists, perhaps due to secondary organ damage, and can be managed by standard therapy. As JG cell tumors are benign, there have been no reported cases of metastases or recurrence after surgery.

PHARMACOLOGIC BLOCKADE

Several aspects make renin an ideal target for pharmacologic blockade. First, renin is limiting in the activity of the RAS, so its inhibition should be achievable and effective in blocking the generation of angiotensins. Second, although Ang I can be metabolized by alternate pathways (see Figure 8–1), renin is the only enzyme that can generate Ang I *in vivo*, as demonstrated by the inactivation of renin in mice,³¹ making it the “gatekeeper” for activity of the RAS. Third, because renin has only one known substrate, angiotensinogen, a specific renin inhibitor would presumably only block the RAS and would thus have a low likelihood of side effects. Nevertheless, as of this writing there are no renin inhibitors approved for clinical use, presumably due to the high cost of synthesis, problems with bioavailability, and the obvious success of competitor classes of drugs. Would development of such an inhibitor be advantageous? Limited research has suggested that renin inhibitors might be more effective in lowering Ang II than ACE inhibition,⁴⁶ and there is the possibility that they could be used in combination with other RAS inhibitors to achieve more effective BP control. It therefore seems likely that the development of this new class of drugs will continue.

SUMMARY

Renin modulates fluid balance and BP through its key role in controlling the activity of the RAS. Although measurement of renin activity and assessment of mutations in the genes encoding renin and other components of the RAS have not proven to be useful in the management of hypertension to date, understanding the factors that regulate the production and release of renin may be important in tailoring effective therapy. The future development of specific renin inhibitors may allow a more effective targeting and inhibition of the RAS in the treatment of cardiovascular disorders.

Angiotensin-Converting Enzymes: Properties and Function

Chris Tikellis, Colin I. Johnston

The renin-angiotensin system (RAS) is an important pathway that regulates blood pressure (BP)¹ and sodium/water homeostasis.² Angiotensin-converting enzyme (ACE) is a key component of the RAS. It is responsible for converting the inactive decapeptide, angiotensin I (Ang I), to the biologic active octapeptide angiotensin II (Ang II), as well as inactivating the vasodilator bradykinin.³ Ang II is thought to be responsible for most of the physiologic and pathophysiologic effects of the RAS.

In mammals ACE occurs as two isoforms that are produced from a single gene with alternate splicing:

1. A somatic form (sACE), which is a type I integral membrane glycoprotein and which is widely distributed in many endothelial cells in variety of tissues, including the heart⁴ and kidney and in the epithelial cells of proximal tubules,⁵ small intestine⁶ and a variety of neuronal cells in the brain.⁷ This enzyme is anchored through the cell membrane and has a short intracellular extension with the major extracellular portion containing two duplicate domains, each containing a catalytic site.
2. A testicular form (germinal ACE or gACE) that is smaller as it only contains the C-terminal domain of somatic ACE and has only a single catalytic site. gACE is only expressed in differentiating male germinal cells,⁸ and studies of ACE gene deletion in animal models have demonstrated a strong association with reduced fertility in males.⁹
3. A soluble form, which is formed in many body fluids, including the plasma and which arises from proteolytic cleavage, by a membrane “secretase”¹⁰ at the membrane anchor of somatic ACE. Plasma ACE is catalytically active.

Gene deletion studies have shown that mice lacking endothelial ACE but having normal plasma ACE are unable to maintain normal BP, particularly when stressed by a low-salt diet, thus suggesting the functional primacy of the tissue RAS.^{11,12} Twenty years after the introduction of specific inhibitors of ACE, the ACE inhibitors or “prills” have been established as preferred treatment for cardiovascular and renal disease (see Chapter 35). However, the classical view of the RAS has been challenged due to the discovery of other enzymes and angiotensin peptides that have been shown to have biologic activity and physiologic importance.

ANGIOTENSIN-CONVERTING ENZYME 2

Structure

Angiotensin-converting enzyme-related carboxypeptidase (ACE2), has been shown to cleave Ang I at different sites from ACE and to convert Ang II to angiotensin-(1-9)

(Ang-[1-9]).^{13,14} Analysis of the genomic sequence for ACE2 has shown that this gene contains 18 exons and maps to chromosomal location Xp22.¹³ ACE2 is an 805 amino acid protein with a transmembrane domain (amino acids 740-763) and a single catalytic domain (amino acids 147-555) and has been classified as a metalloprotease due to its single HEXXH zinc-binding consensus (amino acids 374-378)¹⁴ and its inhibition by EDTA.¹³ Unlike ACE, ACE2 functions as a carboxypeptidase.¹⁵ ACE2 has 60% homology with the testicular ACE isoform and 42% homology with somatic ACE at the metalloprotease catalytic domain^{13,14} but differs from ACE in having only one enzymatic site.

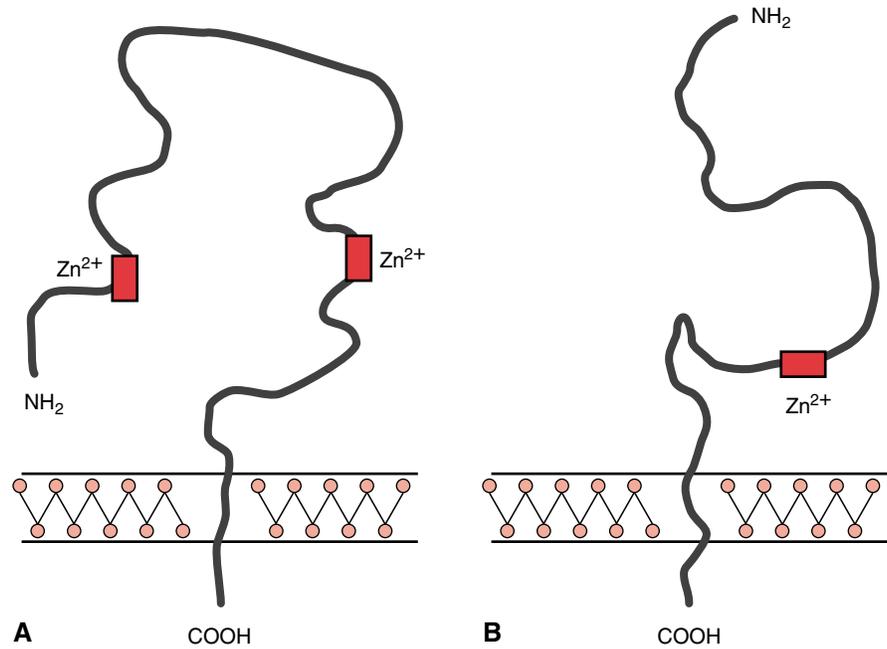

In humans ACE2 transcripts have been identified in the heart, kidney, testis,^{13,14} gastrointestinal tract, brain, and lung.¹⁶ Preliminary data have also localized ACE2 to the retina (Tikellis C, Johnston CI, unpublished data), suggesting more ubiquitous expression than initially thought (Figure 9-1).

Physiologic Function

The full physiologic functions of ACE2 are yet to be elucidated. To date it has been shown that recombinant ACE2 hydrolyses the carboxy terminal leucine from Ang I to generate Ang-(1-9)^{13,14} and also cleaves the C-terminal residue of the peptides des-Arg⁹-bradykinin, neurotensin 1-13, and kinetensin.¹⁴ Tipnis et al. showed that ACE2 was also able to cleave Ang II, resulting in its degradation to the vasodilator angiotensin-(1-7) (Ang-[1-7]).¹³ In vitro studies showed that the catalytic efficiency of ACE2 is greater with Ang II as a substrate than with Ang I,¹⁵ thus indicating that in the RAS the major role for ACE2 is probably the conversion of Ang II to Ang(1-7) (Figure 9-2). (See Chapter 10 for a more complete discussion of Ang-[1-7].)

Ang-(1-7) plays an important role in RAS as it counteracts most actions of Ang II (i.e., it has been shown to have vasodilator actions,¹⁷⁻²² diuretic and natriuretic effects,²³ antiangiogenic action,²⁴ antithrombotic action,²⁵ and antiproliferative effects on vascular smooth muscle²⁶). The biologic actions of Ang-(1-7) are not mediated via AT₁ or AT₂ receptors, and binding experiments have described specific Ang-(1-7) receptors.^{18,27} With the use of knockout mouse technology, the *mas* protooncogene, a seven hydrophobic transmembrane domain protein that was previously described as an orphan G protein coupled receptor, was identified as a potential Ang-(1-7) receptor.²⁸ Furthermore, studies in *mas*-deficient mice confirmed that the Ang (1-7) receptor was expressed in the kidney and that Ang-(1-7) had an antidiuretic effect and a vasodilator effect on aortic rings. Ang-(1-7) undergoes further processing by ACE, which cleave two more amino acids at the C-terminal, resulting in Ang-(1-5)¹⁴ and Ang-(3-5),²⁹ whose actions remain unknown.

Figure 9-1 Schematic representation of ACE (**A**) and ACE2 (**B**), red box denotes active site.

ACE2 is not inhibited by classical ACE inhibitors such as captopril and lisinopril.^{13,14} Potent (picomolar range) and selective inhibitors of ACE2 have been designed and synthesized,³⁰ which will greatly assist in elucidating the physiologic roles of ACE2 *in vivo*.

A preliminary insight into the physiologic roles of ACE2 was gained when Crackower et al. constructed ACE2 mutant mice.³¹ They showed that deletion of ACE2 in these mice resulted in increases in the angiotensin peptides Ang I and Ang II in heart and kidney, implicating ACE2 as an important regulator of a number of angiotensins, including Ang I, Ang II, Ang-(1-9), and Ang-(1-7). Interestingly, BP was not altered in the ACE2 null mice even after the addition of the ACE inhibitor captopril. Most importantly, they demonstrated that ACE2 is essential for normal cardiac development, as deletion of the ACE2 gene in this mouse model resulted in cardiac contractile dysfunction. Furthermore, the loss of ACE2 induced the hypoxia-regulated genes, Bcl2/adenovirus E1B 19kD-interacting protein 3 (BNIP3) and plasminogen activator

inhibitor-1 (PAI-1), in the heart. Crackower et al. postulated that loss of ACE2 from the vascular endothelial cells resulted in constriction of the coronary vessels and thus reduced oxygen delivery to the myocytes.³¹

Other studies have provided further evidence implicating ACE2 in cardiovascular function. Ang-(1-7) formation has been reported to be increased in failing human hearts. A study by Zisman et al. examined Ang-(1-7) formation in human hearts and confirmed with the use of specific inhibitors that Ang-(1-7) formation was attributable to ACE2.³² This is consistent with the hypothesis that ACE2 may have a cardioprotective role in damaged tissue, as in heart failure. In another study, ACE2 transgenic mice were generated that expressed a specific increase in cardiac ACE2.³³ These mice died from ventricular tachycardia and terminal ventricular fibrillation. They overexpressed ACE2 and had down-regulated gap junction proteins, connexin40 and connexin43, which are postulated to account for the electrophysiologic disturbances. The authors suggested that ACE2 may be important for certain aspects of ventricular remodeling. Additional evidence implicating ACE2 in cardiac function is provided by another study that showed increased Ang-(1-7) formation via increased cardiac expression of ACE2 in cardiac membranes from persons with various forms of heart failure.³² Thus, a number of studies provide evidence to implicate ACE2 as an important component of the RAS, particularly in the heart. It is postulated that this enzyme may counterbalance the actions of ACE by converting Ang II, a potent vasoconstrictor, to Ang-(1-7), a vasodilator (see Figure 9-2).

ACE2 has been characterized in the kidney in a rodent model of type 1 diabetes mellitus. Previous studies in this model demonstrated that ACE is down-regulated in the tubules but up-regulated in the glomerulus of the diabetic kidney.³⁴ This redistribution has also been observed for ACE2. Treatment with an ACE inhibitor normalized the distribution of ACE and ACE2 protein,³⁵ suggesting that ACE2 may have a renoprotective role in diabetes.

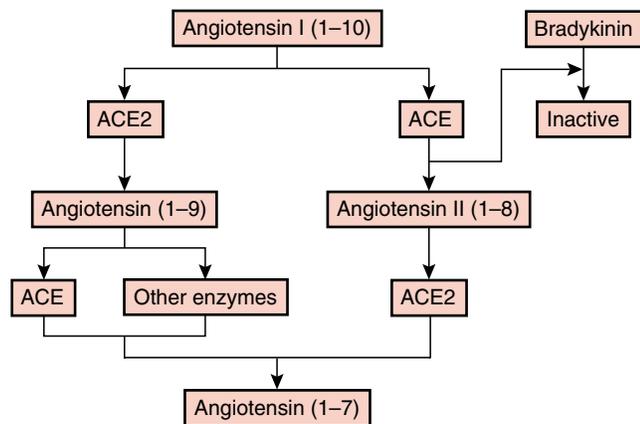

Figure 9-2 The RAS pathway with ACE2.

Thus early studies provide evidence that implicates ACE2 as an important component of the RAS, as it counterbalances the actions of ACE by competing for and inactivating Ang II, a potent vasoconstrictor, generating Ang-(1-7), a vasodilator. Furthermore, the beneficial effect of ACE inhibitors may be due in part to the fact that these inhibitors do not inhibit ACE2.

ACE POLYMORPHISMS

With the discovery of polymorphisms in the ACE gene there was great excitement about a possible association between ACE gene polymorphisms and some diseases. The most intensely studied of these polymorphisms was the biallelic ACE insertion/deletion (I/D) polymorphism, defined by the presence of an extra 287 base pair sequence inside intron 16 of the ACE gene (insertion or “I”) or the absence of these extra base pairs (deletion or “D”). Inheritance of the I/D polymorphism follows Mendelian principles, with 25% of the population homozygous for the DD genotype, 25% homozygous for the II genotype, and 50% heterozygous for the DI genotype. Even though the ACE I/D polymorphism is in an intronic region of the ACE gene it is still responsible for at least half of the phenotypic variance observed in serum ACE levels.³⁶ The D genotype is strongly associated with increased plasma or serum ACE levels. Persons homozygous for deletion (DD) display the highest ACE values; those homozygous for insertion (II), the lowest ACE values; and those heterozygous (I/D), intermediate values.³⁷ Although persons with the ACE DD genotype have high ACE levels, their Ang I and Ang II levels are not elevated.^{38,39}

Ethnic origin is also a determining factor in serum ACE activity. Caucasians with the ACE DD allele, have a greater vasodilator response to bradykinin than African Americans with ACE DD allele.⁴⁰ There are differences in serum ACE activity among ACE genotypes in Caucasians, but not in African Americans or African Caribbeans.⁴¹⁻⁴³

The possible association between the ACE I/D polymorphism and cardiovascular disease remains controversial. Initially, small studies showed an association between the ACE DD genotype and cardiovascular disease. Later, larger and better-conducted trials showed no association. Some of the positive associations that have been identified appear only in certain ethnic groups and in subsets of patients. For example, a correlation was demonstrated between the ACE DD genotype and left ventricular hypertrophy (LVH) in a group of untreated hypertensive subjects, who had an increased risk of LVH.⁴⁴ In a meta-analysis, a positive association was demonstrated between the ACE DD genotype and common carotid artery intima-media thickness (IMT).⁴⁵ Initial studies also showed a positive correlation between the ACE DD genotype and myocardial infarction (MI).⁴⁶ However, more recent larger studies failed to confirm this association and did not demonstrate an increased risk of cardiovascular disease with the DD genotype.⁴⁷

The relationship of the ACE DD genotype to other disorders such as diabetic nephropathy has also been closely examined. Meta-analyses of studies in type 1 and type 2 diabetic subjects demonstrated that the ACE DD genotype was significantly associated with diabetic nephropathy.^{48,49} Similar studies have been carried out in many populations and in

many ethnic groups, and a number of these have found no association between ACE genotype and nephropathy.^{50,51} The mixed results may in part be explained by ethnic differences in the frequency of the D allele, although even within individual ethnic groups, the results of studies are conflicting.

Circulating levels of Ang II are different from levels found in tissues, and can make a pronounced contribution to vasoconstriction in tissue. Increased ACE activity has been observed in hearts of ACE DD persons,⁵² and ACE mRNA levels were found to be increased in left ventricular tissue from heart failure patients with the ACE DD genotype.^{53,54} It appears that the increased levels of ACE mRNA may be cell/tissue specific, as no association of ACE mRNA with ACE I/D genotype was observed in human atria.^{55,56} Therefore, increased ACE mRNA expression may be tightly regulated and site specific, providing another possible reason for the conflicting nature of data from studies assessing ACE polymorphism in association with coronary heart disease (CHD) and LVH. Thus, the observation that tissue ACE mRNA levels are increased in association with the ACE DD allele warrants that future studies examining an association between the ACE DD allele and cardiovascular disease should measure tissue levels of ACE mRNA and activity as well as serum ACE activity.

The ACE I/D polymorphism may have a more important role as an indicator of patient responsiveness to standard ACE inhibitor therapy. In particular, the ACE I/D polymorphism may help identify patient groups who fail to respond to ACE inhibitor therapy. For example, patients with the DD genotype have been shown to be three times less likely to respond to ACE inhibitor therapy than patients with the II genotype.⁵⁷ For the moment there are insufficient data to make a firm conclusion about the role of the ACE I/D polymorphism as an accurate and reliable indicator of ACE inhibitor responsiveness in patients.

Genes encoding for other components of the RAS, such as the M235T polymorphism of the angiotensinogen gene and the A1166C polymorphism of the angiotensin II type I (AT₁) receptor gene, have also been implicated in cardiovascular and renal disease. Patients with the M235T polymorphism have been shown to have elevated ACE and angiotensinogen levels^{58,59} and tend to exhibit hypertension⁵⁹ although no relationship with hypertension was seen in some studies.⁶⁰ However, data are conflicting on whether there is an association with cardiovascular and renal disease.^{59,61-64} Among studies examining the association of the A1166C polymorphism of the AT₁ receptor with cardiovascular and renal disease, some have shown a positive correlation,^{65,66} whereas others have not.^{67,68}

SUMMARY

The conflicting nature of the evidence to date emphasizes that any simple genetic variant is unlikely to have more than a minor impact in genetically complex conditions such as hypertension and cardiovascular or renal disease. In addition, the ACE I/D polymorphism is located in an intron, and the true loci that regulate ACE activity are still undefined. Thus it is highly likely that many interactions between genes and the environment all contribute to initiation and/or progression of cardiovascular and renal disease.

Angiotensin-(1-7)

Debra I. Diz, Mark C. Chappell, E. Ann Tallant,
Carlos M. Ferrario

Angiotensin-(1-7) (Ang-[1-7]) is the first amino-terminal angiotensin peptide product identified as possessing biologic actions. From this observation, new concepts regarding the regulation of cardiovascular function by the renin-angiotensin system (RAS) have evolved. The actions of Ang-(1-7) are as diverse as those of Ang II, including activation of a variety of vasodilator systems to oppose the actions of Ang II. There is strong evidence for a role of endogenous Ang-(1-7) in the control of blood pressure during states with prolonged activation of the RAS as a result of actions on at least one novel receptor [AT₍₁₋₇₎] as well other potential sites. In this chapter, we update the information available for the role of this peptide in the regulation of renal function.

In setting the stage for interpretation of the findings presented on the pleiotropic nature of the RAS, it is important to recognize that a variety of peptide systems express numerous biologically active C- and N-terminal metabolites. Responses to peptide fragments exhibit complex relationships with respect to the major actions of the parent peptides, with both similar and dissimilar actions noted for substance P, opioid, and vasopressin systems.¹⁻⁴ Indeed, extensive studies of the opiate and tachykinin systems reveal a family of receptors linked to different responses in different tissues.⁵⁻¹⁰ For many of these peptide systems, the C-terminal metabolites retain the majority of the actions of the parent peptide, although they may have reduced affinity for binding at the receptor.¹¹⁻¹⁴ On the other hand, N-terminal metabolites for substance P (tachykinin), bradykinin, and vasopressin systems, which exist as peptides with a C-terminal proline,^{3,12,15-18} may act as physiologic or pharmacologic antagonists. There is down-regulation/desensitization of the NK1 receptor by substance P-(1-7),^{16,19} even though this peptide has low affinity for the NK1 receptor.¹⁹ There are reports that weak agonists cause down-regulation of the serotonin,²⁰ parathyroid,⁶ and endothelin²¹ systems by a mechanism independent of receptor internalization. With these concepts in mind, there are striking parallels among other peptide systems and the RAS. Our initiation of the study of the N-terminal metabolite of Ang II nearly 15 years ago led to the recognition that many of the same features that are well accepted for other peptide systems may also be true for the angiotensin peptides and will be highlighted in this chapter.

FORMATION AND METABOLISM OF ANG-(1-7) IN THE KIDNEY

Ang-(1-7) is present in the circulation and in various tissues including the kidney²²⁻²⁴ at levels comparable to those of Ang II. Levels of the peptide in plasma, renal tissue, and urine are altered during physiologic or pathophysiologic conditions including those associated with changes in sodium and

volume (hypertension, low- and high-salt diets). Emerging evidence also supports the concept of an intrarenal angiotensin system distinct from the circulating RAS,²⁵ with concentrations of Ang peptides in proximal tubular fluid,^{26,27} isolated glomeruli,²⁸ interstitium,²⁹ and renal tissue^{24,30-32} generally exceeding those of the circulation. Indeed, renin and angiotensinogen mRNA are present in JG cells, and proximal and distal tubules.³³⁻³⁷ Ang-(1-7) exists within the tubular regions throughout the kidney as shown in Figure 10-1.³⁸

The enzymes responsible for metabolism of the Ang peptides are distinct in pulmonary and renal tissues.²² Processing pathways in the circulation, where Ang II is the predominant peptide by ~twofold, appear to employ the endopeptidase neprilysin as the major activity forming Ang-(1-7) from Ang I.³⁹ Ang-(1-7) is the primary product formed in preparations of isolated proximal tubules and exists in urine at ~fivefold higher levels than Ang II.⁴⁰ In the kidney, Ang-(1-7) can be formed directly from either Ang I or Ang II. Figure 10-2 illustrates schematically the pathways for formation and metabolism of Ang-(1-7) in this tissue. Several endopeptidases present within renal vascular and tubular tissue have the capacity to form and metabolize Ang-(1-7).⁴¹ Neprilysin may contribute to the formation as well as the degradation of the peptide.^{22,42,43} Neprilysin cleaves Ang I to Ang-(1-7) and Ang-(1-7) to Ang-(1-4). Neprilysin inhibitors augment the urinary levels of Ang-(1-7) in human and rat.⁴⁴⁻⁴⁶ ACE also directly metabolizes Ang-(1-7) to Ang-(1-5). Significant urinary excretion of Ang-(1-7) occurs in both rats and humans,^{24,44-46} and chronic ACE inhibitor treatment that lowers blood pressure and stimulates diuresis is associated with enhanced excretion of Ang-(1-7) in both normotensive and hypertensive rats.^{45,46} The *in vivo* clearance of Ang-(1-7) is reduced sixfold with the ACE inhibitor lisinopril, which, depending upon the species (rat, dog, or human), may involve either the N-terminal or C-terminal catalytic domains of ACE.^{47,48} Recent studies reveal that a homolog of ACE termed ACE2^{49,50} (distinct from the ACE.2 knockout model developed by Bernstein and colleagues^{51,52}) exhibits carboxypeptidase activity cleaving a single amino acid residue at the carboxy terminus. ACE2 is not inhibited by ACE inhibitors. ACE2 was originally reported to cleave Ang I to Ang-(1-9),^{49,50} but recent kinetic studies suggest that the conversion of Ang II to Ang-(1-7) is preferred.⁵³ ACE2 expresses the highest efficiency (kcat/Km) among Ang-(1-7)-forming enzymes with a 500-fold greater kcat/Km for Ang II as compared with Ang I. Ang II, apelin-(1-13), and dynorphin A share a kcat/Km ranging from 1800 to 2900 mM⁻¹sec⁻¹, kinetics with at least an order of magnitude greater than for Ang I or [des-Arg⁹]-bradykinin (BK 1-8). ACE2, like ACE, exists in both soluble and membrane-associated forms with the highest densities in the kidney, heart, gut, and testes.⁴⁹

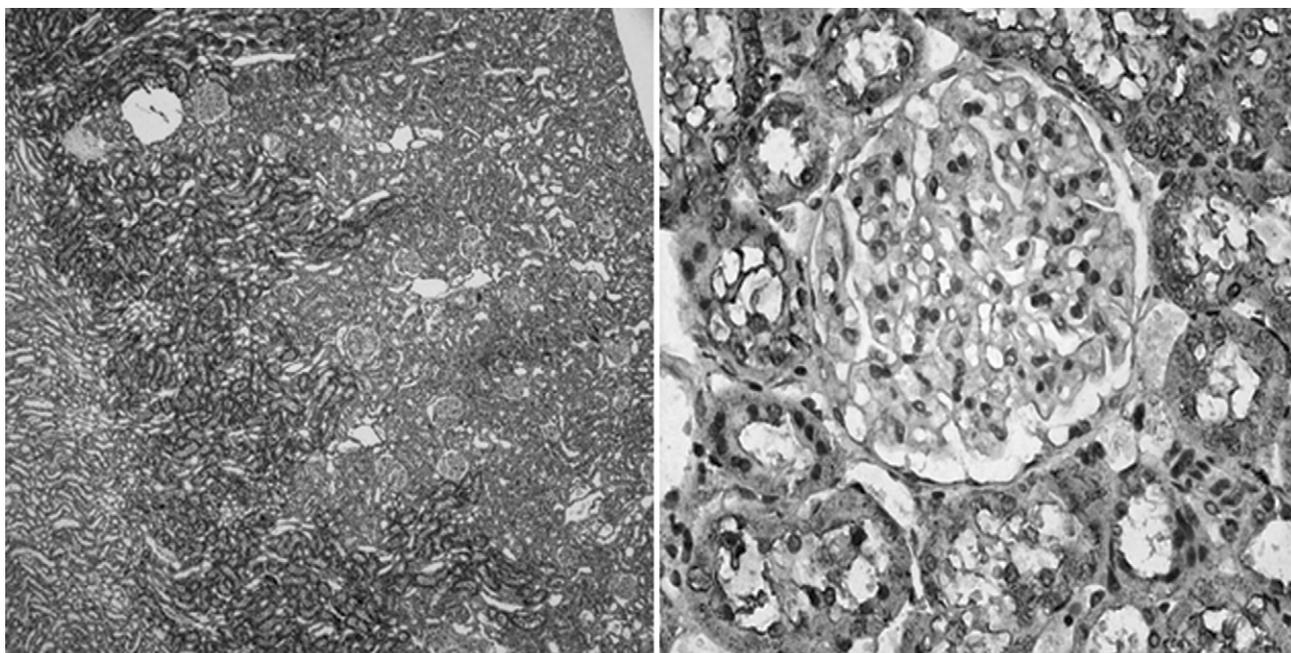

Figure 10-1 Localization of Ang-(1-7) immunoreactivity in the kidney. Photomicrographs of SHR kidney sections showing immunostaining for Ang-(1-7) at 10 \times in the left panel and 100 \times in the right panel. Staining is densest in the tubules.

Differential and independent regulation of the formation of Ang-(1-7) and Ang II is reported in the kidney during ischemia and in hypertensive animals during changes in dietary sodium intake. In rats undergoing acute unilateral ischemia and subsequent reperfusion, increases in Ang II are not accompanied by

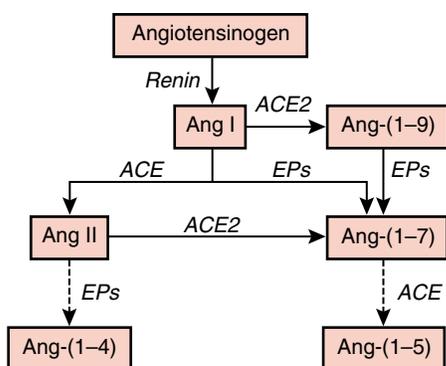

Figure 10-2 Processing pathways for formation and metabolism of Ang-(1-7) in the kidney. Once formed from angiotensinogen by renin, angiotensin (Ang) I can be processed to Ang II or Ang-(1-7) by the pathways shown. The major endopeptidases (EPs) involved in formation of Ang-(1-7) from Ang I or Ang-(1-9) in the kidney include neprilysin, prolyl endopeptidase, and thimet oligopeptidase.⁴¹ The critical positions of converting enzyme (ACE) and its recently identified homolog ACE2 with respect to reciprocal formation and metabolism of Ang II and Ang-(1-7) underscore the importance of studies aimed at determining the contribution of each enzyme during normal physiology and pathophysiology.

increases in Ang-(1-7).²⁴ In hypertensive animals maintained on low- and normal-salt diets differential changes in levels of the two peptides also occur.^{30,46,54} In fact, Ang-(1-7) appears to contribute to maintenance of normal pressure during periods of salt restriction and the accompanying increase in Ang II levels in the circulation.³⁰ In salt-sensitive hypertension in the female mRen.2.Lewis congenics, there is increased ACE and a reduction in ACE2 in the kidney,⁵⁵ providing initial evidence that salt-sensitive hypertension may result from a deficit in formation of Ang-(1-7), as well as an increase in Ang II. In fact, during omapatrilat treatment of salt-sensitive hypertensive patients, this combined NEP and ACE inhibitor increases levels of Ang I and Ang-(1-7) dramatically.⁴⁵ In spontaneous hypertensive rats omapatrilat treatment is associated with sustained increases in Ang-(1-7) and a pronounced water diuresis, without increases in Ang II.⁵⁶ Furthermore, increased expression of ACE2 is seen in the proximal tubules of treated kidneys, which may contribute to the expression of Ang-(1-7) in this cortical area.⁵⁷ Studies in the ACE2 knockout mouse illustrate the importance of this enzyme in regulation of RAS, because higher circulating and tissue levels of Ang II occur.⁵⁸ Spontaneously hypertensive rats (SHR) and the Sabra salt-sensitive rats exhibit reduced mRNA levels and protein expression of ACE2.⁵⁸ Moreover, ACE2 maps to a QTL region on chromosome 10 known to be highly associated with the hypertensive phenotype.⁵⁸ Indeed, the results of these studies suggest that dysregulation of these two enzymatic systems (ACE and ACE2) may lead to altered levels of Ang II and Ang-(1-7). At the present time, little is known about the regulation of ACE2 and its role in hypertension and other cardiovascular pathologies. We would propose that the balance of ACE and ACE2 may serve to regulate the expression of Ang II and Ang-(1-7) in the kidney.

INTRARENAL ACTIONS OF ANG-(1-7)

As illustrated previously, the presence and independent regulation of Ang II and Ang-(1-7) in kidney supports the concept of important and divergent actions for the two peptides within this organ. For Ang II, the actions include potent, but differential, constriction of diverse segments of the renal microvasculature as well as retention of sodium and water through stimulation of various transporters in the proximal epithelium. For Ang-(1-7), most actions are in opposition to those of Ang II. Ang-(1-7) infusions into the renal artery lead to diuresis and natriuresis accompanied by modest increases in glomerular filtration rate (GFR).⁵⁹⁻⁶⁴ Ang-(1-7) induces dilation of precontracted afferent arterioles.⁶⁵ Ang-(1-7) and Ang-(3-7) are potent inhibitors of Na⁺,K⁺-ATPase activity in isolated convoluted proximal tubules and the renal cortex.^{60,66,67} Actions at the Na⁺/H⁺ exchanger may also occur.⁶⁸ Ang-(1-7) stimulates transcellular flux of sodium in renal tubular epithelial cells, which is associated with activation of phospholipase A₂.⁶⁹ Furthermore, inhibition of sodium transport by Ang I is markedly potentiated by captopril suggesting either a shift in processing pathways to Ang-(1-7) or reduced metabolism of the peptide in the proximal tubules of the kidney. The vasopeptidase inhibitor omapatrilat produces a chronic and pronounced diuresis associated with large increases in urinary excretion of Ang-(1-7) and enhanced immunocytochemical staining of the peptide as well as ACE2 in the kidney of the SHR.^{55,56} That the diuresis consists of dilute urine is consistent with the localization of the Ang-(1-7) in all segments of the renal tubules.⁵⁶ The recent observations that the peptide may regulate aquaporin 1 in the proximal tubule⁷⁰ also reveal the potential of Ang-(1-7) as a key regulator in the control of water handling within the kidney.

Renal actions of Ang-(1-7) and Ang II are also comparable in several situations. In perfused straight proximal tubules, peritubular application of Ang-(1-7) displays biphasic effects on bicarbonate transport—a low concentration (10⁻¹² M) stimulates transport, whereas higher levels (10⁻⁸ M) inhibit absorption—similar to what is seen with Ang II.⁶⁸ Intratubular application of Ang-(1-7) stimulates transport in the loop of Henle, but does not affect reabsorption in either the proximal or distal tubule.⁷¹ The lack of an effect may result from the high luminal concentrations of Ang-(1-7) in the proximal or distal segments of the tubule. This would be similar to what occurs with Ang II where application of an AT₁ antagonist or ACE inhibitor attenuates basal reabsorption in the proximal tubule, but there is no additional effect of adding Ang II.⁷² In fact, the natriuretic effects of high doses of Ang II may be due to the conversion of Ang II to Ang-(1-7) at the epithelial surface of the proximal tubule to functionally oppose the AT₁-dependent actions of Ang II. In water-loaded Wistar rats administration of Ang-(1-7) promotes an antidiuretic action.^{73,74} Ang-(1-7) stimulates water transport in collecting duct tubules suggesting a site of action for Ang-(1-7), but the cellular mechanisms have not been defined.⁷⁵ Finally, Ang-(1-7) stimulates ouabain-insensitive Na⁺-ATPase activity in the ovine renal cortex, but inhibits Ang II-dependent stimulation of this ATPase.^{76,77} Burgelova et al.⁷⁸ showed that intrarenal administration of Ang-(1-7) produced natriuresis and blocked the antinatriuretic actions of Ang II. Ang-(1-7) did not attenuate the reduction in GFR or the increase in renal perfusion pressure associated with Ang II; however, it is simi-

lar to what was reported by Handa et al.⁶⁰ Finally, the renal actions of Ang-(1-7) also include an increase in oxidative stress markers such as thiobarbituric acid reactive species (TBARS), an indicator of lipid peroxidation, accompanied by a decrease in reduced glutathione as well as superoxide dismutase and glutathione peroxidase activities.⁷⁹ Together these studies emphasize the complexity of the actions and interactions of Ang-(1-7) and Ang II. Thus, the overall state of activity of the RAS and site(s) of the nephron exposed to the peptides clearly influence the ultimate physiologic action observed.

The cellular mechanisms responsible for actions of Ang-(1-7) in the kidney most likely involve mobilization of arachidonic acid and its subsequent processing through pathways yielding vasodilator and natriuretic products. The *in vivo* depressor response to Ang-(1-7) in the pithed rat was first shown to be dependent upon cyclooxygenase pathways.⁸⁰ Infusion of Ang-(1-7) into isolated rat kidneys causes an increase in prostacyclin in both the urine and the perfusate.⁶¹ A renal source of circulating prostaglandins may in fact participate in the lowering of blood pressure produced by Ang-(1-7). Ang II infusions are associated with activation of prostanoid pathways within the kidney, and in the presence of thromboxane and AT₁ receptor antagonists, a blood pressure lowering effect is seen due to renal release of prostanoids.⁸¹

The natriuretic and diuretic actions of Ang-(1-7) in the perfused kidney are associated with increased levels of prostacyclin that are attenuated by the cyclooxygenase inhibitor indomethacin.⁶¹ Ang-(1-7) infusion into SHR caused diuresis and natriuresis during the early days of infusion, concomitant with increases in urinary prostaglandins measured.⁸² In hypertensive rats treated with lisinopril and losartan, indomethacin causes increases in blood pressure similar to those produced by an antibody to Ang-(1-7) or a neprilysin inhibitor and the treatments are not additive, suggesting that vasodilator prostaglandins mediate the effects of Ang-(1-7) in lisinopril/losartan-treated rats. Ang-(1-7) stimulates arachidonic acid release and inhibits transcellular sodium transport in renal tubular epithelial cells⁶⁹ and blocks the Ang II-stimulated Na⁺-ATPase activity in the proximal tubule.⁷⁷ Low picomolar doses of Ang-(1-7) stimulate phosphatidylcholine incorporation in the renal cortex, providing a potential mechanism for supply of the arachidonic acid substrate⁸³; however, there is no evidence for activation of phospholipase C by Ang-(1-7) in kidney.^{84,85} Ang-(1-7)-dependent inhibition of ouabain-sensitive rubidium (Rb⁸⁶) influx selectively activates the proximal epithelial cytochrome P450 (CYP450) system in isolated tubules to augment sodium excretion.^{40,86} This contrasts with the stimulation of the vascular CYP450 system by Ang II to produce potent vasoconstrictors.⁸⁷⁻⁸⁹ Cyclooxygenase products do not appear to play a role in this effect.⁸⁶

An important concept generated by work over the past 5 years is that increased Ang-(1-7) levels may contribute to the actions of ACE inhibitors. On the basis of knowledge that ACE is a major factor in the clearance and metabolism of Ang-(1-7), early studies revealed that, in animals and patients, ~fivefold increases in circulating levels of Ang-(1-7) occur during chronic ACE inhibition. In agreement with these studies, patients chronically treated with the ACE inhibitor captopril have increases in plasma concentrations of prostacyclin with no significant effect on plasma concentrations of Ang II.⁹⁰ Blockade by the Ang-(1-7) receptor antagonist

D-[Ala⁷]-Ang-(1-7) or sequestration of the peptide with a specific monoclonal antibody reverses the blood pressure lowering actions of an ACE inhibitor alone or when combined with the AT₁ antagonist losartan.^{54,91,92} Interestingly, the Ang-(1-7) receptor antagonist also reverses the blood pressure effects of treatment with losartan alone in the SHR; however, the Ang-(1-7) neutralizing antibody or the neprilysin inhibitor does not reverse the effects on blood pressure to the same extent.⁹² These data suggest that the high levels of Ang II following chronic AT₁ receptor blockade due to disinhibition of renin release may spill over to an Ang-(1-7) receptor site to stimulate prostaglandin release.⁹² Indeed, high resolution autoradiography revealed competition for Ang-(1-7) sites in the mesenteric artery or the aorta by [D-Ala⁷]-Ang-(1-7), Ang II and Ang-(1-7)—all assays were performed in the presence of AT₁ (losartan) and AT₂ receptor (PD123319) antagonists.^{91,92} Together these results suggest that Ang-(1-7) and prostacyclin may account for up to 30% of the antihypertensive actions of ACE inhibition and AT₁ receptor blockade.

RECEPTORS RESPONSIBLE FOR ACTIONS OF ANG-(1-7) IN THE KIDNEY

Accumulated evidence, discussed subsequently, suggests that there are several mechanisms by which Ang-(1-7) produces its actions.^{14,93} At least three potential mechanisms have been identified to account for these actions (Figure 10–3). These include (1) activation of antihypertensive systems (prostaglandins, nitric oxide) by actions at a novel non-AT₁/AT₂ receptor [AT₍₁₋₇₎] that are blocked by [D-Ala⁷]-Ang-(1-7); (2) actions of Ang-(1-7) that are blocked by AT₁ or AT₂ receptor antagonists in addition to [D-Ala⁷]-Ang-(1-7); and (3) Ang-(1-7)-induced homologous or heterologous down-regulation or desensitization of classic AT₁ receptors.

1. Activation of antihypertensive systems (prostaglandins, nitric oxide) by actions at a novel non-AT₁/AT₂ receptor [AT₍₁₋₇₎] that are blocked by [D-Ala⁷]-Ang-(1-7) (see Figure 10–3, First Panel). Many of the actions of Ang-(1-7) are blocked by the nonselective potent peptide antagonist,

[Sar¹-Thr⁸]-Ang II and sarcosine analogs of Ang II compete for Ang-(1-7) receptors in endothelial cells, whereas the AT₁ or AT₂ selective antagonists do not. [D-Ala⁷]-Ang-(1-7) selectively antagonizes several of the actions of Ang-(1-7), but not those of Ang II.⁹⁴ Non-AT₁/AT₂ receptor binding for Ang-(1-7) is reported in human skin fibroblasts,⁹⁵ canine coronary artery endothelium,¹⁴ the mesenteric vasculature,^{96,97} rat thoracic aorta,⁹⁸ and in rat thoracic aortic vascular smooth muscle cells (VSMC) in culture.⁹⁹ The response to an intravenous infusion of [Sar¹-Thr⁸]-Ang II was tested in SHR given the combination of lisinopril and losartan for 8 days, a treatment known to elevate Ang-(1-7) in plasma.^{54,100} A pressor response was observed of magnitude and characteristics similar to that obtained by [D-Ala⁷]-Ang-(1-7), endogenous neutralization of Ang-(1-7) with a monoclonal antibody, or an inhibitor of Ang-(1-7) formation (neprilysin inhibitors). Thus, in the presence of both AT₁ (losartan) blockade and ACE inhibition, interference with the actions of Ang-(1-7) reverses the antihypertensive effect of the peptide, suggesting that the vasodepressor effects of Ang-(1-7) during the combined treatment are mediated by a non-AT₁/AT₂ angiotensin subtype receptor. This receptor is designated as AT₍₁₋₇₎.^{101,102} The fact that these actions of Ang-(1-7) are manifest during ACE inhibition excludes interaction of the peptide with ACE^{103,104} as the mechanism to account for these responses.

Ang-(1-7) infusion transiently decreases blood pressure in SHR and this effect is blocked by [D-Ala⁷]-Ang-(1-7).¹⁰⁵ Ang-(1-7) also causes a depressor response in salt-sensitive Dahl rats that is blocked by [D-Ala⁷]-Ang-(1-7).¹⁰⁶ Ang-(1-7) infusion increases release of prostacyclin and nitric oxide and reduces thromboxane A₂ levels, all of which are prevented by pretreatment with the [D-Ala⁷]-Ang-(1-7). Other studies are consistent with the existence of an AT₍₁₋₇₎ receptor in renal tissue.^{63,77,83} The *in vivo* actions of Ang-(1-7) are attenuated by the antagonist [D-Ala⁷]-Ang-(1-7), but not by the AT₁ antagonist losartan.^{63,78} The natriuretic and diuretic effects of Ang-(1-7) and actions on the afferent arteriole are blocked by [D-Ala⁷]-Ang-(1-7), suggesting that the renal actions of Ang-(1-7) encompass both tubular

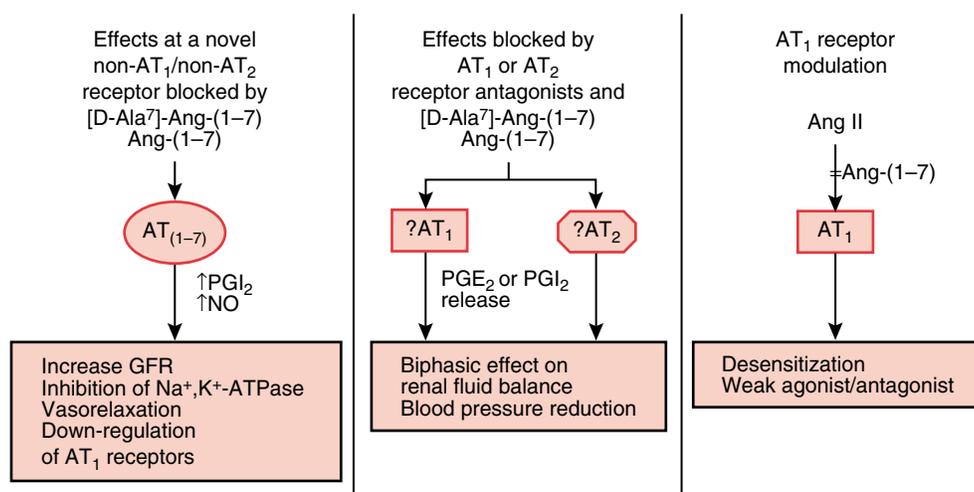

Figure 10–3 Schematic presentation of potential mechanisms for actions of Ang-(1-7).

and vascular binding sites that are non-AT₁/AT₂ receptors. Intrarenal administration of D-[Ala⁷]-Ang-(1-7) to normotensive rats elicits a fall in GFR, urine volume, and sodium excretion, suggesting tonic activity of renal Ang-(1-7) in these animals.⁷⁸ In the afferent arteriole, Ang-(1-7) exhibits potent vasodilator effects that are blocked by D-[Ala⁷]-Ang-(1-7) and nitric oxide synthase inhibitors, but not AT₁ or AT₂ antagonists.⁶⁵ Actions of Ang-(1-7) to inhibit Na⁺,K⁺-ATPase activity (⁸⁶Rb uptake) in isolated proximal tubules from normotensive rats,⁴⁰ consistent with natriuretic actions within the kidney, are blocked by D-[Ala⁷]-Ang-(1-7), but not AT₁ or AT₂ antagonists.

These data provide overwhelming evidence that the actions of Ang-(1-7) are mediated by a non-AT₁/AT₂ receptor. The unique AT₍₁₋₇₎ receptor is defined by its sensitivity to Ang-(1-7), its antagonism by [Sar¹-Thr⁸]-Ang II and [D-Ala⁷]-Ang-(1-7), and its lack of response to losartan or PD123319, either functionally or in competition for binding. Importantly, data from Santos et al. reveal that the *mas* receptor gene codes for an Ang-(1-7) binding site.¹⁰⁷ Studies in *mas* receptor-deficient mice indicate the loss of ¹²⁵I-Ang-(1-7) binding in the kidney of these animals. Functional assessments indicated the loss of vascular responses to Ang-(1-7) as well as effects of the heptapeptide in the collecting duct.¹⁰⁷ In addition, antisense oligonucleotides or small interfering RNAs to *mas* prevented responses to Ang-(1-7) (inhibition of mitogen-stimulated MAP kinase activity), in conjunction with a reduction in *mas* protein.¹⁰⁸ These findings further support the presence of a unique receptor in kidney responsible for the majority of actions of the peptide.

2. Actions of Ang-(1-7) that are blocked by AT₁ or AT₂ receptor antagonists in addition to [D-Ala⁷]-Ang-(1-7) (see Figure 10-3, Second Panel). As with most peptide systems, all of the actions of Ang-(1-7) cannot be attributed to activation of a single receptor. In fact, from the initial observation that Ang-(1-7)-released vasopressin from isolated hypothalamo-neurohypophysial explants,¹⁰⁹ many of the early actions of Ang-(1-7) appeared to be similar to Ang II. With identification of the Ang II receptor subtypes AT₁ and AT₂ by both pharmacologic and molecular approaches, subtype selective antagonists were used to attempt to characterize the actions of Ang-(1-7). The resulting pharmacologic data are far from clear. In addition to the actions of Ang-(1-7) at the novel AT₍₁₋₇₎ receptor highlighted previously, several actions of Ang-(1-7) are similar to those of Ang II or are blocked by AT₁ or AT₂ receptor antagonists. Examples of these responses, which occur at low doses or doses equivalent to Ang II, are found in several tissues, but especially brain and kidney. Moreover, in both binding and functional studies losartan and PD123319 compete for the same subpopulation of sites.¹¹⁰⁻¹¹⁹

In the kidney, Handa et al. reported that Ang-(1-7)-induced effects on oxygen consumption were due to actions blocked in part by losartan and completely by Sar¹Thr⁸-Ang II.⁶⁰ Baracho and coworkers¹²⁰ reported that losartan and [D-Ala⁷]-Ang-(1-7) each caused 100% inhibition of the antidiuretic actions of Ang-(1-7) in isolated collecting tubules or in whole animals, but that neither AT₂ nor vasopressin antagonists had any effect. However, Ang-(1-7) has a poor ability to elicit vasoconstrictor or pressor responses or compete for Ang II binding. Infusion of Ang-(1-7) into

the renal artery also does not antagonize the actions of Ang II on renal blood flow or GFR.⁵⁹⁻⁶¹ Thus, the actions of Ang-(1-7) contrast with the potent vasoconstriction elicited by Ang II through classic AT₁ sites.

To better understand the pharmacology of the receptors mediating the above responses, receptor-binding studies were carried out in membrane preparations from rat kidney. There was evidence for high affinity competition of ¹²⁵I-[Sar¹-Thr⁸]-Ang II binding by Ang-(1-7), which accounted for 10% to 20% of the total binding in the rat kidney (Figure 10-4). All of the binding was competed for by losartan, but both PD123319 and [D-Ala⁷]-Ang-(1-7) competed for 10% to 20% of the binding. Competition with [D-Ala⁷]-Ang-(1-7) was not additive with Ang-(1-7), suggesting that they compete for the same population of receptors. Alternatively, the biphasic nature of the losartan binding data suggest that losartan may discriminate between a classic AT₁ site and a second site that recognizes Ang-(1-7), [D-Ala⁷]-Ang-(1-7), and possibly PD123319, with high affinity. Further work by Garcia and Garvin⁶⁸ concluded that the biphasic effects of Ang-(1-7) in proximal tubules are inhibited primarily by losartan (80%); however, these effects of Ang-(1-7) are also inhibited significantly (40%) by the AT₂ antagonist PD123319. Other studies of low-dose Ang-(1-7) in proximal tubule preparations reveal that actions are blocked by [D-Ala⁷]-Ang-(1-7)^{40,120}; thus, the binding data in kidney tissue strongly parallel the actions of Ang-(1-7) at a high affinity site.

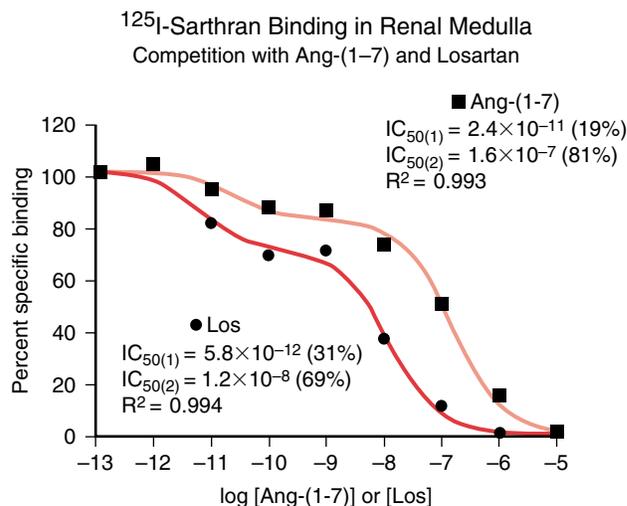

Figure 10-4 Rat kidney membranes express high affinity for both losartan and Ang-(1-7). In membranes prepared from the renal medulla, as shown, or cortex of SD male rats ($n = 3$), binding to the antagonist ¹²⁵I-[Sar¹,Thr⁸]-Ang II (0.2 nM) was competed for by Ang II with an IC₅₀ of 2 nM. Losartan (Los) competed for essentially all of the binding in a biphasic manner in the medulla. Competition by Ang-(1-7) also revealed two sites, one of high (<1 nM; 20%) and one of low affinity (0.2 μM; 80%). A similar percentage of binding was competed for by 1 μM [D-Ala⁷]-Ang-(1-7) and variably by 1 μM PD123319 (not shown). The competition by [D-Ala⁷]-Ang-(1-7) was not additive with 50 nM Ang-(1-7) suggesting that they both compete for the same high affinity site.

The aforementioned data are similar to what is reported for cultured mesangial cells.¹¹⁵ In those studies, ¹²⁵I-[Sar¹]-Ang II binding was displaced completely by losartan, a portion (~20%) was competed for by PD123319 but not CGP42112A, and a similar percentage of the binding (20%) showed a reasonably high affinity (20 nM) for Ang-(1-7). The relationship of the PD123319 component of the binding to the Ang-(1-7) component is not totally clear, because additive effects of the Ang-(1-7) and the AT₂ antagonists were not tested. Another report also found both a typical AT₁ receptor which accounted for 80% of the ¹²⁵I-Ang II binding in renal tissue as well as a PD123319-sensitive, losartan-sensitive component accounting for 20% of the total binding.¹²¹ Ernsberger and colleagues¹¹⁵ designated the novel binding site in the mesangial cells in culture an AT_{1B} in earlier publications to distinguish it from the classic AT₁ receptor. This designation currently creates confusion with the molecular AT_{1B} receptor. Whether the PD123319-sensitive effects represent a separate population of AT₂ receptors or overlap with the Ang-(1-7)- and [D-Ala⁷]-Ang-(1-7)-sensitive component is not clear and is the subject of ongoing investigations. However, a study in whole animals showed that PD123319 and [D-Ala⁷]-Ang-(1-7) each partially reverse the blood pressure lowering effects of AT₁ receptor blockade with losartan.¹²² The effects of the two treatments were not additive, suggesting overlapping mechanisms if not receptors.

Therefore, available functional data support actions of Ang-(1-7) in the kidney through a losartan- and/or PD123319-sensitive site that is also inhibited by [D-Ala⁷]-Ang-(1-7). The receptor clearly does not fit the classical AT₁ receptor classification due to its recognition of Ang-(1-7) and [D-Ala⁷]-Ang-(1-7), because Ang-(1-7) does not activate phospholipase C.¹²³ The fact that only a subset (15%-20%) of the total losartan-sensitive receptors showed high affinity for Ang-(1-7) suggests that either these receptors are isoforms of the AT₁ or AT₂ receptors or the subtype selective antagonists are capable of interacting with AT₍₁₋₇₎ receptors. To begin to distinguish between these possibilities, we reported residual ¹²⁵I-[Sar¹-Thr⁸]-Ang II binding sites in AT_{1A} deficient mouse kidney that are losartan and/or PD123319 sensitive and also show high affinity for Ang-(1-7) and [D-Ala⁷]-Ang-(1-7).^{124,125} That these sites contribute to less than 20% of the sites in wild-type mouse kidney, persist in the kidney of AT_{1A} receptor knockout mice, and now account for the majority of residual binding reveals evidence for actions on a novel gene product. Data by Santos and colleagues¹⁰⁷ indicate the *mas* protein is a [D-Ala⁷]-Ang-(1-7)-sensitive receptor. However, this receptor does not recognize the presumed AT₁ or AT₂ selective antagonists. Alternately, we have evidence that expression of the AT_{1B} receptor in VSMCs conveys an increase in a PD123319-sensitive site with high affinity for Ang-(1-7) and [D-Ala⁷]-Ang-(1-7).¹²⁶ Interestingly, the pattern of distribution of AT_{1B} receptors in kidney parallels the distribution of the actions and binding of Ang-(1-7).^{111-113,119,127}

3. Ang-(1-7)-induced homologous or heterologous down-regulation or desensitization of classic AT₁ receptors (see Figure 10-3, Third Panel). Regulation of receptors and receptor-mediated responses occurs at a number of different levels. These include regulation of the receptor by the ligand itself (homologous regulation) or by unrelated sub-

stances (heterologous regulation). Homologous regulation can be immediate and related to receptor internalization and rapid decreases in receptor numbers. It can be prolonged and include changes in number or affinity of the receptor through regulation at the mRNA and protein, or through alterations in the cellular signaling pathways. Desensitization or the functional uncoupling of the receptor from its effector system is typically a result of agonist-induced receptor phosphorylation.¹²⁸⁻¹³⁰

Reductions in AT₁ receptor density in the presence of elevated levels of Ang II may be due to receptor internalization.^{131,132} Prior exposure to Ang II also may result in a rapid desensitization of cellular responses.^{128,129-135} However, the reduction in the response to Ang II is not associated with changes in receptor number or affinity and inhibiting internalization does not prevent the desensitization. Acute and chronic exposure to elevated Ang-(1-7) decreases AT₁ receptors and AT₁ receptor-mediated responses in brain and kidney tissue and cells in culture. The mechanism for the Ang-(1-7) effects is not likely to be the result of direct pharmacologic antagonism (see next paragraph). Ang-(1-7) may act as a weak agonist at the AT₁ receptor to cause homologous receptor regulation, although the duration or magnitude may be less than that seen with a more potent agonist.^{20,21} Indeed, studies in VSMC or CHO-AT_{1A} cells indicate a direct effect of Ang-(1-7) at the AT₁ receptor, consistent with agonist-induced homologous down-regulation.^{135,136} The response occurs rapidly, is present in cells containing only AT_{1A} receptors without any evidence for Ang-(1-7) receptors, and may be accompanied by reduced activation of phospholipase C by Ang II.

In brain and peripheral tissues, the effects of ACE inhibitors on AT₁ receptors are variable, with decreases occurring in brain and increases occurring in the vasculature.^{137,138-141} Because Ang II is decreased only acutely with ACE inhibition, the variety of responses indicates that factors other than Ang II contribute to the regulation of the AT₁ receptor. Termed heterologous regulation, this is known to occur in addition to the aforementioned ligand-mediated regulation.¹³² Ang-(1-7) activates cellular mechanisms such as prostaglandin or nitric oxide release that may result in acute physiologic antagonism of the response to Ang II as indicated in the preceding sections. We propose that these mediators also participate in the regulation of AT₁ receptors based on a series of findings in cells in culture or kidney slices incubated with Ang-(1-7). Prostaglandins participate in heterologous down-regulation of opioid receptors¹⁴² and substance P NK1 receptors.¹⁹ Nitric oxide decreases AT₁ receptor mRNA.¹⁴³ Short-term incubation of isolated kidney slices with Ang-(1-7) results in a reduction in ¹²⁵I-Ang II-labeled receptors. This effect is reversed completely in the presence of meclofenamate and, at least in part, by [D-Ala⁷]-Ang-(1-7). Although Ang-(1-7) is associated with down-regulation of the AT₁ receptor following these relatively short-term treatments, Neves et al.¹⁴⁴ report that 24-hour treatment with Ang-(1-7) up-regulates AT₁ mRNA in VSMCs isolated from the Akron strain of WKY and SHR. This suggests that chronic exposure to Ang-(1-7) may alter the expression of the AT₁ receptor in a strain-specific manner. The physiologic relevance of these *in vitro* studies is underscored by the additional findings that WKY rats infused for 2 weeks with Ang-(1-7) have a reduction in Ang II-stimulated release of prostacyclin (Figure 10-5) as well as reduced pressor responses to exogenous Ang II.¹⁴⁵

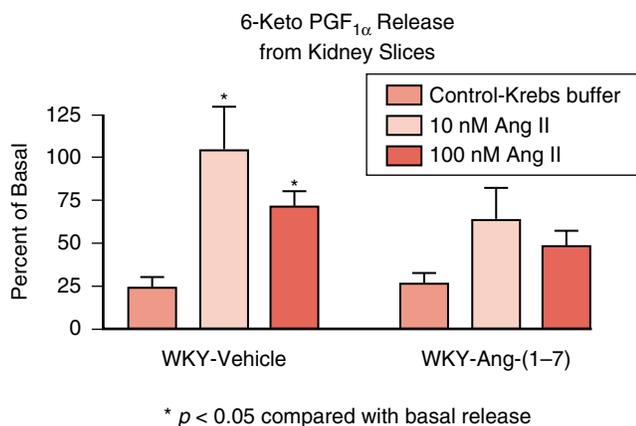

Figure 10-5 Ang II-induced prostacyclin release from rat kidney slices is diminished in rats infused with Ang-(1-7). We tested whether basal or Ang II-stimulated PGI₂ release from kidney slices was altered after chronic treatment with Ang-(1-7) in WKY rats. *Ang-(1-7) (24 μg/kg/hr) or saline vehicle (V) was infused intravenously via osmotic minipumps for 2 weeks as described. † On day 2 or 12 of infusion, the kidneys were removed and slices prepared for incubation in oxygenated Krebs buffer at 37°C; data from both days were pooled for analysis. PGI₂ release was measured as 6-keto-PGF_{1α} in two consecutive 15-minute samples: before (basal) and during incubation with Krebs buffer (control) or 10 or 100 nM Ang II (n = 5-8 each). Ang II significantly increased 6-keto-PGF_{1α} release from kidney slices of vehicle-treated WKY rats threefold. The Ang II response was attenuated in rats that received prolonged infusion of Ang-(1-7). These findings suggest that increased Ang-(1-7) levels down-regulate the Ang II receptor or the receptor signaling pathways. (From *Diz DI, Benter IF, Bosch SM, Ferrario CM. Angiotensin-(1-7) infusion attenuates angiotensin II-induced prostacyclin release from kidney slices. *Am J Hypertens* 11:32A, 1998; †Benter IF, Ferrario CM, Morris M, Diz DI. Angiotensin-(1-7) reduces smooth muscle growth after vascular injury. *Hypertension* 33:207-211, 1999.)

At concentrations 1000-fold higher than that of Ang II, Ang-(1-7) does not antagonize Ang II-dependent vasoconstriction in the rat kidney.⁶⁰ However, high concentrations of Ang-(1-7) bind to the AT₁ receptor and either stimulate AT₁-like responses or antagonize Ang II responses. Ang-(1-7) prevents the Ang II-mediated increase in Ca²⁺ in rat mesangial cells at micromolar concentrations and competes for the AT₁ receptor in these cells.⁸⁴ Micromolar concentrations of Ang-(1-7) constrict rat renal microvessels and reduce AT₁ receptor binding and Ang II-mediated phospholipase C activity in rat aortic VSMCs and CHO cells transfected with the AT_{1A} receptor.^{135,136,146} AT₁ receptor antagonists block down-regulation of the AT₁ receptor by Ang-(1-7), demonstrating that Ang-(1-7) interacts with the AT₁ receptor to reduce Ang II-mediated responses. Therefore, competition for the AT₁ receptor by pharmacologic concentrations of Ang-(1-7) may be responsible for blockade of contractile responses to Ang II by Ang-(1-7) in vascular studies that require micromolar amounts of Ang-(1-7).^{147,148} However,

these supraphysiologic actions of the peptide do not explain the majority of actions attributed to Ang-(1-7) as illustrated in the preceding sections of this chapter.

SUMMARY

The findings of many studies provide strong support for the premise that both exogenous administration and endogenous production of Ang-(1-7) elicit responses within tubular and vascular elements of the kidney. Most, but not all, actions oppose the effects of Ang II at least in part through prostaglandin production. The majority of actions of Ang-(1-7) are blocked by [D-Ala⁷]-Ang-(1-7). This argues strongly for involvement of novel receptors mediating the actions of the heptapeptide. However, as with many previously studied peptide systems, there is likely a family of receptors responsible for the myriad effects of Ang-(1-7). Pharmacologically, both actions and binding sites can be subdivided into those blocked solely by [D-Ala⁷]-Ang-(1-7) and those blocked by either or both presumed selective AT₁ and AT₂ antagonists in addition to the [D-Ala⁷]-Ang-(1-7). It is known that multiple protein isoforms exist within the AT₁ and AT₂ receptor categories based on glycosylation patterns or migration on isoelectric focusing gels. However, no one has yet determined whether these isoforms explain differences in the ability of these classic receptors to interact with Ang-(1-7). Finally, through its unique receptor or by direct interactions, the heptapeptide may play a role in down-regulation or desensitization of AT₁ receptors. Thus, Ang-(1-7) may influence Ang II-mediated responses in specific regions of the kidney by a variety of distinct mechanisms.

The Angiotensin Receptors: AT₁ and AT₂

Helmy M. Siragy, Robert M. Carey

Angiotensin II (Ang II), the principal effector hormone of the renin-angiotensin system (RAS), stimulates a variety of physiologic responses that control blood pressure (BP), renal function, and cellular growth (Figure 11–1). Ang II contributes to the pathogenesis of hypertension, cardiac hypertrophy, heart failure, diabetic renal disease, and myocardial infarction (MI). The biologic effects of Ang II are mediated through its interaction with its cell membrane receptors.^{1–3} Most of the actions of Ang II are mediated by the Ang II type-1 (AT₁) receptor. In contrast to rodents that have two subtypes of the AT₁ receptor (AT_{1A} and AT_{1B}), humans have only one form. The other angiotensin receptor isoform, the AT₂ receptor, has a less well-defined functional role in adult organisms.

ANGIOTENSIN RECEPTORS

The development of highly selective Ang II receptor antagonists has allowed the characterization of at least two distinct Ang II receptor subtypes, AT₁ and AT₂.⁴ Both receptors belong to the super-family of seven transmembrane-spanning region G-protein-coupled receptors^{5,6} and bind Ang II with a similar affinity, but share only 34% sequence homology. The expression of these receptors is not static, and certain hormones, pharmacologic agents, and pathologic conditions can enhance or suppress their expression.^{7,8}

AT₁ RECEPTOR EXPRESSION AND REGULATION IN HUMANS

The AT₁ receptor gene is mapped to band 22 of chromosome 3 and has five exons.⁹ Exon 1 enhances protein synthesis; exon 3 is responsible for amino-terminal extension of the AT₁ receptor; and exon 5 contains the coding region.^{10–15} Multiple factors regulate AT₁ receptor expression. Glucocorticoids,¹⁶ growth hormone,¹⁷ and insulin¹⁸ increase AT₁ receptor expression, whereas mineralocorticoids, estrogen,¹⁹ and nitric oxide²⁰ reduce it. AT₁ receptor cDNA encodes a 39 amino acid protein with molecular weight of 41,000 Daltons.²¹ The AT₁ receptor protein contains three potential sites for *N*-glycosylation on its putative extracellular domains. There are four extracellular domains that contain cysteine residues, which seem to be responsible for the sensitivity of Ang II binding to sulfhydryl reagents.

AT₁ receptor protein is widely distributed in the kidney.^{22–26} It has been localized to the renal vasculature, mainly in vascular smooth muscle and endothelial cells. The AT₂ receptor is also found in the renal vasculature, glomeruli, and juxtaglomerular apparatus, as well as in the nephron, including proximal and distal tubules, particularly on proximal tubule brush border and basolateral membranes, thick ascending

limb epithelia and collecting duct cells, glomerular podocytes, and macula densa cells.^{22,26–31}

AT₁ RECEPTOR SIGNALING

In humans the AT₁ receptor contains 359 amino acids and is coupled primarily to pertussis toxin-insensitive G-proteins that lead to activation of phospholipase C and calcium signaling. Once Ang II binds to the AT₁ receptor, it induces conformational changes in the receptor molecule that mediate signal transduction via several mechanisms. Interestingly the AT₁ receptor has a complex intracellular signaling system mediated by G-protein-coupled and G-protein-independent pathways. Ang II binding sites for the AT₁ receptor are in the N-terminal extracellular domain and the second extracellular loop, while the AT₁ receptor antagonist binding sites are located within the transmembrane regions of the receptor.⁴ AT₁ receptor activation stimulates phospholipases C,^{9,21} A₂, and D³²; increases intracellular calcium and inositol 1,4,5-triphosphate; activates the mitogen-activated protein kinases, extracellular signal-regulated kinases (ERKs), and the JAK/STAT pathway; and enhances protein phosphorylation and stimulation of early growth response genes.^{33–36} The AT₁ receptor has been shown to attenuate the production of cyclic adenosine 3',5'-monophosphate (cAMP) via inhibition of adenylyl cyclase. AT₁ receptor activation enhances vasoconstriction through a reduction in cAMP and an increase in intracellular calcium. The signaling pathways for the AT₁ receptor clearly demonstrate its contribution to the development of hypertension, inflammation, cellular hypertrophy, and matrix formation (Box 11–1). Tyrosine phosphorylation appears to be the major signaling pathway for AT₁ receptor effects.³⁷

CHARACTERISTICS OF ANGIOTENSIN BINDING TO THE AT₁ RECEPTOR

Three dimensional structural analysis of the AT₁ receptor (Figure 11–2) has revealed that portions of the first and third extracellular loops are crucial for the Ang II binding, whereas the second and third intracellular loops are crucial for G-protein-coupling.^{38–42}

AT₂ RECEPTOR EXPRESSION AND DISTRIBUTION

The AT₂ receptor gene is encoded on chromosome Xq22-q2 in humans, and in the rat and mouse, on chromosome Xq3 and chromosome X.^{43–45} It has three exons, but the entire AT₂ receptor coding sequence is contained in the third exon.^{46,47} Absence

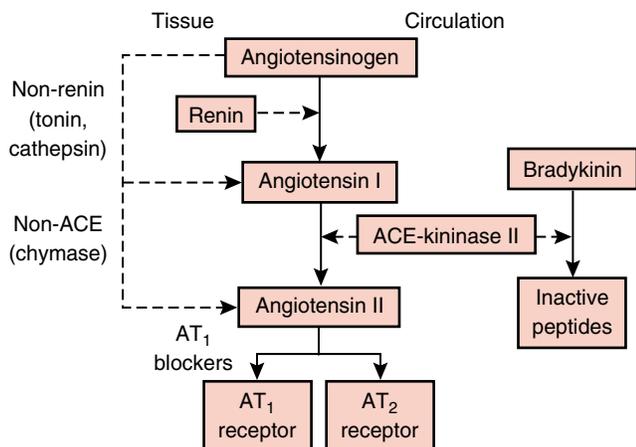

Figure 11-1 Schematic representation of different components of the renin-angiotensin system (RAS). There are circulating and local tissue paracrine components of this system. Also, multiple pathways can lead to angiotensin II (Ang II) formation. AT₁, angiotensin subtype AT₁ receptor; AT₂, angiotensin subtype AT₂ receptor.

of an intron in the coding region indicates absence of isoforms for the AT₂ receptor. The regulation of the AT₂ receptor gene is not well elucidated. cAMP down-regulates the AT₂ receptor via destabilization of its mRNA. Expression of the AT₂ receptor is linked to growth states and growth factors. During embryogenesis and fetal development, the receptor is expressed in large quantities, and expression is decreased in the postnatal period. AT₂ receptor expression is significantly decreased in adults, but it is still detectable in multiple organs, including the heart, kidney, adrenal glands, brain, uterus, and ovaries.⁴⁸⁻⁵² AT₂ receptor expression is up-regulated in several pathologic conditions, such as vascular injury, sodium depletion, post-MI, and congestive heart failure (CHF).^{48,51,53-58} In contrast, AT₂ receptor expression is down-regulated in diabetes mellitus.^{59,60} Insulin, insulin-like growth factor-1, and interleukin-1 β increase AT₂ receptor expression, whereas platelet-derived growth factor, basic fibroblast growth factor, exogenous Ang II, increased intracellular calcium, activation of protein kinase C, and norepinephrine administration down-regulate this receptor.⁶¹⁻⁶⁶

AT₂ RECEPTOR SIGNALING

The AT₂ receptor is considered a G-protein-coupled receptor, but its signaling mechanisms are different from those usually associated with this receptor family. Its receptor third intracellular loop domain is important for initiating cell signaling. The

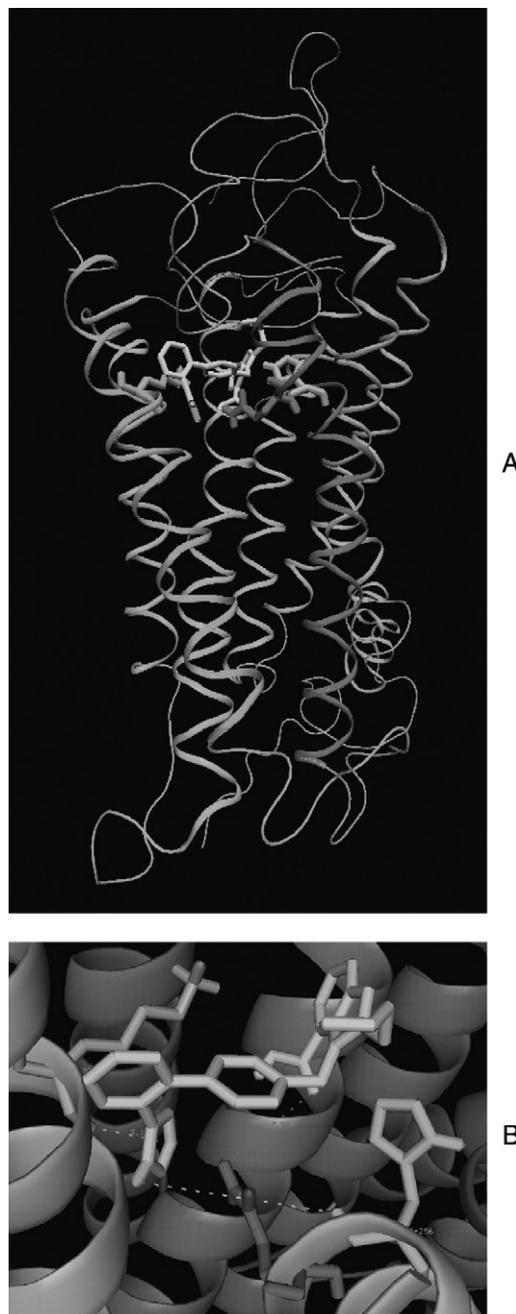

Figure 11-2 Molecular modeling of AT₁ receptor. **(A)** Model of rat AT_{1A} receptor based on high-resolution structure of bovine rhodopsin. The α -trace of the entire receptor viewed from side color coded green except for TM-5 (pink) and TM6 (red). The ligand (yellow) bound to the receptor is candesartan, an insurmountable antagonist of the AT₁ receptor. **(B)** Candesartan (yellow) location in the pocket predicted by AutoDock Computer Program is shown. Residues are shown as Lys¹⁹⁹ (pink), His²⁵⁶ (blue), and Glu²⁵⁷ (red) that directly participate in candesartan binding. (From Takezako I, Gogonea C, Saad Y, et al. "Network leaning" as a mechanism of insurmountable antagonism of the angiotensin II type 1 receptor by non-peptide antagonists. *J Biol Chem* 279(15):15248-15257 2004; With permission.)

AT₂ receptor has low amino acid sequence homology (32%–34%) with the AT₁ receptor. The similarity between the AT₁ and AT₂ receptors is mainly confined to the transmembrane hydrophobic regions of the molecules, which allows for Ang II binding to these receptors.⁶⁷ The AT₂ receptor signaling region is located on the third intracellular loop is different from that of the AT₁ receptor, which allows for signaling mechanisms distinctive from those of the AT₁ receptor.⁶⁷ The differences between the third intracellular loops of these receptors, combined with the differences in their C-terminal domains, allow for unique binding to their respective agonists and antagonists.⁶⁷ The AT₂ receptor signaling mechanisms initiated by the third intracellular loop involve both G_i and protein phosphotyrosine phosphatases.⁶⁸ The AT₂ receptor inhibits ERK activity via okadaic acid-sensitive serine/threonine phosphatase PP2A,⁶⁹ tyrosine/threonine phosphatase MKP-1,^{70–72} and vanadate-sensitive tyrosine phosphatase (SHP-1),⁷³ leading to inhibition of cell growth. Inhibition of ERK contributes to initiation of MKP-1-mediated bcl-2-dephosphorylation.⁷² The AT₂ receptor may activate phospholipase A₂ (PLA₂), leading to release of arachidonic acid and subsequent activation of MAP kinase and P21 *ras*.^{73–75} The AT₂ receptor may influence renal tubular sodium reabsorption via this signaling pathway.

The AT₂ receptor induces sphingolipid and ceramide accumulation.^{76,77} This effect may induce DNA fragmentation (apoptosis) via activation of caspase-3. The AT₂ receptor stimulates bradykinin^{78,79} production with subsequent generation of nitric oxide (NO) and cyclic guanosine 3',5'-monophosphate (cGMP).^{80–82} Thus the AT₂ receptor can stimulate vasodilation through a bradykinin-NO-cGMP cascade.

AT₂ RECEPTOR DISTRIBUTION

During fetal kidney development, the AT₂ receptor is highly expressed in mesenchymal cells of the mesonephros, immature glomeruli, cortical and medullary tubules, and interstitial cells.^{48,83} Although AT₂ receptor expression rapidly declines in the postnatal period, the receptor can still be detected in the adult kidney. Sodium depletion increases AT₂ receptor expression in the kidney.⁴⁸ In the adult kidney, the AT₂ receptor is expressed in the renal vasculature, glomeruli, and tubules.⁸⁴ Autoradiography has revealed AT₂ receptor binding sites in the renal capsule⁸⁵ and juxtaglomerular apparatus.⁸⁶ In children, AT₂ receptors have been localized mainly in the interlobular arteries.⁸⁷ Immunohistochemistry of the adult rat and human kidneys revealed AT₂ receptor staining in glomerular epithelia, tubules, and large renal vessels.^{22,48,83,84,88}

RENAL EFFECTS OF THE AT₂ RECEPTOR

Chronic infusion of subpressor doses of Ang II reduced urinary sodium excretion in AT₂-null mice, but had no such effect in wild-type mice.⁷⁹ The lack of ability to enhance sodium excretion is attributed to inability of the AT₂-null mice to produce enough bradykinin, NO, and cGMP.^{80–82} Similarly, under conditions of renal perfusion pressure, AT₂-null mice were unable to increase their sodium and water excretion as compared with wild-type mice.⁸⁹ These data strongly suggest a role for the AT₂ receptor in sodium excretion and pressure natriuresis (Box 11–2). The AT₂ receptor directly modulates

Box 11–2 Effects of Angiotensin II via AT₂ Receptors

- Cell differentiation
- Tissue regeneration

blood vessel structure and function. Chronic treatment of wild-type mice or mice overexpressing the AT₂ receptor with Ang II produces a vasodepressor response.⁹⁰ In contrast, administration of subpressor dose of Ang II to AT₂-null mice produces a significant increase in BP.⁷⁹ These studies suggest a role for the AT₂ receptor in mediating vasodilation via the bradykinin-NO-cGMP cascade. Further studies have confirmed this hypothesis. Administration of Ang II to animals treated with losartan or valsartan caused a further reduction in BP,⁹¹ and in animals treated with candesartan a sustained vasodilator response without desensitization.⁹² This contrasts with responses via the AT₁ receptor, which internalizes and desensitizes in response to long-term agonist exposure. Similarly, administration of the selective AT₂ receptor agonist CGP-42112A decreases BP, an effect that is blocked by the AT₂ receptor antagonist PD123319 or the NO synthase inhibitor L-NAME.⁹¹ The protective effect of the AT₂ receptor was demonstrated in a rat renal-wrap hypertension model.⁷⁸ In this study AT₂ receptor blockade reduced renal production of bradykinin, NO, and cGMP and reversed the BP-lowering effects of losartan.

The AT₂ receptor improves vascular remodeling by stimulating smooth muscle cell apoptosis. Study of vascular injury in AT₂-null mice demonstrates a reduction in the number of apoptotic cells.⁹³ Interestingly both AT₁ and AT₂ receptors can induce apoptosis of renal tubular cells.⁹⁴ AT₂ receptor blockade reduces tubular cell apoptosis in a rat model of unilateral ureteral obstruction.⁹⁵ In AT₂-null mice unilateral ureteral obstruction is associated with significantly fewer apoptotic cells, confirming the role of AT₂ receptors in stimulating apoptosis.⁹⁶ The most likely candidate signaling molecule that mediates AT₂ receptor-induced apoptosis is ceramide.^{76,77} Consistent with these observations, AT₂ receptor blockade inhibits apoptosis in PC12W cells.⁷⁷

The AT₂ receptor contributes to regulation of glomerular function. Afferent arteriole microperfusion studies demonstrate that the AT₂ receptor mediates vasodilation via release of epoxyeicosatrienoic acid (EET).⁹⁷ Reduction in glomerular AT₂ receptor expression has been seen in patients with glomerular disease.⁹⁸

AT₁ AND AT₂ RECEPTOR CROSS TALK

AT₁ and AT₂ receptors bind to Ang II with similar affinity, but have opposite functional effects (Box 11–3). Whereas the AT₁ receptor is responsible for vasoconstriction, natriuresis, cell hypertrophy, and matrix formation, the AT₂ receptor induces vasodilation, sodium excretion, and inhibition of cell growth and matrix formation. An increase in AT₂ receptor

Box 11-3 Opposing Actions of Angiotensin II at AT₁ and AT₂ Receptors

AT ₁	AT ₂
Vasoconstriction	Vasodilation
Antidiuresis/antinatriuresis	Diuresis/natriuresis
Cell growth and proliferation	Antiproliferation
Aldosterone release	Bradykinin production
Vasopressin release	NO release

expression⁹⁹ and activity¹⁰⁰ may occur during AT₁ receptor blockade. The AT₂ receptor also regulates AT₁ receptor expression and activity, as AT₂-null mice have increased AT₁ receptors. Transfection of vascular smooth muscle cells with the AT₂ receptor gene decreased the expression of the AT₁ receptor.^{101,102} At the cellular level, the AT₁ receptor promotes protein phosphorylation while the AT₂ receptor antagonizes this effect via stimulating protein dephosphorylation. While the AT₁ receptor increases intracellular Ca²⁺ content to promote contraction, the AT₂ receptor produces the opposite effect. The AT₂ receptor had been shown to act as an AT₁ receptor antagonist.¹⁰³ This effect seems to be mediated via direct binding of the AT₂ receptor to the AT₁ receptor to form a heterodimer.

SUMMARY

Although the RAS has been known for many years, only lately we began to understand the molecular and cellular mechanisms of action of Ang II. With the development of the non-peptide antagonists and cloning of angiotensin receptors, we have begun to understand the pathophysiologic mechanisms that involve Ang II in development of renal and cardiovascular diseases. The discovery of opposing functions of AT₁ and AT₂ receptors will help develop new drugs and strategies to prevent and treat cardiovascular and renal diseases.

Aldosterone and Mineralocorticoids

John W. Funder

DEFINITIONS

Aldosterone

Aldosterone is a steroid hormone produced primarily if not exclusively in the adrenal cortex. It is derived from cholesterol by sequential enzymatic reactions, including a final modification of the methyl (CH₃) group at carbon 18 (C18) to produce a unique aldehyde (CHO) group, whence the name aldosterone. Aldosterone is the physiologic mineralocorticoid hormone in terrestrial vertebrates; other steroids, most notably deoxycorticosterone (DOC), can also act as mineralocorticoids, but their secretion is not regulated in such a way that they are physiologic regulators of salt and water balance.

Mineralocorticoid

Mineralocorticoid is defined in effector terms, as a hormone promoting unidirectional transepithelial sodium transport. Aldosterone was isolated from fractionated bovine adrenal glands half a century ago¹ on the basis of this mineralocorticoid activity, and not surprisingly its physiology has been almost exclusively described in epithelial terms. More recently, however, the definition of mineralocorticoid has had to be broadened, to accommodate physiologic actions of aldosterone on blood vessels and in the central nervous system, as detailed later in this chapter. The emerging pathophysiologic roles of mineralocorticoid receptors (MR), also dealt with toward the end of this chapter, similarly call for continuing refinement of their definition.

ALDOSTERONE STRUCTURE AND SYNTHESIS

As noted in the preceding definition, aldosterone is characterized by an aldehyde group at C18. Aldehyde groups are chemically very reactive, and in solution the C18 aldehyde cyclizes with the hydroxyl (OH) group at C11 to form an 11,18 hemiacetal. In common with other adrenal steroids, aldosterone is produced by sequential enzymatic steps (side chain cleavage, 3 β reduction, 21-hydroxylation) from cholesterol. Unlike other hormonal steroids, aldosterone synthesis in the adrenal gland is confined to its outermost layer, the zona glomerulosa. The final enzymatic step is catalyzed in most species by the enzyme aldosterone synthase (CYP11B2), by a multistep process with DOC as substrate; aldosterone synthase shares 11 β hydroxylase activity with the closely related enzyme CYP11B1 (11 β hydroxylase), responsible for the defining step in glucocorticoid (cortisol, corticosterone) synthesis. In some species (e.g., bovine) a single CYP11B enzyme appears responsible for both glucocorticoid and aldosterone synthesis, with the mechanism(s) determining zonal specificity yet to be determined.

Regulation of Aldosterone Secretion

A number of positive (e.g., adrenocorticotrophic hormone [ACTH]) and negative (e.g., nitric oxide [NO]) factors have been shown to affect aldosterone secretion in a variety of experimental situations, but there is consensus that angiotensin II (Ang II) and plasma potassium concentration ([K⁺]) are the two major determinants of aldosterone secretion. The renin-angiotensin-aldosterone system (RAAS) has evolved to defend organ perfusion and blood pressure (BP), in response to reduced circulating volume monitored by the kidney, and to increased renal sympathetic drive. This level of integration provides a powerful counter-regulatory mechanism in situations of acute volume loss, such as major hemorrhage or massive gastrointestinal fluid and electrolyte loss. Although the primary role for aldosterone in the RAAS is usually considered to be that of volume expansion by epithelial sodium and water retention, it is now clear that aldosterone has additional sites of action. These include the amygdala, to stimulate salt appetite; the circumventricular region within the hypothalamus, to raise BP; and the vascular wall, acting as a vasoconstrictor.

Ang II is commonly considered the major determinant of aldosterone secretion, but this is not necessarily the case. Mice in which the gene for angiotensinogen has been knocked out are incapable of producing Ang II in response to physiologic stimuli such as salt restriction. In an elegant series of studies, however, angiotensinogen^{-/-} mice were shown to respond indistinguishably from wild-type in terms of elevating aldosterone in response to a low-salt diet for 2 weeks.² When mice are placed on a low-[Na⁺], low-[K⁺] diet, two things are seen. First, even in wild-type mice the aldosterone response is less than to low [Na⁺] alone. Second, for the first time, the angiotensinogen^{-/-} mice no longer match the wild type in terms of aldosterone response, evidence for the importance of [K⁺] in the process.

In the clinical context there are a number of factors that modify the evolutionary drives of catastrophic volume loss, restricted salt intake, or dietary potassium overload. Western diets are commonly sodium rich; increased sympathetic drive is similarly common, and manifests as essential hypertension. Although the dangers of diuretic-induced hypokalemia have been appropriately recognized, those of a modest and contained degree of hyperkalemia often appear exaggerated. The development of effective angiotensin-converting enzyme (ACE) inhibitors and Ang II receptor (AT₁) blockers has proven of immense clinical utility. The recent development of second-generation MR antagonists, and their side-effect-free therapeutic profile, promise to add an additional dimension to the treatment of cardiovascular disorders, including hypertension (see Chapter 70).

Aldosterone Transport and Metabolism

Aldosterone can be secreted rapidly in response to elevation in Ang II or plasma $[K^+]$, and circulates in the blood loosely bound to albumin (50%-60%) and free (40%-50%). This contrasts with most other adrenal steroids, which are commonly $\geq 95\%$ bound, in considerable part (and with high affinity) to corticosteroid binding globulin (CBG, transcortin). Metabolism occurs both in the liver (glucuronidation) and in the kidney (reduction) to water soluble products that are largely excreted in urine, where free aldosterone represents only $\sim 1\%$ of the total product. The metabolic clearance rate for aldosterone in humans of the order of 1200 L/day, equivalent to the hepatic blood flow, and consistent with the albumin-bound fraction being extracted as equivalent to free in long transit time organs such as the liver.

PHYSIOLOGIC ACTIONS OF ALDOSTERONE

Aldosterone was isolated on the basis of its effect on epithelial sodium transport, and this is commonly considered to be its principal physiologic role. Receptors for aldosterone were first identified in classical target tissues such as the kidney,³ and subsequently in a variety of nonepithelial tissues. In some of the latter aldosterone appears to have physiologic actions,⁴ whereas in others the effects are clearly pathophysiologic.⁵

Common to both epithelial and nonepithelial actions of aldosterone are MR and the enzyme 11β hydroxysteroid dehydrogenase type 2 (11β HSD2). Mineralocorticoid receptors are members of the steroid/thyroid/retinoid/orphan receptor family of nuclear transactivating factors, closely related to receptors for glucocorticoids (GR), androgens (AR), and progestins (PR).⁶ MR are unusual in that they have equivalent high affinity for aldosterone and the physiologic glucocorticoid cortisol (and corticosterone, in mice and rats); in fact, cortisol and corticosterone have >30 -fold higher affinity for MR than for GR. In addition, MR are found in fish, for example, which do not secrete aldosterone, suggesting the possibility of (patho)physiologic roles for MR occupied by glucocorticoids.⁷

Circulating plasma levels of glucocorticoids are commonly ~ 1000 -fold higher than those of aldosterone, and plasma-free levels ~ 100 -fold higher. Given their equivalent affinity for MR, a time-honored question is that of the mechanism allowing aldosterone to occupy and activate MR in its physiologic target tissues. Selectivity of the target-tissue response to aldosterone is vested in the enzyme 11β HSD2, which is coexpressed at very high levels ($3.5\text{--}4 \times 10^6$ molecules per renal principal cell, for example) with MR in aldosterone target tissues. 11β HSD2 converts cortisol and corticosterone to their receptor-inactive 11-keto analogs cortisone and 11-dehydrocorticosterone; aldosterone is not similarly metabolized, as its 11-OH group is protected from enzymatic attack by its cyclization to the 11,18 hemiketal.^{8,9}

Although from clinical studies the operation of 11β HSD2 is crucial to allow aldosterone to selectively activate target tissue MR, conversion of cortisol to cortisone is only one part of the specificity-conferring mechanism. The other action of 11β HSD2 is to stoichiometrically convert NAD to NADH. This action also appears crucial in preventing glucocorticoids

from activating MR in aldosterone target tissues under normal circumstances. The NADH/redox state does play a role in inappropriate MR activation under pathophysiologic conditions, as will be discussed later.

The postreceptor events following MR activation have been relatively lightly explored. In common with other members of the superfamily, MR can act as transcription factor, binding to response elements in the promoter regions of particular genes, and binding an increasing array of coregulators serving to modulate the rate of gene transcription. A variety of candidate MR-regulated genes have been reported— Na^+, K^+ -ATPase subunits, epithelial sodium channel (ENaC) subunits, CHIF (corticosteroid hormone induced factor), GILZ (glucocorticoid induced leucine zipper) protein—of which the most thoroughly explored has been SGK-1 (serum- and glucocorticoid-induced kinase-1). SGK-1 is constitutively expressed in glomeruli and in response to aldosterone in principal cells in the distal tubule.¹⁰ SGK-1, when phosphorylated by insulin (probably *inter alia*), is ultimately responsible for the phosphorylation of ENaC subunits, thereby blocking ENaC internalization and thus increasing intracellular Na^+ . Intracellular Na^+ is substrate for Na^+, K^+ -ATPase on the basolateral surface of the cell membrane, which pumps Na^+ out of the cell into the interstitial space and ultimately the blood. These postreceptor studies have been largely done in kidney, renal cell lines, and to some extent distal colon; comparable studies in nonepithelial aldosterone target tissues are currently in progress.

Nonclassical aldosterone target tissues include the vasculature, the amygdala, and the A3V3 region of the hypothalamus. Vascular smooth muscle expresses both MR and 11β HSD2, and both rapid and prolonged effects of aldosterone at physiologic or near physiologic concentrations have been reported.¹¹⁻¹³ The amygdala similarly expresses both MR and 11β HSD2, but in terms of selectivity is at a disadvantage compared with peripheral tissues in that aldosterone has a very high reflection coefficient at the blood-brain barrier. The A3V3 region lies outside the blood-brain barrier, and expresses MR but not 11β HSD2. Experimental studies in rat and dog (but not sheep) show that aldosterone clearly can raise BP by acting on MR in the A3V3 region, though the extent to which this reflects a physiologic response in humans is yet to be determined.¹⁴

Finally, it is now clear that aldosterone has rapid nongenomic effects. Initially such effects were ascribed to interaction with a membrane receptor for aldosterone, distinct from the classical MR.¹⁵ Subsequent studies in both vascular smooth muscle¹² and cardiomyocytes¹⁶ have shown such rapid nongenomic effects to be mediated via classical MR; whether or not membrane-receptor mediated effects can be shown in these or other tissues remains to be systematically explored. Unlike the estrogen receptor (ER), MR do not have a myristoylation site in their sequence, and are thus unlikely to be plasma membrane located.

CLINICAL SYNDROMES

There are various ways of categorizing clinical disorders, and for simplicity this section will begin with a consideration of disorders of aldosterone secretion, followed by disorders of mineralocorticoid receptor activation, with a final section on essential hypertension. Though some of the syndromes described are

very rare, they have often been illustrative, with the pathophysiology providing insight into the normal physiology.

Aldosterone Synthase Deficiency

Aldosterone deficiency may be part of a generalized hypoadrenal state, may follow deficiency in biosynthetic pathways shared with other adrenal steroids (e.g., 3β HSD, 21 hydroxylase), or may be “pure” aldosterone synthase deficiency. The condition commonly presents in infancy, and is characterized by the signs and symptoms of uncompensated sodium loss—failure to thrive, hyponatremia, hyperkalemia, hyperreninemia, and low or undetectable plasma and urinary aldosterone levels; the latter finding clearly distinguishes the syndrome from pseudohypoaldosteronism. The subject has been comprehensively reviewed.¹⁷

Glucocorticoid Remediable Aldosteronism

Of more relevance to hypertension is the condition of glucocorticoid remediable aldosteronism (GRA), also known as glucocorticoid suppressible hypertension. GRA reflects the transcription of a chimeric gene, located at 8q24, which contains the 5' end of CYP11B1 (11 β hydroxylase) and the 3' end of CYP11B2 (aldosterone synthase). Such a gene is not only transcriptionally activated by ACTH, but also is expressed throughout the adrenal cortex. The diagnosis should be suspected in patients with early onset familial hypertension, and can be confirmed or excluded by PCR for the chimeric gene. Treatment is optimally low dose (0.25-0.5 mg/day) dexamethasone. The occurrence of a chimeric CYP11B1/B2 gene reflects the two genes being located in tandem, and sharing 94% nucleotide identity, thus allowing the possibility of an unequal crossing over at meiosis.¹⁸ The most common explanation for two highly homologous genes in tandem is a relatively recent gene duplication, consistent with the relatively recent appearance of aldosterone, in terrestrial vertebrates.

Primary Aldosteronism

A year after the isolation and characterization of aldosterone in 1953, Jerome Conn reported resolution of hypertension and hypokalemia in a patient after removal of an aldosterone-producing adenoma.¹⁹ For the next 40 years primary aldosteronism was considered to be a rare (<1%) cause of hypertension, despite Conn's estimate that up to 20% of patients with elevated BP may have primary aldosteronism. Over the past decade, thanks to the wider application of the aldosterone:renin ratio as a screening test, and adrenal venous catheterization to lateralize (or not) the source of the aldosterone, it has become clear that 8% to 15% of unselected hypertensives have autonomous aldosterone production; in a recent general practice population study, 30% of patients with moderate hypertension had elevated aldosterone:renin ratios.²⁰ In terms of diagnosis, patients increasingly are found to have bilateral adrenal hyperplasia rather than a discrete adenoma, and are commonly normokalemic, so that hypokalemia is no longer pathognomonic. Treatment is laparoscopic adrenalectomy, or mineralocorticoid receptor blockade in those with bilateral hyperplasia or who are unsuitable for surgery.

Pseudohypoaldosteronism

Although more than 20 years ago defects in MR binding of aldosterone were postulated as the cause of pseudohypoaldosteronism (PHA) from studies on affected patients' leukocytes,²¹ in subsequent studies no abnormalities in gene sequence were found.^{22,23} This apparent conundrum has been resolved by the distinction between PHA type 1 and type 2, where one is caused by an epithelial sodium channel (ENaC) defect, and the other a defect in MR. The phenotype varies, but severe cases can be distinguished from aldosterone synthase deficiency by the often marked elevation in aldosterone as well as renin levels. Treatment is rigorous salt supplementation in infancy, with even severe cases appearing to improve with age, by mechanisms that remain poorly understood.

Pregnancy-Associated Hypertension

In contrast to the inactivating MR mutations that may be found in PHA, a recently discovered point mutation²⁴ has been shown to result in a constitutively partially activated MR, in which both progesterone and spironolactone act as agonists, rather than as antagonists as is the case for the wild-type MR. The syndrome was discovered in a young male hypertensive, whose two sisters suffered severe exacerbations of hypertension in pregnancy, presumably reflecting the agonist effect of progesterone on the mutant MR. The syndrome is rare, and abnormal MR do not appear to underlie the relatively common finding of hypertension in pregnancy.

Apparent Mineralocorticoid Excess

A more common, though still comparatively rare, condition of inappropriate MR activation is that of apparent mineralocorticoid excess (AME), first described by New and Ulick in 1977.²⁵ In this syndrome—of juvenile hypertension, sodium retention, and hypokalemia, in the presence of suppressed renin and aldosterone levels—epithelial MR are activated by cortisol, reflecting deficient activity of the specificity-conferring enzyme 11 β HSD2. The finding of an elevated ratio of urinary free cortisol:cortisone is diagnostic, and patients are treated by MR blockade, on occasion with the suppression of cortisol by dexamethasone administration. Whereas previously it had been assumed that epithelial 11 β HSD2 excluded glucocorticoids from MR, this has been shown not to be the case.²⁶ The enzyme acts to debulk intracellular glucocorticoid levels, from ~100-fold those of aldosterone to ~10-fold, consistent with a role for the forgotten cosubstrate (NAD, from which NADH is generated stoichiometrically) in activation of glucocorticoid-MR complexes, as briefly discussed subsequently and elsewhere in detail.^{27,28}

Essential Hypertension

Although an increasing number of patients with essential hypertension appear to have autonomous aldosterone secretion, the potential role of aldosterone, 11 β HSD2, and MR in the majority of hypertensive patients remains unclear. A number of studies have linked allelic variation in 11 β HSD2 or CYP11B2 with a higher incidence of elevated BP,^{29,30} and there have similarly been sporadic reports of a subgroup of essential hypertensives with impaired conversion of cortisol to cortisone.

The selective MR antagonist eplerenone has been shown to be of equivalent potency to ACE inhibitors, Ca²⁺ channel blockers, β -blockers, or angiotensin receptor blockers (ARBs) in terms of BP reduction.^{31,32} In titration-to-effect studies, a wide (4- to 10-fold) dose range of eplerenone was needed in moderate hypertensives to reduce diastolic BP to <90 mm Hg, with comparable falls in BP (~16/12 mm Hg) at each dose level,³³ further evidence for a significant role for aldosterone in essential hypertension.

Pathophysiology

Whereas the physiologic role of aldosterone in epithelia to retain Na⁺ and water, and to excrete K⁺, are well accepted, its other physiologic roles (as a vasoconstrictor, by a direct action on vascular smooth muscle cells (VSMCs), and in the brain to stimulate salt appetite) are less well explored. In other nonepithelial tissues it is unclear what, if any, are physiologic roles for aldosterone. What is clear, however, is that aldosterone may have direct pathophysiologic effects on blood vessels and cardiomyocytes, almost certainly *inter alia*, in the context of inappropriate salt status.

Mineralocorticoid/Salt Imbalance

In physiologic terms, aldosterone and sodium have a reciprocal relationship; when salt status falls aldosterone rises, and vice versa. When, however, aldosterone secretion is no longer responsive to normal negative feedback—in primary aldosteronism, GRA or in animals infused with aldosterone and given only 0.9% NaCl solution to drink—this reciprocal nexus is broken, and aldosterone levels are inappropriate for salt status, and vice versa. Under these circumstances very marked cerebral, renal, and coronary vascular inflammation can be shown in experimental animals,^{34,35,38} progressing to perivascular and interstitial cardiac fibrosis.^{36,37} Importantly, if infused animals are on a low-salt diet with water as drinking fluid, these changes are not seen; in the human situation of prolonged Na⁺ deficiency, very high levels of aldosterone coexist with no cardiac or vascular toxicity. The mechanisms involved in the deleterious synergy between aldosterone and inappropriate Na⁺ status are currently unclear; their clarification would constitute a major advance in cardiovascular endocrinology.

Vascular Inflammation and Cardiac Fibrosis

As noted previously, inappropriate aldosterone (or other mineralocorticoid) for salt status is followed by progressive vascular inflammation in a variety of organs. Animal models used include the stroke-prone spontaneously hypertensive rat (SHR-sp), where eplerenone has been shown to be very protective of both cerebral and renal vasculature, and tissue architecture³⁵; the aldosterone infused rat on 0.9% NaCl solution to drink, in which eplerenone is similarly protective of renal and coronary vessels, and kidney/heart architecture^{34,38}; and the AngII infused/0.9% NaCl drinking rat, in which BP is Ang II driven, and unaffected by eplerenone or adrenalectomy.^{34,38} On the other hand, adrenalectomy or eplerenone administration completely reverses the vascular and perivascular inflammatory response produced by Ang II/salt, which is

restored in adrenalectomized rats by aldosterone infusion. In all these models, markers of inflammation—ED-1, MCD-1, COX-2, IL-1 β , IL-6, osteopontin—increase over the first 2 to 4 weeks of study, and their levels are returned toward or to baseline by MR blockade.

MR Activation by Glucocorticoids

In tissues coexpressing MR and 11 β HSD2, intracellular glucocorticoid levels are 10 times those of aldosterone, and in unprotected tissues (e.g., cardiomyocytes, most neurons) levels of glucocorticoids are ~100 times higher. Under normal circumstances these glucocorticoid-MR complexes appear inactive, and the glucocorticoid appears to act in tonic inhibitory mode.^{5,39} In other circumstances, however, glucocorticoids act as MR agonists. The first of these is when 11 β HSD2 is deficient or blocked, leading to the syndromes of AME or licorice intoxication. Under these circumstances intracellular cortisol levels rise from ~10 times those of aldosterone toward ~100 times; more importantly, however, levels of intracellular NADH fall precipitously. In other systems NADH has been shown to regulate transcription factor activity by activating corepressors.^{40,41}

Secondly, when 11 β HSD2 is blocked by administration of carbenoxolone, an identical pattern of vascular inflammation is seen as with mineralocorticoid/salt administration; importantly, these effects, presumably of glucocorticoids on MR occur when NADH levels fall as 11 β hydroxysteroid dehydrogenase is blocked by carbenoxolone.⁴² Third, experimental angioplasty in pigs is followed by a constriction in coronary luminal diameter, a constriction blocked by eplerenone treatment.⁴³ These animals were not receiving aldosterone or on a high-salt intake; our interpretation of these data is that under conditions of tissue damage and reactive oxygen species (ROS) generation, intracellular redox status changes—just as it does when 11 β HSD2 is blocked—allowing normal levels of glucocorticoids to activate vascular MR and thus mimic the aldosterone/salt effects.

In this context it should be remembered that in both Randomized Aldactone Evaluation Study (RALES)⁴⁴ and Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS)⁴⁵ aldosterone levels were normal and salt status unremarkable. In the circumstances of heart failure—progressive or postmyocardial infarction—cardiomyocyte levels of ROS are known to be elevated. Under these circumstances, then, it would appear that spironolactone/eplerenone are not acting primarily as aldosterone blockers, but truly as MR antagonists blocking the effects of cortisol via MR in the context of tissue damage.

FUTURE DIRECTIONS

Any prognostication is necessarily speculative, and thus these will be mentioned only briefly, and in no detail.

Ectopic Aldosterone Synthesis

For the past decade there have been claims—commonly but not uniquely based on PCR of steroidogenic enzymes—that aldosterone can be synthesized in neurons, vascular wall and heart. Clinical data are conflicting—aldosterone is elaborated⁴⁶

or extracted⁴⁷ by the failing heart; in unpublished studies we were unable to find any consistent arteriovenous differences, in normal persons or those with severe heart failure. The Ang II/salt studies by Rocha et al.,^{34,38} in which adrenalectomy totally reversed the vascular inflammation, argue powerfully against paracrine secretion of cardiac aldosterone of any consequence. Finally, the low levels of enzyme expression found by PCR, commonly between 0.01% and 1% of adrenal levels, means that each step of ectopic steroid synthesis becomes rate-limiting. Unless the enzymes are concentrated in merely a few cells, their contribution to even local aldosterone concentrations is likely to be negligible.

MR-Independent Effects

Any molecule that circulates at subnanomolar concentrations can only act effectively by relatively high affinity binding. Many acute nongenomic effects of aldosterone have now been shown to be mediated via classical MR, in for example VSMC¹² and cardiomyocytes.¹⁶ This does not exclude the possibility of another receptor for aldosterone, distinct from the classic MR, binding aldosterone and other mineralocorticoids with high affinity (and some degree of specificity, given their low circulating concentrations). It is unlikely that this is one of the 48 members of the steroid superfamily of nuclear transactivating factors identified in the human genome; it may, for example, be an analog of the membrane receptor for progesterone.⁴⁸

Therapeutic Implications

If aldosterone/salt imbalance is followed by inflammatory vascular and perivascular responses, and downstream tissue damage, then MR blockade assumes a particular therapeutic importance. If cortisol can activate MR in the context of tissue damage and ROS generation, leading to further ROS generation and exacerbation of tissue damage, MR blockade should prove of utility in breaking this potentially vicious cycle in conditions in addition to those characterized by mineralocorticoid/salt imbalance. MR blockade, therefore, may prove beneficial not only in the context of obvious cardiovascular disease (atherosclerosis/hypertension/myocarditis/heart failure), but also in conditions as diverse as diabetes, cerebrovascular protection and the prevention of premature labor. These possibilities need to be critically examined at the preclinical level, and if found of interest, transferred into the arena of clinical trials.

The Role of Insulin Resistance and Compensatory Hyperinsulinemia in Patients with Essential Hypertension

Gerald M. Reaven

Essential hypertension is a multifactorial condition, and it should be obvious that one abnormality is not the “cause” of this syndrome. Rather, there are a number of physiologic changes that predispose individuals to develop high blood pressure. One of the goals of this chapter will be to review evidence that resistance to insulin-mediated glucose uptake and compensatory hyperinsulinemia may play such a role. In addition, there is a cluster of abnormalities associated with insulin resistance/hyperinsulinemia that contribute significantly to the risk of cardiovascular disease (CVD) in patients with essential hypertension. This chapter will address both of these issues by attempting to provide answers to the following three questions: (1) Do insulin resistance and/or compensatory hyperinsulinemia play a role in the pathogenesis of essential hypertension? (2) What are the mechanistic links between insulin resistance/hyperinsulinemia and essential hypertension? and (3) Is there a relationship between insulin resistance/hyperinsulinemia and CVD risk in patients with essential hypertension? Although there is considerable evidence from animal models of hypertension concerning these issues, as well as potentially relevant *in vitro* data, the evidence reviewed in this chapter will be limited to studies in human beings.

DO INSULIN RESISTANCE AND/OR COMPENSATORY HYPERINSULINEMIA PLAY A ROLE IN THE PATHOGENESIS OF ESSENTIAL HYPERTENSION?

At the simplest level, there is substantial evidence that patients with essential hypertension are insulin resistant/hyperinsulinemic as compared with normotensive individuals.¹⁻⁸ Furthermore, it has been shown that insulin resistance/hyperinsulinemia exist in normotensive, first-degree relatives of patients with essential hypertension.⁹⁻¹³ Despite this evidence of a strong link between insulin resistance/hyperinsulinemia and essential hypertension, the view that these changes in insulin metabolism play a role in blood pressure regulation continues to be debated. For example, the inability to detect a relationship between plasma insulin concentration and blood pressure in some cross-sectional studies has been interpreted to mean that insulin resistance/hyperinsulinemia is not involved in the pathogenesis of essential hypertension.¹⁴⁻¹⁷ However, a very different view of the relationship between insulin resistance/compensatory hyperinsulinemia and blood pressure emerges from the results of the European Group for the Study of Insulin Resistance.¹⁸ These investigators defined the relationship between a specific meas-

ure of insulin-mediated glucose disposal, fasting insulin concentration, and blood pressure in 333 normotensive individuals, studied in 20 different clinical research centers, and reported that blood pressure was directly related to both insulin resistance and insulin concentration. Furthermore, these relationships were independent of differences in age, gender, and degree of obesity.

The size of the European study, in addition to its use of a direct measure of insulin action, as contrasted to surrogate estimates, provides strong evidence that there is a relationship between insulin resistance, hyperinsulinemia, and blood pressure. In addition, results of prospective studies in which hyperinsulinemia has been used as a surrogate marker of insulin resistance support the view that insulin resistance/hyperinsulinemia are causally linked to the development of essential hypertension.¹⁹⁻²² Perhaps the most compelling in this context is the study by Skarfors et al.,¹⁹ who evaluated risk factors for the development of hypertension in 2130 men observed over a 10-year period. These investigators showed that the individuals with normal blood pressure at baseline who subsequently developed hypertension were more obese and higher plasma insulin (fasting and after intravenous glucose) and triglyceride (TG) concentrations. When baseline blood pressure was excluded from multivariate analysis, independent predictors of the progression to hypertension were obesity (as estimated by body mass index [BMI]), fasting and post-glucose challenge plasma insulin concentrations, and family history of hypertension.

Essentially similar results were reported by Lissner et al.,²⁰ who evaluated risk factors for the development of hypertension in 278 women followed over a 12-year period. In addition, they examined the relationship between blood pressure and risk factors in 219 women not receiving antihypertensive medication. Hypertension developed in approximately one third of the population in the 12-year period. In multiple logistic regression analysis, fasting hyperinsulinemia predicted the transition from normal to high blood pressure, independent of adjustments for initial BMI, waist:hip ratio, and weight gain. Individuals in the highest quartile in terms of fasting plasma insulin concentration were greater than threefold more likely to develop hypertension than those in the lowest quartile, and fasting insulin also predicted changes in blood pressure over the 12-year period.

The ability of insulin to predict changes in blood pressure over time in children and adolescents has also been shown on two occasions. One study²¹ involved a population that ranged

from 3 to 18 years at baseline, and was followed for 16 years. The results indicated that fasting insulin concentrations “seem to regulate actual blood pressure within the normal range and to predict future blood pressure”; conclusions that applied to both boys and girls, and were independent of differences in age and weight. In a somewhat more complicated study, 1865 children and adolescents were followed over a 6-year period, with essentially similar findings concerning the positive predictive power of baseline fasting insulin concentration.²² Perhaps of greater interest was the finding that “high insulin levels seems to precede the development of a potentially atherogenic risk factor profile including low high-density lipoprotein cholesterol (HDL-C), high TG, and high systolic blood pressure.”

More recent skepticism concerning the notion that insulin resistance/hyperinsulinemia plays a causal role in the genesis of essential hypertension stems from population-based studies in which the statistical technique of factor analysis is used to evaluate the relationship between insulin resistance and conditions thought to be related to it. The results of studies employing this approach have found that blood pressure appears to be a “factor” separate from the other cluster of abnormalities that associate with insulin resistance and/or hyperinsulinemia.²³ Although these findings are usually interpreted to signify the lack of an “independent” relationship between blood pressure and insulin resistance/hyperinsulinemia, the etiologic and clinical heterogeneity of patients with essential hypertension provides an obvious reason to question this conclusion. Resistance to insulin-mediated glucose disposal and compensatory hyperinsulinemia are continuous variables,²⁴ not dichotomous ones, and there is no simple way to classify a person as being insulin resistant or insulin sensitive.

An effort to estimate the number of persons with essential hypertension who are insulin resistant was made by measuring blood pressure and the plasma insulin response 120 minutes after a 75-g oral glucose challenge in an unselected population of 732 factory workers.²⁵ As a result of these

measurements, 41 individuals were identified as having essential hypertension.

Figure 13–1 illustrates the distribution of the plasma insulin responses to the glucose challenge of these individuals and those of 41 participants in the same survey with normal blood pressure. The two groups were matched for age, gender, degree of obesity, ethnic background, type of employment in the factory, and level of physical activity. Only 10% of the normotensive persons had plasma insulin concentrations that exceeded 80 mU/L when determined 120 minutes after the oral glucose challenge. In contrast, the plasma insulin concentration was >80 mU/L in 45% of the persons with essential hypertension. On the basis of these and other findings,⁸ no more than half of the persons with essential hypertension can be considered to be insulin resistant/hyperinsulinemic.

If at most only half of the persons with high blood pressure are insulin resistant/hyperinsulinemic, it should not be surprising that population-based studies, in which surrogate markers of insulin resistance are applied to primarily normotensive individuals, do not always discern a relationship between insulin resistance and blood pressure. When the fact that at least half the persons with essential hypertension are not insulin resistant is added to these confounding variables, it is not difficult to understand why studies based on the use of factor analysis find that blood pressure does not segregate with whatever surrogate measures of insulin resistance are being used. It should also be emphasized that the results of population-based studies that conclude that insulin resistance is not related to the development of essential hypertension do not negate the observations that (1) the prevalence of insulin resistance/hyperinsulinemia is increased in patients with essential hypertension; (2) these changes can be seen in normotensive, first-degree relatives of patients with essential hypertension; and (3) insulin resistance/hyperinsulinemia have been shown in prospective studies to be independent predictors of the development of essential hypertension. The

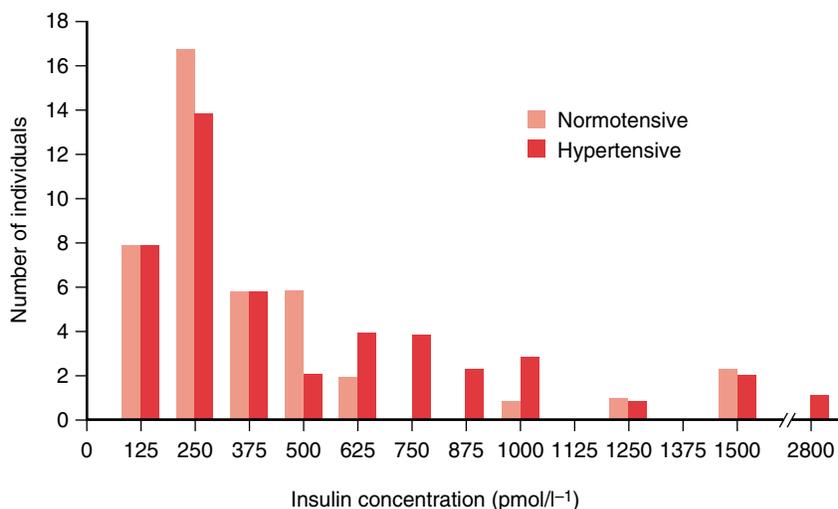

Figure 13–1 Frequency distribution of the plasma insulin response 2 hours after a 75-g oral glucose challenge in normotensive and hypertensive volunteers. (Reprinted from Zavaroni I, Mazza S, Dall’Aglione E, et al. Prevalence of hyperinsulinaemia in patients with high blood pressure. *J Intern Med* 231:235-240, 1992, with permission of the authors and the journal.)

fact that insulin resistance/hyperinsulinemia does not contribute to the etiology of essential hypertension in some individuals should not obscure the conclusion, based on a large database, that it does in others.

Finally, the view that insulin resistance and compensatory hyperinsulinemia play a role in the pathogenesis of essential hypertension has been challenged by evidence that hyperinsulinemia, per se, does not necessarily result in an increase in blood pressure. Perhaps the evidence most often cited in this context is that the acute administration of insulin to normal volunteers causes vasodilation, and does not increase blood pressure.²⁶ On the other hand, there is no a priori reason to believe that the chronic effects of compensatory hyperinsulinemia on blood pressure regulation in insulin-resistant subjects should be the same as the acute effects of a primary increase in insulin concentration in healthy volunteers.

Turning to the association between chronic hyperinsulinemia and blood pressure regulation, it has been argued that the prevalence of hypertension is not increased in patients with insulin-secreting tumors of the pancreas. However, neither fasting nor postprandial plasma insulin concentrations in patients with an insulinoma are particularly elevated when the plasma concentration of proinsulin is considered, and the diagnosis of insulinoma is based upon the development of fasting hypoglycemia in the face of a plasma insulin concentration that does not decline as the plasma glucose level falls. At a more physiologic level, there is considerable evidence that chronic hyperinsulinemia plays a role in blood pressure regulation. For example, weight loss, which enhances insulin sensitivity and lowers plasma insulin concentrations in nondiabetic individuals,²⁷ can also decrease blood pressure in persons with essential hypertension.²⁸ This change seems to be correlated with the improvement in insulin resistance.²⁹ In a similar vein, there is evidence that blood pressure can be lowered in obese individuals by physical training without any change in weight, but only in those individuals who were hyperinsulinemic and/or hypertriglyceridemic before the training program was initiated.³⁰ Because there is also evidence that insulin sensitivity is directly related to level of habitual physical activity,³¹ it is reasonable to conclude that the decrease in blood pressure in these individuals was associated with an improvement in insulin-stimulated glucose uptake. It is also worth noting that blood pressure falls when insulin dose is reduced in obese patients with type 2 diabetes and hypertension,³² and that insulin treatment increases blood pressure in patients with type 2 diabetes.³³ Thus, evidence that the acute administration of insulin does not increase blood pressure in normal individuals, or that blood pressure is not elevated in patients with an insulinoma, appears to be, at the least, counterbalanced by evidence that modulation of insulin resistance and/or insulin level in insulin-resistant individuals leads to predictable changes in blood pressure.

WHAT ARE THE POSSIBLE MECHANISTIC LINKS BETWEEN INSULIN RESISTANCE/HYPERINSULINEMIA AND ESSENTIAL HYPERTENSION?

Before discussing possible mechanisms by which insulin resistance/hyperinsulinemia increase the risk of developing hypertension, three fundamental issues must be emphasized. First, as

emphasized previously, not all persons with essential hypertension are insulin resistant, nor do all insulin-resistant individuals become hypertensive. Second, the relationship between insulin resistance and the development of hypertension is analogous to the role played by insulin resistance in the pathogenesis of type 2 diabetes.^{34,35} Hyperglycemia develops in insulin-resistant individuals only when they no longer are able to secrete the large amount of insulin necessary to overcome the insulin resistance. In a similar fashion, it seems likely that hypertension develops only when some unknown compensatory response (or responses) is no longer able to overcome the metabolic changes associated with insulin resistance/hyperinsulinemia that favor an increase in blood pressure. Third, although insulin resistance is the fundamental defect, it is most likely that it is the compensatory hyperinsulinemia that increases the risk of an individual becoming hypertensive. This seeming paradox is because insulin action varies dramatically in a given individual as a function of the tissue in question. Resistance to insulin action at the level of the muscle (stimulation of glucose uptake) and the adipose tissue (inhibition of lipolysis) are highly correlated,³⁶ and the presence of these defects in insulin action can coexist in the same person with normal insulin action on the kidney and sympathetic nervous system.³⁷⁻⁴⁰

An example that may best illustrate the general principles outlined previously is the relationship between insulin resistance/hyperinsulinemia, the kidney, and salt sensitivity. The fact that the infusion of insulin into normal individuals increases sodium retention has been known for some time,⁴¹ and there is evidence that this is also true of persons with essential hypertension.³⁸ If the link between insulin resistance and hypertension is attributable to enhanced sodium retention, as a consequence of compensatory hyperinsulinemia, it might be predicted that such patients would also be salt sensitive. There is evidence in both normotensive and hypertensive individuals that this is the case.^{42,43}

Perhaps the clearest example of the complex nature of the relationship between insulin resistance, compensatory hyperinsulinemia, the kidney and blood pressure regulation evolved from a study comparing changes in these variables in response with diets varying in sodium intake. Table 13-1 contains results of such measurements in 19 healthy volunteers who ingested alternating diets containing either low (25 mmol/day) or high (250 mmol/day) amounts of sodium, consumed in random order for 5 days each.⁴⁴ The high-sodium diet resulted in significant increases in body weight and 24-hour urinary sodium excretion, along with the expected decreases in concentrations of plasma renin activity (PRA) and aldosterone and increase in atrial natriuretic peptide (ANP) concentration. However, the average mean arterial pressure (MAP) of the 19 individuals in this study did not change. Insulin-mediated glucose disposal, as quantified by determining the steady-state plasma glucose (SSPG) concentration at the end of a 180-minute infusion of octreotide, insulin, and glucose, was similar when measured at the end of each dietary sodium intake. Because the steady-state plasma insulin concentrations were the same on both occasions, insulin-mediated glucose disposal rates were not affected by the 10-fold difference in sodium intake. Furthermore, plasma insulin concentrations 120 minutes after a 75-g oral glucose challenge were also similar when measured at the end of each period of sodium intake. Finally, there was an increase in 24-hour urinary nitrate and nitrite (NOx) excretion of borderline statistical significance.

Table 13-1 Experimental Variables at the End of the Low- and High-Sodium Diets (Mean + SEM)

Variable	Low	High	<i>p</i>
Weight (kg)	78.8 + 3.1	79.4 + 3.0	.005
Urinary Na (mmol/day)	12.7 + 2.8	174 + 14	.0001
MAP (mm Hg)	82.7 + 2.6	82.9 + 2	NS
SSPI (pmol/L)	306 + 42	330 + 49	NS
SSPG (mmol/L)	8.25 + 1.01	7.83 + 1.00	NS
Insulin (pmol/L)	270 + 33	258 + 32	NS
ANP (pmol/L)	4.6 + 0.7	10.3 + 1.3	.009
PRA (ng/ml/hr)	2.8 + 0.4	0.41 + 0.1	.0001
Aldosterone (pmol/L)	674 + 75	92 + 11	.0001
Urinary NOx (umol/day)	1119 + 94	1353 + 136	.06

Adapted from Facchini FS, DoNascimento C, Reaven GM, et al. Blood pressure, sodium intake, insulin resistance, and urinary nitrate excretion. *Hypertension* 33:1008-1012, 1999. Na, sodium; SSPI, steady-state plasma insulin; SSPG, steady-state plasma glucose; ANP, atrial natriuretic peptide; PRA, plasma renin activity.

The salt-induced increase in body weight was directly related to baseline degree of insulin resistance (SSPG, $p = .03$) and plasma insulin concentration 120 minutes after an oral glucose challenge ($p = .07$), and inversely related to the ability to increase urinary sodium excretion ($p = .01$). The inability to increase sodium excretion was also significantly related to both SSPG ($p = .04$) and the postglucose challenge insulin concentration ($p = .11$). In contrast, changes in ANP, PRA, and aldosterone concentrations and urinary NOx excretion were unrelated to the changes in body weight and sodium excretion in response to the high-salt diet.

Although the data in Table 13-1 indicated that MAP did not change significantly with the high-salt diet, there was considerable individual variability, and multiple regression analysis in the whole population showed that the greater the weight gain in response to the high-salt diet, the greater the increase in MAP ($r = 0.51$, $p < .05$). The only other significant variable associated with a salt-induced increase in MAP was the 24-hour urinary NOx excretion, and the results in Figure 13-2 demonstrate a highly significant inverse relationship ($r = -0.77$, $p < .001$) between these two variables. These results suggest that only those individuals who were insulin resistant/hyperinsulinemic retained a significant amount of salt and gained weight in response to a high-salt diet. However, as seen in Figure 13-2, if insulin-resistant individuals increased their urinary NOx excretion, their blood pressure did not increase. Obviously, 24-hour urinary NOx excretion is only a surrogate measure of nitric oxide production, but it can be speculated that the daylong increase in circulating insulin concentrations that is characteristic of insulin-resistant individuals acts on a insulin-sensitive kidney to retain-salt and water in response to a high-salt diet. Unless this can be compensated for by an increase in nitric oxide production, blood pressure is likely to increase. Whether or not this ultimately proves to be a correct formulation remains to be seen, but these results help explain why the prevalence of salt sensitivity is increased in insulin-resistant/hyperinsulinemic individuals.^{42,43}

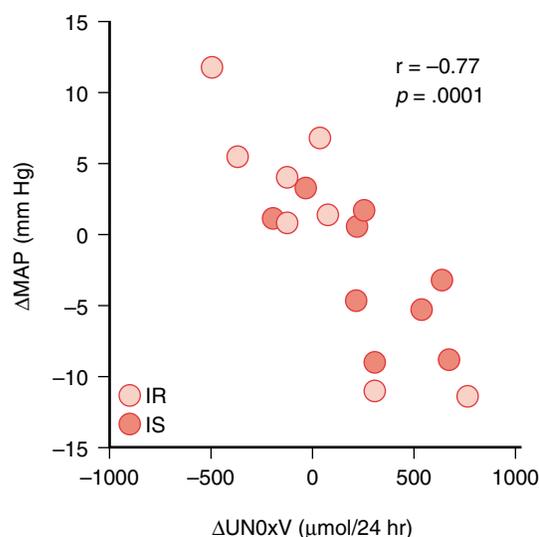

Figure 13-2 Relationship between the change in mean arterial blood pressure (Δ MAP) in response to the high-salt diet and the concomitant change in the 24-hour urinary excretion of nitrites and nitrates (Δ UNOxV) in insulin-resistant (IR) and insulin-sensitive (IS) individuals. (Reprinted from Facchini FS, DoNascimento C, Reaven GM, et al. Blood pressure, sodium intake, insulin-resistance, and urinary nitrate excretion. *Hypertension* 33:1008-1012, 1999, with permission of the authors and the journal.)

Insulin activation of the sympathetic nervous system (SNS) provides a somewhat broader approach to understanding why insulin-resistant and hyperinsulinemic individuals are at increased risk to develop hypertension. An increase in heart rate is recognized as not only a manifestation of enhanced SNS activity, but also as a significant predictor of the development of hypertension.^{45,46} The fact that heart rate is also related to both insulin resistance and hyperinsulinemia³⁹ is consistent with the view that these abnormalities of insulin metabolism predispose individuals to develop hypertension via activation of the SNS. Results of the population-based Normative Aging Study provide further support for this point of view in that SNS activity, as estimated by 24-hour urinary excretion of norepinephrine, was elevated in hyperinsulinemic, and presumably insulin-resistant subjects.⁴⁷ Furthermore, results of that study identified a significant relationship between plasma insulin concentration and urinary norepinephrine excretion, independent of differences in other relevant variables, including BMI and regional fat distribution.

Finally, the possibility that stimulation of the SNS by compensatory hyperinsulinemia in insulin-resistant individuals plays a role in the development of essential hypertension is another example of differential insulin sensitivity. Specifically, both heart rate and plasma norepinephrine concentrations appear to increase normally in response to hyperinsulinemia in individuals who demonstrate a defect in insulin-mediated glucose disposal by muscle.⁴⁸

This discussion of the possible causal relationship between insulin resistance/hyperinsulinemia and the development of essential hypertension has focused on two, somewhat related, potential mechanisms. These are not the only possibilities, but

they seem to be the explanations for which there is the most evidence at this time. At the least, they provide a testable hypothesis as to the nature of these relationships.

INSULIN RESISTANCE, COMPENSATORY HYPERINSULINEMIA, AND CARDIOVASCULAR DISEASE IN PATIENTS WITH ESSENTIAL HYPERTENSION

The advent of more effective antihypertensive drugs has greatly decreased morbidity and mortality in patients with high blood pressure. However, the beneficial effects of lowering blood pressure have been more obvious in decreasing risk of stroke as compared with CVD.⁴⁹ Because CVD is the major cause of morbidity and mortality in patients with hypertension, this apparent paradox has received a great deal of attention. Not surprisingly, many different explanations have been proposed to account for this finding, but the simplest explanation is that approximately half of the patients with essential hypertension are insulin resistant/hyperinsulinemic, and exhibit the cluster of CVD risk factors common to such individuals.²⁵ Thus the subset of patients with essential hypertension that are also insulin resistant are likely to have some degree of glucose intolerance, as well as the atherogenic lipoprotein phenotype characteristic of insulin-resistant/hyperinsulinemic individuals: high TG and low HDL-C concentrations, smaller and denser low-density lipoprotein particles, and an exaggerated degree of postprandial lipemia.⁵⁰

Furthermore, there is evidence that patients in whom essential hypertension is associated with insulin resistance are at the greatest CVD risk.⁵¹⁻⁵³ For example, Figure 13-3 compares the plasma glucose and insulin concentrations in response to a 75-g oral glucose challenge in untreated patients with essential hypertension, without clinical evidence of CVD, who have ischemic heart disease by Minnesota

Code criteria, with those of healthy volunteers, as well as a matched group of equally hypertensive individuals with normal electrocardiograms.⁵¹ It is apparent that patients with essential hypertension and electrocardiographic evidence of CVD were somewhat glucose intolerant and hyperinsulinemic as compared with either the normotensive control group or those with normal electrocardiograms. Not surprisingly, measurement of insulin-mediated glucose disposal demonstrated that patients with essential hypertension and ischemic electrocardiographic changes were insulin resistant. In addition, the data in Table 13-2 show that patients with high blood pressure and abnormal electrocardiograms were also significantly more dyslipidemic (higher plasma TG and lower HDL-C concentrations) as compared with normotensive individuals or hypertensive patients with normal electrocardiograms. The existence of these CVD risk factors in the hypertensive patients with abnormal electrocardiograms was seen in the absence of pharmacologic treatment of their high blood pressure. Furthermore, the magnitude of the abnormalities in insulin, glucose, and lipid metabolism in patients with high blood pressure is much greater than the adverse effects of any antihypertensive treatment.⁵⁴ Finally, lowering blood pressure with antihypertensive treatment does not return these metabolic abnormalities to normal.^{5,6}

The importance of the link between dyslipidemia and CVD in insulin-resistant/hyperinsulinemic patients with essential hypertension and CVD has received additional support from two reports from the Copenhagen Male Study. In the first publication,⁵² Jeppesen et al. evaluated the hypothesis that blood pressure is less predictive of CVD in individuals with the dyslipidemia characteristic of insulin-resistant/hyperinsulinemic individuals—a high TG and a low HDL-C concentration—than in those without these changes in lipid metabolism. Their results were consistent with the proposed hypothesis in that the development of CVD in individuals with a high TG and low HDL-C concentration was independent of differences in baseline systolic or diastolic blood pressure. In contrast, the

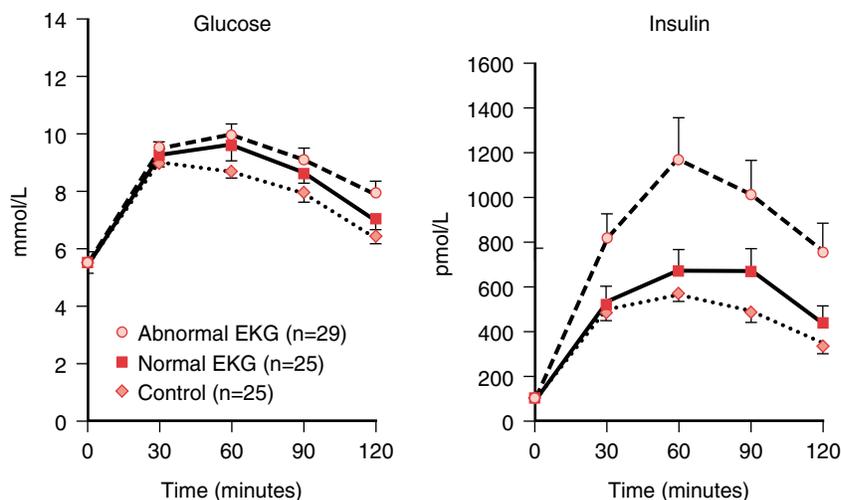

Figure 13-3 Plasma glucose and insulin responses to an oral glucose challenge in control and hypertensive patients with either a normal or an abnormal electrocardiogram as defined by Minnesota Code Criteria. higher the systolic ($p < .001$) or diastolic ($p < .03$) blood pressure at the beginning of the study, the greater the incidence of CVD in those without the dyslipidemia associated with insulin resistance/hyperinsulinemia.

In a second study,⁵³ the 2906 participants enrolled in the Copenhagen Male Study were divided into three groups on the basis of their fasting plasma TG and HDL-C concentrations. Individuals whose plasma TG and HDL-C concentrations were in the upper third or lower third, respectively, of the whole population, were assigned to the high TG/low HDL-C group. At the other extreme, a low TG/high HDL-C group was composed of those individuals whose plasma TG and HDL-C concentrations were in the lower third and upper third, respectively, of the study population for these two lipid measurements. The intermediate group consisted of those participants whose lipid values did not qualify them for either of the two extreme groups. The investigators then defined the interaction between TG/HDL-C groups and four conventional CVD risk factors: smoking, sedentary lifestyle, hypercholesterolemia, and essential hypertension. Irrespective of which of the four conventional CVD risk factors were considered, there was a two to three times higher risk of CVD in the high TG/low HDL-C group. The incidence of CVD in the face of any of the four conventional CVD risk factors was less than 5% during the 8-year period of observation as long as the individual with one of the conventional risk factors was also in the lowest TG/highest HDL-C group.

It should be emphasized that Jeppesen et al. used a high plasma TG and low HDL-C concentration as a surrogate marker of insulin resistance/hyperinsulinemia, without necessarily suggesting that these specific changes in lipoprotein metabolism were the total explanation of why CVD risk was increased in this subset of the population with essential hypertension. There is no reason to suspect that the hyperinsulinemia, glucose intolerance, dyslipidemia, and procoagulant state associated with the insulin-resistance syndrome will not contribute to the increased CVD risk in those patients with essential hypertension that are also insulin resistant.⁵⁰ In addition, changes in endothelial function that might contribute to increased CVD risk also vary as a function of differences in insulin-mediated glucose disposal in patients with essential hypertension. For example, the first step in the process of atherogenesis is the binding of

circulating mononuclear cells to the endothelium,⁵⁵ and the data in the right panel of Figure 13-4 indicate that the binding of mononuclear cells isolated from patients with hypertension to endothelial cells in vitro is directly related to their degree of insulin resistance as quantified by the SSPG concentration at the end of a 180-minute infusion of octreotide, insulin, and glucose.⁵⁶ However, it can also be seen by comparing the two panels of Figure 13-4 that the relationship between SSPG concentration and binding of isolated mononuclear cells to endothelium was similar in normotensive and hypertensive volunteers in that the more insulin resistant an individual (the higher the SSPG concentration), the greater the adherence of his or her isolated mononuclear cells to endothelium.

Essentially identical findings were observed when the relationship between plasma asymmetric dimethylarginine (ADMA) concentration and insulin-mediated glucose disposal was evaluated.⁵⁷ Plasma concentrations of ADMA, an endogenous inhibitor of nitric oxide synthase, have been shown to be predictive of CVD in several clinical syndromes,⁵⁸ and Figure 13-5 depicts the relationship between SSPG concentration (the specific measurement of insulin resistance) and plasma ADMA concentrations in normal volunteers (*left panel*) and patients with essential hypertension (*right panel*). While plasma ADMA and SSPG concentrations vary widely in both experimental groups, the elevations in plasma ADMA concentrations are associated with higher SSPG concentrations (greater degrees of insulin resistance) irrespective of blood pressure. Thus plasma ADMA concentrations are increased to a similar degree in insulin-resistant individuals, whether normotensive or hypertensive.

SUMMARY

There is a large body of experimental evidence that insulin resistance and compensatory hyperinsulinemia are more prevalent in patients with essential hypertension than in their first-degree relatives. Insulin resistance and/or compensatory hyperinsulinemia have also been shown in several large prospective, population-based studies to predict the development of essential hypertension. However, not all patients with essential hypertension are insulin resistant/hyperinsulinemic, and the

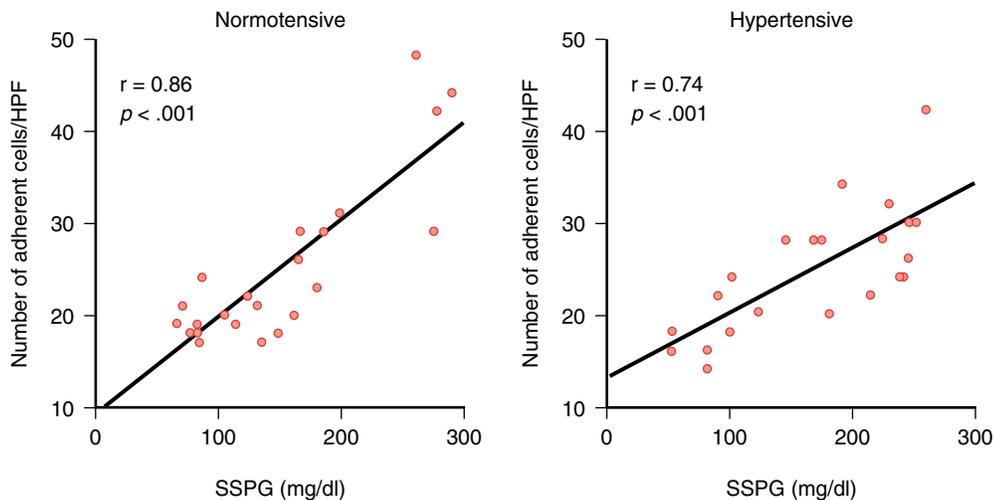

Figure 13-4 Relationship between the steady-state plasma glucose (SSPG) concentration and the adherence of mononuclear cells isolated from the plasma of volunteers (*left panel*) who are normotensive and patients with essential hypertension (*right panel*) to cultured endothelial cells. The SSPG concentration is the average of four measurements of plasma glucose concentration obtained during the last 30 minutes of a 180-minute infusion of somatostatin, glucose, and insulin; the higher the SSPG concentration the more insulin resistant the individual. (Adapted from Chen N-G, Abbasi F, Lamendola, C, et al. Mononuclear cell adherence to cultured endothelium is enhanced by hypertension and insulin resistance in healthy nondiabetic volunteers. *Circulation* 100:940-943, 1999, with permission of the authors and the journal.)

increase in blood pressure in these individuals is unrelated to any change in insulin action. This heterogeneity in the multiple factors that increase the likelihood of a person developing hypertension almost certainly accounts for the continuing argument as to whether insulin resistance/hyperinsulinemia play a role in the etiology of essential hypertension. The fact that insulin resistance/compensatory hyperinsulinemia does not provide a single unifying hypothesis to account for the etiology of essential hypertension should not obscure the important role

played by the defect in insulin-mediated glucose disposal in increasing the likelihood that blood pressure will increase. Of greater clinical relevance is the compelling evidence that it is the subset of patients with essential hypertension that are also insulin resistant, with the well-known cluster of associated CVD risk factors, that are at greatest CVD risk. Consequently, effective treatment of patients with essential hypertension should not be limited to simply lowering blood pressure, but must also address the multiple CVD risk factors often present in these patients.

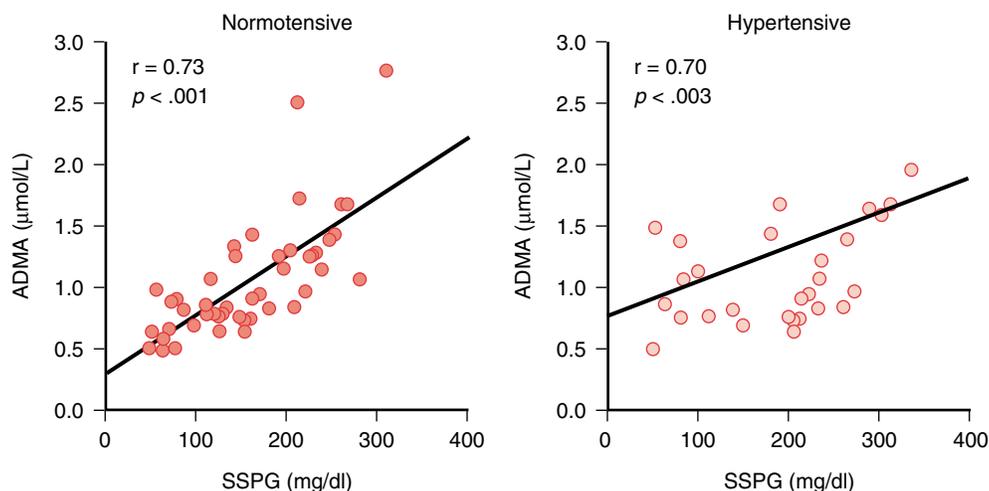

Figure 13-5 Relationship between the steady-state plasma glucose (SSPG) and f asymmetric dimethylarginine (ADMA) concentrations in normotensive (*left panel*) and hypertensive (*right panel*) individuals. The SSPG concentration provides a measure of insulin resistance as described in the legend to Figure 13-4. (Adapted from Stuhlinger MC, Abbasi F, Chu JW, et al. Remodeling of Resistance Arteries in Hypertension

Ernesto L. Schiffrin, Hope Intengan

Essential hypertension is characterized by the presence of increased peripheral vascular resistance to blood flow.¹ This results from increased energy dissipation which occurs mainly at the level of small arteries and arterioles, vessels with a lumen diameter measuring less than 400 μm and usually more than 50 μm , the major site of generation of vascular resistance.² These vessels include small arteries with a lumen of 400 to 100 μm and arterioles that have smaller diameters. Resistance arteries may play an important role in the development of hypertension and its complications.^{3,4} Resistance to flow varies inversely with the fourth power of the blood vessel radius according to Poiseuille's Law. Thus, small decreases in lumen size will significantly increase resistance. The vascular changes that result in a decreased lumen size in resistance arteries in hypertension may be structural, mechanical, or functional. We do not know whether they are a primary abnormalities or the consequences of hemodynamic or endocrine, paracrine, or autocrine effects triggered by blood pressure elevation or other unknown mechanisms, which could be genetic, metabolic, or humoral.

STRUCTURAL CHANGES IN RESISTANCE ARTERIES IN HYPERTENSION

Small Arteries

Structural changes of small, resistance arteries in hypertension may occur as eutrophic or hypertrophic remodeling (Figure 14–1).⁵ Eutrophic remodeling is usually found in mild to moderate (stage 1) hypertension.^{6,7} It is characterized by a reduced outer diameter and lumen, whereas the cross-sectional area of the media is normal, resulting in a greater media:lumen ratio. In this type of remodeling there is no true vascular hypertrophy, but rather a rearrangement of smooth muscle cells around a smaller lumen, associated with an increased extracellular matrix deposition (mainly collagen fibers and fibronectin).⁸ In experimental hypertensive models, this type of remodeling is generally found when the renin-angiotensin system plays an important role, such as in spontaneously hypertensive rats (SHR)⁹ and 2-kidney 1 clip Goldblatt hypertensive rats.¹⁰ In humans, eutrophic remodeling is found in patients with essential hypertension and modest blood pressure elevations.^{5–8,11} The mechanism that leads to eutrophic remodeling is unclear. Maintenance of media volume may involve a combination of growth and apoptosis, the latter localized peripherally in the vessel. Inward cell growth decreases lumen diameter. Enhanced apoptosis occurs indeed in various models of hypertension, including deoxycorticosterone (DOCA)-salt hypertensive rats¹² and angiotensin-induced hypertensive rats.¹³ Eutrophic remodeling may also be the result of chronic vasoconstriction.¹⁴

In hypertrophic remodeling there is true vascular hypertrophy, with thickening of the media that encroaches on the lumen, associated with increased media:lumen ratio and media cross-sectional area (see Figure 14–1). Hypertrophic remodeling predominates in rat models of severe hypertension in which the endothelin system is activated, such as DOCA-salt hypertensive rats,¹⁵ 1-kidney 1 clip Goldblatt hypertensive rats,¹⁶ and Dahl-salt sensitive hypertensive rats.¹⁷ In humans, hypertrophic remodeling has been reported in renovascular hypertension and pheochromocytoma.¹⁸ Both types of remodeling may be present to varying degrees, and “remodeling” and “growth” indices¹¹ are used to approximate their relative contributions. In hypertrophic remodeling there may be increased smooth muscle cell number and/or size¹⁹ as well as augmented deposition of extracellular proteins such as collagen and fibronectin. In small arteries from SHR²⁰ and from essential hypertensive patients,⁸ collagen deposition is significantly enhanced, which may play an important role modulating cell growth (Figure 14–2).

Diminished activity of matrix metalloproteinases (MMP), which degrade extracellular matrix proteins,²¹ may play a role in the accumulation of extracellular matrix in resistance arteries. Serum concentrations of MMP-1 were diminished in hypertensive patients in whom vascular type I collagen was augmented.²² In the mesenteric arterial bed, MMP-1 and MMP-3 activity were decreased in young SHR before established hypertension developed, whereas pro-MMP2 and activated MMP-2 were diminished in mesenteric arteries from adult SHR.²³ These changes may favor accumulation of types IV and V collagen, fibronectin, and proteoglycans.^{24,25}

The stiffness of the wall of small arteries is altered in experimental and essential hypertension.²³ Distensibility and compliance of the vessel wall are determined by the stiffness of wall components, the geometry of the vessel and intraluminal pressure. Second-order cerebral small arteries from stroke-prone SHR (SHR-sp) are less distensible than those of their normotensive counterparts, which may account in part for the reduction in their external diameter.²⁶ In contrast, third-order small arteries of less than 200 μm in diameter have normal wall mechanics, and therefore present true remodeling rather than changes attributable to altered wall mechanics.²⁶ In genetic and experimental rat models of salt-sensitive hypertension, mesenteric resistance artery stiffness not different from that in normotensive controls.^{27,28} However, in SHR the stiffness of mesenteric small arteries may be initially reduced,²⁹ followed later by increases in the stiffness of wall components, with reduced compliance and distensibility, in part a consequence of collagen deposition.²⁰ This underlines the heterogeneity of remodeling and mechanical changes in resistance vessels along the vascular tree, in different vascular beds and in different experimental models. Wall stiffness of subcutaneous small arteries from hypertensive patients either

Figure 14-1 Eutrophic and hypertrophic remodeling of resistance arteries in hypertension and potential agents that play a role in inducing the different types of remodeling of small arteries. As hypertension progresses, eutrophic remodeling may evolve toward hypertrophic remodeling under the influence of angiotensin II and/or endothelin-1, other growth factors, and high blood pressure. (Reproduced with permission from Intengan HD, Schiffrin EL. Structure and mechanical properties of resistance arteries in hypertension: Review. *Hypertension* 36:312-318, 2000.)

was not increased compared with that of normotensive subjects³⁰ or was slightly decreased.⁸ Different mechanisms may account for changes in stiffness. As a consequence of the closer alignment of cellular and fibrillar components resulting from changes in cell-extracellular attachment, collagen fibers may be recruited at higher distending pressures in small arteries from mild hypertensive patients early in the disease. Later, because of the smaller lumen and greater collagen:elastin ratio, compliance of resistance arteries may be progressively reduced in vessels from hypertensive subjects as a result of tensing of the collagen jacket at earlier portions of the pressure curve. Decreased wall stiffness in cerebral arterioles from SHR-sp, has been attributed to increased elastin content.³¹ In contrast, in peripheral resistance arteries, small artery stiffness was increased in SHR in association with increased volume density of collagen and/or increased collagen:elastin ratio.²⁰ Extracellular constituents other than collagen and elastin, such as proteoglycans may also modulate vascular stiffness. Removal of chondroitin-dermatan sulfate-containing glycosaminoglycans from mesenteric resistance arteries may increase their stiffness.³²

Arterioles

Large arterioles (lumen diameter <100 μm) also undergo remodeling as described for small arteries. Rarefaction, with reduction of arteriolar density, occurs at the level of smaller arterioles (lumen diameter <40 μm) and may increase vascular resistance. It may initially be functional and later anatomic and permanent. Rarefaction has been reported in different experimental rat models of hypertension.³³

FUNCTIONAL ABNORMALITIES OF RESISTANCE ARTERIES IN HYPERTENSION

Enhanced constriction of resistance arteries in hypertension may increase peripheral resistance by reducing lumen diameter.

Increased responsiveness to norepinephrine and enhanced myogenic tone have been reported in experimental hypertension.^{34,35} Impaired endothelium-dependent relaxation has been repeatedly reported³⁶ and may also contribute to increased constriction. However, most vasoconstrictor agents, including endothelin-1, vasopressin, and norepinephrine elicit normal or diminished constrictor responses,^{34,37} suggesting that augmented vasoconstriction in hypertension may result from amplification of vasoconstrictor responses by the structural or mechanical reduction of lumen diameter, according to Laplace's law.³⁸ Whether this actually occurs has been challenged.³⁹ Enhanced constriction in response to angiotensin II may be present as a consequence of post-receptor signaling changes, either in the coupling of the receptor to G proteins or in other events in the cascade that lead to increased calcium release and entry into the smooth muscle cell in hypertension.⁴⁰

Extracellular matrix components may contribute to abnormal function of resistance arteries in hypertension (see Figure 14-2). Peptides with the integrin-binding sequence arginine-glycine-aspartate (RGD) induced endothelium-dependent relaxation of rat skeletal muscle arterioles by binding to $\alpha_v\beta_3$ integrins.⁴¹ Because $\alpha_v\beta_3$ integrins are more abundant in arteries from adult SHR,²⁰ $\alpha_v\beta_3$ -mediated relaxation could be enhanced. However, in hypertension, $\alpha_v\beta_3$ integrins may be unavailable for ligand binding or occupied, and may therefore not induce vascular relaxation. Another RGD-containing peptide, glycine-arginine-glycine-aspartate-serine-proline (GRGDSP), induced endothelium-independent afferent arteriole constriction with increased intracellular calcium concentration.⁴² In hypertension and with aging, fibronectin and $\alpha_5\beta_1$ integrins are increased,²⁰ and accordingly $\alpha_5\beta_1$ -integrin occupancy could contribute to increased contractility and vascular resistance. Modulation of MMPs may also play a role in changes in vasoactive behavior. Inhibition of vascular MMP-2 in rat mesenteric arteries reduced the vasoconstrictor effects of big endothelin-1. The mechanism for this effect was cleavage of big endothelin-1 and release of the new vasoconstrictor peptide ET-1[1-32].⁴³

Figure 14–2 Associations between extracellular matrix proteins and integrins on the smooth muscle cell surface, and intracellular signaling pathways leading to cytoskeletal reorganization and to cell motility, migration, and growth. These processes contribute to rearrangement of smooth muscle cells, increased deposition of extracellular matrix components and changes in cell-cell and cell-matrix interactions, processes that are at the origin of mechanical alterations and structural remodeling in hypertension. G-protein–coupled receptors (angiotensin, endothelin, and others), acting directly or via transactivation of growth factor receptors, as well as biomechanical strain, activate MAP kinases via membrane-associated c-Src that induces association with the adaptor protein complex Shc-Grb-Sos and downstream activation of the Ras:Raf:MAP kinase cascade. MAP kinase acts on nuclear and cytoplasmic targets to initiate cell growth. G-protein–coupled receptors interact with integrins via p130^{Cas}. Extracellular matrix components directly activate integrins, and via focal adhesion kinase (FAK)-dependent pathways, phosphorylate cytoskeletal proteins (paxillin, talin, actin) that regulate cytoskeletal organization and motility. Integrin-activated FAK also influences cell growth by activating MAP kinases. By mechanisms that remain unclear, integrin activation triggers opening of various channels, including L-type Ca²⁺ channels, modifying Ca²⁺ transport and vascular smooth muscle cell contraction. Functional and structural interactions between extracellular matrix proteins and smooth muscle cells through adhesion molecules may be important in maintaining vascular wall integrity. Alterations in these interactions, possibly by modifications in cell attachment sites, could contribute to changes in vascular media stiffness. ECM, extracellular matrix; FAK, p125 focal adhesion kinase; ERKs; extracellular signal-regulated kinases, also known as mitogen-activated protein (MAP) kinases; MEK, mitogen-activated ERK-activating kinase, also known as MAP kinase kinase (MAPKK). SUMMARY

Abnormalities of endothelial cells, smooth muscle cells, adhesion molecules, and the extracellular matrix in the vasculature may contribute to structural, mechanical, or functional changes that reduce the lumen diameter of small arteries and arterioles and contribute to increases in vascular resistance in hypertension. A deeper understanding of these

vascular alterations and the mechanisms that produce them may lead to the development of new therapeutic approaches to prevent target organ damage in cardiovascular disease.

Clinical Applications of Arterial Stiffness in Hypertension

Roland Asmar

Epidemiologic studies have shown that cardiovascular disease related to arterial lesions is the leading cause of morbidity and mortality in the Western countries. Arterial abnormalities have been observed at early stages of cardiovascular diseases, particularly in the presence of risk factors, principally hypertension. The arteries are the site of hypertension-induced organ damage that compromises the function of various organs: the kidney (nephrosclerosis), the brain (stroke), the heart (angina-myocardial infarction), and the aorta (aneurysm). Therapeutic trials have shown that arterial lesions appear in some treated hypertensive patients and that the effect of cardiovascular drugs on the arterial wall may differ among compounds. Accordingly, assessment of arterial wall properties has been embraced by the world of hypertension research as an important activity.

During the last decade we have had an extraordinary advance in the methodologic aspects of noninvasive determination of the mechanical properties of the large arteries, principally arterial stiffness, related to the development of new ultrasound techniques and computer processing. A consequence of this remarkable development is the availability of devices that allow not only the evaluation of arterial stiffness but also its estimation at different sites in the arterial tree and assessment of other hemodynamic parameters of the arterial wall such as pulse pressure, pulse contour analysis, arterial diameter, wall thickness, and distal compliance.

The growing interest in arterial stiffness is reflected by an increasing number of publications, by the number of ongoing studies, and by development of drugs that act specifically on the arterial wall. Despite this increasing interest, there remains a profusion of methodology and terminology in the literature that can cause confusion and make it impossible to compare results between studies and between research groups.¹ This review is focused on the clinical applications of arterial stiffness measurements in patients at high cardiovascular risk, principally those with hypertension.

DEFINITIONS AND REFERENCE VALUES

In clinical research, *arterial stiffness* is the most simple and common term used to describe the mechanical properties of the large arteries.²⁻⁵ The terms *compliance* and *distensibility* are also widely used, although they imply a more quantitative approach. Some fundamental hemodynamic principles should be recalled to understand the different definitions used to describe arterial stiffness in clinical practice, to note their limitations, and to provide some normal values.

Hemodynamic Basis

The most widely accepted model of the arterial system is a simple tube with one end representing the peripheral resist-

ance and the other receiving blood from the heart.⁵ A wave generated by cardiac contraction travels along the tube toward the periphery and is reflected back from the periphery. Thus the pressure wave at any point along the tube is the resultant of both the incident and the reflected waves (Figure 15-1). The incident wave is influenced by the left ventricular ejection and the arterial stiffness (pulse wave velocity [PWV]); the reflected wave is related to arterial stiffness and the characteristics of the reflected waves. *Local* arterial stiffness refers to measurements performed locally on a cross-sectional area of straight artery. *Regional* (segmental) stiffness refers to measurements performed over a segment of the arterial tree or on a regional arterial circulation. *Systemic* (global) stiffness refers to the compliance of the whole arterial tree. In clinic, arterial stiffness should be investigated either locally to explore vascular damage or in the regional and/or systemic circulations to explore the interactions between the heart and vessels (Table 15-1).

Indices of Local Arterial Stiffness

In most cases, measurements are done locally on superficial and straight arteries. The vessel is considered a portion of a cylindrical tube in which the relationship between blood pressure and volume (or lumen diameter or cross-sectional area) is established, and its slope represents an index of stiffness. From these measurements, stiffness changes were described as universally accepted indices called *distensibility*, *compliance*, *elastic modulus* (Peterson), and *incremental elastic modulus* (Young) (see Table 15-1). Because of the curvilinearity of the pressure-diameter relationship, all of these parameters are highly pressure dependent. Thus, to evaluate the degree of stiffness of the arterial wall material, blood pressure should be considered and isobaric measurements should be performed according to the local arterial pressure.

Local determinations of arterial stiffness are performed by using ultrasound techniques in which several aspects have to be considered. First, the stiffness indices represent dynamic and not static measurements.^{5,6} Therefore, changes in pressure (pulse pressure) and changes in volume (or lumen diameter or cross-sectional area) are measured locally at the same arterial location (e.g., the carotid). Second, because the measurements are exclusively cross-sectional, it is assumed that the length of the artery remains constant over time. Third, because the arterial tree is heterogeneous, it is important to investigate both proximal (elastic) and distal arteries (muscular).⁷

Indices of Regional and Systemic Arterial Stiffness

The most common measure of regional (segmental) arterial stiffness is PWV.⁸ The principle of PWV is based on the fact that left ventricular ejection volume of blood into the

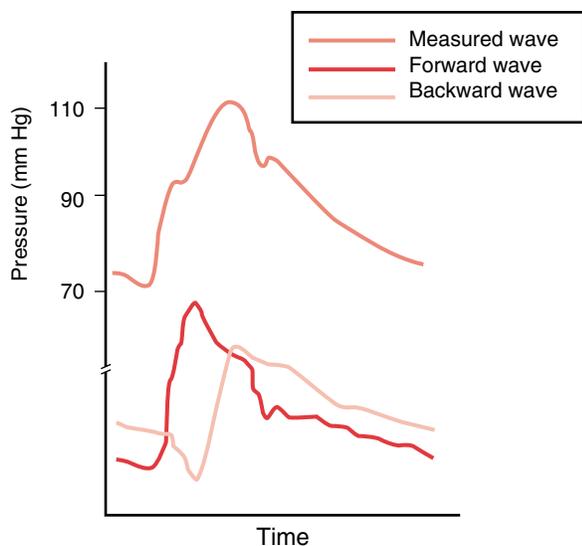

Figure 15-1 Decomposition of the measured (—) blood pressure into a forward (— incident) wave and a backward (.... reflected) wave.

ascending aorta dilates the aortic wall and generates a pulse wave that is propagated throughout the arterial tree at a finite speed determined by the elastic and geometric properties of the arterial wall and the characteristics (density) of the contained fluid (blood). Higher velocity corresponds to higher arterial stiffness. PWV is related to the Young's modulus (E) of a thin-walled homogenous elastic tube by the formula $PWV = \sqrt{E \cdot h / 2r\rho}$, where ρ is the density of blood (1.05), E the

incremental elastic modulus, and $h/2r$ the wall thickness divided by diameter. PWV velocity is calculated by using the formula $PWV = D/T$, where D represents the distance traveled by the pulse between two recording sites and T represents the transit time needed by the front wave (which is not influenced by wave reflection) to travel from one site to the other (Figure 15-2).

Characteristic impedance is another valuable index of arterial stiffness and relates absolute arterial pressure to absolute velocity of flow at the same site in the absence of wave reflections.⁵ Characteristic impedance (Z_c) is related to PWV by the formula $Z_c = PWV/\rho$ (ρ = blood density).

It is important to note that the mechanical properties of arteries and wave reflections are constantly interacting. When the arterial wall is stiff, wave travel is rapid, and the reflected wave merges with the systolic part of the incident wave, causing a supplementary increase in pressure in systole (called augmentation index) and a low pressure in diastole, resulting in an increase in pulse pressure.^{5,9} This is a manifestation rather than a measure or index of arterial stiffness.

Systemic or total (called also "capacitive") arterial compliance (C) is an estimate of the compliance of the whole arterial tree via simple models of the arterial circulation by using analysis of the arterial pressure wave. During diastole, the general shape of the diastolic pressure curve commonly assumes a simple monoexponential form, enabling an analogy with the electrical RC model. The limitation of this classical model is that pressure oscillations are considered to be instantaneous and occurring simultaneously in all parts of the arterial tree.¹⁰ Moreover, methods for calculating total arterial compliance likewise require noninvasive estimation of cardiac output and assumption of a Windkessel model in which no wave reflection

Table 15-1 Definition and Units of the Various Indices of Arterial Stiffness

Arterial distensibility	Relative diameter (or area) change for a pressure increment; the inverse of elastic modulus $\Delta D/(\Delta P \cdot D)$ (mm Hg ⁻¹)
Arterial compliance	Absolute diameter (or area) change for a given pressure step at fixed vessel length $\Delta D/\Delta P$ (cm/mm Hg) (or cm ² /mm Hg)
Volume elastic modulus	Pressure step required for (theoretical) 100% increase in volume $\Delta P/(\Delta V/V)$ (mm Hg) = $\Delta P/(\Delta A/A)$ (mm Hg) where there is no change in length
Elastic modulus	The pressure step required for (theoretical) 100% stretch from resting diameter at fixed vessel length $(\Delta P \cdot D)/\Delta D$ (mm Hg)
Young's modulus	Elastic modulus per unit area; the pressure step per square centimeter required for (theoretical) 100% stretch from resting length $\Delta P \cdot D/(\Delta D \cdot h)$ (mm Hg/cm)
Pulse wave velocity	Speed of travel of the pulse along an arterial segment Distance/ Δt (cm/s)
Characteristic impedance	Relationship between pressure change and flow velocity in the absence of wave reflections $\Delta P/\Delta V$ [(mm Hg/cm)/s]
Stiffness index	Ratio of logarithm (systolic/diastolic pressures) to (relative change in diameter) β Index = $(P_s/P_d)/[(D_s - D_d)/D_d]$ (nondimensional)
"Capacitive compliance"	Relationship between pressure fall and volume fall in the arterial tree during the exponential component of diastolic pressure decay $\Delta V/\Delta P$ (cm ³ /mm Hg)
"Oscillatory compliance"	Relationship between oscillating pressure change and oscillating volume change around the exponential pressure decay during diastole $\Delta V/\Delta P$ (cm ³ /mm Hg)

Note that mm Hg were used (100 mm Hg = 13.33 kPa) and that the ratio between stroke volume and pulse pressure or the beta index, a semi-logarithmic transformation of the volume elastic modulus, are not considered as true indices of arterial stiffness. Abbreviations: P, pressure; D, diameter; V, volume; h, wall thickness; t, time; s, systolic; d, diastolic; A, cross-sectional area.

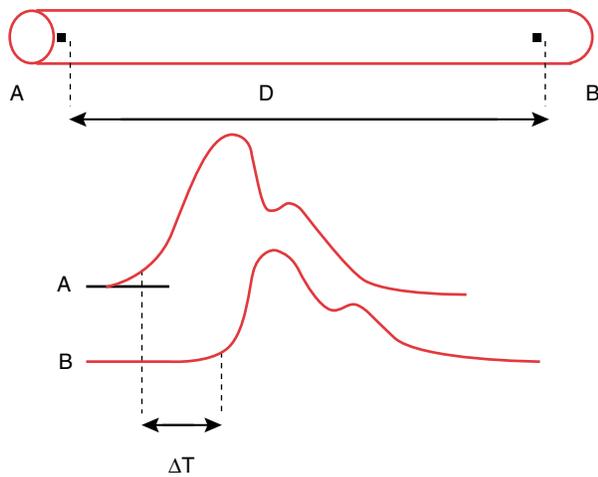

Figure 15–2 Pulse wave velocity measurement. A = Wave recorded by the proximal transducer; B = wave recorded by the distal transducer; ΔT = time delay between the foot waves; D = distance travelled by the wave.

exits. Nevertheless, methods of pulse wave analysis concentrated exclusively on diastolic decay and using a modified Windkessel model have been proposed.¹¹

METHODS, DEVICES, AND PROCEDURES

This chapter will not give an exhaustive analysis of all the available methods and their reproducibility but will focus on some of those commonly used (Table 15–2).

Assessment of Systemic and Segmental Arterial Stiffness and Wave Reflections

Most of these devices use measurements of pulse transit time or pulse contour analysis.

Automated Doppler Recording for Pulse Wave Velocity Measurement

This system gives an automated measurement of PWV by using continuous Doppler.¹²

Cardiovision System

The Cardiovision System (IMDP, Las Vegas, NV) uses computerized oscillometry (obtained from a brachial pressure cuff) to measure blood pressure and to derive an index of unloaded brachial arterial stiffness.¹³

Complior System

The Complior System (Artech-Medical, Pantin, France) gives an automated measurement of PWV based on dedicated pressure transducers directly applied on the skin.¹⁴ Two arterial segments, mainly the aortic trunk, the upper or the lower limbs, can be evaluated simultaneously. The system allows an indirect estimation of the central pulse pressure according to the classical water-hammer formula.

HDI/Pulse Wave CR 2000

This technique (Hypertension Diagnosis Inc., Minnesota) is based on the radial pulse recording with a piezoelectric sensor strapped on the wrist and calibrated with a brachial oscillometric blood pressure recording.^{11,15} The modified Windkessel model, on which this method is based, allows determination of proximal “capacitive” compliance (C1, which normally approximates 1.71–2.2 cm³/mm Hg) and distal “oscillatory” compliance (C2, which normally approximates 0.054–0.075 cm³/mm Hg).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been proposed as a non-invasive means of obtaining local distensibility or arterial PWV.¹⁶

QKd System

The method is developed as an add-on device of the ambulatory blood pressure monitoring (ABPM) recording device Diasys (Novacor, Rueil-Malmaison, France).¹⁷

Second Derivative of the Finger Plethysmogram (SDPTG)

This method (Fukuda Electric Co., Tokyo, Japan) is based on the analysis of the information contained in the derivatives of

Table 15–2 Methods and Devices to Assess Arterial Stiffness

Method/Device	Global Stiffness	Local Stiffness
Applanation Tonometry	PCA	
Automated Ultrasound recording	PWV	
Cine MRI	PWV	Aorta
Complior	PWV	
CR-2000	PCA

the peripheral blood pressure pulse waveform obtained by finger plethysmography.¹⁸

SphygmoCor System

The SphygmoCor device (PWV Medical, Sydney, Australia) is based on a peripheral pressure pulse recording with the applanation tonometer (Millar).^{9,19} From the radial or carotid artery recording, this system calculates an index of wave reflection, the augmentation index, and the carotid and aortic pulse pressure. It also allows the measurements of transit time to calculate PWV between two arterial pressure waves recorded successively with the R wave of the electrocardiogram (ECG).

Subclavian Pulse Tracing and Doppler Echocardiography Method

Measurements of arterial pressure at the level of the subclavian artery with a strain gauge transducer and measurement of aortic flow velocity with Doppler echocardiography are computerized to calculate arterial compliance with an electrical model.²⁰

Assessment of Local Arterial Stiffness

Transesophageal Echocardiography

Transesophageal echocardiography enables measurement of the ascending aorta wall thickness and changes in diameter. Combination with the subclavian blood pressure enables calculation of the elastic modulus.²¹

Vascular Echography Coupled with Frame Grabber Processing

Simultaneous measurement of blood pressure, carotid arterial diameter, and intima media thickness allows calculation of Peterson's elastic modulus, Young's elastic modulus, and beta index, which requires a semi-logarithmic transformation of the pressure measurements.²²

Wall Track System

The Wall Track System (WTS) (Pie Medical, Maastricht, The Netherlands) includes a vascular echo tracking device for the measurement of internal diameter at diastole, its pulsatile changes, and the intima media wall thickness.²³ The WTS also

allows measurements of transit time to calculate PWV between two arterial sites recorded successively with the R wave of the ECG. The combination of WTS and local blood pressure recordings allows the calculation of local compliance and wall distensibility coefficients. Use of an additional pressure-adjusted water-filled cuff allows the calculation at the level of the radial artery of the elastic modulus over a large range of distension pressures.

User Procedures: Standardization of the Examination Conditions

The patient conditions and the examination procedure are very similar to those used for blood pressure measurements and are summarized in Box 15–1.^{24–29}

DIAGNOSTIC VALUE OF ARTERIAL STIFFNESS MEASUREMENTS

Age and Gender

Numerous studies have shown that arterial stiffness is closely related to age, the major factor influencing the mechanical properties of arteries. Various mechanisms, including the role of the endothelium, and media have been invoked to explain the observed changes with age.

An age-dependent increase in arterial stiffness and pulse pressure (both accompanied by an increase in systolic blood pressure [SBP] and a decrease in diastolic blood pressure [DBP] with age) in both healthy populations and populations with cardiovascular disease has been described independently of mean blood pressure or presence of other risk factors.^{5,30} Aging has a different effect on central (elastic) arteries than on peripheral (muscular) arteries and arterioles. Central arteries stiffen progressively, whereas the stiffness of muscular arteries changes little with age.^{7,31} These results have been reported in both sexes, although arterial diameter and length are smaller in women than in men. The extent of the increase in arterial stiffness with age may depend on several environmental or genetic factors.

Blood Pressure

Relationships between arterial stiffness and blood pressure level vary widely among studies, depending on whether we consider the central or peripheral arterial pulse wave and the systolic, diastolic, mean, or pulse pressure. Population studies

Box 15–1 Standardization of the Examination Procedure

- Rest period for at least 10 minutes at stable room temperature.
- Supine position is preferred. Patients may neither speak nor sleep during assessments.
- Patients have to refrain from smoking, eating, and drinking caffeine or alcohol for at least 3 hours before the examination.
- Repeated measurements should be performed under the same conditions, by the same observer, and using validated automated procedures where possible.
- The time of drug intake should be mentioned.
- A quality control of the obtained data has to be performed.
- If appropriate, correction for important confounding factors is possible. Absolute unadjusted values must always be given.
- Investigators have to be trained to avoid observer bias errors.

performed in untreated normotensives and hypertensives with large ranges of age and without any cardiovascular disease analyzed the determinants of PWV by using adequate statistical methods. Their results are in agreement and show that the major determinants of PWV are, independently, age and SBP. These findings are predictable, because the major determinant of SBP is the stiffness of large arteries. The influence of age and SBP differs in central arteries (carotid-femoral PWV), in which age is the major determinant, and in peripheral arteries (arm PWV), in which blood pressure is the major determinant. Table 15–3 shows the normal values of PWV measured in different arterial segments.

Hypertension

Increased PWVs have been reported in hypertensives as compared with normotensives. However, these results have varied according to the arterial segment, blood pressure, and age adjustment.

It is well established that arterial abnormalities appear at an early stage of hypertension. These cannot be attributed solely to the stretching effect of elevated blood pressure but also reflect intrinsic alterations of the arterial wall that could represent either adaptive changes to the increase in arterial pressure or primary abnormalities of the vessel wall.

Borderline and White-Coat Hypertension

Comparison of aortic (carotid-femoral) and arm (brachial-radial) PWVs, between young borderline hypertensives and age-matched normotensives showed higher PWVs in the borderline hypertensives at any mean blood pressure level.³² These results suggested that the increased arterial stiffness noticed in borderline hypertensive patients is not solely due to the elevated pressure but also reflects intrinsic arterial wall changes (Figure 15–3). Similar results were observed in patients with white-coat hypertension as compared with normotensive controls.

Persistent Hypertension

Numerous studies have reported stiffer arteries in patients with established hypertension as compared with normoten-

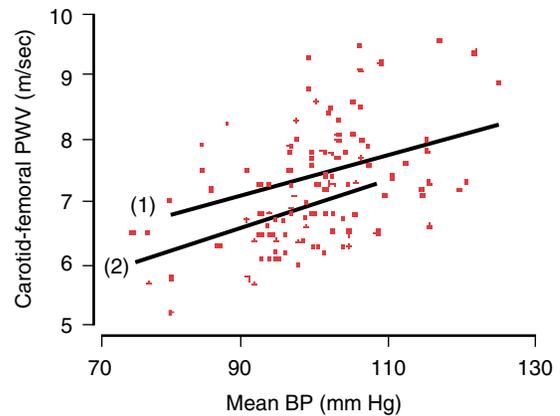

Figure 15–3 Correlation between PWV and mean BP in borderline hypertensives (1,●) and normotensives (2▲). At any BP level, PWV is higher in age-matched hypertensives. (Adapted from Girerd X, Chanudet X, Larroque P, et al. Early arterial modifications in young patients with borderline hypertension. *J Hypertens* 7(Suppl):S45-S47, 1989.)

sive controls. Comparison of aortic (carotid-femoral) and arm (brachial-radial) PWVs between patients with essential hypertension and age-matched normotensive controls showed higher PWVs in hypertensives at any age. A population study of aortic pulse wave velocity (carotid-femoral) in normotensive and hypertensive patients showed higher PWV in hypertensives as compared with normotensives (11.8 ± 2.7 versus 8.5 ± 1.5 m/sec) (Figure 15–4).

Taken together, these findings showed (1) in borderline hypertension, higher carotid-femoral and brachial-radial PWV than in age-matched normotensives; (2) in white-coat hypertension, higher carotid-femoral PWV than in age-matched normotensives; (3) in sustained hypertension, higher pulse wave velocity than in normotensives at any given age. The elevated PWV and increased arterial stiffness cannot be attributed solely to the stretching effect of elevated blood pressure. Early hypertension-related abnormalities in the arterial wall also contribute.

In normotensives, there is a continuous decrease in compliance and distensibility from central to peripheral arteries.^{5,33}

Table 15–3 Normal Values of Pulse Wave Velocity

Velocity	Normal Values
Thoracic aorta	400–530 cm/sec
Abdominal aorta	500–570 cm/sec
Aortic arch-femoral	5.1 age (years) + 533 cm/sec
	9.2 age (years) + 615 cm/sec
Carotid-femoral (site to site)	775–980 cm/sec
	0.06 systolic BP (mm Hg) + 0.09 age (years) - 2.3×10^2 m/sec
Carotid-femoral (distance subtraction)	620–930 cm/sec
Brachial-radial	880 cm/sec
	0.61 age (years) + 817 cm/sec
	4.8 age (years) + 998 cm/sec
Femoral-foot artery	830 cm/sec
	4.43 age (years) + 718 cm/sec
	5.6 age (years) + 791 cm/sec

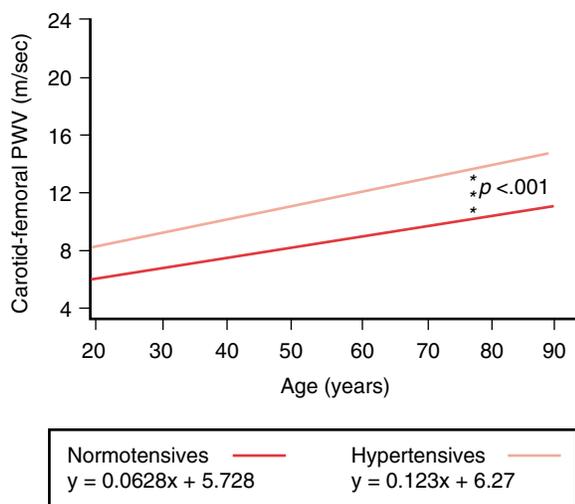

Figure 15-4 Linear correlations between PWV and age in established hypertensive patients (—) and in normotensive persons (—). PWV is higher in hypertensives than in normotensives. (Adapted from Asmar et al.)³⁰

This physiologic stiffness gradient is significantly attenuated in hypertensives whether they are young or old. The reduced stiffness gradient in hypertensives is mainly due to a significant decrease in distensibility of central arteries, whereas minimal changes in distensibility of the peripheral muscular arteries are usually observed.^{33,34}

Hypertension and Other Cardiovascular Risk Factors

Diabetes

Most authors have reported stiffer arteries in diabetic than in nondiabetic (both type 1 and 2) patients with or without hypertension, even at early stages of the disease.^{30,35} The stiffness changes occurred predominantly in the central aorta and the lower limb. Moreover, some authors found a relationship between arterial stiffness and glycemia control or duration of disease, a finding that is disputed by others. Several mechanisms have been proposed to explain the stiffer arteries: hemostatic abnormalities, hyperinsulinemia, nonenzymatic glycosylation, changes in the autonomic nervous system, and clustering of other risk factors. Specific studies of the relationship between insulin or insulin resistance and arterial stiffness are emerging.

Dyslipidemia

Based on experimental and clinical studies, it has been reported that cholesterol excess alters endothelial function, leading to a decreased ability of arterial vessels to relax. Whether this abnormality is associated with increased stiffness of the arterial wall in humans remains controversial.³⁰ At present, there is limited evidence for an association between cholesterol levels or dyslipidemia and large artery stiffness.³⁶ Longitudinal studies relating arterial stiffness to cholesterol metabolism and to endothelial function are lacking.

Smoking

Cigarette smoking increases stiffness of both medium and large arteries. Whether the arterial effect of smoking is related to concomitant blood pressure changes or is pressure independent is still debated. Longitudinal studies involving smoking and arterial stiffness as a primary goal are lacking.³⁷

Hypertension and Organ Damage

Congestive Heart Failure

Arterial compliance measured at the aortic, carotid, iliac, or brachial artery levels is significantly impaired in patients with congestive heart failure (CHF).^{5,11,30,38} Further studies are needed to evaluate the role of arterial stiffness in the prognosis of CHF and its improvement with treatment.

End-Stage Renal Disease

Patients with end-stage renal disease (ESRD) have a high prevalence of systolic hypertension caused by increased arterial stiffness. In comparison with nonuremic patients, aortic PWV is increased in ESRD, especially in younger persons. The arterial stiffening is more pronounced in the aorta than in the peripheral arteries, in association with arterial calcification, low high-density lipoprotein cholesterol levels, and altered mechanisms of endothelium-dependent flow dilation.³⁹

ARTERIAL STIFFNESS AND PROGNOSIS

Prospective epidemiologic studies have directed attention to SBP and pulse pressure PP as a better predictor of cardiovascular and all-cause mortality than DBP. These studies highlighted the role of pulse pressure and arterial stiffness in the pathophysiology of cardiovascular disease and emphasized that these parameters give more information than blood pressure determination alone.⁴⁰⁻⁴⁴

Aortic Pulse Wave Velocity as an Independent Predictor of Cardiovascular Risk

Because left ventricular ejection remains stable or even decreases with age, arterial stiffness is probably the principal factor responsible for increased SBP and pulse pressure during aging. Thus the question has arisen whether the aortic PWV might be a risk factor for cardiovascular or overall mortality. Blacher et al.⁴⁵ showed three significant predictors of cardiovascular mortality in patients with ESRD: aortic PWV, age, and duration of hemodialysis. After adjustment for all confounding factors, the odds ratio for PWV (>1270 cm/sec) was 4.4 (confidence interval [CI]: 2.3-8.5) for all-cause mortality and 5.0 (CI: 2.3-10.9) for cardiovascular mortality.

In patients with essential hypertension, a study based on calculation of cardiovascular risk with the Framingham equations⁴⁶ showed an increased risk of cardiovascular complications in parallel with the increase in aortic PWV, with aortic PWV being the strongest predictor of cardiovascular mortality. Elsewhere, Laurent et al.⁴⁷ analyzed the prognostic value of PWV in a longitudinal study in hypertensive patients and

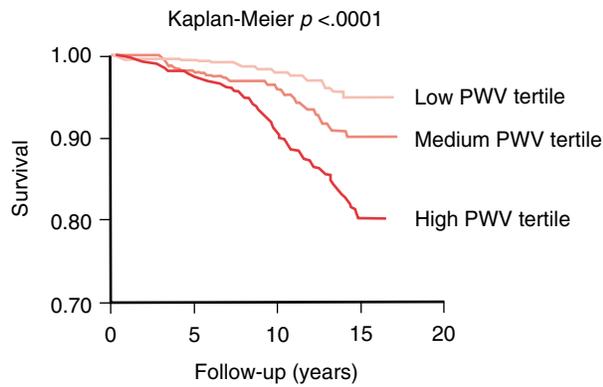

Figure 15-5 Aortic stiffness and all-cause mortality in hypertensive patients. Mortality is higher in the high PWV tertile. Similar results were observed for cardiovascular mortality. (Adapted from Laurent et al.)⁴⁷

clearly demonstrated that aortic stiffness, as evaluated by carotid-femoral PWV, is an independent predictor of all-cause and cardiovascular mortality. The same authors showed that aortic stiffness is also an independent predictor of primary coronary events and of fatal stroke in hypertensive patients.^{48,49} These findings suggest that increased arterial stiffness, as evaluated by aortic PWV, should be considered an independent predictor of all-cause and cardiovascular mortality, primary coronary events, and fatal stroke in patients at high cardiovascular risk with hypertension.

ARTERIAL STIFFNESS: PHARMACOLOGY AND THERAPEUTICS

Hypertension

There is a need for pharmacologic studies focusing on arterial wall properties at both proximal and distal levels. This has been investigated with nitrates and nitrite donors,⁵⁰ which have been shown to decrease arterial stiffness at doses not affecting resistance vessels, and to a lesser extent, with angiotensin-converting enzyme inhibitors and calcium antagonists.

In principle, the demonstrated ability of antihypertensive agents to reduce arterial stiffness is not surprising, because blood pressure reduction unloads the stiffer components of the arterial wall. Whether classes of antihypertensive agents vary in their ability to affect arterial structure and thus influence arterial stiffness via a pressure-independent mechanism is more difficult to demonstrate, because the demonstration requires large-scale trials. In long-term studies it is generally accepted that angiotensin-converting enzyme inhibitors, calcium antagonists, and some β -blocking agents share a similar ability to decrease arterial stiffness in hypertensive patients. Results with diuretics may differ according to the patient's age and the arterial site.⁵¹⁻⁵³

In the short term, a pressure-independent decrease in arterial stiffness is generally mediated by smooth muscle relaxation caused either by a direct drug effect or by a resultant change in endothelial function. In the long term, the occurrence of a pressure-independent decrease in arterial stiffness implies a pharmacologic remodeling of the arterial wall.

Various pressure-independent changes in arterial structure have been described in response to long-term drug treatment, including angiotensin-converting enzyme inhibitors (with or without diuretics), aldosterone antagonists, or even amino-guanidine derivatives.^{54,55} Reduction in pulsatile mechanical stress through the decrease in arterial stiffness is a desirable goal of drug treatment to reduce arterial wall hypertrophy and lumen enlargement.

Guérin et al.^{45,59} analyzed the impact of PWV reduction (improvement in arterial stiffness) in terms of mortality in patients at high cardiovascular risk caused by ESRD. Their results showed that the degree of PWV reduction is an independent predictor of mortality (Figure 15-6). These important findings showed that improvement of PWV has a direct benefit in terms of mortality.

Clinical trials including the study of polymorphisms of candidate genes should consider not only the renin-angiotensin system but also the various systems involved in arterial structure, vasomotor tone, and remodeling. A pressure-independent decrease in arterial stiffness was observed in hypertensive persons with a polymorphism in the angiotensin II type 1 (AT₁) receptor gene.⁵⁶

Other Arterial Diseases

Studies of the effects of drugs on arterial stiffness in persons with cardiovascular risk factors are scarce. In patients with familial hypercholesterolemia, radial artery compliance was largely increased after a 2-year treatment with simvastatin, whereas no significant change was observed after 6 months of treatment.⁵⁷ Systemic compliance is higher, and aortic-femoral PWV and central pulse pressure lower in women receiving menopausal hormonal therapy, suggesting that such therapy may decrease stiffness of the aorta and large arteries in postmenopausal women. Removing women from their hormonal therapy for 4 weeks reduced arterial compliance, and reinstating therapy for a further 4 weeks restored compliance to prestudy levels, independent of blood pressure changes.⁵⁸

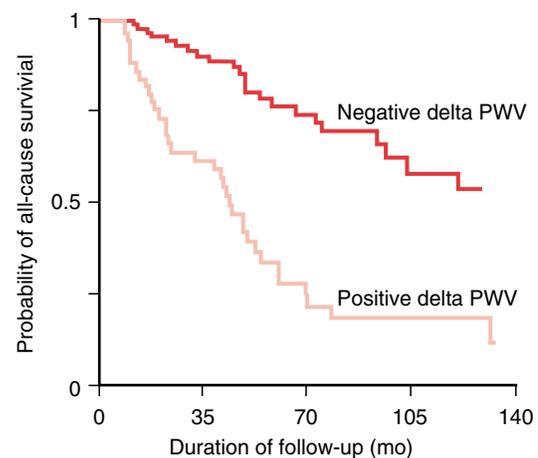

Figure 15-6 Probability of all-cause survival according to delta PWV under antihypertensive therapy. Comparison between PWV responders (negative delta PWV) and nonresponders (positive delta PWV) was highly significant ($p < .00001$). (Adapted from Guérin et al.)⁵⁹

Nonpharmacologic Treatment

Most studies of nonpharmacologic therapies have involved relatively small numbers of persons. Aerobically trained athletes have greater large arterial compliance than matched sedentary controls. A single, 30-minute cycling exercise at 65% of maximal oxygen consumption induced a small increase in aortic compliance and reduction in PWV and central SBP. Furthermore, 4 weeks of moderate-intensity exercise (65% max) performed for 30 minutes, three times per week in previously sedentary persons increased resting arterial compliance. A pressure-independent decrease in arterial stiffness may be observed through changes in several environmental factors such as sodium intake. Weight loss in healthy obese men induced a significant fall in mean blood pressure, associated with a tendency toward a blood pressure-dependent decrease in large artery stiffness. Six-week fish oil therapy improved systemic arterial compliance in non-insulin-dependent diabetes mellitus, whereas no change occurred in blood pressure, cardiac output, and systemic vascular resistance. PWV increased less in healthy adults who were taking more than 300 mg/day of standardized garlic powder for more than 2 years than in age- and sex-matched control subjects. Finally, isoflavones derived from either soy products or red clover increased large artery compliance in postmenopausal women.

Endothelium in Hypertension: Nitric Oxide

Lukas E. Spieker, Thomas F. Lüscher

The vascular endothelium synthesizes and releases a spectrum of vasoactive substances and therefore plays a fundamental role in the basal and dynamic regulation of the circulation.¹ Due to its strategic anatomic position, the endothelium is constantly exposed to the different risk factors for atherosclerosis.

NITRIC OXIDE

Nitric oxide (NO)—originally described as endothelium-derived relaxing factor (EDRF)—is released from endothelial cells in response to shear stress produced by blood flow, and in response to activation of a variety of receptors (Figure 16–1).^{2–4} NO is a free radical gas with an *in vivo* half-life of a few seconds, which is readily able to cross biological membranes.^{2,5,6} After diffusion from endothelial to vascular smooth muscle cells, NO increases intracellular cyclic guanosine monophosphate (cGMP) concentrations by activation of the enzyme guanylate cyclase leading to relaxation of the smooth muscle cells.⁷

NO is synthesized by NO synthase (NOS) from L-arginine.⁷ The conversion from L-arginine to NO can be inhibited by false substrates for the NOS, for example, by N^G-monomethyl-arginine (L-NMMA).⁸ Because there is a continuous basal release of NO that determines the tone of peripheral blood vessels, systemic inhibition of NO synthesis causes an increase in arterial blood pressure.^{9–13} There are two major types of NOS in the vasculature: a constitutive and an inducible isoform. The former, which is present in endothelial cells, is called endothelial NOS (eNOS), the latter is an important inflammatory mediator released by macrophages in response to immunologic stimuli.⁹ NO has also antithrombotic, antiproliferative, leukocyte-adhesion inhibiting effects, and influences myocardial contractility.^{10,13,15,16} The hemodynamic effects of pharmacologic NO inhibition include an increase in systemic and pulmonary arterial blood pressure, and a decrease in cardiac output (Table 16–1).

Nitric Oxide in Experimental Hypertension

Endothelium-derived NO-mediated vascular relaxation is impaired in spontaneously hypertensive animals.^{10–13} Thus, the bioavailability of NO is reduced. Surprisingly, the NO pathway is paradoxically up-regulated in the resistance circulation and the heart of spontaneously hypertensive rats (SHR).^{14,15} Adult SHR possess a higher activity of eNOS than their normotensive counterparts.¹⁶ Very young prehypertensive SHR have, in contrast, lower eNOS activity than young normotensive rats without a genetic background for hypertension, indicating that the increased activity of eNOS in adult SHR is indeed related to hypertension (Figure 16–2).

Moreover, the plasma concentrations of the oxidative product of NO metabolism, nitrate, are higher in hypertensive rats than in normotensive controls.¹⁴ These results indicate that the basal release of NO is increased in hypertensive rats.

Thus, it appears that in SHR, there must be a factor blunting the hemodynamic effect of NO.¹⁷ Indeed, NO production is increased in stroke-prone SHR (SHR-sp), but bioavailability is reduced.¹⁸ Direct *in situ* measurement of NO release by a porphyrinic microsensor in SHR-sp confirmed that hypertension is associated with increased NO decomposition by superoxide anions, (i.e., free oxygen radicals) (Figure 16–3).¹⁹

In other models of hypertension (i.e., in Dahl salt-sensitive rats; in two-kidney, one clip experimental hypertension; and in deoxycorticosterone [DOCA]-salt hypertensive rats) endothelium-dependent relaxation is also impaired.^{20–24} However, NO production by eNOS is reduced rather than up-regulated in Dahl salt-sensitive rats (see Figure 16–3).^{22,25,26} L-Arginine, the substrate of NO production by eNOS, normalizes blood pressure and simultaneously increases urinary excretion of nitrate, the degradation product of nitric oxide, in Dahl salt-sensitive rats.^{27–30} Further mechanisms contribute to the pathogenesis of salt-sensitive hypertension, for example, decreased expression of endothelial endothelin B receptors, which mediate NO release,^{23,25,31} and altered expression of the constitutive brain NOS as well as the inducible NOS isoform, possibly leading to alterations in renal sympathetic nervous activity and sodium handling.^{32–35}

Nitric Oxide in Human Hypertension

There are several techniques for the assessment of NO bioavailability in humans. Most often, flow-mediated vasodilation of the brachial artery, a marker of endothelial function, is assessed by high-resolution ultrasonography (Figure 16–4). Alternatively, endothelium-dependent and endothelium-independent vasomotion in reaction to intraarterially infused vasoactive substances are assessed using venous occlusion plethysmography (Figure 16–5). Among the most often used endothelium-dependent vasodilators are acetylcholine and serotonin. Sodium nitroprusside or nitroglycerine serve as endothelium-independent vasodilators.

Endothelium-dependent vasodilation in response to acetylcholine is impaired in patients with arterial hypertension, in forearm circulation (see Figure 16–5),^{36–46} as well as in the coronary vascular bed.^{47,48} Endothelium-dependent vasodilation in the human forearm and coronary vascular beds are strongly correlated.^{49,50}

Basal NO activity is decreased in hypertensive patients.⁵¹ Furthermore, urinary excretion of the metabolic oxidation product of nitric oxide, ¹⁵N nitrate, after administration of ¹⁵N-labeled arginine (i.e., the substrate for the generation of NO) is reduced in hypertensive patients compared with

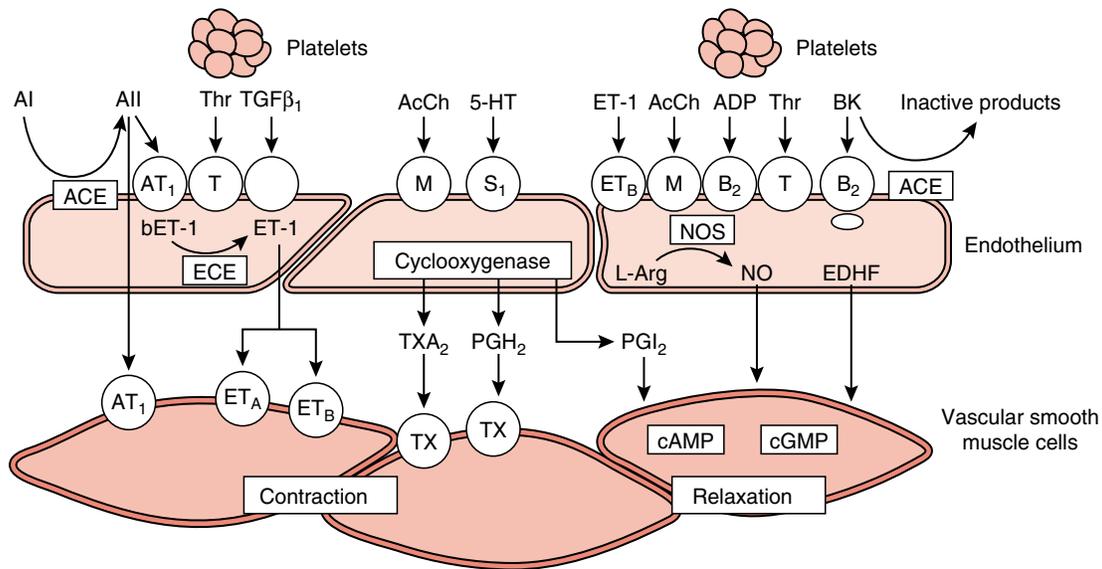

Figure 16-1 Endothelium-derived vasoactive substances. Nitric oxide (NO) is released from endothelial cells in response to shear stress and to activation of a variety of receptors. NO exerts vasodilating and antiproliferative effects on smooth muscle cells and inhibits thrombocyte-aggregation and leukocyte-adhesion. Endothelin-1 (ET-1) exerts its major vascular effects—vasoconstriction and cell proliferation—through activation of specific ET_A receptors on vascular smooth muscle cells. In contrast, endothelial ET_B receptors mediate vasodilation via release of NO and prostacyclin. Additionally, ET_B receptors in the lung were shown to be a major pathway for the clearance of ET-1 from plasma. ACE, angiotensin-converting enzyme; ACh, acetylcholine; All, angiotensin II; AT₁, angiotensin 1 receptor; BK, bradykinin; COX, cyclooxygenase; ECE, endothelin-converting enzyme; EDHF, endothelium-derived hyperpolarizing factor; ET_A and ET_B, endothelin A and B receptor; ET-1, endothelin-1; PGH₂, prostaglandin H₂; PGI₂, prostacyclin; S, serotonergic receptor; Thr, thrombin; T, thromboxane receptor; TXA₂, thromboxane; 5-HT, 5-hydroxytryptamine (serotonin). (Modified from Lüscher TF, Noll G. Endothelium-derived vasoactive substances. In Braunwald E (ed). Heart Disease, 5th ed. Philadelphia, WB Saunders, 1997; p 1165.)

Table 16-1 Hemodynamic Effects of NOS Inhibition in Healthy Volunteers

	Baseline	L-NMMA (mg/kg/min)	
		0.3	1.0
SBP	134 ± 7	152 ± 5	150 ± 3*
DBP	73 ± 4	87 ± 5	85 ± 5†
SVR	1114 ± 124	1413 ± 145*	1973 ± 203‡
HR	67 ± 4	70 ± 6	63 ± 6
CI	3.5 ± 0.3	3.1 ± 0.2*	2.3 ± 0.2§
SVI	53 ± 6	48 ± 6	38 ± 5†
CVP	4 ± 0.7	3.6 ± 0.4	4.3 ± 0.05
B/min	23.1 ± 3.5	14 ± 4.5	18.6 ± 5.5

Modified after Spieker LE, Corti R, Binggeli C, et al. Baroreceptor dysfunction induced by nitric oxide synthase inhibition in humans. *J Am Coll Cardiol* 36:213-218, 2000. **p*<.05, †*p*<.01, ‡*p*<.001, §*p*<.0001, for each data point compared with baseline values. L-NMMA, NG-monomethyl-L-arginine; SBP, systolic blood pressure (mm Hg); DBP, diastolic blood pressure (mm Hg); SVR, systemic vascular resistance (dyne·s⁻¹·cm⁻⁵); HR, heart rate (beats/min); CI, cardiac index (L·min⁻¹·m⁻²); SVI, stroke volume index (ml·min⁻¹·m⁻²); CVP, central venous pressure (mm Hg); B/min, sympathetic bursts per minute.

normotensive controls (see Figure 16-5).⁵² Thus whole-body NO production in patients with essential hypertension is diminished under basal conditions. In line with these findings, the vasoconstrictor response to L-NMMA, an inhibitor of NO synthesis, was significantly less in hypertensive patients compared with normotensives, whereas there was no difference in the response to norepinephrine, an endothelium-independent vasoconstrictor, between hypertensives and normotensives.^{51,53}

Normotensive offspring of hypertensive parents exhibit impaired endothelium-dependent vasodilation to acetylcholine.⁵⁴ In parallel to manifest hypertension, in normotensive offspring, vasoconstriction resulting from inhibition of NO synthesis is decreased.⁵⁵ Thus derangement of endothelial function in hypertension is likely to be caused in part by genetic factors, and not just a consequence of elevated blood pressure (although the hemodynamic factor importantly contributes).⁵⁶

NITRIC OXIDE AND OXIDATIVE STRESS IN HYPERTENSION

Oxidative stress plays an important role in the pathogenesis of hypertension (Figure 16-6). Superoxide anion (O₂⁻), an oxygen radical, can scavenge NO to form peroxynitrite (ONOO⁻), effectively reducing the bioavailability of endothelium-derived NO.^{19,57} In addition, O₂⁻ can act as a vasoconstrictor.⁵⁸⁻⁶¹ Nicotinamide adenine dinucleotide (NADH) dehydrogenase,

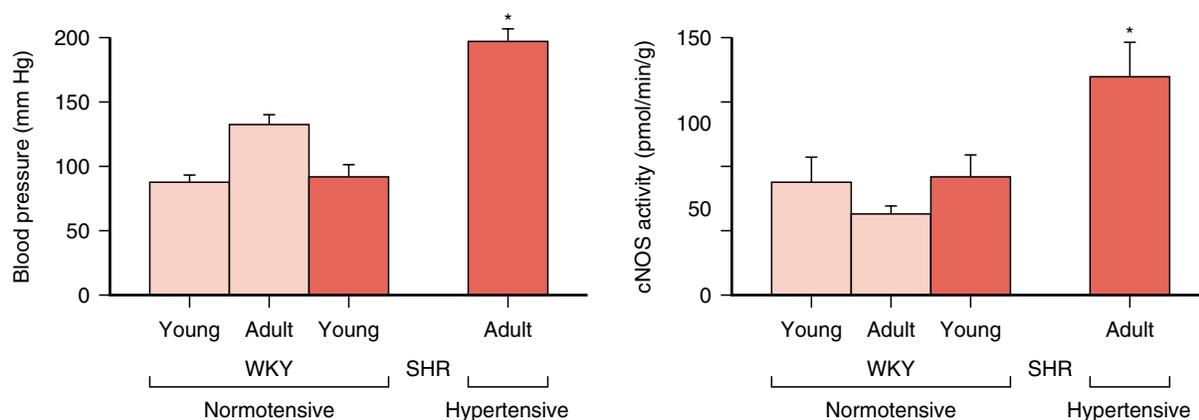

Figure 16-2 Increased activity of constitutive nitric oxide synthase (NOS) in cardiac endothelium of spontaneously hypertensive rats (SHR; black bars). Adult SHR possess a higher activity of constitutive NOS than their normotensive counterparts (Wistar-Kyoto rats, WKY; open bars). Very young prehypertensive SHR have, in contrast, lower constitutive NOS activity than the normotensive, indicating that the increased activity of NOS in adult SHR is indeed related to hypertension. (Modified from Nava E, Noll G, Lüscher TF. Increased activity of constitutive nitric oxide synthase in cardiac endothelium in spontaneous hypertension. *Circulation* 91:2310-2313, 1995.)

a mitochondrial enzyme of the respiratory chain, seems to be a major source of O_2^- .⁶² Expression of NAD(P)H oxidase in human coronary artery smooth muscle cells is up-regulated by pulsatile stretch, generating increased oxidative stress.⁶³ Another source of O_2^- is cyclooxygenase (COX).⁶⁴ In contrast, xanthine oxidase, another generator of superoxide anions, does not appear to play a significant role in essential hypertension.^{63,65}

Paradoxically, NOS (i.e., the NO-generating enzyme) can also produce O_2^- .⁶⁶⁻⁶⁸ Production of O_2^- in SHR-sp, an experimental model of genetic hypertension, can be prevented by NOS inhibition.⁶⁸ Administration of exogenous tetrahydrobiopterin (BH_4), an essential cofactor for NOS, can reduce excess O_2^- in the aorta of SHR-sp (see Figure 16-6).⁶⁸ In prehypertensive SHR, the calcium ionophore A23187-stimulated -

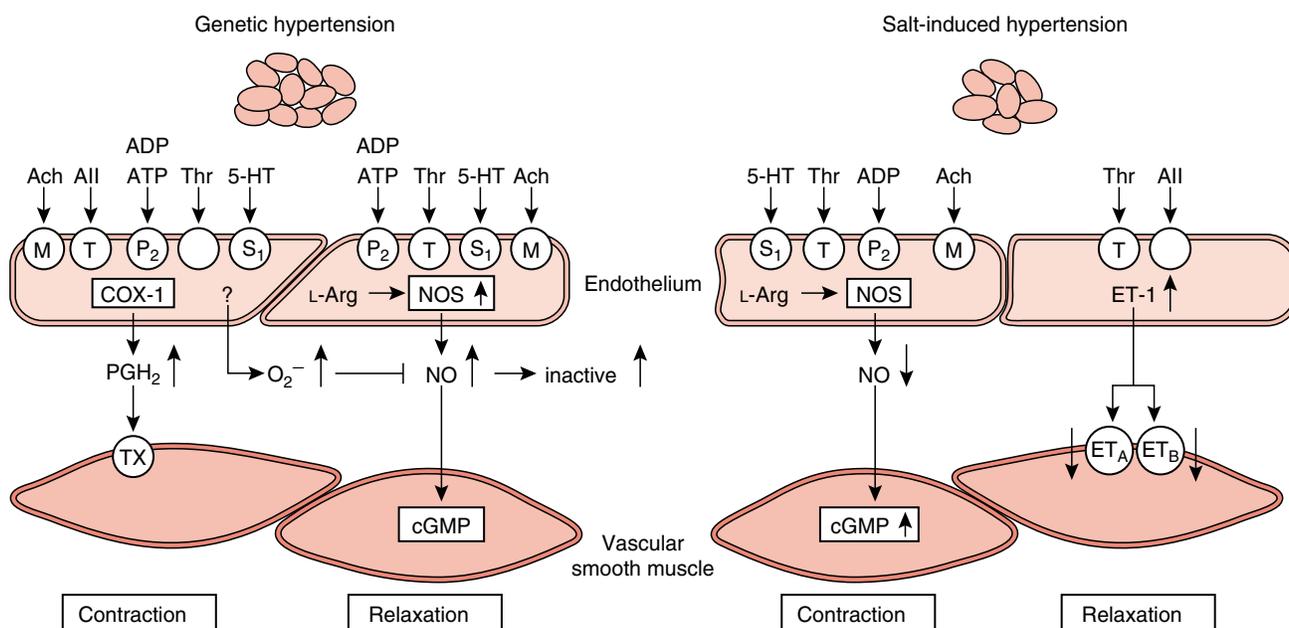

Figure 16-3 Heterogeneity of endothelial dysfunction in experimental hypertension. In spontaneous hypertension (left panel) nitric oxide synthase (NOS) is up-regulated and nitric oxide (NO) is inactivated by superoxide anions (O_2^-). In addition, the production of thromboxane (TXA_2) and prostaglandin H₂ (PGH₂) is increased. In salt-related hypertension (right panel) NO production is reduced and the endothelin (ET) system is up-regulated. ACE, angiotensin-converting enzyme; ACh, acetylcholine; All, angiotensin II; AT₁, angiotensin 1 receptor; cGMP, cyclic guanosine monophosphate; COX, cyclooxygenase; ET_A and ET_B, endothelin A and B receptor; ET-1, endothelin-1; L-Arg, L-arginine; M, muscarinic receptor; O_2^- , superoxide anion; PGI₂, prostacyclin; S, serotonergic receptor; T, thrombin receptor; Thr, thrombin; TX, thromboxane receptor; 5-HT, 5-hydroxytryptamine (serotonin). (Modified from Spieker LE, Noll G, Ruschitzka FT, et al. Working under pressure: The vascular endothelium in arterial hypertension. *J Hum Hypertens* 14:617-630, 2000.)

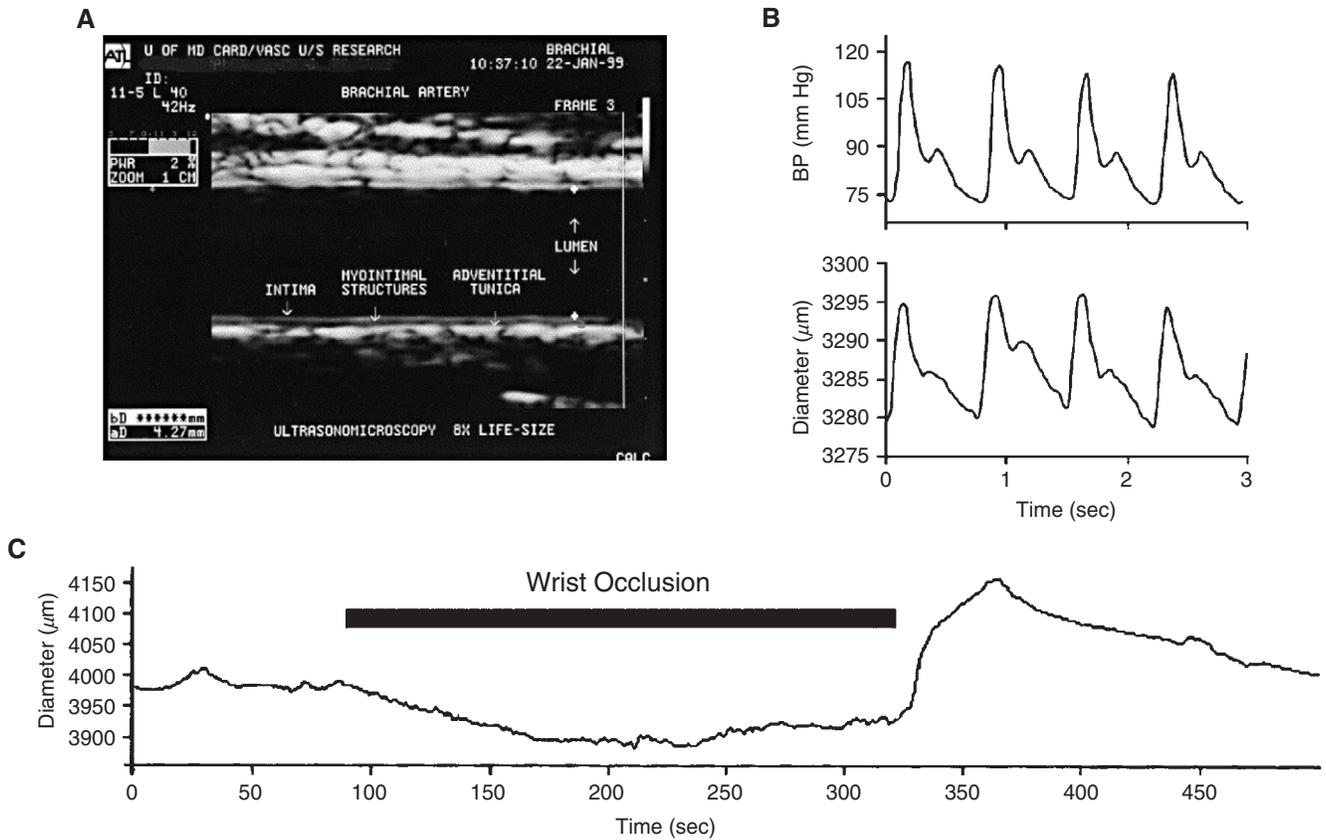

Figure 16-4 Flow-mediated vasodilation of the brachial artery is measured by high-resolution ultrasonography (A). With the use of echo-tracking, arterial diameter can be measured on a beat-to-beat base (B). After establishing stable baseline conditions, flow-mediated vasodilation is measured after release of a blood pressure cuff placed around the wrist and inflated to suprasystolic pressure for 5 minutes (C). The resulting hyperemic blood flow to the hand after release of the wrist cuff leads to a more or less pronounced vasodilation of the brachial artery, which is mediated by endothelium-derived nitric oxide (NO).

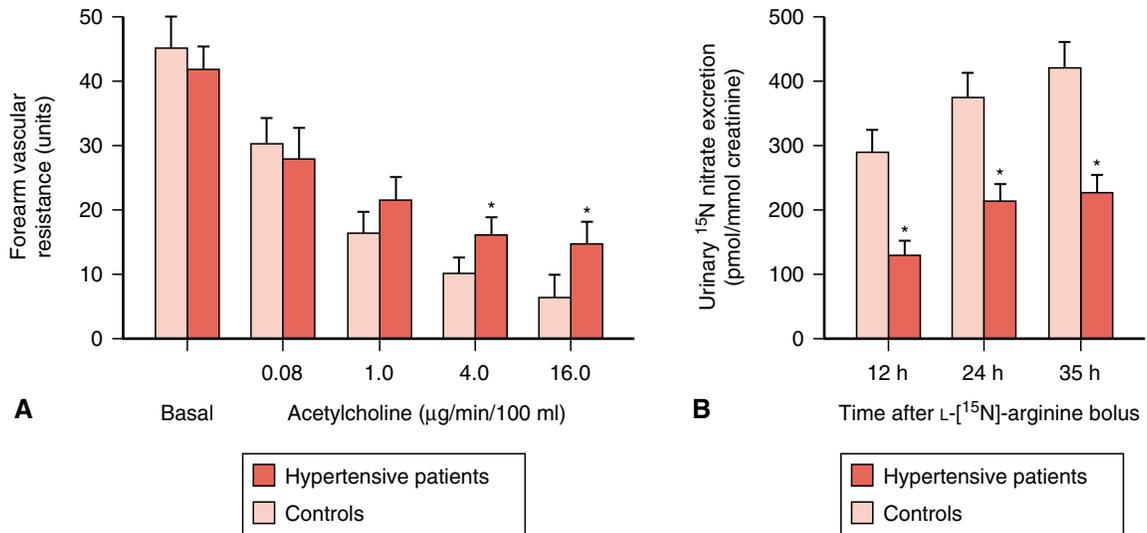

Figure 16-5 Endothelial dysfunction in arterial hypertension. (A) Patients with hypertension exhibit decreased endothelium-dependent vasodilation in response to acetylcholine compared with normotensive controls. (B) Cumulative urinary excretion of ¹⁵N nitrate after administration of ¹⁵N-labeled arginine (i.e., the substrate for enzymatic production of nitric oxide [NO]). Urinary excretion of the metabolic oxidation product of NO, nitrate, is reduced in hypertensive patients compared with normotensive controls. These data show that whole-body NO production in patients with essential hypertension is diminished under basal conditions. (A modified from Linder L, Kiowski W, Bühler FR, et al. Indirect evidence for release of endothelium-derived relaxing factor in human forearm circulation in vivo: Blunted response in essential hypertension. *Circulation* 81:1762-1767, 1990. B modified from Forte P, Copland M, Smith LM, et al. Basal nitric oxide synthesis in essential hypertension. *Lancet* 349:837-842, 1997.)

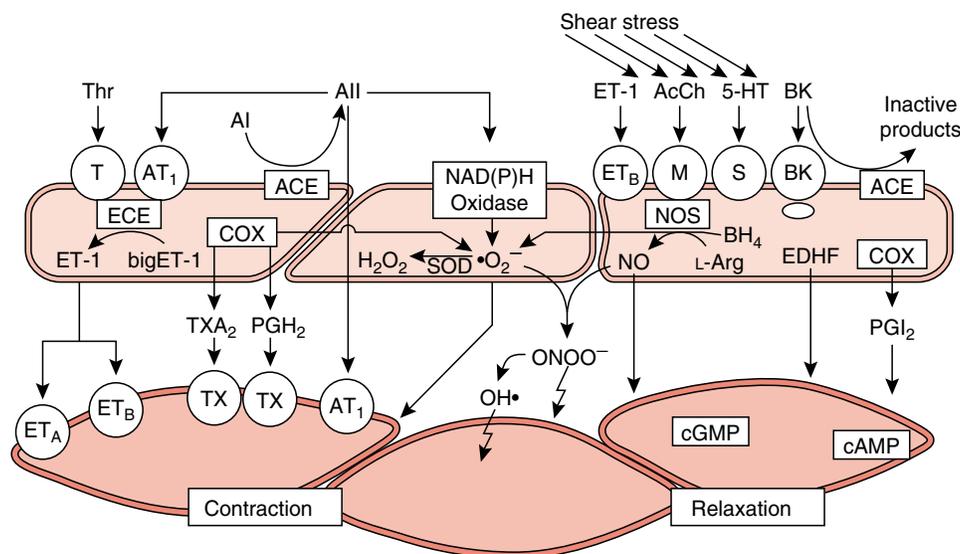

Figure 16-6 Role of oxidative stress in the pathogenesis of endothelial dysfunction in hypertension. Superoxide anion ($\cdot\text{O}_2^-$), generated by angiotensin II-activated NAD(P)H oxidase, by dysfunctional nitric oxide synthase (NOS), and by cyclooxygenase (COX), can scavenge the vasodilator NO to form the highly reactive peroxynitrite. Peroxynitrite can damage cell membranes and oxidize lipids. In addition, $\cdot\text{O}_2^-$ can act as a vasoconstrictor. ACE, angiotensin-converting enzyme; ACh, acetylcholine; All, angiotensin II; AT₁, angiotensin 1 receptor; BH₄, tetrahydrobiopterin; BK, bradykinin; COX, cyclooxygenase; ECE, endothelin-converting enzyme; EDHF, endothelium-derived hyperpolarizing factor; ET_A and ET_B, endothelin A and B receptor; ET-1, endothelin-1; H₂O₂, hydrogen peroxide; L-Arg, L-arginine; NAD(P)H oxidase, nicotinamide adenine dinucleotide oxidase; $\cdot\text{O}_2^-$, superoxide anion; OH \cdot , hydroxyl radical; ONOO $^-$, peroxynitrite; PGH₂, prostaglandin H₂; PGI₂, prostacyclin; S, serotonergic receptor; SOD, superoxide dismutase; Thr, thrombin; TXA, thromboxane receptor; TXA₂, thromboxane; 5-HT, 5-hydroxytryptamine (serotonin). (Modified from Spieker LE, Noll G, Ruschitzka FT, et al. Working under pressure: The vascular endothelium in arterial hypertension. *J Hum Hypertens* 14:617-630, 2000.)

(i.e., a receptor-independent activator of NOS) production of O_2^- was significantly higher than in control rats. NO release was reduced in SHR aortas, with opposite results in the presence of exogenous BH₄. Thus, dysfunctional eNOS may be a source of O_2^- in prehypertensive SHR and contribute to the development of hypertension and its vascular complications.^{66,69}

O_2^- is finally detoxified by superoxide dismutase (SOD), forming H₂O₂, which is further metabolized by catalase.⁷⁰ However, the reaction between the two radicals O_2^- and NO is three times faster than the detoxification of O_2^- by SOD.⁷¹ Depending on the relative concentrations of NO and SOD, there may be a propensity for O_2^- to preferentially react with NO, resulting in decreased bioavailability of NO.

The gene for cytosolic SOD (i.e., SOD1) is located on the 21q22.1 region of chromosome 21.⁷² Therefore, patients with Down syndrome (trisomy 21) have an extra copy of the SOD gene. Because of gene dosage excess, their SOD activity is 50% greater than in the diploid population, leading to reduced O_2^- levels.⁷³ Indeed, patients with Down syndrome have lower blood pressure levels, indicating a major role for O_2^- in the regulation of arterial blood pressure. Furthermore, the normal age-associated increase of blood pressure is absent in patients with Down syndrome.⁷⁴

Interactions between Nitric Oxide, Angiotensin II, and Superoxide Anions

The renin-angiotensin system plays a major role in hypertension (see Figure 16-1).⁷⁵ Apart from direct vasoconstrictor

effects of angiotensin II (Ang II), there are important interactions between Ang II, oxygen radicals, and NO.

Ang II stimulates generation of O_2^- by increasing the expression of the NAD(P)H oxidase gene (p22phox) and increasing the activity of NAD(P)H oxidase.⁷⁶⁻⁷⁹ The vasoconstrictor effect of Ang II is enhanced in the absence of NO, and diminished during coinfusion of the antioxidant vitamin C.⁸⁰ Thus, the vasoconstrictive effect of Ang II is modulated by reactive oxygen species, mainly O_2^- , and their interaction with endothelium-derived NO (see Figure 16-6). Furthermore, Ang II increases the production of endothelin (ET) in the blood vessel wall, which exerts vasoconstriction and induces proliferation of the vascular smooth muscle cells.⁸¹

NITRIC OXIDE AND PROSTAGLANDINS

Prostacyclin (PGI₂) is an endothelium-derived relaxing factor, which is released in response to shear stress (see Figure 16-1).^{3,82-84} PGI₂ is synthesized by COX from arachidonic acid.⁸⁵ PGI₂ increases intracellular cyclic adenosine monophosphate (cAMP) in smooth muscle cells and platelets. In contrast to NO, PGI₂ does not contribute to the maintenance of basal vascular tone of large conduit arteries.⁸⁶ Instead, its platelet inhibitory effects are most important. The synergistic effect of both PGI₂ and NO enhances their antiplatelet activity.⁸⁷ A novel interesting concept in atherosclerosis is selective inhibition of COX-2, which lowers CRP levels and improves endothelial function.⁸⁸

Depending on the animal model of hypertension and the vascular bed, endothelium-dependent contractions to acetylcholine, a muscarinic receptor-dependent stimulator of NO synthesis, have been documented (see Figure 16–3). Because this response is inhibited by COX inhibitors and thromboxane receptor antagonists, the most likely contractile factors are thromboxane A_2 and prostaglandin H_2 .^{89,90}

Interactions between COX products and NO have been demonstrated.⁹¹ In hypertensive patients, indomethacin, a COX inhibitor, significantly increased the response to acetylcholine, an effect that could be blocked by coinfusion of L-NMMA, an inhibitor of NO synthesis.⁹² Therefore, COX inhibition restores NO-mediated vasodilation in essential hypertension, suggesting that COX-dependent substances can impair NO bioavailability. COX is indeed a source of the NO-scavenger O_2^- .⁶⁴

NITRIC OXIDE AND ENDOTHELIUM-DERIVED HYPERPOLARIZING FACTOR

Inhibitors of the L-arginine pathway do not prevent all endothelium-dependent relaxations.⁹³ Because vascular smooth muscle cells become hyperpolarized under these conditions, an endothelium-dependent hyperpolarizing factor (EDHF) of unknown chemical structure has been proposed (see Figure 16–1).^{94,95} There is evidence that a calcium-dependent potassium channel on endothelial or smooth muscle cells is important in mediating endothelium-dependent hyperpolarization, a mechanism that is impaired in arterial hypertension.^{96–98} Endothelium-dependent hyperpolarization may also be involved in the compensation for the impaired NO-system in patients with essential hypertension.^{99,100}

INTERACTIONS BETWEEN NITRIC OXIDE AND ENDOTHELIN

More than a decade ago, a novel vasoconstrictor peptide synthesized by vascular endothelial cells was identified.^{101,102} The family of ETs consists of three closely related peptides—ET-1, ET-2, and ET-3—which are converted by endothelin-converting enzymes (ECE) from “big endothelins” originating from large preproendothelin peptides cleaved by endopeptidases.^{103–107} The ET peptides are synthesized not only in vascular endothelial and smooth muscle cells, but also in neural, renal, and pulmonary cells, and some leukocytes.^{108,109} The chemical structure of the endothelins is closely related to neurotoxins (sarafotoxins) produced by scorpions and snakes.^{110–112} Factors modulating the expression of ET-1 include shear-stress, epinephrine, Ang II, thrombin, inflammatory cytokines (tumor necrosis factor α , interleukin-1, and interleukin-2), transforming growth factor β , and hypoxia.^{113–125} ET-1 is metabolized by a neutral endopeptidase, which also cleaves natriuretic peptides.^{126,127}

Imbalance of endothelium-derived relaxing and contracting substances disturbs the normal function of the vascular endothelium.^{1,128} Endothelin acts as the natural counterpart to endothelium-derived NO, which exerts vasodilating, antithrombotic, and antiproliferative effects, and inhibits leukocyte-adhesion to the vascular wall.¹¹³ In addition to its pressor effect in humans,^{129,130} ET-1 induces vascular and

myocardial hypertrophy,^{131–133} independent risk factors for cardiovascular morbidity and mortality.^{134–136} In patients with essential hypertension, carotid wall thickening and left ventricular mass correlate with reduced endothelium-dependent vasodilation.^{137,138}

ET-1 has a paracrine rather than an endocrine mode of action, which is reflected by plasma levels of ET-1 in the picomolar range.^{139,140} Infusion of an ET receptor antagonist into the brachial artery or systemically in healthy humans leads to vasodilation, indicating a role of ET-1 in the maintenance of basal vascular tone.^{141,142} When ET-1 is infused, vasoconstriction follows a brief phase of vasodilation, which may be explained by relaxation of smooth muscle cells caused by ET_B receptor-mediated release of the vasodilators NO and PGI₂ (see Figure 16–1). Additionally, ET-1 may also exert effects on the central and autonomic nervous systems and alter baroreflex function.^{143–154} In the kidney, sodium reabsorption is modulated.¹⁵⁵

The ET system is activated in several but not all animal models of arterial hypertension.^{132,156–165} ET plasma levels have been reported to be elevated in certain patients with essential hypertension,¹⁶⁶ but this is a subject of controversy.^{53,167} The causal role of ET-1 in the pathogenesis of hypertension thus remains unclear.¹⁶⁸

Because most ET-1 synthesized in endothelial cells is secreted abluminally, it might attain a higher concentration in the vessel wall than in plasma. Indeed, significant correlations between the amount of immunoreactive ET-1 in the tunica media and blood pressure, total serum cholesterol, and number of atherosclerotic sites have been found.¹⁶⁹ In blood vessels of healthy controls, ET-1 was detectable almost exclusively in endothelial cells, whereas in patients with coronary artery disease and/or arterial hypertension, sizable amounts of ET-1 were detectable in the tunica media of different types of arteries.¹⁶⁹ Furthermore, there is evidence that certain gene polymorphisms of ET-1 and ET receptors can be associated with blood pressure.^{170–173} Moreover, in hypertensive patients, TAK-044, a mixed ET_{A/B} receptor antagonist, caused a significantly greater vasodilation than in normotensive subjects.⁵³ Because in this study, plasma levels of ET-1 were similar in normotensive and hypertensive patients, increased sensitivity to endogenous ET-1 in hypertension has to be postulated. Decreased bioavailability of NO may be involved in this phenomenon, because NO antagonizes some of the effects of ET-1.

EFFECTS OF ANTIHYPERTENSIVE THERAPY ON NO BIOAVAILABILITY IN HYPERTENSIVE PATIENTS

In hypertensive animals, most classes of antihypertensive drugs (e.g., calcium-channel blockers, ACE inhibitors, AT₁ receptor antagonists) improve endothelium-dependent vasodilation.^{99,174–180} Surprisingly and in contrast to animal experiments, antihypertensive therapy cannot consistently restore impaired endothelium-dependent vasodilation in patients with arterial hypertension.^{36–46,181} However, depending on the antihypertensive drug and its pharmacologic profile, improvements in endothelium-dependent vasodilation can be achieved (Table 16–2).^{38,40,42,182–192} The multifactorial etiology of essential hypertension as well as the duration of blood pressure elevation may explain certain inconsistent results of different investigators.^{193,194}

*This effect was paralleled by an enhanced endothelium-independent vasodilation to dosium nitroprusside.

Ang II, angiotensin II; ACE, angiotensin-converting enzyme; ACh, acetylcholine; Bk, bradykinin; Ca, calcium; L-NMMA, N^G-monomethyl-L-arginine; MCh, methacholine; NO, nitric oxide.

In addition to certain ACE inhibitors, several calcium channel blocking agents were successful in improving endothelial function in human hypertension (see Table 16-2). Antioxidant properties of an antihypertensive drug are important, because oxidative stress plays a central role in the pathophysiology of human hypertension. Endothelial function of patients with hypertension is improved by ascorbic acid, an antioxidant vitamin, which restores the imbalance of increased NO decomposition by superoxide.¹⁹⁵ Scavenging of reactive oxygen species by antioxidants may become an important therapeutic strategy,^{19,196} because chronic treat-

ment with vitamin C is in fact able to lower blood pressure in patients with hypertension.¹⁹⁷

Treatment with candesartan, an AT₁-receptor antagonist, reduced the vasodilator response to the mixed ET_{A/B}-receptor antagonist TAK-044 that was initially more pronounced in hypertensive patients than in normotensive controls.¹⁸⁷ This was paralleled by a reduction in circulating plasma ET-1 levels. Furthermore, the impaired vasoconstrictor response to L-NMMA, an inhibitor of NO synthesis, was augmented by antihypertensive treatment in hypertensives. Thus, the Ang II receptor blocker candesartan improves tonic NO release and

reduces vasoconstriction to endogenous ET-1 in the forearm of hypertensive patients.

Interestingly, infusion of nebivolol, but not other β -blockers, intraarterially in the forearm of healthy subjects is associated with an increase in forearm blood flow.¹⁹⁸ The increase in forearm blood flow achieved by nebivolol can be prevented by coinfusion of the NO synthesis inhibitor L-NMMA. Similar results have been obtained in the human venous circulation.¹⁹⁹ This strongly suggests that nebivolol stimulates the formation of NO in the vasculature and may therefore have an interesting hemodynamic profile, which leads—unlike other β -blockers—to peripheral vasodilation in addition to the classical β -blocking effects on the sympathetic nervous system, heart rate, and cardiac contractility.^{200,201} Nebivolol also causes NO-dependent vasodilation in hypertensive patients.¹⁸⁸ It is currently not known if this favorable effect persists during chronic treatment with this new type of β_1 -blocker.

The effects of newer antihypertensive agents (e.g., ET receptor antagonists, ECE inhibitors, and inhibitors of neutral endopeptidases cleaving natriuretic peptides) on endothelial function in hypertension remain to be elucidated.

SUMMARY

The vascular endothelium, by synthesizing and releasing vasoactive substances, plays a crucial role in the pathogenesis of hypertension. Because of its position between intraarterial pressure and smooth muscle cells responsible for peripheral resistance, the endothelium is thought to be both victim and offender in arterial hypertension. The delicate balance of endothelium-derived factors, which is disturbed in hypertension, can be restored by specific antihypertensive and antioxidant treatment.

Endothelin in Hypertension

John A. Schirger, Guido Boerrigter, and John C. Burnett, Jr.

The endothelin (ET) system has been the focus of much attention in recent years, and excellent reviews are available.¹⁻⁴ In this chapter we provide an overview of the ET system before focusing on it in hypertension and its major complication, heart failure. We also provide a special emphasis on clinical trials.

The vascular endothelium is an important source of vasodilating and vasoconstricting factors (Figure 17-1). One of these vasoconstricting factors is ET-1, the most-potent human vasoconstrictor identified so far,⁵ which opposes, for example, the vasodilating actions of nitric oxide (NO) and the C-type (vascular) natriuretic peptide CNP. The ET system includes three 21-amino acid peptide hormones—ET-1, ET-2, and ET-3—with ET-1 playing the prominent role in the cardiovascular system. ET is not stored in vesicles, and its secretion is primarily regulated at the level of synthesis. The final step in the biosynthesis is cleavage of ET from its precursor big-ET by an endothelin-converting enzyme (ECE). Stimuli for ET secretion include intraarterial pressure, low shear stress, angiotensin II (Ang II), vasopressin, catecholamines, and transforming growth factor β . There are two ET receptor subtypes, ET-A and ET-B, which belong to the superfamily of transmembrane receptors linked with guanine-nucleotide binding (G) proteins. In the vasculature, ET vasoconstricts via ET-A and ET-B receptors on vascular smooth muscle cells (VSMCs), while activation of ET-B receptors on endothelial cells leads to vasodilation. Under physiologic conditions, ET-1 appears to act as an autocrine and paracrine factor rather than an endocrine hormone, with about 80% of ET secreted via the basal membrane. The ET system contributes to basal vascular tone, as pharmacologic ET receptor blockade lowers the mean arterial pressure (MAP) by about 10 mm Hg. Apart from its vasomotor actions, ET promotes VSMC proliferation and has been implicated in the pathogenesis of atherosclerosis.⁶ In addition to their presence in the vasculature, ETs and their receptors are present and function in various tissues (Figure 17-2).

Physiologic actions of ET include participation in the redistribution of tissue blood flow that occurs during physical exercise. In a rat model, ET-A receptor blockade attenuated the physiologic blood flow reduction to the internal organs, thus decreasing blood flow to active muscles during exercise.⁷ In addition, exercise training in rats led not only to improved cardiac function with physiologic hypertrophy but also to an increase in ET messenger ribonucleic acid (mRNA) expression.⁸ However, the same authors report that pathologic hypertrophy in spontaneously hypertensive rats is associated with an increase in ET mRNA expression, whereas exercise-induced physiologic hypertrophy in Wistar-Kyoto rats is not associated with alterations in ET mRNA.⁹ Subsequently we discuss in more depth the vascular, renal, myocardial, and humoral actions of ET.

BIOLOGIC ACTIONS OF ENDOTHELIN

Vascular Actions

Vasoconstriction, with an increase in arterial pressure, is the most central action of ET. In the key study by Yanagisawa, bolus administration of ET in the rat produced a marked sustained hypertensive response.⁵ In isolated porcine coronary arteries, ET produced a dose-dependent and sustained vasoconstriction. In other animal preparations, exogenous ET produced marked increases in systemic and regional vascular resistances, with decreases in cardiac output—the latter thought to be related, in part, to myocardial ischemia secondary to intense coronary vasoconstriction.^{6,10} ET was even more constricting in isolated veins as compared with arteries, in part secondary to the reduced presence of NO in veins.¹¹

The role of ET as a vasoconstrictor and regulator of arterial pressure has been demonstrated in studies in which the ET gene was transferred by adenoviral gene delivery into normal rats.¹² ET gene transfer resulted in an increase in arterial pressure that could be reversed by ET receptor blockade. These vasoconstrictor responses have not been limited to animal models or tissues. Administration of ET or big ET to normal humans has produced potent and reversible vasoconstrictor responses.¹³ Infusion of exogenous ET has been reported to produce significant coronary vasoconstriction in humans, supporting a role for ET as an important potential mediator of myocardial ischemia in states of ET activation. Such vasoconstricting actions may be most important in the presence of a deficiency of counter regulatory humoral factors such as NO and CNP, as in some forms of hypertension. Thus the vasoconstricting action of ET *in vivo* probably reflects not simply a direct action of ET but rather an imbalance between ET, NO, and CNP. This concept has been underscored by the report that inhibition of NO *in vivo* markedly potentiates the coronary, renal, pulmonary, and systemic vasoconstricting and hypertensive responses to exogenous ET administered at pathophysiologic concentrations.¹⁴

Growth of the vascular wall in states such as hypertension has been thought to be due in part to ET.¹⁵ This effect on vascular remodeling is most evident in isolated VSMCs and can be reversed by ET receptor blockade or by counterregulatory humoral factors such as atrial natriuretic peptide (ANP) or CNP.

Renal Actions

The kidney has emerged as central in the biology of ET. Studies have clearly demonstrated that the renal circulation may be more sensitive than others in vasoconstrictor responsiveness to ET. Administration of ET at concentrations that mimic those observed in pathophysiologic states results in renal vasoconstriction in association with a decrease in

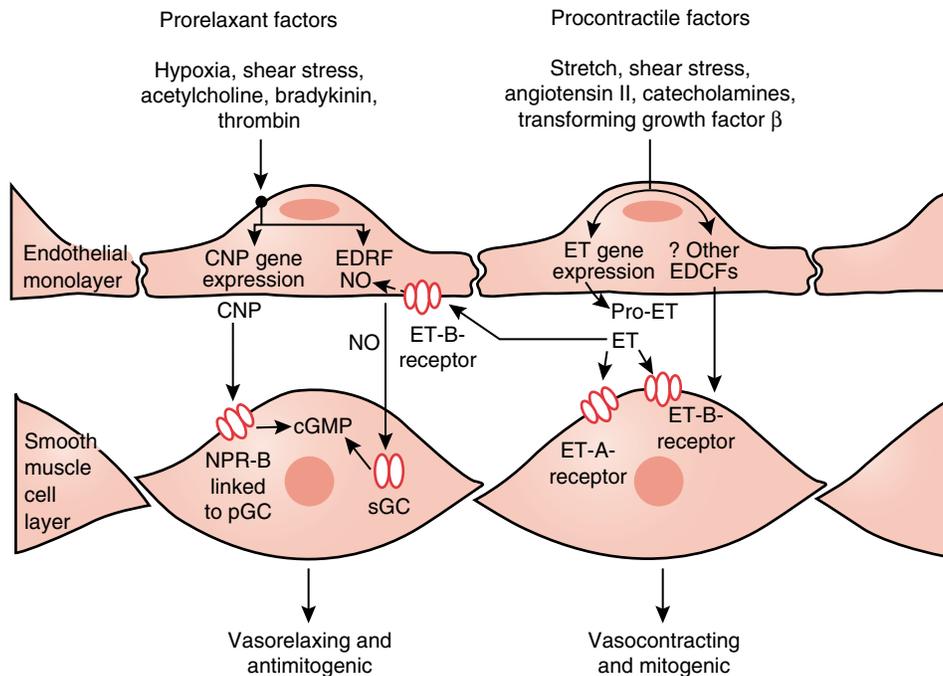

Figure 17-1 Schematic diagram of endothelial and vascular smooth muscle cells with vasorelaxing (left) and vasoconstricting (right) factors. Figure 17-2 Twenty-one amino acid sequence of endothelin-1 and major ET-A and ET-B receptor-mediated biologic actions.

sodium excretion.¹⁶ These studies are complemented by evidence that ET administration to normal humans produces renal vasoconstriction and sodium retention.¹⁷ It is important to note, however, that although the renal actions of exogenously administered ET in dogs and humans appear to be mediated by the ET-A receptor (see section Endothelin

Receptors), and ET-A receptor antagonism may attenuate decreases in urinary sodium excretion and glomerular filtration rate (GFR) in the normal dog,¹⁸ administration of an ET-A receptor antagonist in a model of canine congestive heart failure (CHF) results in sustained sodium retention without changing GFR (see discussion of congestive heart failure).¹⁹

These important renal actions of ET in humans and experimental animals have prompted studies to determine whether ET has a role in renal disease. Such a role is supported by increased renal production of ET in disease models such as acute and chronic renal failure (CRF), as well as by reports of increased urinary ET in models of renal transplant rejection and contrast nephropathy.^{20,21} Thus ET is an important modulator of renal function and may participate in the pathophysiology of renal diseases that are associated with elevations in arterial pressure.

Myocardial Actions

Another important target for ET is the heart. ET has been reported to have positive inotropic actions in isolated cardiomyocytes and in the intact heart.²² Although this effect may be offset by coronary vasoconstriction and myocardial ischemia, the autocrine/paracrine action of endogenous ET may augment myocardial contractility. In an animal model of CHF with increased expression of ET, ET-A receptor blockade results in improved cardiac relaxation.^{10,23}

ET may also have growth-promoting effects on ventricular myocytes and cardiac fibroblasts. In an animal model of ventricular hypertrophy produced by pressure overload of the left ventricle, blockade of ET attenuated ventricular hypertrophy independent of any reduction in cardiac afterload.²⁴ In isolated cardiac fibroblasts, ET receptors are expressed and may be activated by other humoral factors such as Ang II. Once activated, ET may serve as a mediator for production of collagen and thus induce cardiac fibrosis and impair myocardial relaxation.²⁵

It is well established that ET is synthesized in cardiac myocytes and fibroblasts as well as endothelial cells, and it has been reported that ET mediates Ang II-induced myocyte hypertrophy and fibroblast proliferation.^{26,27} Also, ET directly stimulates collagen synthesis through the ET-A receptor in adult rat cardiac fibroblasts.²⁸ ET is reported to reduce matrix metalloproteinase (MMP)-1 (interstitial collagenase) in skin fibroblasts and in adult rat cardiac fibroblasts²⁹ and to decrease MMP-2 in rat mesangial cells and in adult canine cardiac fibroblasts.³⁰ Similar to data for Ang II, these data suggest that ET stimulates myocardial fibrosis, not only by enhancing collagen synthesis, but also by diminishing MMP activity. Interestingly, Fernandez-Patron et al.³¹ reported that MMP-2 cleaved big ET-1 to produce mature ET, suggesting an interaction between the MMP system and ET in the regulation of vascular reactivity.

We have investigated the crosstalk between cardiotrophin 1 (CT-1) and the ET system. CT-1 is a potent hypertrophic factor in cardiomyocytes and signals through the glycoprotein 130/leukemia inhibitory factor (gp130/LIF) receptor complex.^{32,33} We have elucidated in canine cardiac fibroblasts an interaction between the CT-1/gp130/LIF receptor complex and the ET/ET-A receptor axis in regulatory DNA synthesis.²⁵ ET, derived from cardiac fibroblasts, has been known to mediate a hypertrophic response via the ET-A receptor in cardiomyocytes.²⁶ In addition, CT-1 and ET share a common signal transduction system, which includes mitogen-activated protein kinase activation.³² Saito et al. have reported that ANP- and β -major histocompatibility complex-luciferase activation by ET was inhibited when cardiomyocytes were transfected with a dominant negative mutant of gp130.³⁴ We hypothesized that CT-1 activation of DNA synthesis in the cardiac fibroblast

would be modulated by ET via the ET-A receptor. This was confirmed by the findings that the specific ET-A receptor antagonist, BQ-123, inhibited not only ET-stimulated but also CT-1-stimulated DNA synthesis. Conversely, pretreatment with antibodies for the gp130/LIF receptor abolished the action of ET. We also demonstrated that ET stimulates the translocation of the LIF receptor from the cytosol to the cell surface. Our data suggest that an interaction between the CT-1/gp130/LIF receptor and ET/ET-A receptor occurs in cardiac fibroblasts and that crosstalk between these two systems may be of importance in cardiac fibroblast activation and cardiac remodeling.

Humoral Actions

ET has key interactions with other neurohumoral systems. ET interacts importantly with NO via activation of the ET-B receptor (see later section), which is expressed primarily in vascular endothelium. ET thus releases NO, underscoring the unique balance between these two humoral pathways that mediate divergent actions on underlying vascular smooth muscle. ET also releases other vasodilating humoral factors of endothelial cell origin, such as CNP and adrenomedullin.^{35,36} In addition, the production and release of ANP are linked to ET.

An important synergism exists between Ang II and ET. Ang II may enhance the vascular responsiveness to a given concentration of ET. Studies have also demonstrated that many of the myocardial actions of Ang II may occur via ET.³⁷ Ang II-mediated myocardial hypertrophy may involve activation of an ET receptor subtype, activation of myocardial ET production, or both. Furthermore, Ang II is a potent stimulus for ET gene expression in isolated cultured cardiac fibroblasts,³⁸ and inhibition of Ang II generation may therefore inhibit the tissue activation of ET. We have reported that activation of circulating and tissue ET in a model of heart failure could be markedly attenuated by chronic angiotensin-converting enzyme (ACE) inhibition.³⁹ The latter observation supports the view that some of the actions of ACE inhibition occur through inhibition of ET synthesis.

An additional key action of ET involves stimulation of the synthesis and release of aldosterone.⁴⁰ Studies in isolated zona glomerulosa cells have reported that ET is a potent activator of aldosterone synthesis.⁴¹ Both ET-A and ET-B receptors appear to be involved.⁴² The report that the aldosterone system coexists with ET in the heart, along with the known promoting effect of aldosterone on myocardial fibrosis, underscores the importance of exploring the emerging relationship between the ET system and aldosterone.

ENDOTHELIN RECEPTORS

The multiple biologic actions of ET are mediated by at least two receptor subtypes, ET-A and ET-B (Figure 17-3). The ET-A receptor is widely expressed and is the principal receptor for the ET system in vascular smooth muscle. The ET-A receptor has higher affinity for ET-1 than for ET-3. ET-A receptor activation results in vasoconstriction via activation of phospholipase C and an increase in intracellular calcium.⁴³ The ET-B receptor was initially thought to be expressed only in vascular endothelial cells and to release vasodilating substances such as NO and prostacyclin, as well as the newly identified vasodilating peptide adrenomedullin. More-recent studies have

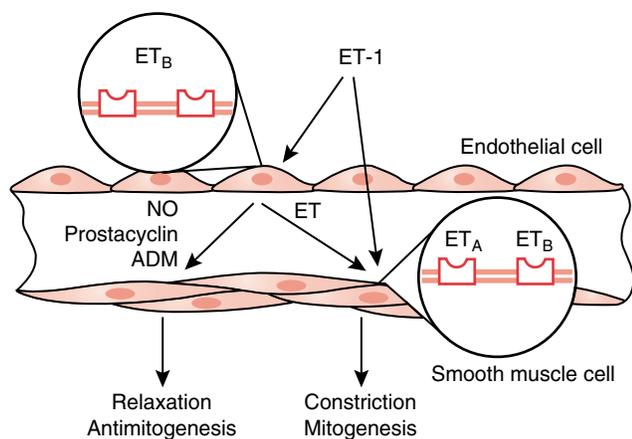

Figure 17-3 ET receptor subtypes. ET-B receptors on endothelial cells stimulate secretion of the vasorelaxing and antimitogenic factors nitric oxide (NO), prostacyclin, and adrenomedullin (ADM), as well as the vasoconstrictor endothelin. Both ET-A and ET-B receptors on vascular smooth muscle cells promote vasoconstriction and mitogenesis.

demonstrated expression of the ET-B receptor in other vascular tissues such as the aorta, pulmonary vasculature, and coronary circulation and that its expression may be upregulated in pathophysiologic states in which the endothelium is damaged.⁴⁴⁻⁴⁷ ET-B expression may be regulated by other humoral factors, such as Ang II.⁴⁸

In addition to mediating vasorelaxation through the release of endogenous vasodilators, a vasoconstricting role for ET-B receptor activation has been reported in vitro, and studies suggest that ET-B receptor blockade may be necessary to reverse all of the vasoconstricting actions of ET. ET-A receptor antagonism with the selective ET-A receptor antagonist BQ-123 has been shown in vitro to incompletely inhibit the actions of ET. Furthermore, Fukuroda et al. demonstrated that the combination of a selective ET-B antagonist, BQ-788, with BQ-123 produced a synergistic inhibition of ET-mediated vasoconstriction in vitro.⁴⁹ Leadly et al. demonstrated in normal dogs a vasoconstrictor response to low doses of the selective ET-B receptor agonist sarafotoxin S6c in vivo, with increases in peripheral but not renal vascular resistance.⁵⁰ In addition, Haynes et al. reported that selective ET-B receptor activation with sarafotoxin S6c resulted in significant vasoconstriction in the human forearm.⁵¹

ET-B receptor activation has both direct and indirect vasoconstricting actions, the latter by increasing endogenous ET secretion, resulting in ET-A receptor activation. In vitro studies demonstrate that activation of the ET-B receptor upregulates the preproET-1 gene, with increased ET secretion from cultured endothelial and mesangial cells and cardiac myocytes.⁵² This mechanism could account for ET-B receptor-mediated vasoconstriction via local activation of the ET-A receptor. Rasmussen et al. demonstrated that ET-B receptor activation with sarafotoxin S6c mediates systemic and pulmonary vasoconstriction, with decreases in cardiac output and SvO_2 .⁵³ Selective ET-A receptor blockade attenuated the systemic vasoconstrictor action of high-dose sarafotoxin S6c. In addition, dual ET-A and ET-B receptor antagonism attenuated the increases in systemic and pulmonary vascular resist-

ance and the decreases in cardiac output seen with S6c. These studies suggest a role for the ET-B receptor in promoting vasoconstriction, at least to some extent via the ET-A receptor, probably through increased endogenous ET production. However, although the potential cardiopulmonary protective properties of dual ET-A/ET-B receptor blockade may represent an important therapeutic strategy in states of ET activation, there remains concern that blockade of ET-B, which can also serve as a clearance receptor, could enhance circulating concentrations of ET during dual receptor inhibition.⁵⁴

ACTIVATION AND BLOCKADE OF THE ENDOTHELIN SYSTEM IN HYPERTENSION

Given the success of antagonizing vasoconstricting neurohormonal systems that are activated in cardiovascular disease, it seems reasonable to try to antagonize the ET system in hypertension and heart failure. Consequently, a multitude of ET blockers have been developed and tested (Table 17-1). From a theoretical perspective, three ways to antagonize ET actions appear promising: (1) combined/dual ET-A/ET-B receptor blockade, (2) selective ET-A receptor blockade, or (3) inhibition of the ECE.

The potent vasoconstricting and growth-promoting properties of ET have suggested a potential role for ET in the pathogenesis of systemic hypertension. Circulating ET is not usually increased in hypertension, and any observed elevations are small and usually related to renal dysfunction.⁵⁵ In contrast, circulating ET is markedly increased in humans with hemangioendothelioma or severe forms of transplant-related hypertension.^{56,57} Plasma ET is also increased in several models of experimental hypertension, including mineralocorticoid hypertension, the spontaneously hypertensive rat, and renovascular hypertension.^{58,59} The lack of increase of plasma ET in human essential hypertension could be explained by the paracrine/autocrine function of ET; that is, ET secretion from the endothelial cell is albuminally directed, thus increasing tissue and not circulating concentrations of ET.⁶⁰

Overexpression of ET-1 by gene transfer techniques has resulted in transient increases in plasma ET with associated hypertension.¹² Furthermore, ET synthesis has been shown to be increased in the vascular wall of the mineralocorticoid hypertensive rat.⁶¹ A correlation has been reported between the magnitude of vascular wall hypertrophy and ET gene expression in this model of hypertension. However, this positive correlation is offset by an attenuated vascular responsiveness to exogenous ET, suggesting receptor down-regulation.

In human hypertension, however, the vasoconstricting responsiveness to ET has been reported to be enhanced.⁶² ET infusion has been shown to result in an enhanced vasoconstrictor response in the hand veins of human hypertensives.⁶³ In contrast, no difference in the response to α receptor stimulation or in basal plasma ET concentration was observed between hypertensive and normotensive individuals in this study. Although some studies support a predominant role for the ET-A receptor in mediating the vasoconstrictor effects of ET-1 in hypertension, others report vasoconstriction mediated through the ET-B receptor in hypertension as well.⁶⁴ This may be due to a modification in the relative distribution of ET-B receptors on the endothelium and vascular smooth muscle in hypertension. Although the effect of ET-A activation appears straightforward,

Table 17-1 Endothelin Inhibitors

Drug Type	Peptide	Nonpeptide

the effect of ET-B receptor activation is more complex and quite controversial. As mentioned previously, some studies have shown that ET-B blockade in addition to ET-A blockade enhances vasodilation, whereas other studies have shown the opposite. Just et al. used different experimental strategies to elucidate the role of the ET-B receptor in the rat renal microcirculation and concluded that ET-B receptors when stimulated alone exert a net vasoconstrictor response but cause a net dilator influence when costimulated with ET-A receptors.⁶⁵ These findings suggest a complex interaction between the two receptor subtypes. The effect of ET-B activation/ET-B antagonism appears to be complex and to depend on factors such as species, vascular bed, pathophysiologic status, and experimental strategy. For that reason, absent large clinical trials comparing nonselective ET antagonists with selective ET-A antagonists, the controversy regarding which strategy would be more beneficial in hypertension will likely continue.

Hypertension in association with chronic kidney disease is common and may contribute to further renal damage, as well as to acceleration of atherosclerosis and ventricular dysfunction. ET concentration in blood vessels and glomeruli have been reported to be increased in experimental models of CRF.⁶⁶ Furthermore, ET receptor antagonists lower arterial pressure and reduce renal glomerular sclerosis and proteinuria in these models.⁶⁷

Goddard and colleagues have addressed the pathophysiologic significance of ET in the pathophysiology of CRF.⁶⁸ These investigators studied the systemic and renal hemodynamic effects of ET receptor antagonists in CRF, examining differences between ET-A versus selective ET-B and combined ET-A and ET-B receptor blockade. In this key randomized placebo-controlled crossover study, ET-A blockade alone and in combination with ET-B blockade reduced blood pressure in patients with CRF. This effect was greater with ET-A blockade alone (Figure 17-4). ET-A blockade significantly increased renal blood flow and reduced renal vascular resistance when administered alone but not when combined with ET-B blockade. These changes in renal hemodynamics were associated with a reduction in effective filtration fraction. In healthy controls, ET-A blockade alone or in combination with ET-B blockade had minimal effects

on renal hemodynamics. Furthermore, ET-B blockade alone produced systemic and renal vasoconstriction both in patients with CRF and in healthy controls. Thus, this study demonstrated that ET-A receptor antagonism was highly effective in decreasing blood pressure in CRF—findings also consistent with renal protection. Importantly, because ET-B appears to play a key role in the maintenance of renal blood flow, combined ET-A and ET-B receptor antagonism, although it results in a lowering of blood pressure, does not confer these renal protective actions.

Nonselective and selective ET receptor blockade have been evaluated in clinical trials in patients with systemic hypertension. The nonselective ET-A/ET-B antagonist bosentan (500 and 2000 mg daily) reduced diastolic and systolic blood pressure significantly as compared with placebo and to a similar degree as enalapril (20 mg once daily).⁶⁹ Bosentan, which has been approved for the treatment of pulmonary hypertension, is associated with considerable risk of liver toxicity, making it an unlikely first-line drug in systemic hypertension, for which many alternatives are available. The selective ET-A antagonist darusentan significantly reduced diastolic and systolic pressure as compared with placebo.⁷⁰ No increase in hepatic transaminases was observed. Importantly, both clinical trials had, as their primary endpoint, change in blood pressure, and the treatment periods were 4 and 6 weeks, respectively. Given the known effects of ET-1 on VSMC hypertrophy and proliferation, it would be important to see how long-term selective or nonselective ET antagonism compares with established antihypertensive drug treatment in preventing hypertension-related target organ damage. Important endpoints in addition to mortality include cardiac hypertrophy and heart failure, as well as stroke and myocardial infarction.

ENDOTHELIN IN CONGESTIVE HEART FAILURE

The ET system is clearly activated in both experimental and human CHF.⁷¹ Plasma ET correlates with the severity of CHF,⁷² and ET is known to promote vasoconstriction, as well as myocardial remodeling and fibrosis in CHF. These findings

Rights were not granted to include this figure in electronic media.

Figure 17-4 Mean systemic arterial pressure after endothelin receptor antagonism in healthy humans and patients with chronic renal failure. Values are given as mean placebo-corrected % change from baseline \pm standard error of measurement. Infusion of low-dose antagonist/placebo was done from 0-15 minutes; infusion of high-dose antagonist (10x low-dose)/placebo was done from 90-105 minutes. BQ-123, selective endothelin-A receptor antagonist, diamonds; BQ-788, selective endothelin-B receptor antagonist, triangle; BQ-123/BQ-788, circles. (From Goddard J, Johnston NR, Hand MF, et al. Endothelin-A receptor antagonism reduces blood pressure and increases renal blood flow in hypertensive patients with chronic renal failure. *Circulation* 109:1186-1193, 2004.)

have led to studies in experimental models of CHF that established hemodynamic improvements with ET receptor antagonism.^{73,74} Initial clinical studies also showed improved hemodynamic function with administration of ET receptor antagonists.^{75,76} The issue of whether nonselective or selective ET-A receptor antagonism is the best strategy to pursue is controversial. Although the ET-B receptor serves a clearance function and promotes vasorelaxation under physiologic conditions, under pathophysiologic conditions such as CHF, it promotes vasoconstriction and may activate other growth-promoting and vasoconstrictive factors. Nevertheless, studies with both selective and nonselective ET receptor antagonism showed hemodynamic improvement.

Disappointingly, clinical trials with both selective and nonselective ET receptor antagonism failed to show improvements in myocardial remodeling and, indeed, in one case showed an increase in congestive symptoms (see later). The reasons for this are not entirely clear, but a previous animal study showed that ET-A receptor antagonism in normal dogs results in increased sodium retention.¹⁸ We have carried out a series of studies that suggest mechanisms for these clinical findings.¹⁹ We first established that the ET system is activated early in the course of CHF. Specifically, at the transition to overt CHF as defined by the onset of sodium retention, the ET system is activated in both tissue and plasma in the absence of activation of Ang II or aldosterone (the renin-angiotensin-aldosterone system, RAAS). In a model of severe pacing-induced canine CHF, we defined the effects of chronic ET-A receptor antagonism initiated early in the progression of CHF on cardiac hemodynamics, neurohumoral function, and sodium homeostasis. We found that in addition to improving cardiac function and decreasing MAP, ET-A receptor blockade

resulted in sustained sodium retention and further activation of the RAAS (Figure 17-5). These findings suggest a mechanism for the increase in congestive symptoms noted in clinical trials with ET receptor antagonism. Carefully designed clinical trials that use dosing regimens different from those in the original studies may be warranted given the clear pathophysiologic role of ET in CHF.

Following are short summaries of studies with ET antagonists in experimental or human CHF. Several of these studies are available only as summaries from scientific meetings or as abstracts, because it is not uncommon that the results of negative trials are not published in full form.

Bosentan (RO 470203) is the best-developed ET-A/ET-B blocker and the only one to have been tested in a large clinical trial. Bosentan improved survival in a rat model of CHF when started 7 days after coronary artery ligation.⁷⁷ However, in a randomized placebo-controlled trial in 1613 patients with CHF (Endothelin Antagonist Bosentan for Lowering Cardiac Events in Heart Failure), bosentan did not improve mortality.⁷⁸ Bosentan was not different from placebo in the primary endpoints but was associated with worsening CHF caused by fluid retention, perhaps related to the renal mechanisms discussed in the preceding paragraph.

Tezosentan (RO 610612) was developed as an intravenous dual ET receptor antagonist for use in acute heart failure. Compared with placebo, tezosentan dose dependently increases cardiac index (CI) and decreases pulmonary capillary wedge pressure (PCWP) and pulmonary and systemic vascular resistance (PVR and SVR).⁷⁹ In the Randomized Intravenous Tezosentan (RITZ)-2 trial with 184 patients, tezosentan increased CI, decreased PCWP, and improved dyspnea score as compared with placebo.⁸⁰ In the symptom-

Figure 17-5 Urinary sodium excretion (UNaV) (left) and plasma renin activity (PRA) in control (open bar), untreated congestive heart failure (black bar), and congestive heart failure treated with LU 135252 (hatched bar). * $p < .05$ vs. control; † $p < .05$ vs. untreated. (From Schirger JA, Chen HH, Jougasaki M, et al. Endothelin A receptor antagonism in experimental congestive heart failure results in augmentation of the renin-angiotensin system and sustained sodium retention. *Circulation* 109:249-254, 2004.)

based RITZ-1 trial with 675 patients, tezosentan did not improve the primary endpoint (the patient's assessment of dyspnea after 24 hours). Furthermore, tezosentan did not change the combined secondary endpoint, time to death, or worsening symptoms of CHF. Likewise, mortality at 6 months was unchanged.

In the Enrasentan Cooperative Randomized Evaluation (ENCORE) trial, patients taking standard medication were randomized to enrasentan or placebo.⁸⁰ Enrasentan (SB 217242) treatment was associated with trends to worsening CHF, increased rate of withdrawal for adverse events, and excess mortality. Patients taking enrasentan were almost three times as likely to be hospitalized. In another randomized controlled trial, 72 patients with asymptomatic left ventricular dysfunction were randomized to enrasentan or the ACE inhibitor enalapril. Compared with enalapril, enrasentan increased CI significantly after 6 months of treatment; however, the primary endpoint, left ventricular end-diastolic volume index, was significantly increased, suggesting an adverse remodeling effect of enrasentan.⁸¹

Sakai et al. demonstrated that ET-A blockade with the peptide BQ-123 could improve long-term survival in a rat model of CHF.²⁴ In contrast, orally available darusentan (LU 135252) in a similar rat model did not improve survival. When given in combination with the ACE inhibitor trandolapril, there was no additional survival benefit as compared with trandolapril alone.⁸² There have been several human trials with selective ET-A blockers. Darusentan in addition to standard therapy was evaluated in 157 patients in the Heart Failure ET(A) Receptor Blockade Trial (HEAT).⁸³ ET-A blockade with darusentan for 3 weeks increased CI and decreased SVR without changes in MAP or PCWP. However, there was a worrisome trend for higher mortality and a higher percentage of patients with worsening CHF in the treatment group. This might be attributed in part to the fact that patients were immediately assigned to either 30, 100, or 300 mg of darusentan without careful up-titration. The Endothelin-A Receptor Antagonist Trial in Heart Failure (EARTH) evaluated the effect of darusentan in addition to standard medication over a 6-month period. Although darusentan administration was safe, no benefit was apparent

for the treatment group (European Society of Cardiology Meeting, 2002, Berlin, Anand IS and Luescher TF).

Givertz et al. studied the effect of acute intravenous administration of the selective ET-A receptor antagonist sitaxsentan (TBC 11251) in a randomized placebo-controlled trial in 48 patients with New York Heart Association classes III and IV CHF.⁸⁴ Sitaxsentan decreased PVR, mean and systolic pulmonary artery pressure, and right atrial pressure. Interestingly, heart rate, MAP, PCWP, CI, and SVR remained unchanged. As expected, sitaxsentan administration was associated with a decrease in circulating ET.

In summary, ET receptor antagonism in CHF has not been demonstrated to be widely safe or efficacious to date. A novel molecule has recently been introduced that inhibits both ECE and neutral endopeptidase 24.11 (NEP). NEP is an enzyme that degrades the natriuretic peptides as well as other vasoactive compounds such as ET. Selective NEP inhibitors were tested in the past to enhance the beneficial vasodilating and natriuretic actions of the natriuretic peptides, but in CHF trials NEP inhibitors were not superior to standard therapy, perhaps because of the simultaneous inhibition of ET degradation. As mentioned previously, ET antagonism in clinical trials appears to be associated with fluid retention. Therefore, combined NEP/ECE inhibition could combine the beneficial actions of both strategies while attenuating the negative effects. Mulder et al. reported that ECE-NEP inhibition in a rat model of CHF was associated with beneficial effects as compared with placebo and NEP inhibition alone,⁸⁵ whereas Dickstein et al. reported the beneficial hemodynamic effects of combined ECE-NEP inhibition with SLV306 in patients with CHF.⁸⁶ Further studies appear warranted to pursue the strategy of dual ECE-NEP inhibition in cardiovascular diseases.

SUMMARY

The lack of adequate antihypertensive treatment strategies underscores our lack of understanding of the mechanisms responsible for blood pressure elevation and its complications,

including stroke, myocardial infarction, and heart failure. A neurohumoral basis for hypertension is supported by studies of humans with hypertension, of their offspring, and of experimental models.

ET, a peptide primarily of endothelial origin, may play a role in the pathogenesis of hypertension. ET possesses many of the properties that result in increased arterial pressure as well as its multiorgan complications. The elevation of blood pressure with genetic overexpression of ET by gene transfer and the lowering of blood pressure with ET receptor antagonism in humans with essential hypertension and hypertension associated with CRF provide the rationale for examining the contribution of this peptide to these disease processes.

Natriuretic Peptides

Vito M. Campese, Mitra K. Nadim

Since the discovery by DeBold et al.¹ in 1981 that atrial extracts have potent natriuretic and vasodepressor activity, the natriuretic system has become known as a functionally important endocrine system of cardiovascular and renal origin that participates in the integrative control of their function. This led to the discovery of the atrial natriuretic peptide (ANP) and to the recognition of its importance in the regulation of sodium balance and blood pressure. Subsequently, four other natriuretic peptides, brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), dendroaspis natriuretic peptide (DNP), and urodilatin were discovered. Elevated plasma ANP levels have been reported in a variety of disease states associated with pathologic volume expansion such as congestive heart failure (CHF), chronic renal failure, and cirrhosis. It has been proposed that elevated ANP levels may represent a compensatory homeostatic response to chronic volume overload. The term *natriuretic peptides* has remained even though these peptides perform a multitude of functions besides natriuresis, including vasodilation, antiproliferative effects, vascular remodeling, and modulation of noradrenergic and the renin-angiotensin-aldosterone systems.

CHEMISTRY OF NATRIURETIC PEPTIDES

Five distinct natriuretic peptides have been recognized, and at least three are the products of separate genes and subject to independent regulation. The first to be identified was ANP, a 28-amino acid (AA) peptide synthesized and secreted by the atria.¹ ANP contains a 17-AA ring closed by a disulfide bond between two cysteine residues. The ANP gene in humans is located on the short arm of chromosome 1 and is composed of three exons separated by two introns with regulatory elements upstream of the coding sequence.² ANP is synthesized as a 151-AA prohormone (preproANP) and is stored in atrial myocytes as a 126-AA prohormone (proANP). When secreted, proANP is cleaved between AA 98 and 99 yielding an N-terminal moiety of 98-AA (N-ANP) and the biologically active C-terminal hormone (ANP) in equimolar amounts.³ ANP has a very short half-life (2.5 minutes), whereas N-ANP has a much longer half-life (approximately 21 minutes) in plasma. Thus the plasma concentration of N-ANP is approximately 50 times greater than that of ANP. The AA sequence of ANP is identical in most mammals studied, with the exception of rodents and rabbits, in which isoleucine replaces methionine at position 110.

BNP is a 32-AA peptide, structurally similar to ANP that retains the 17-AA ring structure. A single copy gene consisting of three exons and two introns, which is also located on chromosome 1, encodes human BNP. The gene regulation of BNP is completely different from that of ANP: ANP is

stored largely as proANP, whereas BNP is stored as the mature hormone in human and rat heart, and as proBNP in pig and sheep heart.⁴ In contrast to ANP, the structure of BNP shows marked interspecies variability. In humans, the mature circulating form consists of a 32-AA residue peptide and a higher-molecular-weight component, probably proBNP. Two precursor forms of relatively high molecular mass, preproBNP (134-AAs) and proBNP (108-AAs) have been identified in human cardiac tissue⁵ and plasma.⁶ In rats, the circulating mature form is a 45-AA residue peptide, whereas in pigs, two circulating forms have been identified. Because of interspecies variability in structure, it is not surprising that species-specific antisera are required for measurements of BNP in plasma, and actions of BNP differ among species.

The third peptide to be discovered was CNP.⁷ Human CNP consists of a precursor preproCNP of 126-AAs and a proCNP of 103-AAs, which is then processed to form two peptides, CNP-53 and CNP-22. CNP-22 is the only form that possesses substantial biologic activity.⁸ Among the natriuretic peptides, CNP has the highest AA identity between species. Human CNP-53 has two AA substitutions as compared with the porcine and rat CNP-53, whereas human CNP-22 is identical to the porcine and rat CNP-22.⁸ Structures of CNP-22 and proCNP appear to be identical in all mammalian species studied. CNP shares the 17-AA ring configuration, which is essential for biologic activity, with ANP and BNP, but lacks the carboxy terminal extension. The CNP gene is located on human chromosome 2.⁹ It also has three exons, although the coding region of preproCNP is encoded within the first two. The regulatory mechanisms for the transcription of the CNP gene appear to differ from those that regulate ANP and BNP.¹⁰

Recently a new member of the natriuretic peptide family, DNP, a 38-AA natriuretic peptide, was isolated from the venom of the green mamba snake, *Dendroaspis angusticeps*.¹¹ DNP contains a 17-AA disulfide ring structure similar to ANP, BNP, and CNP with a 15-residue carboxy terminal extension. In addition, it has 12- and 14-AA residues in common with ANP and BNP-respectively. The gene encoding the peptide has yet to be cloned.

A nonglycosylated 32-AA natriuretic peptide was isolated from human urine and termed *urodilatin*.¹² Initially, this compound was thought to be ANP excreted in the urine. Subsequent studies demonstrated that urodilatin and ANP are different. The AA sequence of urodilatin is identical to that of ANP except for the presence of four additional AAs (Thr-Ala-Pro-Arg) in the amino terminal.¹³ Urodilatin and ANP are derived from the same gene and a common precursor peptide, proANP.¹³ In contrast to ANP, urodilatin is not detected in plasma and appears to be restricted to kidney.

TISSUE DISTRIBUTION OF NATRIURETIC PEPTIDES

ANP gene expression is highest in normal adult atria and much lower in ventricles. However, in pathologic states, such as heart failure and ventricular hypertrophy, ANP gene expression in the ventricles may increase markedly. ANP mRNA is present in several areas of the brain, particularly in areas involved with blood pressure regulation, such as hypothalamus and brain stem. ANP mRNA has also been found in the anterior pituitary; kidney; vascular tissue; and particularly, the great cardiac veins, inferior vena cava, adrenal medulla, eye, lung, and gastrointestinal tract.¹⁴

BNP was initially isolated from the brain of pigs¹⁵ and dogs.¹⁶ Shortly thereafter, its name became a misnomer when it was discovered that the highest expression level of BNP was in the ventricular myocardium. Whereas ANP mRNA is largely present in atria, BNP mRNA is expressed in ventricles. BNP mRNA has also been found in extracardiac tissues, including porcine and human brain, bovine adrenal medulla, and human amnion tissue. In rats, extracardiac expression of this peptide is scant. Two types of secretory granules have been identified in human and porcine myocytes: One contains only ANP and the other contains both ANP and BNP.¹⁷ Cosecretion of ANP and BNP has been demonstrated in porcine cardiocytes.¹⁸

CNP was also initially isolated from porcine brain,⁷ and subsequently from rat and human brain extracts,¹⁹ in which it occurs in greater concentration than either ANP or BNP. CNP is the only hormone in the heart and brain of the primitive cartilaginous fish and is believed to be an ancestral peptide of the natriuretic peptide family.²⁰ Immunoreactive CNP and CNP gene transcripts are found in abundance in the cerebral cortex, brain stem, cerebellum, basal ganglia, hypothalamus, and spinal cord of most species. In cerebrospinal fluid, CNP is about 10-fold higher in concentration than ANP or BNP. The concentration of CNP in plasma, however, is at the lower limit of detection and it has been proposed to act in a paracrine or autocrine manner to regulate local vascular tone.²¹ CNP is detectable in a variety of peripheral tissues including endothelium, kidney, adrenal glands, heart, small and large bowel, thymus, uterus, and testis.²²⁻²⁸ CNP in the atrial and ventricular myocardium may have important local actions. Some have suggested that CNP in the myocardium derives from the endothelium of coronary arteries.²⁹ CNP has been localized in the endothelium in humans, primarily as the CNP-53 AA precursor, which may be a storage form to be transformed into the active CNP-22 when needed. CNP-53 has also been detected in human plasma, suggesting a possible physiologic role.³⁰ It is not clear, however, whether plasma concentrations of CNP provide a sensitive index of local production in the vasculature or in other tissues. Using *in situ* hybridization, Cataliotti et al. have demonstrated CNP mRNA expression in tubular epithelium and in the visceral and parietal layer of glomeruli in human kidneys.³¹ CNP immunoreactivity was positive in the proximal, distal, and medullary collecting ducts.

DNP-like immunoreactivity has been detected in canine and human plasma and atrial myocardium.^{32,33} Urodilatin is synthesized exclusively in kidney tubules and secreted into the tubular lumen.³⁴ Immunohistochemical studies have shown urodilatin-like immunoreactivity in the distal and collecting tubules, especially in the cortical collecting duct. Urodilatin is

not detectable in plasma and is presumed to be processed in the distal tubule from the same precursor as ANP.³⁵ However, urodilatin gene expression has not been detected in kidney.

NATRIURETIC PEPTIDE RECEPTORS

All natriuretic peptides exert their biologic effects by interacting with specific receptors. Molecular cloning techniques have identified three different subtypes of natriuretic peptide receptors (NPRs), NPR-A, NPR-B and NPR-C, which have been localized to three human chromosomes; however, the designations do not correspond to the relative affinities for ANP, BNP, and CNP.³⁶ NPR-A and NPR-B mediate the biologic actions of the hormones, whereas NPR-C mainly acts as a clearance receptor.³⁷ The NPRs are transmembrane proteins that are members of the receptor guanylyl cyclase family found in target tissues of the natriuretic peptides. Each receptor contains an extracellular binding domain to which a natriuretic peptide can bind. NPR-A and NPR-B have an extracellular ligand-binding domain, an intracellular guanylate cyclase domain, and a protein kinase-like domain that catalyzes the formation of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP).³⁸ Intracellular cGMP targets include cGMP-dependent protein kinases, cGMP-gated ion channels, and cGMP-regulated cyclic nucleotide phosphodiesterases.³⁹ ANP, BNP, and urodilatin selectively activate NPR-A. In canines, synthetic DNP increases urinary cGMP excretion, suggesting that DNP may function through the NPR-A receptor, which is linked to particulate guanylyl cyclase and cGMP generation.³³ However, the existence of a new, yet to be discovered natriuretic peptide receptor cannot be excluded. ANP has greater affinity for the NPR-A than does BNP,⁴⁰ whereas CNP has very low affinity for this receptor. By contrast, CNP binds more selectively with NPR-B, with an affinity three orders of magnitude greater than that of either ANP or BNP.⁴¹ This raises the possibility of developing specific antagonists for these receptors.

ANP, BNP, and CNP all bind to the NPR-C receptor, which functions mainly as a clearance receptor.^{42,43} NPR-C contains an extracellular ligand binding domain and a short (37-AA) intracellular domain, but unlike NPR-A and NPR-B, lacks the intracellular protein kinase-like and guanylyl cyclase regions. NPR-C is thought to act through internalization and lysosomal hydrolysis of the natriuretic peptide-receptor complex, followed by return to the cell surface. Some studies suggest that NPR-C acts by activating the phosphoinositol pathway⁴⁴ or by inhibiting cyclic adenosine monophosphate (cAMP) production;⁴⁵ others have suggested that this receptor may mediate antiproliferative effects of ANP, as well as the inhibitory effects of ANP on adrenergic neurotransmission in peripheral tissues and cells.⁴⁶ The neuromodulatory effects of ANP via NPR-C involves suppression of adenylyl cyclase activity via a pertussis-toxin-sensitive G protein.⁴⁷

The number and distribution of NPRs vary widely among tissues. NPR-A is expressed in heart, lungs, kidney, adrenal glands, adipose tissue, eye, pregnant uterus, and placenta.^{48,49} In the kidney, NPR-A is expressed in renal vessels, glomeruli, inner medullary collecting duct, and papillae, consistent with the predominant role of ANP at these sites.⁵⁰ The distribution of NPR-B overlaps somewhat with that of NPR-A, but this receptor is present in lower density than NPR-A in large ves-

sels and kidney and in higher density in brain. The distribution of NPR-B in kidneys of Sprague-Dawley rats was studied by reverse transcriptase polymerase chain reaction (RT-PCR) techniques: NPR-B receptors were present in glomeruli, distal convoluted tubules, and cortical and outer medullary and inner medullary tubules, but not in proximal convoluted tubules or in thin or thick ascending limbs.⁵¹ Using RT-PCR, expression of NPR-A has been shown to be four times more abundant in human arteries than in veins, whereas expression of NPR-B was approximately the same.⁵² NPR-C is the most abundant NPR in most tissues, and is expressed in the heart, kidney, brain, endothelium, smooth muscle cells, and adrenal glands.^{4,37} More than 90% of all ANP receptors in kidney are NPR-C. These receptors are mainly localized in the vascular and glomerular structures of the cortex, particularly in the podocytes of glomerular cells.^{50,53} Genes for all three NPR subtypes are expressed in the rat heart.⁵⁴ cGMP generation in purified myocytes was stimulated only by ANP and BNP, which bind specifically to NPR-A, whereas CNP, which binds to NPR-B, was ineffective. Therefore, rat ventricular myocytes appear to express predominantly NPR-A. The mRNAs for all three NPRs were also found in cultures of fibroblasts from the rat heart.⁵⁴ In contrast to myocytes, large increases in cGMP were observed in response to both ANP and CNP in cardiac fibroblasts.

The number and distribution of NPRs may vary in response to a variety of hormones, intracellular mediators, and metabolic and pathologic conditions. In sheep kidney, sodium depletion enhances expression of NPR-B mRNA twofold.⁵⁵ In cultured bovine carotid artery endothelial cells, high-salt medium induced a marked reduction in the number of NPR-C, whereas NPR-A density was not affected.⁵⁶ Chronic oral salt supplementation in mice resulted in selective down-regulation of NPR-C gene expression in the kidney independent of changes of ANP levels and expression of NPR-A.⁵⁷ NPR-C gene expression is also reduced in the kidney of Dahl salt-sensitive and salt-resistant rats after chronic salt loading, whereas expression of NPR-A and NPR-B is not altered.⁵³ These studies support the notion that NPR-C plays an important role in the regulation of salt balance and in the pathophysiology of salt-sensitive hypertension. After induction of myocardial infarction (MI) in rats, NPR-C expression increased in the infarcted and noninfarcted regions of the left ventricular wall, while it decreased in the kidneys and lungs. BNP and ANP mRNA levels, as well as circulating ANP and BNP also increased, suggesting that the increase in circulating ANP and BNP levels in this condition may be due, at least in part, to reduced peripheral clearance by NPR-C.⁵⁸

Recently, the mechanisms involved in the regulation of NPR-C have received considerable attention. Down-regulation of NPR-C in tissues has typically been attributed to increased ANP levels in the circulation, which result in increased cGMP production through the activation of NPR-A and guanylate cyclase.^{59,60} However, *in vitro*, NPR-C gene expression in pulmonary arterial smooth muscle cells was not reduced by high concentrations of ANP or cGMP.⁶¹ In addition, studies in ANP knockout mice (-/-) subjected to hypoxia or dietary salt supplementation indicate selective reduction in NPR-C in the absence of circulating ANP.^{57,62,63} This down-regulation may contribute to the increase in circulating ANP levels seen under hypoxic conditions and may enhance the vasodilator effects of ANP in lung, thus regulating hypoxic

pulmonary vasoconstriction and hypertension. A variety of growth factors, including fibroblast growth factor (FGF), protein kinase A and C, platelet-derived growth factor (PDGF), and β -adrenergic agonists have recently been shown to regulate ANP receptors in tissues.^{62,64,65} In pulmonary arterial smooth muscle cells, rapid reduction in NPR-C mRNA levels have been demonstrated in response to very low concentrations of FGF and PDGF.⁶¹ This observation was found to be mediated by overexpression of tyrosine kinase-activating growth factors. This study suggests that, *in vivo*, these growth factors could also potentially be physiologic regulators of NPR-C gene expression.

REGULATION OF NATRIURETIC PEPTIDE SECRETION

ANP and BNP are continuously released from the heart, but certain mechanical and neuroendocrine stimuli also increase their rate of synthesis and/or secretion. Atrial stretch is the principal stimulus for ANP release. In response to acute stretching of the atria, ANP secretion from atrial cardiocytes is increased, leading to an immediate rise in plasma levels of the hormone. Release of ANP is not Ca^{2+} dependent and derives from an acutely releasable pool that is exhausted within minutes after the initial stretch stimulus. Stretch over a 4-hour period does not alter ANP gene expression in atria but does stimulate it after 24 hours. Studies in isolated atrial tissues and myocytes have revealed an increase in ANP release after resting tension is increased, suggesting that atrial stretch-induced ANP release acts independently of central nervous system (CNS) effects and heart beat.¹⁴ The transplanted heart resembles the normal heart in its response to exercise by increasing secretion of ANP.⁶⁶

Stretch of myocardial cells affects the secretion of natriuretic peptides only transiently, suggesting that chronic stimulation of ANP secretion may be under the influence of other factors, such as endothelin-1 (ET-1),^{67,68} catecholamines,⁶⁹ acetylcholine, glucocorticoids, angiotensin II (Ang II),⁷⁰ thyroid hormones, prostaglandins,⁷¹ Na, K-ATPase inhibitors,⁷² vasopressin, and adrenomedullin.⁷³ Of these factors, ET-1 appears to be the most powerful stimulator of ANP, although this action is transient, probably as a result of desensitization of ET-1 receptor binding, and down-regulation of phospholipase C activity.⁷⁴ Administration of BQ123, an ET-1 subtype A (ET_A) receptor antagonist, reduces stretch-induced ANP release, suggesting that ET-1 acts as a modulator of ANP secretion in a paracrine fashion. In a study by Leskinen et al., the release of ANP in response to atrial stretch in rats was shown to be mediated by endothelin (ET) as opposed to a direct mechanical effect.⁶⁸ However, ET receptor blockers had no significant effect on baseline plasma concentrations of ANP in the absence of stretch. ET-1 also stimulates BNP gene expression in cultured neonatal atrial cardiocytes as well as in adult atrial tissue.⁷⁵ Using isolated rabbit hearts, Focaccio et al. showed that Ang II causes release of ANP in the absence of hemodynamic changes.⁷⁰ How much of this effect is due to atrial stretch as a result of change in hemodynamics versus direct action of the vasoconstrictor remains to be determined.

The neuroendocrine component of ANP release from the atria is mediated by oxytocin.⁷⁶ Baroreceptors in the brain respond to blood volume expansion by releasing oxytocin.⁷⁷

Specific oxytocin receptors in the heart mediate the action of oxytocin to release ANP, which then exerts negative inotropic and chronotropic effects via activation of guanylyl cyclase and elevation of cGMP. BNP release is not affected by oxytocin.

Transcriptional control of natriuretic peptide production is not the same in atria as in ventricles.⁷⁸⁻⁸¹ Whereas natriuretic peptide expression in the atria appears to be governed by mechanical stimuli, in the ventricles, the expression of ANP and BNP appear to be mainly dependent on the endocrine environment. Following aortic banding in rats, Ogawa et al. reported down-regulation of ventricular expression of natriuretic peptides following treatment with a low dose of the angiotensin-converting enzyme (ACE) inhibitor ramipril, whereas ANP production did not change with either a low or high dose of the ACE inhibitor.⁸⁰ In rats with deoxycorticosterone acetate (DOCA)-salt hypertension and renovascular hypertension, ventricular ANP and BNP gene expression, blood pressure and the development of left ventricular hypertrophy (LVH) were reduced after chronic blockade of ET_A.^{78,79} However, natriuretic peptide stores and mRNA levels in the atria were not modified by ET_A blockade, suggesting that, in vivo, modulation of ANP production is independent of endocrine factors and is mainly determined by atrial wall stretch. In contrast, in DOCA-salt hypertension, blockade of ET receptor type B (ET_B) worsened hypertension and increased LVH without an increase in ventricular natriuretic peptide (VNP) transcript levels in comparison with animals treated with DOCA-salt alone.⁸¹ This study supports the hypothesis that mechanical stimuli per se are not the only determinant of ventricular natriuretic peptide gene expression and that the increase in blood pressure does not correlate with the enhancement of natriuretic peptide expression in the ventricles.

BNP secretion and gene expression are affected by acute stretch in some, but not all experimental models.⁸² Because BNP is predominantly secreted from the ventricles, the main stimulus for BNP release appears to be ventricular stretch. With chronic stimulation, as seen in DOCA-salt treated rats, both ANP and BNP mRNAs increase in atria and ventricles.⁸³ ANP and BNP mRNA levels are also increased in the hearts of spontaneously hypertensive rats (SHR),⁸⁴ of dogs subjected to rapid ventricular pacing,⁸⁵ and of humans with CHF.⁸⁶

ANP and BNP are cosecreted, but seem to respond differently to the same stimuli. For example, unlike ANP, the plasma concentration of BNP does not change when normal subjects assume the supine position. BNP release is stimulated by increases in left ventricular end-diastolic pressure, pulmonary artery pressure, and pulmonary artery wedge pressure.^{87,88} In patients with chronic renal failure, removal of fluids reduced blood levels of BNP.⁸⁹ In isolated perfused heart, BNP and ANP release is stimulated by ventricular stretch.⁹⁰

The transcription of the CNP gene is regulated by many factors, such as tumor necrosis factor (TNF), interleukin-1, and transforming growth factor (TGF). These cytokines influence vascular cell proliferation, migration, and contraction, effects that can be modulated by CNP. In conditions characterized by widespread damage to endothelium, such as sepsis, hypoxia, and chronic renal failure, blood levels of CNP are elevated.⁹¹ The markedly elevated plasma levels of CNP in chronic renal failure could be related in part to endothelial damage and in part to reduced clearance of the peptide. Plasma concentrations of CNP are not increased in chronic

CHF, a condition associated with very high levels of ANP and BNP. Whether this reflects no increase in myocardial production or whether plasma concentrations are not necessarily a marker of tissue activation of CNP remains to be established.

METABOLISM OF NATRIURETIC PEPTIDES

The metabolism of natriuretic peptides involves two main pathways: enzymatic degradation by neutral endopeptidase 24.11 (NEP) and receptor-mediated clearance via the NPR-C clearance receptor.⁴⁹ NEP 24.11 is a membrane-bound metalloprotease that cleaves ANP between AA 105 and 106, thus, opening the ring structure and inactivating the peptide.⁹² It is widely distributed throughout the body and is expressed in high concentrations in the brush border membranes of the renal proximal tubules.⁹³ NEP degrades the peptides in the following order of CNP < ANP < BNP.⁹⁴ The second mechanism involved in elimination of natriuretic peptides is via clearance receptors. NPR-C serves a clearance function for natriuretic peptides in tissues. NPR-C binds to natriuretic peptides in the order of ANP < CNP < BNP.⁴⁰ Urodilatin is also inactivated by NPR-C and by enzymatic degradation through NEP, but is more resistant to enzymatic degradation than ANP, which may explain the greater natriuretic effects of urodilatin than ANP.⁹⁵ Recently, natriuretic and renal hemodynamic actions of synthetic DNP were shown to be attenuated by HS-142, a natriuretic peptide receptor antagonist, while NEP inhibition had no effect.⁹⁶ These findings suggest that the actions of DNP are mediated partly via the natriuretic peptide guanylyl cyclase receptors and that DNP either is resistant to degradation by NEP due to its long C-terminus or is not a substrate at all.

Inhibition of NEP and occupation of NPR-C produce increases in plasma ANP concentration, urine sodium and volume excretion, and a decrease in blood pressure.^{97,98} Coadministration of these agents produces greater effects than those achieved when either of these agents is administered alone.⁹⁷ At physiologic plasma concentrations of ANP, NPR-C may play a dominant role over NEP. In rats with heart failure, inhibition of NEP and NPR-C induces a significant rise in plasma ANP with vasodilation, natriuresis, and diuresis.⁸⁴ Under these circumstances, the clearance receptor appears to play a lesser role than that of NEP in the metabolism of the peptide because of receptor occupancy, receptor down-regulation, or decreased internalization of the receptor-ligand complex.⁹⁹

OTHER NATRIURETIC PEPTIDES

The cardiac ventricle of rainbow trout contains a VNP structurally more similar to ANP than to BNP.¹⁰⁰ Only VNP has been isolated from rainbow trout or from a related species, the chum salmon, *Oncorhynchus keta*. In these species, attempts to isolate ANP from atria using immunoreactivity to mammalian ANP as an assay system have been unsuccessful. A new natriuretic peptide isolated from trout atria exhibits low relaxant activity in the chick rectum and extremely low vasorelaxant activity in the rat aortic strip (only 1/400 that of human ANP). This peptide was equipotent with trout VNP and human ANP in relaxing trout epibranchial arteries.¹⁰¹

Two related peptides are guanylin and uroguanylin, 15-AA and 16-AA peptides produced primarily in the gastrointestinal mucosa. These peptides act through the cGMP pathway to regulate sodium and water transport across the intestinal mucosa and may also coordinate intestinal absorption with subsequent renal excretion of sodium.¹⁰²

PHYSIOLOGIC ACTIONS OF NATRIURETIC PEPTIDES

Renal Effects

In low doses, sufficient to achieve a doubling of basal plasma levels, ANP causes natriuresis but no change in blood pressure, unless the infusion is prolonged.^{103,104} ANP causes intravascular volume contraction, as documented by increases in serum albumin and hematocrit, due in part to diuresis and in part to a shift of fluids from the capillary beds into the interstitium,¹⁰⁵ resulting in decreased preload and blood pressure.¹⁰⁶

Qualitatively, the effects of BNP are similar to those of ANP. BNP is natriuretic in both animals and human subjects, even at doses that produce plasma levels comparable with those in heart failure. Equimolar infusions of ANP and BNP achieve similar increments in plasma concentrations, but the increase in cGMP during ANP infusion is fourfold that observed during BNP infusion. The natriuresis and contraction in plasma volume caused by the two peptides are comparable.

The mechanisms of the natriuretic action of BNP and ANP are complex. ANP raises glomerular filtration rate (GFR) in the isolated perfused rat kidney in spite of decreased systemic arterial pressure and renal blood flow,¹⁰⁷ and increased single nephron GFR, measured by the micropuncture technique.¹⁰⁸ ANP also increases GFR in normal subjects¹⁰⁹ and in patients with essential hypertension.¹¹⁰ These findings suggest that the renal hemodynamic effects of ANP account, at least in part, for its natriuretic action. The increase in GFR has been ascribed to constriction of the efferent glomerular arterioles, accompanied by dilation of the afferent glomerular arterioles.¹⁰⁷ Unlike ANP, despite similar natriuretic effects, BNP does not alter GFR in humans,¹¹¹ suggesting that at least some of the natriuretic effects of natriuretic peptides must be due to mechanisms other than changes in GFR. ANP inhibits sodium transport in the proximal tubule¹¹² and in the inner medullary collecting duct.¹¹³ ANP causes diuresis and natriuresis, at least in part by inhibiting the V2 receptor-mediated action of vasopressin in the collecting duct. The site of interaction of ANP and vasopressin is post cAMP synthesis.¹¹⁴

Shin et al. demonstrated increases in ANP mRNA expression in the kidneys of streptozotocin-induced diabetic rats; urinary ANP excretion correlated with urinary sodium excretion in these animals.¹¹⁵ In a subsequent study, the authors were able to demonstrate an increase in renal cortical and medullary CNP mRNA levels in the diabetic rats with an accompanying elevation of urinary CNP excretion rate that improved with salt restriction and insulin treatment, implying that CNP synthesized in kidney is responsive to the alteration of water and electrolyte homeostasis in diabetic rats.¹¹⁶

DNP is similar to ANP and BNP in that it has potent natriuretic and diuretic properties.³³ In dogs, infusion of DNP was associated with increases in plasma cGMP and urinary cGMP excretion independent of increases in plasma ANP, BNP, or

CNP suggesting that the renal actions of DNP are direct and not mediated by the other natriuretic peptides.³³ In addition, administration of exogenous DNP led to decreases in distal tubular reabsorption of sodium and arterial pressure in the absence of any change in GFR or renal blood flow.

The discovery of selective antagonists of natriuretic peptides has allowed further clarification of their physiologic roles. A selective NPR antagonist, HS-142-1, was isolated from a fungal culture broth of *Aureobasidium* species.¹¹⁷ HS-142-1 selectively and reversibly blocks guanylyl cyclase-linked NPR-A and NPR-B receptors and interferes with cGMP production.¹¹⁸ Studies with HS-142-1 have confirmed a role for the endogenous natriuretic peptides in the control of renal sodium excretion and in the natriuretic response to volume expansion. This drug blocks the natriuretic and diuretic actions of the ANPs in control animals as well as in animals with experimentally induced heart failure. HS-142-1 increases renal vascular resistance, renin, aldosterone, and catecholamines secretion, but does not affect basal renal blood flow.^{118,119}

Using NPR-A knockout mice, the contribution of NPR-A signaling to acute renal salt handling has been studied.¹²⁰ Following intravenous administration of ANP, wild-type mice responded with elevated urine and sodium excretion, whereas NPR-A-null mice were unresponsive to ANP. This suggests that ANP regulation of diuresis and natriuresis is solely through NPR-A and that no other receptor can compensate. In order to determine whether natriuretic factors other than ANP are released by the heart in response to elevated blood pressure, NPR-A knockout and wild-type mice were volume expanded.¹²⁰ Plasma ANP concentrations were elevated in animals of both genotypes, but urine flow, sodium excretion and urinary cGMP were increased only in the wild type. These results imply that for acute sodium and volume handling, NPR-A is most likely the sole mediator of renal response to cardiac peptides. Because basal urine and sodium excretory rates did not differ between wild-type and null mice, it seems likely that a mechanism other than natriuretic peptide signaling through NPR-A regulates chronic salt and water handling by the kidney.

Transgenic mice overexpressing an ANP fusion gene have low blood pressure regardless of their dietary salt composition but are not different from wild-type mice in their urinary salt output.¹²¹ These mice adequately compensate for the renal effects but not the hemodynamic effects of ANP.¹²² This suggests the presence of a compensatory mechanism, which prevents renal salt and water loss in the face of high natriuretic peptide levels. This compensatory mechanism can be overridden by acute volume expansion, and thus ANP-induced natriuresis is observed.¹²¹

Urodilatin, by means of its renal paracrine interaction, exerts essential physiologic regulation of sodium and water excretion. Urodilatin excretion correlates directly with urinary sodium excretion.¹³ High dietary sodium intake or saline infusion results in increased urodilatin excretion, whereas no such correlation is evident between urine sodium excretion and ANP excretion.¹³ In addition, circadian rhythm of urinary sodium excretion is correlated with urinary urodilatin excretion. Intravenous administration of urodilatin in normal volunteers results in greater natriuresis than administration of ANP with fewer hypotensive effects.¹²³ When injected into healthy men in doses >20 ng/kg/min, urodilatin

induces diuresis and natriuresis and inhibits renin secretion; higher doses lower blood pressure.¹²³ The natriuretic action of urodilatin is due in part to an increase in GFR and in part to direct effects on distal tubules. Urinary excretion of urodilatin increases in concert with renal sodium excretion, being higher during salt ingestion or after an acute saline infusion.¹²⁴ The natriuretic effect of urodilatin is stronger than that of ANP in healthy men and in experimental models of CHF.^{95,125} This has led to the suggestion that urodilatin may be more important than ANP in the regulation of sodium excretion. The mechanisms underlying the greater potency of urodilatin over ANP are not clear, but its relative resistance to NEP degradation may be a contributory factor.

Hemodynamic Effects

Homozygous ANP-null mice develop hypertension and cardiac hypertrophy. Following a high-salt diet, ANP-deficient mice had significantly higher blood pressures than those maintained on a standard diet, suggesting a salt-sensitive form of hypertension.¹²⁶ Sustained low-dose infusions of ANP reduce peripheral vascular resistance and blood pressure in animals and in humans, whereas infusions of higher doses cause a decrease in blood pressure accompanied by a rise in peripheral vascular resistance, probably as a result of activation of counterregulatory hormones. In this instance, the hypotensive action of ANP is largely related to a shift of intravascular fluid into the interstitium, thus decreasing preload. Infusion of BNP in high doses into hypertensive rats also causes a profound and sustained fall in blood pressure.¹²⁷ However, when administered to hypertensive or normotensive human subjects in doses sufficient to raise plasma concentrations to levels comparable with those seen in heart failure, BNP causes no significant change in blood pressure or heart rate.¹²⁸ When administered in higher doses to normal subjects, BNP causes decreases in systemic vascular resistance and in blood pressure, a rise in cardiac index, and significant reductions in pulmonary capillary wedge pressure, pulmonary vascular resistance, and right atrial pressure.¹²⁹ When administered in high doses to patients with CHF, BNP causes similar hemodynamic changes, but systemic blood pressure and pulmonary vascular resistance do not change. The vasorelaxation caused by BNP is associated with and, probably dependent on, the release of cGMP.

ANP and BNP may attenuate the vasoconstriction caused by infusion of norepinephrine and angiotensin II. Thus ANP and BNP may modulate changes in blood pressure caused by other neuroendocrine homeostatic mechanisms and local endothelial factors. Studies of the role of natriuretic peptides in the control of basal cardiovascular tone have been made possible by the discovery of selective antagonists. HS-142-1 causes constriction of the coronary circulation in anesthetized mongrel dogs without any significant change in systemic hemodynamics, including arterial pressure, heart rate, or cardiac filling pressure.¹³⁰ These actions were associated with a decrease in plasma cGMP; circulating ANP levels did not change. This observation suggests that ANP is an important regulator of basal coronary vascular tone.

CNP is produced in blood vessels and in cultured vascular endothelial cells and acts as an endothelium-derived relaxing peptide.¹³¹ CNP can induce relaxation and inhibit growth of vascular smooth muscle cells and has powerful venodilator

effects.¹³²⁻¹³⁴ Using a NPR-B specific monoclonal antibody that inhibited CNP-stimulated cGMP accumulation, Drewett et al. demonstrated that CNP relaxes vascular smooth muscle by virtue of its binding to NPR-B.¹³² In vitro studies have shown that CNP dilates saphenous, femoral, and renal veins, both in the presence and in the absence of the endothelium, but the venous relaxation is more potent in the absence of the endothelium.¹³⁵ In addition, CNP may be an important regulator of basal coronary vascular tone. This effect may be due to receptor-mediated clearance of CNP by endothelial NPR-C, CNP-mediated release of endothelium-dependent vasoconstrictors, or metabolism by endothelial NEP. In isolated human blood vessels in vitro, CNP causes venous relaxation and, to a lesser degree, arterial relaxation. Arterial relaxation is less pronounced with CNP than with ANP.¹³⁶ In human gastroepiploic artery, Ikeda et al.⁵² found that ANP raised cGMP production by one order of magnitude more than in veins. CNP stimulated cGMP production weakly and equally in these vessels. Analyzed by RT-PCR, expression of NPR-A receptor was four times more abundant in arteries than in veins. Expression of NPR-B was approximately the same in arteries and veins. In cardiac myocytes, CNP reduces contractility and induces accumulation of cGMP, effects opposite of those induced by ET-1.¹³⁷

Intravenous administration of CNP to normal rats (5-50 µg/kg) induces hypotension, a fall in right atrial pressure, and a small diuresis and natriuresis.³⁰ These responses are attenuated in SHR.¹³⁸ In dogs, intravenous infusions of CNP cause hemodynamic effects similar to those in rats, but the natriuretic effect is less evident.¹³⁹ Intravenous injection of CNP in normal humans elicits limited biologic actions. When infused intravenously in doses sufficient to achieve plasma concentrations of approximately 60 fmol/ml (circulating levels of CNP in humans are <10 fmol/ml), CNP has no significant biologic actions.¹⁴⁰ When infused in doses sufficient to achieve plasma concentrations of 770 fmol/ml, CNP exerts significant natriuretic, kaliuretic, and hypotensive actions.¹⁴¹ However, the natriuretic action of CNP appears to be less than that of ANP or BNP. The hemodynamic actions of CNP are more pronounced than those of ANP despite lesser increase in plasma cGMP, raising the possibility that some of the actions of CNP are not mediated by cGMP. Wei et al. showed that the vasorelaxant effects of CNP are inhibited by potassium chloride, but not by blockade of adrenoreceptors, nitric oxide synthase, prostaglandin synthesis, or by methylene blue, an inhibitor of guanylate cyclase.¹⁴² CNP causes potassium channel activation and membrane hyperpolarization in porcine coronary artery smooth muscle cells.¹⁴²

DNP has been shown to relax isolated rodent aorta and canine coronary arteries^{11,143} with a potency comparable with ANP. In addition, DNP augments the formation of cGMP in aortic endothelial and smooth muscle cells and displaces ANP binding from the NPRs.¹¹ Relaxation of an isolated canine coronary artery by DNP was reduced by HS-142, an inhibitor of guanylate cyclase.¹⁴³ In vitro, DNP has been shown to cause a dose-dependent relaxation of human blood vessels with a greater effect on the arteries than the veins.¹⁴⁴ DNP resulted in less arterial relaxation than ANP or CNP and similar relaxation to BNP, while in veins, DNP caused the greatest relaxation of the natriuretic peptides.

Mice with genetically altered natriuretic peptide expression have been used to investigate the contribution of natriuretic

peptides to blood pressure regulation. Overexpression of the ANP gene lowers systemic blood pressure.¹⁴⁵ On the other hand, ANP knockout mice have higher blood pressures than wild-type controls, independent of salt intake.¹⁴⁶ ANP-deficient mice on a high-salt diet have significantly higher blood pressures than those maintained on a standard diet, suggesting a salt-sensitive form of hypertension. In response to acute intravascular volume expansion, wild-type mice show a greater natriuresis than ANP-null mice while on a low-salt diet. However, animals fed a high-salt diet exhibit enhanced natriuresis irrespective of genotype. These studies demonstrated that ANP lowers blood pressure independently of renal salt excretion.¹²⁶ Given that both ANP knockout and transgenic mice can maintain salt balance regardless of dietary salt intake, ANP may be more important for blood pressure regulation than for renal salt handling.

NPR-A knockout mice have been used to investigate the contribution of natriuretic peptides to blood pressure regulation via NPR-A.^{147,148} Disruption of the NPR-A gene has been shown to result in chronic elevations of blood pressure in mice on normal and high-salt diets.¹⁴⁷ Aldosterone and ANP concentrations are not affected by genotype, suggesting that mutations in the NPR-A gene could explain some salt-resistant forms of essential hypertension and that the NPR-A signaling pathway could potentially operate independently of ANP. In a study by Lopez et al., both ANP and BNP caused dose-dependent relaxation of precontracted aortic rings from wild-type but not NPR-A-null mice. In wild-type animals, ANP was much more potent than CNP in lowering blood pressure; however, in NPR-A-null animals, ANP had no effect on blood pressure even at very high levels, whereas CNP was as effective as in wild-type animals.¹⁴⁷ This study demonstrates that ANP and BNP act through NPR-A, whereas CNP acts through another receptor to regulate blood pressure.

Antiproliferative Effect

Vascular remodeling is central to the pathophysiology of hypertension and atherosclerosis. The pivotal role of vasoactive substances present in the blood vessel in the control of vascular growth is well known. Whereas vasoconstricting peptides such as Ang II promote vascular growth, vasodilating substances such as natriuretic peptides inhibit vascular growth. ANP has been shown to be antimitogenic in endothelial and vascular smooth muscle cells^{133,149,150} and to attenuate the growth response to adrenergic stimuli¹⁵¹ and induce apoptosis in neonatal rat cardiomyocytes.¹⁵² Moreover, ANP-induced apoptosis occurs through the induction of p53 and inhibition of Bcl2 proteins.¹⁵³ The apoptotic effect of ANP can be inhibited by specific blockade of NPR-A or modulated by ET (an antiapoptotic factor). Similar effects have been noted in neonatal rat cardiac myocytes.¹⁵²

In cultured vascular smooth muscle cells, CNP exerts a growth-inhibitory action and antagonizes the growth-promoting action of Ang II, which is mediated through the Ang II subtype 1 receptor.¹⁵⁴ CNP, like the other natriuretic factors, blunts stimulated ET-1 production *in vitro*,¹⁵⁵ apparently via cGMP. As ET-1 causes vascular smooth muscle cell proliferation, CNP could locally inhibit vascular smooth muscle cell proliferation via this mechanism. CNP exerts growth inhibitory effects in human vascular smooth muscle cells and can reduce the response of these cells to growth factors.^{133,156,157}

Endothelial secretion of CNP is stimulated by various cytokines and growth factors, such as TGF- β and TNF- α , that are produced and activated in proliferative vascular lesions.^{131,158} *In vivo*, CNP infusion reduces the extent of the vascular injury response in rats with carotid artery injury.¹⁵⁹

Overexpression of CNP via local adenovirus-mediated gene transfer has been shown to suppress vascular remodeling and thus prevent restenosis in porcine coronary arteries *in vivo* following balloon injury.¹⁶⁰ This strategy may prevent restenosis after angioplasty in humans. In the rat mesangio-proliferative anti-Thy 1.1 model, CNP was involved in the regulation of mesangial cell proliferation and matrix production, suggesting that it may regulate tissue homeostasis and contribute to resolution of mesangio-proliferative diseases.¹⁶¹

Modulation of Sympathetic Nervous System Activity

The effects of ANP on blood pressure and fluid and electrolyte balance are largely mediated via the kidney and the vasculature. However, evidence indicates that the effects of ANP on the CNS also contribute to fluid and electrolyte balance and hemodynamic regulation. Although natriuretic peptides are unable to cross the blood-brain barrier, they are capable of reaching sites in the CNS outside this barrier such as the subfornical organ, hypothalamic median eminence, and area postrema. ANP decreases sympathetic tone via an action on the brain stem.¹⁶² Dampening of baroreceptors, suppression of the release of catecholamines from autonomic nerve endings and suppression of sympathetic outflow from the CNS are some of the mechanisms that are responsible for this reduction in sympathetic tone.^{162,163} Injection of BNP into the ventrolateral medulla, an area of the brain important in the noradrenergic control of blood pressure, causes a decrease in blood pressure and heart rate in rats.¹⁶⁴ Microinjection of a monoclonal anti-ANP antibody into the anterior hypothalamus decreases blood pressure in SHR, but not in normotensive control Wistar-Kyoto (WKY) rats.^{165,166} This suggests that the activity of ANP is enhanced in the hypothalamus of SHR as a result of either increased production of ANP in the brain or increased receptor sensitivity.¹⁶⁷ On the other hand, inhibition of the action of endogenous ANP in the nucleus tractus solitarius raises blood pressure, suggesting a role in the tonic regulation of cardiovascular baroreceptor signal to this area of the brain.¹⁶³ ANP synthesis in key brain nuclei that regulate the cardiovascular system is affected by changes in blood volume.¹⁶⁸ ANP inhibits salt appetite, water drinking, and vasopressin secretion from the pituitary, and this central action of the peptide contributes to controlling fluid and electrolyte homeostasis.^{169,170} Patients with advanced CHF manifest activation of the sympathetic nervous system (SNS), decreased heart rate variability, and loss of modulation of muscle SNS activity in the low-frequency range. Infusion of ANP augments the variability of SNS activity, suggesting a beneficial effect on neurogenic circulatory control.¹⁷¹

ANP and BNP are present in Purkinje fibers of several mammals, including humans.¹⁷²⁻¹⁷⁴ ANP has also been shown in the nodose ganglia of the heart, pathways that carry afferent stimuli from the cardiopulmonary area.¹⁷⁵ Furthermore, ANP interferes with α_1 -adrenergic receptor activation in the rat heart¹⁷⁶ and the human kidney.¹⁷⁷ The physiologic relevance of these observations is not fully understood.

CNP was initially considered to act principally as a neuropeptide. However, the functional significance of CNP within the CNS remains largely unknown. In neuronal cell lines, CNP increases cGMP production.¹⁷⁸ Studies in rats and sheep indicate that CNP may stimulate water drinking and reduce blood pressure and adrenocortical activity.¹⁷⁹ CNP may exert prejunctional inhibition of norepinephrine release.¹⁸⁰ The highest concentration of CNP in the body is present in the pituitary, where it may inhibit the release of luteinizing hormone (LH) via NPR-A activation.¹⁸¹ CNP increases catecholamine synthesis in the adrenal medulla via cGMP-mediated activation of tyrosine hydroxylase, a rate-limiting enzyme in the synthesis of these amines.¹⁸² By contrast, in incubated rat hypothalamic slices, CNP inhibits spontaneous release of norepinephrine and increases its neuronal uptake and storage.¹⁸³ These studies suggest that CNP may be involved in the regulation of noradrenergic neurotransmission at the presynaptic level.

Antiinflammatory Effects

A link between natriuretic peptides, specifically ANP, and the immune system has recently been demonstrated.¹⁸⁴⁻¹⁸⁸ ANP mediates macrophage function by influencing the production of proinflammatory factors. ANP has recently been reported to inhibit the production of TNF- α in macrophages,^{185,186} reperfused liver,¹⁸⁷ and whole human blood¹⁸⁵ and to attenuate changes in endothelial morphology and permeability induced by TNF- α ,¹⁸⁹ thus influencing important pathophysiological features of inflammation. More recently, several studies have demonstrated that ANP^{184,187,188} and CNP¹⁸⁸ specifically suppress TNF- α -induced expression of adhesion molecules via cGMP-mediated inhibition of nuclear factor (NF)- κ B expression.^{187,188,190}

Effects on the Renin-Angiotensin-Aldosterone System (RAAS)

Secretion of renin and aldosterone are markedly inhibited following ANP infusion.¹⁹¹ ANP decreased renin secretion from isolated renin-secreting cells, but failed to inhibit renin secretion in nonfiltering kidneys, or to alter furosemide-induced renin release from isolated afferent arterioles.¹⁹¹ However, NEP inhibition blunted the rise in renin secretion in bumetanide-treated rats, suggesting that ANP may influence, directly or indirectly, intracellular signaling in the macula densa.¹⁹² In human subjects, BNP causes a fall or no change in plasma renin activity.^{129,193} ANP, but not BNP, inhibits the plasma aldosterone response to Ang II.¹⁹⁴ The decrease in plasma aldosterone is due to the decrease in plasma renin activity and to a direct effect of ANP on the adrenal zonal glomerulosa to inhibit aldosterone synthesis. The increase in sodium load delivered to the macula densa following ANP infusion may be responsible for the decrease in renin secretion.

Infusion of small doses of ANP and BNP inhibits the RAAS, but CNP does not appear to affect this system when infused in doses that do not alter blood pressure. Only when infused in very high doses does CNP decrease plasma aldosterone and increase plasma and urinary concentrations of cGMP. CNP modulates adrenocorticotrophic hormone-induced aldosterone secretion¹⁹⁵ and inhibits vascular ACE activity and thus may serve as an endogenous regulator of the RAAS.¹⁹⁶

Following Ang II inhibition via an ACE inhibitor or Ang II receptor blocker, renal CNP mRNA expression increased in streptozocin-diabetic (STZ) rats and controls; this effect was more pronounced in the controls. These results demonstrate a direct stimulatory effect of the RAAS on renal CNP mRNA levels.¹⁹⁷ In patients with essential hypertension, plasma ANP levels increased by 15.7% despite the drop in blood pressure and the slight decrease of atrial and ventricular diameters following treatment with irbesartan, an Ang II receptor blocker.¹⁹⁸

Infusion of Ang II in isolated rat kidney leads to decreased renal excretion of urodilatin. The alterations in urodilatin excretion cannot be explained by vasoconstriction per se, because ET-1 infusion does not alter urodilatin excretion.¹⁹⁹

In addition to renin and aldosterone suppression, ANP also antagonizes all of the known effects of Ang II, including peripheral vasoconstriction, stimulation of proximal sodium fluid reabsorption, central dipsogenic actions, and growth-promoting activities in vascular smooth muscle cells. These effects have been attributed to ANP-induced decreases in cytosolic calcium due to cGMP-dependent stimulation of sarcolemmal Ca²⁺ ATPase activity.²⁰⁰

Other Actions of Natriuretic Peptides

CNP has been isolated from the small and large intestine of rats,¹⁸³ and administration of CNP to dogs reduced jejunal electrolyte and fluid secretion.²⁰¹ This suggests that CNP may contribute to fluid homeostasis by modulating intestinal excretion of electrolytes. CNP relaxes pulmonary arteries and bronchial smooth muscle cells of guinea pigs.²⁰² In vitro, CNP causes dose-dependent relaxation of bronchial smooth muscle and stimulates cGMP release from human respiratory epithelial cells.²⁰³ The significance of these observations in pulmonary diseases remains to be ascertained.

Negative,^{204,205} positive,²⁰⁶⁻²⁰⁸ biphasic (initially inotropic then negative inotropic),²⁰⁹ and no inotropic²¹⁰ effect have been reported for CNP in different species. These discrepancies could be due to differential effects of CNP on various cell types (i.e., endothelial cells or fibroblasts versus cardiac myocytes) or to species differences.

Transgenic mice overexpressing BNP exhibit skeletal abnormalities due to endochondral ossification, such as elongated limbs and crooked tails, the severity of which correlated with the elevation in plasma BNP concentration.²¹¹ In vitro, CNP was more potent than BNP in promoting growth of embryonic mouse tibias, whereas ANP overexpressing mice had no skeletal defects.²¹¹ Mice deficient in cGMP-dependent protein kinase II, an intracellular mediator of guanylyl cyclase signaling, have defects in endochondral ossification that lead to dwarfism.²¹² These studies support a role for natriuretic peptide modulation of bone and cartilage growth via guanylyl cyclase-coupled receptors.

INTERACTIONS AMONG NATRIURETIC PEPTIDES

Potentially important interactions among natriuretic peptides occur in vivo. Very high infusion rates (0.1 μ g/kg/min) of BNP increase plasma levels of ANP in humans; much lower infusion rates of CNP (5 pmol/kg/min) increase plasma concentrations of ANP but not BNP.²¹³ CNP production and

release by bovine aortic endothelial cells is enhanced by ANP or BNP.²¹⁴ In the presence of background low-dose ANP infusions, coinfusion of BNP abruptly and reversibly increases plasma ANP levels by 50% and has additive physiologic effects. Similarly, in the presence of background BNP infusion, coinfusion of ANP causes a reversible increase in plasma BNP concentration and results in additive physiologic effects. These studies support the notion that natriuretic peptides compete for clearance in shared degradative pathways, rather than affecting each other's production rates.²¹³

PATHOPHYSIOLOGY OF NATRIURETIC PEPTIDES

Hypertension

ANP is involved in the pathogenesis of salt-sensitive hypertension. Molecular genetic studies show that disruption of the proANP gene in mice causes a form of salt-sensitive hypertension and cardiac hypertrophy.¹⁴⁶ By contrast, transgenic mice overexpressing the genes for ANP or BNP have lower blood pressure than normal littermates and do not develop pulmonary hypertension when exposed to chronic hypoxia.^{145,215} Chronic blockade of endogenous ANP with a monoclonal antibody has been shown to accelerate the development and exacerbate the severity of hypertension in stroke-prone SHR (SHR-sp) and DOCA-salt hypertensive rats.²¹⁶ In contrast, administration of an NEP inhibitor, SCH 34826, which protects endogenous ANP from hydrolysis, prevents salt-sensitive hypertension in SHR.²¹⁷

ANP levels are increased in response to salt loading in WKY rats but not in salt-sensitive SHR.²¹⁸ ANP infusion in doses that achieved plasma ANP levels well within the physiologic range abolished the salt-induced exacerbation of hypertension in salt-sensitive SHR.²¹⁹ ANP secretion in response to increased atrial pressure was impaired in prehypertensive Dahl salt-sensitive rats but exaggerated in more advanced phases when hypertension was complicated by LVH.²²⁰ In normotensive salt-resistant rats, dietary salt supplementation is associated with increased plasma ANP levels.²²¹ In contrast, salt-sensitive SHR fail to increase plasma ANP levels appropriately in response to dietary salt supplementation, resulting in an inability to mount a natriuretic response and normalize blood pressure in the presence of dietary salt.^{221,222} In hypertension caused by excess mineralocorticoid, the concentration of ANP increases in concert with the phenomenon of "escape." Administration of HS-142-1 exacerbates hypertension in this model.²²³

Measurements of plasma ANP levels in patients with essential hypertension have provided conflicting results. Some studies have shown low to normal plasma ANP levels,²²⁴⁻²²⁶ whereas others have shown increased levels.²²⁷⁻²²⁹ Sagnella et al. showed an increase in plasma ANP levels during high salt intake in patients with essential hypertension.²³⁰ Kohno et al.²³¹ showed that sodium loading increased plasma ANP more in salt-sensitive than in salt-resistant patients. Nimura, on the other hand, showed a blunted increase in plasma ANP in response to high dietary salt intake in salt-sensitive compared with salt-resistant patients.²³² We have demonstrated that salt-sensitive hypertensive African Americans manifest abnormal ANP secretion in response to increased dietary sodium intake.²³³

Salt-resistant patients fail to manifest the expected rise in ANP, whereas salt-sensitive patients show a paradoxical decrease in ANP. In these patients, reduced atrial secretion of ANP could be, at least in part, responsible for the reduced ability to excrete sodium and for the sodium-induced rise in blood pressure. In whites, we noticed a similar tendency for ANP to decrease during high salt intake, but the decrease did not reach statistical significance. The discrepancies in the literature could be due partly to methodologic differences in ANP measurement and to differences in age, dietary salt intake, left ventricular function, and genetics among populations studied.

Ferrari et al.²³⁴ and Weidmann et al.²³⁵ observed markedly reduced plasma ANP during high sodium intake in offspring of hypertensive parents compared with offspring of normotensive parents. They suggested that a relative ANP deficiency might predispose individuals to develop essential hypertension. Male and female offspring of hypertensive individuals manifest lower BNP levels than offspring of normotensive individuals.²³⁶

Using the candidate gene approach, Rutledge et al.²³⁷ have shown that an Hpa II variant within a polymorphic region in intron 2 of the ANP gene is more common among hypertensive African Americans (25%) than among normotensive controls (3.4%). Although subjects were not characterized according to their salt-sensitivity status, this study supports the hypothesis that a deficit of ANP secretion or augmented metabolism may be genetically determined and contribute to salt-sensitivity and hypertension in African Americans. Frequency of the Hpa II allelic variant was also higher among a cohort of white hypertensive Germans compared with normotensive individuals.²³⁸ In a case control study of a Japanese population, an association was found between a polymorphic marker located within the 5' region of the ANP gene and hypertension.²³⁹ By contrast, no difference in the prevalence of the ANP-Hpa II wild-type allele was found between salt-sensitive and salt-resistant normotensive Caucasians.²⁴⁰ Other investigators have also failed to find an association between the ANP gene and high blood pressure.²⁴¹ One possible explanation for these differences is that the pathogenetic role of ANP may vary among populations of different ethnic backgrounds, or that appropriate size populations were not used in some of these studies. In aldosterone-producing adenoma, a secondary form of hypertension, a significant association between allelic variants of the ANP gene and aldosterone responsiveness to Ang II has been demonstrated.²⁴² A second polymorphic marker (Sca I) for ANP has been identified at position 2238 (T and C), but the prevalence of this marker did not differ between hypertensive and normotensive Blacks. In a Japanese study of 233 individuals with essential hypertension and 213 age-matched normotensive controls, neither the G1837A nor the T2238C polymorphism of the ANP gene was associated with hypertension.²⁴³

A pathophysiologic role of natriuretic peptides and their receptors in the development of obesity-related hypertension has been suggested by several investigators.²⁴⁴⁻²⁴⁷ High levels of NPR-A and NPR-C have been detected in animal and human adipose tissue.²⁴⁷⁻²⁴⁹ Suppression of NPR-C gene expression in adipose tissue, accompanied by increased ANP activity, resulting in natriuresis and diuresis was demonstrated in rats following fasting.²⁴⁷ In obese hypertensive subjects, NPR-A:NPR-C ratio and ANP levels were significantly lower than in nonobese hypertensive subjects,

suggesting that overexpression of NPR-C may lead to increased peripheral clearance of natriuretic peptides such as ANP and thus lower its biologic activity. Lower biologic activity of ANP is further suggested by the presence of higher plasma renin and aldosterone levels, which are physiologically inhibited by ANP, in obese hypertensives in comparison to obese normotensives.²⁴⁷

Elevated plasma ANP levels have been demonstrated in pregnant women compared with nonpregnant controls.²⁵⁰⁻²⁵² ANP levels were even higher in pregnant women suffering from both gestational hypertension and preeclampsia.²⁵⁰⁻²⁵⁴ The increase in plasma ANP levels seen in preeclampsia does not appear to reflect underlying volume status, because preeclampsia is usually associated with normal or reduced blood volume²⁵⁵ and low right atrial pressures.²⁵⁶ The increase in ANP levels may be due to ET, because ET has been shown to stimulate ANP release in vivo and in vitro²⁵⁷ and maternal plasma levels of ET-1 are elevated in preeclampsia.²⁵⁸

Taken together, experimental and clinical studies suggest a role for ANP in the regulation of blood pressure and in the pathogenesis of some forms of hypertension.

Congestive Heart Failure

In acute congestive heart failure (CHF), secretion of ANP increases in response to an acute rise in atrial filling pressure and atrial stretch. By contrast, controversy remains with regard to the acute response of BNP. In vitro studies have indicated that when isolated myocytes are subjected to acute stretch, BNP gene expression may be more immediately responsive than ANP gene expression.²⁵⁹ In vivo studies, however, have indicated that acute changes in cardiac filling pressures caused by volume expansion,²⁶⁰ mitral stenosis repair in humans,²⁶¹ or rapid left ventricular pacing in anesthetized dogs do not increase circulating BNP levels.²⁶² This is consistent with the observation that BNP concentrations in the normal heart are markedly lower than those of ANP. In anesthetized dogs with acute CHF, an infusion of exogenous BNP sufficient to achieve circulating concentrations similar to those observed in chronic CHF resulted in markedly increased plasma and urine cGMP, reduced cardiac filling pressure, diuresis, natriuresis, attenuated release of renin, and inhibition of distal tubular sodium reabsorption.²⁶² This provides a rationale for the use of BNP in the management of acute CHF. In anesthetized dogs with acute CHF induced by rapid ventricular pacing, administration of HS-142-1 caused a decrease in GFR and an increase in distal fractional sodium reabsorption, supporting a functional role for the endogenous natriuretic peptide system in preserving sodium homeostasis and GFR in acute CHF.²⁶³

Increased levels of DNP have been detected in the atrial and ventricular myocardium of dogs with CHF²⁶⁴ and in the blood of patients with New York Heart Association (NYHA) class III or IV heart failure,³² suggesting that DNP increase may be part of a compensatory neurohumoral response of the failing heart to maintain cardiovascular homeostasis.

In CHF, ANP secretion increases in proportion to the severity of heart failure. Ventricular production of ANP increases, but remains lower than atrial production.²⁶⁵ Plasma levels of BNP also increase and may exceed levels of ANP. Plasma BNP correlates more closely than ANP with severity of heart failure and outcome.²⁶⁶ Plasma BNP levels correlate with left ventric-

ular wall thickness and left ventricular mass.²⁶⁷ BNP is considered to be a backup hormone that, in chronic CHF, is synthesized and released into the plasma to complement the actions of ANP. In contrast, plasma CNP does not change, even though cardiac tissue content may be increased.¹³⁶

Natriuretic peptides secreted in CHF inhibit the production of Ang II, aldosterone, catecholamines, and ETs, defending the patient against sodium and water retention. The vasodilator and volume contracting properties of the natriuretic peptides reduce systemic vascular resistance, decrease ventricular filling pressure, and improve myocardial performance. Blocking the actions of these peptides with specific receptor antagonists results in accelerated progression of heart failure and stimulation of renin, aldosterone, catecholamines, and ET-1.^{119,268} Furthermore, these peptides inhibit the growth of cardiac fibroblasts, thus reducing cardiac remodeling and collagen accumulation. Calderone et al. reported the ability of ANP to attenuate the growth-promoting effects of noradrenaline on myocardial cells, thus, protecting the heart from the adverse effects of enhanced sympathetic activity such as interstitial fibrosis and myocardial hypertrophy.²⁶⁹ Similar effects have been shown for BNP and CNP.

The cGMP response to ANP in heart failure is diminished compared with that in normal subjects, probably due to down-regulation of specific receptors caused by chronic exposure to high levels of the peptide. This results in further deterioration of heart failure. In contrast, the cGMP response to CNP is enhanced in patients with CHF compared with normal subjects, suggesting receptor up-regulation.²⁷⁰ The significance of these changes remains obscure.

Ischemic Heart Disease

After acute myocardial infarction (AMI), levels of BNP rise during the first 24 hours.²⁷¹⁻²⁷⁵ AMI is associated with stimulation of the RAAS and SNS. Elevation of natriuretic peptides may be a counterregulatory attempt to control the extent of vasoconstriction. BNP levels are higher in patients with unstable angina than in those with stable angina or healthy controls.²⁷⁶ BNP gene expression and tissue BNP stores increased in an experimental model of transmural infarction.²⁷⁷ These studies suggest that myocardial ischemia augments the synthesis and release of BNP. Marumoto et al. measured levels of ANP and BNP during exercise in patients with stable angina and normal resting left ventricular function and in normal control subjects.²⁷⁸ Despite similar rate-pressure products, the levels of both ANP and BNP during exercise were significantly elevated in patients with angina compared with normal controls.

Some evidence suggests that natriuretic peptides may themselves contribute to myocardial injury. Infarct size after ischemia-reperfusion is smaller in genetically engineered mice lacking NPR-A and mice pretreated with HS-142-1, an NPR-A antagonist, than in wild-type or untreated controls. This reduction in infarct size was accompanied by decreases in neutrophil infiltration, P-selectin expression, and activation of NF- κ B. ANP directly induced P-selectin expression and H₂O₂-induced activation of NF- κ B.²⁷⁹ These results suggest that blockade of NPR-A may alleviate ischemia-reperfusion injury and provide the basis for future clinical interventions. By contrast, other evidence suggests that administration of natriuretic peptide may alleviate ischemia-induced myocardial

damage. Administration of low-dose urodilatin at the time of reperfusion results in a dose-dependent increase in myocardial cGMP and limits necrosis.²⁸⁰ The reason for these apparently conflicting data is not clear and more studies are necessary.

Arrhythmia

ANP and BNP levels are reportedly increased in patients with supraventricular and ventricular tachyarrhythmias.²⁸¹⁻²⁸⁸ Successful treatment with chemical or electrical cardioversion was followed by a decrease in plasma ANP levels in these patients. In patients with atrial fibrillation, elevated ANP levels were unrelated to echocardiographic dimensions, ventricular rate, and blood pressure.²⁸¹ Increased plasma ANP concentration in atrial arrhythmias has been attributed to elevation of atrial pressure,²⁸⁷ and the reduction in ANP levels following cardioversion has been explained by the decrease in atrial pressure resulting from restoration of sinus rhythm.²⁸³ BNP levels have been shown to be beneficial in detecting patients with nonvalvular atrial fibrillation who are at high risk for thromboembolic complications.²⁸⁹

Atherosclerosis

CNP, which is expressed in the vascular endothelium, has antiatherosclerotic effects. The migration of medial smooth muscle cells (SMCs) into the intima is proposed to be an important contributor to intimal thickening in atherosclerotic lesions. Natriuretic peptides, particularly CNP, inhibit oxidized-low-density lipoprotein-mediated SMC migration through a cGMP-dependent process, suggesting that they may act as antimigration factors during the process of intimal thickening in hypercholesterolemia-induced coronary atherosclerosis.²⁹⁰⁻²⁹² In cultured vascular SMC, CNP has been shown to antagonize the mitogenic activity of Ang II.¹⁵⁴ Furthermore, NPR-B is up-regulated *in vivo* in SMCs in the intimal layer of atherosclerotic arteries. This finding could support a regulatory role of natriuretic peptides in atherogenesis.²⁹³ In addition, the vasodilator effects of ANP and cGMP are reduced in atherosclerotic rabbit aortas.²⁹⁴

Increased NEP activity has been demonstrated in atherosclerotic arteries and plasma of cholesterol-fed rabbits.²⁹⁵ Treatment with an NEP inhibitor (UK73967) decreased plasma cholesterol, preserved the arterial concentration of CNP by suppressing local degradation, and inhibited atheroma formation in these animals. The precise mechanism for inhibition of atheroma formation by the NEP inhibitor and whether these findings are reproducible in humans with hypercholesterolemia remain to be determined.

Nephrotic Syndrome

Most,²⁹⁶ although not all,^{297,298} studies have demonstrated slightly elevated ANP levels in nephrotic patients, particularly in those with low plasma renin activity, suggesting that the increase in ANP may be the result of volume expansion. Increased plasma CNP concentrations and urinary CNP excretion have also been reported in patients with nephrotic syndrome.³¹ Some have attempted to treat edema in nephrotic patients with ANP infusion, but the natriuretic response was less than that seen in control subjects.²⁹⁹

Chronic Kidney Disease

Patients with end-stage renal disease have been shown to have markedly elevated ANP and BNP levels that decline somewhat after dialysis.³⁰⁰⁻³⁰³ The main factors responsible for the high plasma concentrations of ANP and BNP are extracellular volume expansion, decreased metabolism and clearance of the peptides and concomitant heart disease. In studies on dialysis patients without heart failure, both BNP and ANP were strong independent predictors of left ventricular mass, ejection fraction, and risk of death.³⁰⁴⁻³⁰⁶ A positive correlation between ANP and left ventricular mass and severity of hypertension was observed in 21 pediatric patients on chronic peritoneal dialysis.³⁰⁷

CNP gene expression has been detected in human kidneys, and increased plasma concentrations of CNP have been reported in patients with chronic kidney disease.¹⁴¹ The renal actions of CNP remain unclear, however.

Respiratory Diseases

Animal studies have shown that ANP and BNP reduce elevated pulmonary vascular tone and attenuate hypoxia-induced pulmonary hypertension.³⁰⁸⁻³¹¹ Plasma ANP levels are elevated in chronic respiratory failure and do not change with short-term oxygen therapy.³¹² BNP levels are also elevated in patients with chronic obstructive pulmonary disease (COPD) and acute hypoxia and are positively correlated with the degree of hypoxia.³¹³ In one study, plasma levels of ANP and BNP were elevated in patients with COPD and PaO₂ <60 mm Hg and correlated significantly with the degree of hypoxemia. Plasma CNP was not detectable in these patients. Plasma levels of ANP and BNP were significantly decreased by long-term oxygen therapy. Moreover, plasma ANP and BNP levels were elevated in COPD patients with right ventricular hypertrophy compared with patients without right ventricular hypertrophy.³¹⁴ These data suggest that in COPD patients, the major stimulus for ANP and BNP secretion may be hypoxemia, but a rise in right ventricular pressure may also play a role.

Plasma ANP concentrations have been reported to be markedly elevated in patients with acute lung injury and to correlate well with the severity of the injury.^{315,316} In patients with chronic thromboembolic pulmonary hypertension, BNP levels were strongly associated with the severity of pulmonary hypertension and decreased significantly following pulmonary thromboendarterectomy.³¹⁷ Sustained elevation of postoperative BNP indicated the presence of residual pulmonary hypertension, suggesting a role for BNP measurement in the evaluation of the efficacy of pulmonary thromboendarterectomy in this condition. In patients with acute pulmonary embolism, BNP levels were also significantly higher in those who had concomitant right ventricular dysfunction.³¹⁸ Thus plasma BNP levels may be of clinical importance as a tool for assessment of right ventricular function in patients with acute pulmonary embolism.

Stroke

Stroke susceptibility loci in SHR-sp have been mapped close to a marker derived from the ANP gene, and structural and functional differences in the ANP gene have been reported in SHR-sp versus stroke-resistant SHR.³¹⁹ Molecular variants,

including a polymorphism within exon 1 (G664A) that encodes a valine-to-methionine substitution in the biologically active proANP, have been identified in humans.³²⁰ Studies looking at whether G664A is a risk factor in stroke patients and whether there is an association with any particular ischemic stroke subtype have provided conflicting results.^{320,321} Hassan et al. studied 436 patients who presented with ischemic stroke or transient ischemic attack and compared them with 295 community control subjects.³²¹ Their results indicated that the ANP gene G664A polymorphism was unlikely to be a major risk factor for ischemic stroke. In contrast, in a study by Rubattu et al., this marker was associated with a twofold increase in the incidence of stroke in human subjects.³²⁰ In the latter study, patients with hemorrhagic stroke were included and an ethnically mixed population was tested, possibly accounting for the differences between the two studies. The prevalence of this polymorphic marker in African Americans remains to be established.

Increased levels of ANP have been found in patients with stroke.³²² ANP has been shown to act directly on the nervous system to inhibit water and sodium accumulation in ischemic brain edema, and thus may be protective through both its vascular and antiedema effects.

Alzheimer's Disease

Accumulation of the neurotoxic peptide amyloid beta-protein Abeta in the cerebrum is thought to play a central role in the pathogenesis of Alzheimer's disease.³²³ Interestingly, Abeta is degraded by a protease which is indistinguishable from insulin-degrading enzyme, a thiol metalloendopeptidase related to NEP that also metabolizes insulin, glucagon, and ANP.³²⁴ Insulin and ANP inhibit the metabolism of Abeta by competing for the insulin-degrading enzyme.³²⁴ The role of ANP in the prevention or treatment of Alzheimer's disease remains to be determined.

Cirrhosis

The mechanisms of sodium retention in cirrhosis are complex and include activation of vasoconstrictors, such as Ang II and norepinephrine.³²⁵ Increased secretion of prostaglandins and ANP compensates, at least in part, for the sodium-retaining actions of these vasoconstrictors. Plasma levels of ANP and BNP are usually elevated in patients with cirrhosis,^{326,327} with the exception of patients with hyponatremia, in whom the levels may actually be decreased.³²⁸ By contrast, urinary excretion of urodilatin is unchanged in patients with cirrhosis even in the presence of increased plasma levels of ANP,³²⁹ suggesting that ANP and urodilatin in cirrhosis are regulated independently. Patients with well-compensated cirrhosis remain in sodium balance, presumably as a result of the natriuretic effects of these elevated levels of ANP. When cirrhosis decompensates, ANP becomes unable to offset the sodium-retaining actions of Ang II and aldosterone and of increased activation of the SNS.³³⁰ With the development of refractory ascites, cirrhotic patients become unresponsive to the natriuretic effects of ANP. This may be in part mediated by further increased activity of the SNS.³³¹ In a rat model of cirrhosis, the ANP response could be entirely restored by renal denervation, suggesting a key role for the SNS in the mediation of unresponsiveness to ANP.³³² Increased circulating DNP levels have been

demonstrated in patients with cirrhosis and ascites when compared with both cirrhotic patients without ascites and healthy subjects. In addition, circulating levels of DNP increased in relation to the severity of cirrhosis.³³³ Unlike ANP, BNP, and DNP, CNP levels are decreased in patients with cirrhosis.³³⁴

Administration of HS-142-1 reduces renal plasma flow and GFR in cirrhotic rats with ascites, suggesting that natriuretic peptides may play a role in preservation of renal function and urine sodium excretion in this condition.³³⁵

CLINICAL USES OF NATRIURETIC PEPTIDES

Diagnostic Use

During the past several years there has been interest in the use of natriuretic peptides as tools for emergent diagnosis and screening of the population for left ventricular systolic and diastolic dysfunction, particularly targeting high-risk groups.³³⁶⁻³⁴¹ Plasma BNP levels have a higher sensitivity and specificity for identification of left ventricular systolic dysfunction than ANP, are capable of differentiating between chronic heart failure patients with moderately and severely impaired exercise capacity and provide a useful indication of which patients are more likely to have heart failure and require further clinical assessment.³⁴²⁻³⁴⁴

Plasma BNP concentration has been suggested as a surrogate therapeutic end-point for patients with heart failure.³⁴⁵⁻³⁴⁷ In a double blind study in patients with NYHA class III or IV heart failure, Troughton et al.³⁴⁵ demonstrated that pharmacotherapy guided by BNP levels reduces cardiovascular events and delays time to first cardiovascular event compared with intensive clinically guided therapy.

In patients with type 1 diabetes without evidence of microalbuminuria, ANP infusion has been shown to increase albumin excretion.³⁴⁸⁻³⁵⁰ Thus, ANP infusion may unmask underlying alterations in glomerular permselectivity and predict diabetic nephropathy. Longitudinal studies are needed to determine whether measurement of ANP-induced microalbuminuria might allow the early detection of at risk patients with diabetes.

Prognostic Use

Plasma concentrations of BNP and ANP are increased in patients with chronic heart failure and accurately predict left ventricular ejection fraction, morbidity and mortality in these patients.^{273,274,346,351-353} In patients admitted with decompensated CHF, changes in BNP levels during treatment were strong predictors for mortality and early readmission.^{346,354} Plasma N-ANP and BNP levels also predict severity of AMI, including infarct size, likelihood of ventricular remodeling and lower ejection fraction and associated mortality independent of ventricular function.^{271,355-361} In the Cooperative New Scandinavian Enalapril Survival Study (CONSENSUS) II trial³⁶² and the Survival and Ventricular Enlargement (SAVE) trial,³⁶³ levels of ANP, measured post-MI, were related to survival. However, when left ventricular ejection fraction was added to the analysis, the independent prognostic value of ANP was diminished. N-ANP was an independent predictor

of death, cardiovascular mortality, and heart failure in a subgroup of patients with AMI from the CONSENSUS II trial,³⁶⁴ Thrombolysis in Myocardial Infarction (TIMI) II trial,³⁵⁸ and SAVE trial.³⁶⁵

Therapeutic Use

Natriuretic peptides, particularly BNP, have been shown to have therapeutic potential for various pathologic conditions. Nesiritide, a recombinant human BNP, recently gained FDA approval as the first new parenteral agent approved for heart failure therapy. In patients with decompensated CHF, nesiritide, in addition to standard therapy resulted in improvement in hemodynamics, including a prompt fall in systemic vascular resistance and pulmonary capillary wedge pressure, associated with rapid clinical improvement and a reduction in self-reported symptoms.³⁶⁶⁻³⁶⁹ Nesiritide also caused fewer arrhythmias in patients with decompensated CHF compared with dobutamine.³⁷⁰ This therapy represents a novel approach to the management of CHF, enhancing naturally occurring protective mechanisms.

Infusion of ANP into patients with AMI improved left ventricular ejection fraction and appeared to be more beneficial in its effects on autonomic nervous activity, plasma renin activity, and myocardial oxygen consumption than nitroglycerin.^{371,372} Infusion of ANP during exercise thallium stress testing in patients with stable angina and normal left ventricular function decreased the extent and severity of the myocardial perfusion defect and prevented ischemia ST-segment depression.³⁷³ In patients with angina pectoris induced by hyperventilation, both ANP³⁷⁴ and BNP³⁷⁵ have been shown to suppress chest pain and electrocardiographic changes by preventing vasospasm via cGMP amplification. In patients with compensated cirrhosis, infusion of ANP in doses that increase plasma concentrations to levels comparable with those observed in patients with ascites, decreases left ventricular end-diastolic volume, stroke volume, cardiac output, and blood pressure, and increases GFR and urinary sodium excretion.³⁷⁶ However, the use of ANP in cirrhosis is generally limited by intolerable drug-induced hypotension, in part because the hypotensive action of ANP in these patients is not associated with an appropriate increase in plasma norepinephrine.³⁷⁷ When combined with terlipressin (a vasopressor analog), increased systemic vascular resistance prevented ANP-induced vasodilation and enhanced the natriuretic effect of ANP in patients with cirrhosis and refractory ascites.³⁷⁸

Use of ANP in patients with renal failure has not been promising. In patients with renal insufficiency receiving ANP or mannitol infusion prior to cardiac catheterization, acute renal failure occurred to a similar extent in both groups.³⁷⁹ In a multicenter, randomized, double-blind, placebo-controlled study, administration of anaritide, a synthetic form of ANP, in critically ill patients with acute tubular necrosis did not improve the overall rate of dialysis-free survival.³⁸⁰ Anaritide improved dialysis-free survival in patients with oliguria, but worsened it in those with nonoliguric acute renal failure. A more recent study showed no significant beneficial effect of ANP in dialysis-free survival or reduction in dialysis in subjects with oliguric acute renal failure.³⁸¹

In a study by Mitaka et al.,³⁸² infusion of ANP-induced diuresis and improved pulmonary gas exchange in patients with acute lung injury during mechanical ventilation. Bindels

et al.³⁸³ studied the effects of infusion of ANP versus inhalation of nitric oxide in patients with an early acute respiratory distress syndrome. ANP did not alter mean pulmonary artery pressure, pulmonary artery resistance index, extravascular lung water index, or pulmonary gas exchange. In contrast, nitric oxide inhalation improved all these indices.

Although the role of ANP as a pharmacotherapeutic agent is limited due to its low oral bioavailability, its narrow therapeutic range, and short half-life, ANP gene therapy may potentially be useful for some conditions. ANP gene delivery has been shown to reduce mortality due to cerebrovascular disorders and stroke in Dahl salt-sensitive rats.³⁸⁴ A single injection of an adenovirus harboring the human ANP gene (Ad.RSV-cANP) caused a significant reduction of blood pressure that lasted for more than 3 weeks. The stroke mortality rate of Dahl salt-sensitive rats decreased significantly from 54% to 17% at 3 weeks after ANP gene delivery compared with rats injected with control virus. A significant reduction in salt-induced aortic hypertrophy as evidenced by decreased thickness of the aortic wall was evident following ANP gene delivery. This technology may have potential value in treating individuals at high risk of stroke.

Administration of synthetic DNP to dogs with severe CHF has beneficial cardiovascular, renal, and humoral effects.²⁶⁴ DNP decreased right atrial and pulmonary capillary wedge pressure, increased GFR in association with natriuresis and diuresis despite a reduction in mean arterial pressure, increased plasma and urinary cGMP, and suppressed plasma renin activity. Thus DNP may have potential as a new intravenous agent for the treatment of decompensated CHF.

Agents that interfere with the receptor binding or metabolism of natriuretic peptides are potential therapeutic targets. Selective antagonists of NPRs have helped define the functions of these natriuretic peptides, but have not yet proved useful in the clinical arena. More promising are the NEP inhibitors. Potent inhibitors of NEP provided useful tools to test the role of NEP in the inactivation of natriuretic peptides, as well as in probing the functions of these peptides. These drugs potentiate the natriuretic and hypotensive responses to intravenous infusions of ANP, as well as the natriuretic response to volume expansion.³⁸⁵ NEP inhibition results in diuresis and natriuresis in rats with CHF^{386,387} and chronic kidney disease.³⁸⁸ In rats with chronic heart failure, ONO-9902, a NEP inhibitor, reduced left ventricular end-diastolic pressure and increased cardiac output. These changes were associated with decreased plasma levels of ANP, BNP, and ET-1.³⁸⁹ In salt-sensitive models of hypertension, such as the DOCA-salt rat model, NEP inhibitors reduce blood pressure.³⁹⁰ These actions occur despite minimal increases in plasma ANP levels and are associated with increased urinary excretion of cGMP, suggesting that the antihypertensive response to NEP inhibition cannot be attributed exclusively to changes in plasma concentration of ANP and that NEP inhibitors may raise local tissue levels of ANP without increasing plasma levels. The actions of NEP inhibitors have also been attributed to reduced inactivation of other vasoactive peptides, such as bradykinin.³⁹¹ This hypothesis is unlikely because SCH 34826, an oral NEP inhibitor, failed to affect the depressor response to bradykinin.³⁹⁰ Moreover, administration of a bradykinin antagonist failed to alter the hypotensive response to the oral administration of SCH 34826 in the DOCA-salt rat. NEP inhibitors can also potentiate the renal

effects of ANP, and this response is partially inhibited by bradykinin antagonists.³⁹²

Studies with NEP inhibitors in humans have been promising. In patients with heart failure caused by left ventricular systolic dysfunction, administration of candoxatril, a specific NEP inhibitor, increased sodium excretion, reduced right and left atrial pressures without any increase in renin activity and improved exercise capacity.³⁹³⁻³⁹⁶ NEP inhibitors such as phosphoramidion and UK 73967 have been shown to potentiate the myocardial protective action of ANP and BNP against neutrophil-induced endothelial cytotoxicity, which is known to play a role in ischemia-reperfusion myocardial injury.³⁹⁷

Vasopeptidase inhibitors are a new class of drugs that inhibit both NEP and ACE, augmenting any beneficial effect of the elevation of natriuretic peptides.^{398,399} Simultaneous inhibition of NEP and ACE results in increases in natriuretic peptides (ANP, BNP, and CNP) and vasodilatory peptides (bradykinin and adrenomedullin), thereby enhancing vasodilation, decreasing vascular tone, and lowering blood pressure. None of these drugs has been approved for human use due to a high frequency of angioedema.

Since the discovery of the natriuretic peptides in 1981, extensive research has revealed many potential therapeutic uses of these peptides. Future efforts in this in this area may allow fulfillment of their therapeutic potential.

Vasodilator Peptides: CGRP, Substance P, and Adrenomedullin

Ralph E. Watson, Donald J. DiPette, Scott C. Supowit, Khurshed. A Katki, Huawei Zhao

There is mounting evidence that the potent vasodilator peptides calcitonin gene-related peptide (CGRP), substance P (SP), and adrenomedullin (ADM) regulate cardiovascular function both in the normal state and in hypertension. Evidence from human studies and experiments in rat and mouse models of hypertension has shed more light on the possible roles of these neuropeptides in human hypertension.

CALCITONIN GENE-RELATED PEPTIDE

CGRP is a 37-amino acid neuropeptide derived from the tissue-specific splicing of the primary RNA transcript of the calcitonin/CGRP gene,^{1,2} which will be referred to as the α -CGRP gene. Calcitonin is produced mainly in the parafollicular cells of the thyroid, but CGRP synthesis occurs almost exclusively in regions of the central and peripheral nervous systems.³ β -CGRP is a second CGRP gene that does not produce calcitonin, but also produces CGRP, primarily in central neuronal tissues.^{3,4} The two CGRP genes, α -CGRP and β -CGRP in the rat and I and II in humans, differ in their protein sequences by one and three amino acids respectively, and the biologic activities of the two peptides are quite similar in most vascular beds.⁵

Distribution and Localization of CGRP

Immunoreactive CGRP and its receptors are widely distributed in the nervous and cardiovascular systems.^{5,6} In the peripheral nervous system, common sites of CGRP synthesis are in the spinal nerve dorsal root ganglia (DRG). These structures contain the cell bodies of sensory nerves that terminate centrally in laminae I/II of the dorsal horn of the spinal cord and peripherally in blood vessels and all other tissues innervated by the sensory nervous system.⁷ Blood vessels in all vascular beds are surrounded by a dense perivascular CGRP neural network.³ Circulating CGRP is thought to be a spillover phenomenon from the perivascular nerve terminals caused by release of CGRP to promote vasodilation and other functions.³ Receptors for CGRP have been identified in the media and intima of resistance vessels.

Cardiovascular Actions of CGRP

CGRP is the most potent vasodilator discovered to date, and it has positive chronotropic and inotropic effects.^{8,9} CGRP selectively dilates many vascular beds, especially the coronary vasculature.^{3,8,10} Systemic administration of CGRP decreases blood pressure (BP) in a dose-dependent manner in nor-

motensive animals and humans.^{3,6} The primary mechanism is peripheral arterial dilation.^{3,6,9} The CGRP receptors are coupled to G proteins. G proteins are located in the intracellular portion of the plasma membrane, and they bind activated receptor complexes. Through conformational changes and cyclic binding and hydrolysis of guanosine triphosphate, G proteins, directly or indirectly, affect alterations in channel gating, thus coupling cell surface receptors to intracellular responses. In a number of tissues, including vascular smooth muscle, CGRP increases intracellular cyclic adenosine monophosphate (cAMP). CGRP may also activate adenosine triphosphate-activated potassium channels of vascular smooth muscle.³ The vasodilator response evoked by CGRP may, in part, be mediated by nitric oxide (NO) release.³ Various vascular beds may differ in their dependence on the endothelium for the dilator response to CGRP.³ The NO-mediated vasodilator response is endothelium dependent, whereas the other mechanisms directly affect the vascular smooth muscle. Thus CGRP can dilate blood vessels through endothelium-dependent and endothelium-independent mechanisms.

Role of CGRP in Human Hypertension

CGRP administration can significantly decrease BP in humans,^{3,6} but it is not clear what role CGRP plays in human hypertension. The levels of circulating immunoreactive CGRP in hypertensive humans reported in different studies have been inconsistent.^{3,6} Several factors are probably responsible, including the assay itself, heterogeneity of essential hypertension, severity and duration of the BP elevation, the degree of target organ damage, and the variety of treatment regimens used in the patients.³

Role of CGRP in Rat Models of Experimental Hypertension

In contrast to human hypertension, a direct role for CGRP in experimental hypertension has now been established. We have previously reported that CGRP plays a compensatory vasodilator role to attenuate the BP increase in three rat models of acquired hypertension: (1) deoxycorticosterone-salt (DOC-salt),^{11,12} (2) subtotal nephrectomy-salt (SN-salt),¹³ and (3) *N*-nitro-L-arginine methyl ester (L-NAME)-induced hypertension during pregnancy.¹⁴ Considerable progress has been made in elucidating the mechanism of the antihypertensive effects of CGRP in these settings. In the DOC-salt model, the depressor activity of CGRP appears to be mediated by a significant increase in the neuronal synthesis and release of

the peptide, whereas in the SN-salt and L-NAME models, the BP lowering effect of CGRP is mediated by a marked increase in vascular reactivity to the dilator actions of the neuropeptide. In contrast, the spontaneously hypertensive rat (SHR), a genetic model of hypertension,¹⁵ displays a significant age-related decrease in CGRP production, which may contribute to the increased BP through the loss of a potent vasodilator system.¹⁶ These and related studies have been the subject of several reviews.^{7,17} Therefore, we will focus on recent reports that use α -CGRP null mice.

Characterization of the α -CGRP Knockout Mouse

To assess the long-term role of CGRP in the regulation of cardiovascular function, permanent deletion of this gene was achieved by targeted disruption of the calcitonin/ α -CGRP gene locus.¹⁸ The β -CGRP gene is intact in these knockout (KO) mice; however, α -CGRP is by far the predominant CGRP species produced in DRG neurons.³ The mice used in these studies were genotyped using standard polymerase chain reaction techniques. In our initial studies, systolic blood pressure, determined by tail-cuff BP, was significantly ($p < .01$) higher in the KO mice (160 ± 6.1 mm Hg) compared with controls (125 ± 5 mm Hg).¹⁹ To confirm this finding, previously instrumented KO and wild-type (WT) mice (25- to 30-g males) were studied fully awake and unrestrained. As shown in Figure 19–1, the mean arterial pressure (MAP) was significantly elevated in the KO mice compared with the controls. The mice were sacrificed and the DRG were removed and frozen for later quantification of α -CGRP, β -CGRP, and SP mRNA and peptide levels. Figure 19–2 shows the absence of the α -CGRP mRNA in the KO mice following Northern blot analysis. Experiments were also performed to determine whether β -CGRP and SP mRNA levels were altered in KO mice. As expected, the mRNA species for β -CGRP and SP were present in both groups, and normalization of the hybridization signals (β -CGRP and SP) to 18S rRNA levels indicated that there was no significant difference in the synthesis of these mRNAs between genotypes.

Figure 19–1 Systolic BP measurements in α -CGRP KO and WT mice of either sex, with the tail-cuff method. BP values were obtained for each animal by taking four to six readings daily for 5 days. Mean \pm SEM for each group ($n = 7$) are presented for both male and female mice. Asterisk indicates significant differences from WT ($p < .05$). (From Gangula PR, Zhao H, Supowit SC, et al. Increased blood pressure in alpha-calcitonin gene-related peptide/calcitonin gene knockout mice. *Hypertension* 35:470-475, 2000.) BP, blood pressure; KO, knockout; WT, wild-type; SEM, standard error of measure.

Immunostaining for immunoreactive CGRP (iCGRP) was performed in the spinal cords of both KO and control mice. We observed intense staining of CGRP in laminae I/II of the dorsal horn of the spinal cord in the WT mice. Even though the antibody used in these studies recognizes both α - and β -CGRP, no staining of iCGRP was observed in the KO mice.

Please refer to the printed publication.

Figure 19–2 Northern blot analysis of mRNA from DRG from WT and α -CGRP KO male (A) and female (B) mice. Total cellular RNA samples isolated from DRG taken from WT and α -CGRP KO mice were fractionated on a denaturing formaldehyde-agarose gel and transferred to a nylon membrane. The membrane was hybridized with the ³²P-labeled α -CGRP genomic DNA insert. The α -CGRP was removed from the membrane, which was subsequently hybridized with ³²P-labeled 18S rDNA probe (bottom). After hybridization with each probe, the membrane was washed and placed on a phosphor screen, and the image was generated from PhosphorImager analyses of the exposed screen. Note the lack of α -CGRP mRNA in the α -CGRP KO group. (From Gangula PR, Zhao H, Supowit SC, et al. Increased blood pressure in alpha-calcitonin gene-related peptide/calcitonin gene knockout mice. *Hypertension* 35:470-475, 2000.) mRNA, messenger ribonucleic acid; DRG, dorsal root ganglion; WT, wild-type; KO, knockout; rDNA, ribosomal deoxyribonucleic acid.

In later studies the BP phenotype of the mutant mice was confirmed by radiotelemetric recording. Both α -CGRP KO and WT controls underwent probe implantation and recording was begun 1 week after the surgery to allow for recovery. The telemetric analyses were based on data for 7 consecutive days. Comparisons were made of harmonic patterns, rhythm-adjusted mean (MESOR = average 24-hour arterial pressure), amplitude, and acrophase (clock time of peak amplitude).²⁰ As anticipated, both the α -CGRP KO and WT mice displayed a 24-hour rhythm characterized by several nighttime peaks. As shown in Figure 19–3, the average 24-hour MAP was approximately 12 to 20 mm Hg higher in the KO mice compared with the controls, consistent with our previous data. These mice were then placed on a high-salt (3.2% Na) diet for 2 weeks and BP and heart rate were recorded by telemetry. No increase in MAP or heart rate was observed in either strain. These findings are in agreement with our previous studies showing that a chronic high-salt diet does not increase the MAP (measured acutely) in either the α -CGRP KO or WT mice.

It should be noted that, to delete the α -CGRP gene, it was also necessary to inactivate the calcitonin gene, as well as katalcalcin, that is derived from the processing of the calcitonin peptide precursor.³ It is important to note that it has been clearly demonstrated that neither endogenous calcitonin nor katalcalcin plays a role in cardiovascular regulation.^{3,21} A second KO mouse, specific for α -CGRP, has been generated, but on a different genetic background, by Lu et al.²² Interestingly these KO mice do not appear to display an increased baseline

Rights were not granted to include this figure in electronic media.

Figure 19–3 MAP determinations made with an indwelling carotid arterial catheter in α -CGRP KO and WT mice of either sex in a fully awake and unrestrained state. Mean \pm SEM for each group ($n = 7$) are presented for both male and female mice. Asterisk indicates significant differences from WT ($p < .05$). (From Gangula PR, Zhao H, Supowit SC, et al. Increased blood pressure in alpha-calcitonin gene-related peptide/calcitonin gene knockout mice. Hypertension 35:470-475, 2000.) MAP, mean arterial pressure; KO, knockout; WT, wild-type; SEM, standard error of measure.

MAP. Another α -CGRP-specific KO strain that has the same genetic background as the mice used in our study has been generated and shown to display a significantly elevated BP and heart rate compared with controls.²³ Although differences in genetic background or experimental approach may account for the discrepancy between the findings of Lu et al.²² and the results reported by us and Oh-hashii et al.,²³ these data indicate that α -CGRP plays a significant role in the regulation of basal BP.

DOC-Salt-Induced Hypertension in the α -CGRP KO Mouse

Hypertension was induced in 8- to 10-week-old male α -CGRP KO mice and their WT counterparts by uninephrectomy, DOC administration, and 0.9% saline drinking water. Control KO and WT mice were sham operated and given tap water to drink. Three weeks after initiation of the protocol, all mice had arterial catheters surgically placed for continuous MAP recording and were studied in a conscious and unrestrained state. The DOC-salt protocol produced a significant increase in MAP in the α -CGRP KO and WT animals. When normalized to baseline BP, the MAP was 15% and 30% higher in the WT and CGRP KO mice, respectively. This MAP increase in the DOC-salt KO mice compared with untreated KO mice was significantly greater than that observed in the WT groups. Cardiac hypertrophy (heart/body weight) was present in the control CGRP KO (0.51 ± 0.02) compared with control WT (0.45 ± 0.01) mice. As expected, there was a significant increase in heart to body weight ratios in the two DOC groups (DOC-salt KO, 0.68 ± 0.02 vs. DOC-salt WT, 0.68 ± 0.02) when compared with their matching control group. These data indicate that deletion of the α -CGRP gene not only increases baseline BP and cardiac weight, but also enhances the BP response to DOC-salt treatment.²⁴

Blood Pressure Response to Capsaicin Administration in α -CGRP KO and WT Mice

Several lines of evidence indicate that the efferent vasodilator activity of the sensory nervous system is mediated primarily by capsaicin (the active ingredient in pepper)-sensitive C-fiber and A δ -fiber classes of sensory nerves. To study the hypotensive role of CGRP following stimulation of capsaicin-sensitive sensory nerves, we used α -CGRP KO mice and WT controls in conjunction with the CGRP antagonist (CGRP₈₋₃₇).²⁵ In the anesthetized state the MAP of the KO mice was still approximately 15 mm Hg higher than that of the WT controls. Intravenous administration of capsaicin to WT mice produced a rapid but transient (~30 seconds) bradycardia accompanied by a 40% decrease in MAP. This response was followed by a sustained (4-6 minutes) hypotensive effect that reduced the MAP by 20%. Pretreatment of the WT mice with atropine abolished the transient bradycardia and hypotension, but was without effect on the prolonged hypotensive response. In contrast, the prolonged hypotensive response was blocked by administration of CGRP₈₋₃₇. In the CGRP KO mice, capsaicin again produced a transient, atropine-sensitive bradycardia and reduction in MAP (40%), but the sustained hypotensive response was absent. Pretreatment of both mouse strains with

the capsaicin antagonist, capsazepine, blocked all of the actions of capsaicin. These data indicate that although the initial hemodynamic effects of capsaicin treatment result from transient vagal stimulation, the sensory nerve component of the sustained capsaicin-mediated hypotensive response is primarily dependent on α -CGRP.

Coronary Flows in the α -CGRP KO Mouse

Studies performed in the rat suggest that capsaicin-sensitive sensory nerves participate in the regulation of basal coronary blood flow. To test the hypothesis that α -CGRP plays a critical role in the regulation of coronary blood flow, Langendorff-perfused heart preparations were used to compare coronary flow rates between α -CGRP KO and WT control mice under various pressure-loading conditions.²⁶ Deletion of the α -CGRP gene in both sexes resulted in a significant 20% to 30% reduction in coronary flow at all pressures tested. In addition, coronary flow for both strains of mice was consistently lower in females than in males. These data suggest that CGRP is responsible for up to 30% of basal coronary blood flow. Histopathologic analysis showed no obvious structural or pathologic alterations in the myocardium or coronary vasculature between genotypes. Because blood vessel diameter is directly related to coronary flow, studies were performed to determine the range of blood vessel diameters (optical micrometer) in heart sections from the KO and WT mice. No detectable differences were observed between strains. Thus, the mechanism of this reduction in coronary flow is likely to be decreased coronary vasodilation resulting from ablation of α -CGRP from perivascular sensory nerve terminals.

Summary

CGRP and its receptors are widely distributed in the nervous and cardiovascular systems. CGRP is the most potent vasodilator discovered to date and has positive chronotropic and inotropic effects. CGRP selectively dilates many vascular beds, especially the coronary vasculature. Systemic administration of CGRP decreases BP in a dose-dependent manner in normotensive animals and humans, primarily by peripheral arterial dilation. It can dilate blood vessels through endothelium-dependent and endothelium-independent mechanisms. Although CGRP administration can significantly decrease high BP in humans, it is not clear what role CGRP plays in human hypertension. However, a direct role for CGRP in experimental hypertension has now been established in several models of hypertension. In acquired rat models, CGRP plays a compensatory vasodilator role to attenuate the BP increase. In the DOC-salt model, the depressor activity of CGRP appears to be mediated by a significant increase in the neuronal synthesis and release of the peptide. In the SN-salt and L-NAME models, the BP lowering effect of CGRP is mediated by a marked increase in vascular reactivity to CGRP. By contrast, the SHR, a genetic model of hypertension, displays a significant age-related decrease in CGRP production, which may contribute to the increased BP through the loss of a potent vasodilator system.

MAPs in mice with a permanent deletion of the α -CGRP gene are significantly elevated compared with controls. This deletion also increases cardiac weight and enhances the BP response to DOC-salt hypertension. In addition, whereas the

initial hemodynamic effects of capsaicin treatment in mice result from transient vagal stimulation, the sensory nerve component of the sustained capsaicin-mediated hypotensive response is primarily dependent on α -CGRP. Studies of CGRP KO mice suggest that CGRP is responsible for up to 30% of basal coronary blood flow.

SUBSTANCE P

SP is an 11-amino acid peptide sensory neurotransmitter that mediates pain, touch, and temperature. It is involved in many physiologic activities including smooth muscle contraction and vasodilation.^{5,6,17,27-29} SP was first described in 1931 as “an atropine-resistant factor, which stimulates smooth muscle and lowers blood pressure.”³⁰ Its structure was first identified in 1971.³¹ SP is a member of the tachykinin family. The five major mammalian tachykinins are SP, neurokinin A (NKA), neurokinin B (NKB), neuropeptide K, and neuropeptide- γ (NP- γ).³²⁻³⁴ SP is derived from tissue-specific alternative splicing of the preprotachykinin I gene and is produced almost exclusively in neuronal tissues.³² An important site of SP synthesis is the DRG, which contain the cell bodies of sensory neurons that extend centrally to the spinal cord and peripherally to blood vessels.⁷ SP and its receptor (NK-1 receptor) are present throughout the central and peripheral nervous systems.³⁵⁻³⁷ SP receptors are also found in endothelial cells.³⁵ SP is often located in and released from the same sensory nerve endings as CGRP.³⁶ SP has been shown to regulate blood flow of various organs.

Cardiovascular Actions of Substance P

SP is a potent vasodilator, but has little effect on heart rate and cardiac contractility.³⁵ Of the three tachykinin receptor subtypes NK-1, NK-2, and NK-3, SP is the preferred ligand (binding-molecule) for NK-1 receptors, NKA for NK-2, and NKB for NK-3, but all three tachykinins have some affinity for all three NK receptors if a high enough dose is given.³⁵ The three receptors all belong to the superfamily of G-protein-coupled receptors. SP induces vasodilation by an endothelium-dependent mechanism involving the release of both NO and a hyperpolarizing/vasodilator factor different from NO.^{6,35,38}

Release of Substance P from Sensory Nerve Terminals

Sensory nerve fibers are classified as capsaicin-sensitive and capsaicin-insensitive. The capsaicin-sensitive nerves have the receptor for capsaicin. When capsaicin-sensitive sensory nerve fibers are exposed to capsaicin, they release SP. SP-rich nerve fibers are part of the sensory nervous system, comprising mostly capsaicin-sensitive C-fiber and A δ -fiber nerves that respond to chemical, thermal, and mechanical stimuli.^{27,28,39} These stimuli cause SP release. If the stimulus is powerful enough, it also causes propagation of sensory information back to the central nervous system. Although these nerves have traditionally been thought to “sense” stimuli in the periphery and transmit the information centrally, there is evidence that they also have an efferent function. It is clear that DRG-neuron-derived peptides are released at peripheral sensory nerve terminals in the absence of afferent nerve stim-

ulation.⁴⁰ The continuous release of peptides from DRG neurons may reflect a paracrine function, with the released peptides binding to nearby receptors. This implies that these neurons participate in the continuous regulation of blood flow and other tissue activities. It has been postulated that some DRG neurons are specialized in controlling peripheral effector mechanisms, but have no role in sensation.⁴⁰

Role of Substance P in Hypertension

Decreased levels of SP have been found in stroke-prone spontaneously hypertensive rats (SHR-sp) and in human essential hypertension.⁴¹ Therefore, SP could contribute to elevated BP by the decreased activity of a counterregulatory mechanism. A nonpeptide SP receptor (NK-1) antagonist has been used to study the hemodynamic role of the peptide in five experimental models of hypertension, including the DOC-salt; SN-salt; SHR; two-kidney, one-clip rats; and one-kidney, one-clip rats.^{15,41-43} In conscious unrestrained rats, the SP antagonist induced significant increases in MAP in the three salt-dependent models, DOC-salt, SN-salt, and one-kidney, one-clip rats. However, the antagonist caused no significant effect on the MAP in the salt-independent models, SHR and two-kidney, one-clip. This suggests that SP may act as a partial compensatory mechanism to counteract the BP increase in salt-dependent hypertension.

Studies performed in our laboratory, confirmed the depressor effects of SP using a peripherally acting NK-1 receptor antagonist (spantide-II) and determined the neuronal expression and release of SP in both the SN-salt and DOC-salt models.^{42,43} In addition, we studied the Dahl salt-sensitive and Dahl salt-resistant rats, a model of hypertension that has both genetic and salt-dependent components.⁴⁴

To determine the role and mechanism of action of SP in SN-salt hypertension, we induced hypertension in 4- to 6-week-old male Sprague-Dawley rats by subtotal nephrectomy and 1% saline drinking water. Sham-operated rats were given either tap water or 1% saline to drink.⁴² Eleven to 13 days later, all rats had intravenous (for drug administration) and arterial (for continuous monitoring of MAP) catheters surgically implanted and were studied in the conscious and unrestrained state. Baseline MAP was significantly elevated in the SN-salt rats (157 ± 6 mm Hg) compared with tap water-fed (128 ± 3 mm Hg) and 1% saline-fed controls (132 ± 5 mm Hg). As shown in Figure 19-4, intravenous vehicle administration did not significantly alter the MAP in any of the groups. In contrast, intravenous administration of spantide-II resulted in a rapid increase of the already elevated MAP in the SN-salt rats compared with both control groups.⁴² To determine whether neuronal expression of SP is altered in this model, we quantified SP mRNA and peptide levels in DRG from all the study groups. As shown in Figure 19-5, the SP mRNA and peptide levels were not elevated in the SN-salt rats compared with controls.⁴² To determine whether the mechanism of the anti-hypertensive effect of SP in the SN-salt model is due to increased vascular reactivity to the dilator activity of this neuropeptide, similar to our findings with CGRP, we administered exogenous SP to these three groups.⁴² As shown in Figure 19-6, this resulted in a significantly greater decrease in MAP in the SN-salt rats compared with both control groups. This suggests that, in SN-salt hypertension, SP plays a counterregulatory role in the absence of an increase in production

of SP. One possible mechanism of this compensatory vasodilator response is enhanced vascular reactivity to SP.⁴²

Summary

Taken together, various lines of research suggest a potential dual role of SP in essential hypertension and regulation of regional organ blood flow:

1. A deficiency of SP could result in hypertension and decreased organ blood flow.
2. Enhanced vascular reactivity to SP could be a compensatory vasodilator response to hypertension or decreased organ blood flow.

All of these experiments were performed acutely, so the long-term participation of SP in hypertension is unknown. Studies in humans are also needed. Nevertheless, these studies point to the SP-containing sensory afferent neurons having an important efferent cardiovascular function.

ADRENOMEDULLIN

Adrenomedullin (ADM) was discovered in 1993, when peptide extracts from human pheochromocytoma were studied.⁴⁵ The name comes from its abundance in normal adrenal medulla, as well as in pheochromocytoma tissue arising from adrenal medulla.⁴⁵ It is a 52-amino acid peptide with a unique 6-amino acid ring structure formed by an intramolecular disulfide bond between residues 16 and 21. It also has a C-terminal amide structure. Both of these features are similar to structures found in CGRP and amylin (a 37-amino acid peptide packaged with insulin in pancreatic β -cell secretory granules that inhibits glycogen synthesis and glucose utilization).⁴⁶ Thus ADM is considered a member of the CGRP/amylin/calcitonin superfamily of peptides. ADM has a potent and long-lasting hypotensive effect.⁴⁵ The ADM gene is situated in a single locus of chromosome 11.⁴⁷ ADM antagonists such as ADM-(22-52) and ADM-(40-52) do not contain the ring and lack agonist activity.⁴⁶

Distribution of Adrenomedullin

ADM immunoreactivity in the rat and pig is found in the adrenal gland, heart, lung, and kidney.^{48,49} Since the discovery that the ADM gene is more highly expressed in endothelial cells than even the adrenal medulla,⁵⁰ ADM is now regarded as a secretory product of the vascular endothelium, like NO and endothelin, and ADM expression has been found in all tissues of the body.⁵¹

Adrenomedullin in Human Hypertension

Plasma ADM levels are increased in hypertensive patients compared with normotensive controls, especially if there is an increase in serum creatinine or renin levels.⁵²⁻⁵⁷ There is a progressive rise in ADM proportionate to the severity of the hypertension and the target organ damage.⁵⁵⁻⁵⁷ This suggests that ADM is released to compensate for the elevated BP.⁵¹ After control of BP with antihypertensive medication, plasma ADM levels do not come down.⁵² Plasma ADM levels are directly proportional to serum creatinine levels and inversely related to

glomerular filtration rates (GFRs) in hypertensive patients.⁵² Neither acute nor chronic salt-loading changes plasma ADM levels in normotensives or essential hypertensives.⁵⁸

Adrenomedullin in Experimental Models of Hypertension

In Dahl salt-sensitive rats, plasma ADM and cardiac ventricle ADM concentration and mRNA levels were higher in rats with high-salt than low-salt intake.⁵⁹ Plasma ADM correlated well with the weight of the left ventricle, suggesting that ADM participates in the pathophysiology of salt-dependent hypertension and cardiac hypertrophy.⁵⁹ In DOCA-treated SHR that developed malignant hypertension, plasma and renal tissue ADM were significantly higher than in control rats.⁶⁰ Chronic ADM infusion in Dahl salt-sensitive rats significantly improved renal function (serum creatinine, creatinine clearance, and urinary protein excretion) and histologic findings (glomerular injury score) without changing MAP compared with untreated controls, suggesting that ADM has renoprotective effects in this experimental model of hypertension.⁶¹ Chronic infusion of ADM significantly prolonged life in this model.⁶² Human ADM gene delivery delays BP rise and protects against cardiovascular remodeling and renal injury in several rat models of hypertension.⁶³⁻⁶⁵

Circulating Adrenomedullin in Other Disease States

ADM levels are also increased in patients with congestive heart failure (CHF),⁶⁶ renal disease,⁵³ and acute myocardial infarction (MI).⁶⁷ In CHF, there is a progressive increase in plasma ADM level from New York Heart Association classification I to IV.⁶⁶ Among acute MI patients, plasma ADM levels were higher in those who developed CHF than those without CHF. ADM may be increased to compensate for the increase in vasoconstrictors seen in acute MI.⁶⁷

In hepatic cirrhosis, a progressive increase in ADM levels has been observed with increasing disease severity.⁶⁸ There is an inverse relationship between ADM levels and GFR,⁶⁹ creatinine clearance, and sodium excretion,⁷⁰ suggesting that ADM might play a role in the hemodynamic changes that lead to ascites and edema in cirrhosis.^{51,70}

Of all the conditions studied, the greatest increase in ADM is seen in septic shock.^{71,72} ADM likely plays a key role in its pathophysiology. Because a correlation between ADM levels and the relaxation of vascular tone has been demonstrated,⁷³ it is likely that ADM is directly responsible for the hypotension characteristic of septic shock.⁵¹

Biologic Actions of Adrenomedullin

Intravenous infusion of ADM into many animals and humans causes a potent and sustained hypotension, mainly through NO production in blood vessels.⁵¹ The effects are comparable with CGRP.⁵¹ Interestingly, injection of ADM directly into the corpus cavernosum of the cat penis causes a significant, dose-dependent increase in penile length and increased intracavernous pressure.⁷⁴ The mechanism is unclear but is not NO dependent, because the NO inhibitor (*N* ω -nitro-L-arginine methyl ester) does not block the effect. ADM has antiproliferative effects and inhibits coro-

nary artery smooth muscle migration, and so may inhibit vascular remodeling.⁷⁵ It also may have a role in uterine growth and revascularization.⁷⁶ There is still considerable debate about the exact role of ADM in cell and tumor growth.⁵¹

ADM inhibits adrenocorticotrophic hormone (ACTH) release from the pituitary and aldosterone production, but may increase renal blood flow, urine output, and urinary sodium excretion.⁵¹ It may also play a paracrine regulatory role in skeletal growth. It causes pulmonary vasodilation and inhibits bronchoconstriction. ADM is expressed in most key mucosal surfaces and has antimicrobial properties against both gram-positive and gram-negative bacteria.

Adrenomedullin Receptors

Are there separate ADM receptors or do CGRP receptors mediate the effects of ADM? ADM receptors have always been linked to the CGRP receptors.^{3,51} There are two subtypes of CGRP receptors, based on the potency of the CGRP receptor antagonist fragment CGRP₈₋₃₇.⁷⁷ CGRP₁ receptors require much lower concentrations of CGRP₈₋₃₇ than CGRP₂ receptors for antagonism. The vasodilating effects of ADM on the rat mesenteric vessels (a prototypic CGRP₁ receptor) are blocked by CGRP₈₋₃₇.⁷⁸ Many subsequent studies have documented the blocking of some ADM effects by CGRP₈₋₃₇. In addition, ADM binds with high affinity to and activates CGRP receptors in neuroblastoma cells, a model of CGRP₁ receptors.⁷⁹ Several later studies supported the high-affinity binding of ADM to almost all CGRP receptors, with an affinity of one tenth to one hundredth that of CGRP itself.⁵¹

ADM has a low affinity for the CGRP receptors in guinea pig vas deferens, a model of CGRP₂ receptors, suggesting that ADM has lower affinity for CGRP₂ than CGRP₁ receptors.⁸⁰ However studies of the inhibitory effects of CGRP₈₋₃₇ on ADM actions must be interpreted with caution.⁵¹ In some studies, very high concentrations of CGRP₈₋₃₇ were used, which may bind to specific ADM receptors and make interpretation difficult.^{51,81} In vivo studies demonstrating that CGRP₈₋₃₇ blocks CGRP effects but not ADM effects at the same concentrations provide strong evidence for specific ADM effects.^{51,82-84}

Are there specific ADM receptors? It is clear that CGRP receptors mediate at least *some* of the effects of ADM, but receptors in cultured rat vascular smooth muscle cells were found to have 23 times greater affinity for ADM than for CGRP, which is unlike any known CGRP receptor.⁸⁵ This suggests that a specific ADM receptor exists. Surprisingly, the effects of ADM on these cells were inhibited by high doses of CGRP₈₋₃₇.⁸⁵ In another study, CGRP₈₋₃₇ blocked the effects of ADM in cultured rat vascular smooth muscle cells, but the binding of ADM in these cells was not inhibited by CGRP or high doses of CGRP₈₋₃₇.⁸⁶ These two studies clearly indicate the existence of receptors with higher affinity for ADM than for CGRP, which make these very different from any known CGRP receptors.^{51,85,86} Specific ADM binding sites have been found in rat heart, lung, spleen, liver, skeletal muscle, and spinal cord.⁸⁷

The human ADM fragment ADM₂₂₋₅₂ is a specific ADM receptor antagonist.⁸⁸ In rabbit endothelial cells and rat cerebral blood vessels, it is an effective antagonist,^{89,90} but in rat mesangial (glomerular support) cells and human neuroblas-

toma cells, it was no more potent an antagonist of ADM than CGRP₈₋₃₇.⁸⁸ In rat vascular smooth muscle cells, ADM₂₂₋₅₂ is a very weak antagonist.⁹¹ In rat cardiac cells and cat hindlimb vascular bed, ADM₂₂₋₅₂ not only is inactive against ADM, but inhibits CGRP effects.^{92,93} Therefore, a much better antagonist needs to be developed.

The identification and characterization of the functional CGRP and ADM receptor(s) has been very controversial, especially since the publication of the "RAMP" (receptor activity modifying protein) hypothesis.⁹⁴ This hypothesis states that both ADM and CGRP signal through a common receptor, calcitonin receptor-like receptor (CRLR). Ligand specificity is determined by coexpression of either of two chaperone proteins RAMP1 (CGRP) or RAMP2 (ADM). Another RAMP (RAMP3) has also been postulated to confer ADM specificity to CRLR. So far, three biologic functions for RAMPs have been defined: They transport CRLR to the cell surface, define its pharmacology, and determine its glycosylation state. It now appears that a functional CGRP (or ADM) receptor must include three proteins in a complex: the ligand-binding, membrane-spanning protein (CRLR); a chaperone (RAMP1 or 2); and a third peptide, the receptor component protein, that couples the receptor to the cellular signal transduction pathway.⁹⁵

Summary

ADM may play a significant role in human hypertension as a compensatory vasodilator. Studies in several rat models of hypertension suggest that ADM delays BP rise and protects against cardiovascular remodeling and renal injury. ADM levels are increased in several other disease states, usually as a compensatory response to vascular changes. But the greatest increase in plasma ADM levels is seen in septic shock, where ADM is probably directly responsible for the characteristic hypotension.

The effects of ADM are probably the result of binding to both CGRP and specific ADM binding sites. These effects can be blocked by both a CGRP₁ receptor antagonist (CGRP₈₋₃₇) and an ADM receptor antagonist (ADM₂₂₋₅₂). However, neither of these antagonists is very potent, and their specificities are doubtful. We need small, nonpeptide, potent, specific antagonists to definitively study the physiology of ADM receptors.

In addition to vasodilation, ADM has many other actions, including the following:

1. Antiproliferative inhibition of smooth muscle cell migration, and thus inhibition of vascular remodeling
2. A role in uterine growth and revascularization
3. Possibly a role in cell and tumor growth
4. Inhibition of ACTH release from the pituitary and of aldosterone production
5. Increases in renal blood flow, GFR, and urinary sodium excretion and decreases in distal tubular sodium reabsorption
6. Regulation of skeletal growth
7. Pulmonary vasodilation and inhibition of bronchoconstriction
8. Antimicrobial properties against both gram-positive and gram-negative bacteria

Figure 19-6 SP decreases MAP in SN-salt rats in a dose-dependent manner. The three groups of animals ($n = 6/\text{group}$) were instrumented for continuous MAP recording and intravenous drug administration as described previously. With the rats fully awake and unrestrained, the vehicle (0.1 ml of saline) was administered followed by a single dose of $12 \text{ nmol} \cdot \text{L}^{-1} \cdot \text{kg}^{-1}$ SP, and the change in MAP was recorded. In another experiment, the same three groups of animals were used, and a dose of $24 \text{ nmol} \cdot \text{L}^{-1} \cdot \text{kg}^{-1}$ of SP was injected intravenously. Values reported are decrease in $\text{MAP} \pm \text{SEM}$ (mm Hg). $*p < .05$ SN-salt versus control-NS (tap water) and control-HS (1% saline) at the indicated dose. $**p < .01$ SN-salt versus control-NS (tap water) and control-HS (1% saline) at the indicated dose. (From Katki KA, Supowit SC, DiPette DJ. Substance P in subtotal nephrectomy-salt hypertension. *Hypertension* 39[part 2]:389-393, 2002.) SP, substance P; MAP, mean arterial pressure; SN, subtotal nephrectomy; SEM, standard error of measure.

The mechanisms of action of ADM are still not clear. cAMP is often a second messenger for ADM, but other processes are probably involved. The role of NO is also unclear.

SUMMARY

Several lines of evidence suggest that the vasodilator peptides CGRP, SP, and ADM may play important roles in human hypertension. These exact roles still need to be elucidated.

Acknowledgments

The Kallikrein-Kinin System as a Regulator of Cardiovascular and Renal Function

Oscar A. Carretero, Xiao-Ping Yang, Nour-Eddine Rhaleb

Both genetic and environmental factors acting via intermediate phenotypes participate in the regulation of blood pressure, the etiology of hypertension, and the development of target organ damage. Vasoactive systems are important components of these intermediate phenotypes. They can act as local hormones (intracrine, autocrine, and paracrine) or as endocrine and neuroendocrine systems. We use the term *intracrine* to indicate hormones that act within the cells that synthesize them, such as reactive oxygen species (O_2^-) and products of protooncogenes. The term *autocrine* is used to indicate hormones that act on the cell membrane receptors where they are produced, such as growth factors. The term *paracrine* denotes hormones that act near the site where they are produced, such as kinins, eicosanoids, nitric oxide (NO), and endothelium-derived hyperpolarizing factor (EDHF). *Endocrine* refers to hormones such as aldosterone that are released into the extracellular fluid and act on distant target tissues, although they can also act in an autocrine and paracrine fashion. Finally, *neuroendocrine* hormones such as catecholamines are released by neurons and act near or distant from the site of release.

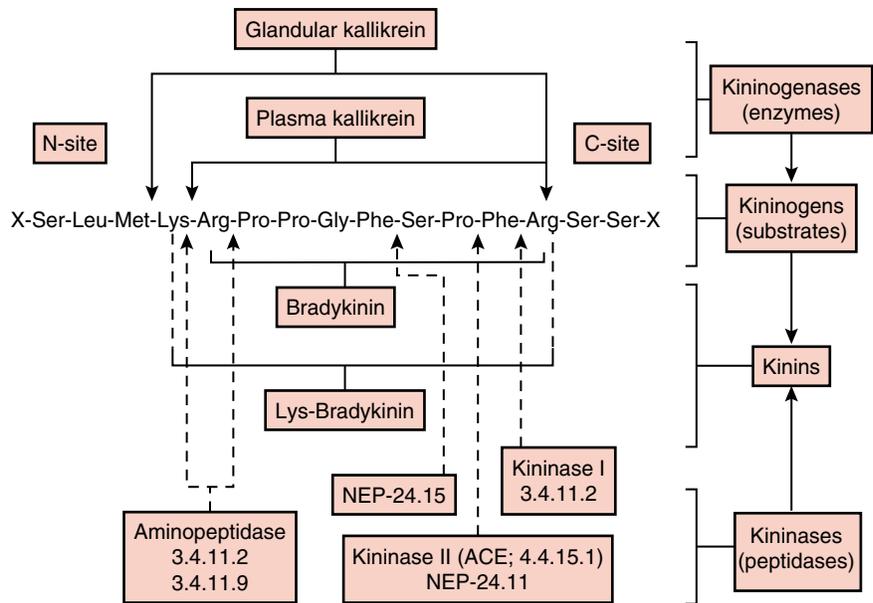

Blood pressure is the result of a balance between vasopressor and vasodepressor systems. Alteration of this equilibrium may result in (1) hypertension, (2) target organ damage, (3) effective antihypertensive treatment, or (4) hypotension and shock. Changes in this balance could be caused by (1) genetic factors such as mutations in one of the genes of the vasoactive system and/or (2) environmental factors that alter the activity of vasoactive systems. Endocrine and neuroendocrine vasopressor systems, such as the renin-angiotensin-aldosterone system and catecholamines, play a well-established and important role in the regulation of blood pressure, the pathogenesis of some forms of hypertension, and target organ damage. The role of vasodepressor systems is less well established; however, evidence suggests that they play an important role in the regulation of blood flow, renal function, the pathogenesis of salt-induced hypertension and target organ damage, and the cardioprotective effects of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs).¹⁻⁵ Vasodepressor hormones such as kinins, eicosanoids, NO, and EDHF act as local hormonal systems, opposing the effects of vasopressor systems. Some vasodepressor systems such as atrial (ANP), brain (BNP), and C-type (CNP) natriuretic peptides may act as both endocrine and local hormones. Here we will review the kinin-generating system and the role of kinins in (1) the regulation of local blood flow, (2) water and sodium excretion, (3) the regulation of blood pressure and the pathogenesis of hypertension, and (4) the therapeutic effects of ACE inhibitors and ARBs.

THE KININ-GENERATING SYSTEM

Kininogenases such as glandular and plasma kallikreins are enzymes that generate kinins by hydrolyzing substrates known as *kininogens*, which circulate at high concentrations in plasma. Kinins are rapidly destroyed by a group of peptidases known as kininases (Figure 20–1). Plasma and glandular (tissue) kallikrein are potent kininogenases and both are serine proteases. A single gene encodes for plasma kallikrein, and there is a large family of glandular kallikrein genes; however, KLK1 is the only glandular kallikrein that generates kinins (hereafter referred to as *glandular kallikrein*, or simply *kallikrein*). Plasma kallikrein, also known as *Fletcher factor*, is expressed mainly in the liver; in plasma it is found in the zymogen form (prekallikrein) and differs from glandular kallikrein in its biochemical, immunologic, and functional characteristics. It preferentially releases bradykinin from high-molecular-weight kininogen (HMWK), also known as *Fitzgerald factor*. Together with HMWK and Hageman factor, it is involved in coagulation, fibrinolysis, and possibly, activation of the complement system. The plasma kallikrein-HMWK system, acting through the release of bradykinin, could be involved in the local regulation of blood flow and in some of the effects of ACE inhibitors. On the other hand, patients with congenital deficiency of plasma HMWK (Fitzgerald trait) have normal amounts of kinins in their blood.⁶ (For a review of the plasma kallikrein-HMWK system, see references 7–9.)

Glandular kallikrein belongs to a family of serine proteases with very high homology; the genes encoding for these enzymes are tightly clustered and arranged in tandem on the same chromosome. The number of family members varies widely among mammals; it is estimated that the kallikrein family contains at least three genes in humans, 20 in the rat, and 23 to 30 in the mouse, many of them pseudogenes.¹⁰ Despite the highly homologous amino acid composition of the serine proteases encoded by the glandular kallikrein gene family, most are not kininogenases and act on entirely different substrates. For example, tonin, a rat enzyme of the kallikrein family, hydrolyzes angiotensinogen and generates angiotensin II; prostate-specific antigen, a human enzyme of the kallikrein family, hydrolyzes semenogelin, a high-molecular-weight seminal vesicle protein.^{11,12} We have isolated a new member of the kallikrein family from the submandibular gland.^{13,14} This protease produces contraction of isolated aortic rings and (like tonin) also generates angiotensin II, suggesting that localized regions of variability are important in determining substrate specificity and possibly function of all enzymes of the kallikrein family. (For a review of the

Figure 20-1 Site of kininogen cleavage (solid arrows) by the main kininogenases (glandular and plasma kallikrein). The broken arrows indicate sites of kinin cleavage by kininases (kininase I, kininase II, neutral endopeptidases 24.11 and 24.15, and aminopeptidases). (From Carretero OA, Scicil AG. Kinins paracrine hormone. 34(Suppl 26):S-52-S-59, 1988.)

molecular biology of the glandular kallikrein-kininogen system see references 15-17.)

True glandular kallikrein or KLK1 is encoded by a single gene having five exons and four introns. Other members of the kallikrein gene family have a similar exonic and intronic structure, with the splice junctions completely conserved. The 5' and 3' flanking regions have a high homology among the various genes; however, gene regulation and site of expression are different, suggesting that small variations in the nucleotide sequence of the 5' region are important in the regulation of expression. The glandular kallikrein gene is expressed mainly in the submandibular gland, pancreas, and kidney; however, using the polymerase chain reaction, we have demonstrated its mRNA in vascular tissue, heart, and adrenal glands, although in smaller amounts.^{18,19} Glandular kallikrein and kallikrein-like enzymes have also been found in the arteries and veins,²⁰ heart,²¹ brain,²² pituitary gland,^{23,24} pancreas,²⁵ intestine,^{26,27} salivary and sweat glands,²⁸ spleen,²⁹ adrenal glands,³⁰ blood cells,¹⁹ and the exocrine secretions of these structures. Some of these are probably true glandular kallikrein, whereas others may be separate members of the kallikrein family.

There is immunoreactive glandular kallikrein in plasma, primarily the inactive form; however, a small portion is in the active form.³¹⁻³⁵ In humans³⁶ and rabbits,³⁷ 50% or more of urinary kallikrein is the inactive or zymogen form, whereas in rats most is in the active form.³⁸ Glandular kallikrein can release kinins from low-molecular-weight kininogen (LMWK) and HMWK. In humans, glandular kallikrein releases lys-bradykinin (kallidin), whereas in rodents it releases bradykinin.^{39,40}

Kininogens (kallikrein substrates) are the precursors of kinins. In plasma there are two main forms, characterized as LMWK and HMWK.^{41,42} Both are potent inhibitors of cysteine proteinases such as calpain and cathepsins H, L, and B.⁴³⁻⁴⁵ In the rat there is a third kininogen known as t-kininogen, because it releases kinins when incubated with trypsin but not with tissue or plasma kallikrein. It is one of the main acute phase reactants of inflammation in the rat. All kininogens inhibit thiol

proteases such as cathepsin M, H, and calpains.⁴⁶⁻⁴⁹ HMWK is involved in the early stages of surface-activated coagulation (intrinsic coagulation pathway).^{7,9,50}

Kininases are peptidases found in blood and other tissues that hydrolyze kinins and other peptidic hormones.⁵¹ The best known is ACE or kininase II, which converts angiotensin I to II and inactivates kinin substance P and other peptides.^{51,52} Another important kininase is neutral endopeptidase 24.11 (NEP-24.11), also known as enkephalinase, which not only hydrolyzes kinins and enkephalins but also destroys ANP, BNP, and endothelin.^{53,54} Research performed in our laboratory suggests that it may be an important renal kininase, at least in the rat.⁵⁵ Other kininases include MEP-24.15, aminopeptidases, and carboxypeptidases; however, it is not known whether they play an important role in the degradation of kinins in vivo. After inhibition of most of these enzymes in vivo, plasma concentrations of endogenous kinins do not increase significantly, and their half-life remains less than 20 seconds, suggesting that other peptidases are also important in kinin metabolism.⁵⁶

Kinins are oligopeptides containing the sequence of bradykinin in their structure. They act mainly as local hormones, because they circulate at very low concentrations (1-50 fmol/ml) and are rapidly hydrolyzed by kininases. In tissues such as the kidney, heart, and aorta, kinin concentrations are higher (100-350 fmol/g).⁵⁷ Eicosanoids, NO, EDHF, tissue plasminogen activator (tPA), and cytokines mediate at least some of the effects of exogenously administered kinins⁵⁸⁻⁶² (Figure 20-2). At least two subtypes of kinin receptors have been well characterized by using analogs of bradykinin, B₁ and B₂.^{63,64} These receptors have been cloned and belong to the family of seven transmembrane receptors linked to G proteins.⁶⁵ B₁ receptors are not present or are present only at very low density in normal tissues but are expressed and synthesized de novo during tissue injury, inflammation, and administration of lipopolysaccharides such as endotoxin. In some species, including rabbits, they mediate contraction of the isolated aorta and relaxation of mesenteric arteries. The

Please refer to the printed publication.

Figure 20-2 Kinins act via the B₂ and B₁ receptors. Most of the known effects of kinins are mediated by the B₂ receptor, which acts by stimulating the release of various intermediaries: eicosanoids, endothelial-derived hyperpolarizing factor (EDHF), nitric oxide (NO), tissue plasminogen activator (tPA), and glucose transporter (GLU-1 and -2). (Modified from Carretero OA. Kinins: Local hormones in regulation of blood pressure and renal function. *Choices Cardiol* 7(Suppl 1): 10-14, 1993.)

main agonists for this receptor are des-Arg⁹-bradykinin and des-Arg⁹-kallidin. B₂ receptors mediate most of the effects of bradykinin and are the main receptors for the agonists bradykinin and kallidin (lys-bradykinin). Studies using kinin analogs with agonistic and antagonistic properties in various tissues suggest the existence of other subtypes of receptors.⁶⁶⁻⁶⁹ Stewart and Vavrek⁷⁰ discovered that substitution of D-phenylalanine for proline at position 7 of bradykinin converts it into a specific antagonist for B₂ receptors, while the substitution of Phe⁸ in des-Arg⁹BK by a residue with aliphatic (Ala, Ile, Leu, D-Leu, norleucine) or saturated cyclic hydrocarbon chains (cyclohexylalanine) produced antagonists for B₁ receptors.^{71,72} Further modifications have resulted in a very potent B₂ receptor antagonist with long-lasting effects in vivo, DArg⁰-Hyp³-Thi⁵-DThi⁷-Oic⁸-bradykinin or icatibant (Hoe-140),⁷³ which has become an important tool for studying the role of kinins. Orally active kinin antagonists have been developed for the possible treatment of inflammation, hyperalgesia, and perhaps cancer.⁷⁴⁻⁷⁸

In humans, it has been reported that the B₂ receptor is activated by kallikreins and other serine proteases and that this effect is blocked by the kinin antagonist icatibant.⁷⁹ Some ACE inhibitors potentiate the effect of bradykinin not only by inhibiting its hydrolysis but also by cross-talk between ACE and the B₂ receptor.⁸⁰ The B₂ receptor forms heterodimers with the angiotensin type 1 receptor (AT₁), causing increased activation of the angiotensin receptor. The stability of this heterodimer is not affected by bradykinin, angiotensin, or their antagonists.⁸¹ The B₂ receptor also forms a complex with endothelial NO synthase (eNOS), inhibiting the generation of NO, and this effect is reversed by bradykinin.⁸² The pathophysiological role of these interactions of the B₂ receptor is not known; however, it has been reported that in preeclampsia there is an increase in AT₁ and B₂ heterodimers that could mediate an enhanced response to angiotensin II. Thus, in

some situations these interactions of the B₂ receptor could play a physiopathologic role.

THE KALLIKREIN-KININ SYSTEM IN THE VASCULATURE AND IN THE REGULATION OF LOCAL BLOOD FLOW

Arteries and veins contain a kallikrein-like enzyme, and both vascular tissue and smooth muscle cells in culture contain mRNA for glandular kallikrein.^{18,20} Vascular smooth muscle cells in culture release both glandular kallikrein and kininogen⁸³. Thus the components of the kallikrein-kinin system are present in vascular tissue, where they could play an important role in the regulation of vascular resistance. Blood flow-induced dilation of isolated arteries from mice with deletion of the gene expressing glandular kallikrein was found to be significantly reduced as compared with controls, suggesting that the kallikrein-kinin system in the arterial wall participates in this process.^{84,85} The action of ACE inhibitors on local potentiation of the vasodilator effect of kinins appears to be partly attributable to their prevention of bradykinin degradation and subsequent increases in the production of endothelium-derived relaxing factors (EDRFs) such as NO. In spontaneously hypertensive rats (SHR) and in the canine coronary artery, ACE inhibitors potentiate the endothelium-dependent relaxation evoked by bradykinin.^{86,87} This vasorelaxation appears to be associated primarily with increased release of NO.

When the arterial endothelium is removed, the smooth muscle cells begin to proliferate in the medium; they then migrate across the internal elastic lamina into the intima, where they cause neointimal hyperplasia, mimicking some of the vascular changes that occur in atherosclerosis. ACE inhibitors have been shown to inhibit neointima formation.^{88,89} Blocking kinins or

inhibiting NO synthesis lessens the protective effect of the ACE inhibitor, suggesting that it may be mediated by a local increase in kinins, which stimulates the release of NO.^{90,91}

Kinins play an important role in the local regulation of blood flow in organs rich in glandular kallikrein such as the submandibular gland, uteroplacental complex, and kidney.⁹²⁻⁹⁵ In rats nephrectomized 48 hours earlier to exclude the renal renin-angiotensin system, use of an ACE (kininase II) inhibitor significantly increased blood flow in the submandibular gland but did not affect blood pressure. In contrast, 10 minutes after sympathetic stimulation of the gland to increase kallikrein secretion in the vascular compartment, the ACE inhibitor markedly decreased blood pressure and increased kinin concentrations in arterial blood.^{35,96} Changes in both blood flow and blood pressure were blocked by antibodies to kinins and glandular kallikrein. The effect of the ACE inhibitor on basal glandular blood flow was also blocked by a kinin antagonist.⁹² At low doses, the antagonist caused no significant change in blood flow when the ACE inhibitor was not administered, whereas at high doses, basal blood flow decreased significantly. These data suggest that in organs rich in glandular kallikrein, kinins play a role in the regulation of basal blood flow. Studies using kinin antibodies and antagonists clearly indicate that kinins act as paracrine hormones, regulating blood flow within the gland. These studies also indicate that the effect of ACE inhibitors on blood flow is mediated by kinins.⁹² In nephrectomized pregnant rabbits infused with an angiotensin antagonist to block the uterine renin-angiotensin system, ACE inhibitors increased both uterine and placental blood flow and immunoreactive prostaglandin E₂ (PGE₂), whereas these effects were blocked by a kinin antibody.⁹³ This suggests that endogenously generated kinins play a role in the regulation of uterine blood flow, either directly or through the release of prostaglandins.

In organs rich in glandular kallikrein, such as the submandibular gland and uteroplacental complex, kinins appear to play an important role in the regulation of blood flow, especially when ACE is inhibited. In addition, the local arterial kallikrein-kinin system also participates in the regulation of blood flow and in the vascular protective effect of ACE inhibitors.

KININS IN THE REGULATION OF RENAL BLOOD FLOW

Kinins may play an important role in the regulation of renal blood flow. Blocking renal kinins by infusing low doses of a kinin antagonist into the renal artery of sodium-depleted dogs decreased renal blood flow and autoregulation of the glomerular filtration rate (GFR) without changing blood pressure.⁹⁷ The changes in renal blood flow were blocked by prior inhibition of ACE, suggesting that either they were mediated by renin release caused by an agonistic effect of the antagonist or else renal kinins may have increased when ACE was inhibited, thereby competing more effectively with the antagonist. The changes in GFR autoregulation were not altered by the ACE inhibitor and may have been due to a change in either the relationship between afferent and efferent glomerular arteriolar resistance or the coefficient of filtration.⁹⁷ We have shown that the vasodilator effect of bradykinin in the renal efferent arteriole is mediated by cytochrome P450 metabolites

of arachidonic acid called *epoxyeicosatrienoic acids* (EETs) and that bradykinin stimulates the glomeruli to release another cytochrome P450 metabolite, the vasoconstrictor eicosanoid 20-hydroxyeicosatetraenoic acid (20-HETE), and also an unidentified vasodilator prostaglandin, which together participate in regulation of the downstream glomerular circulation and perhaps in the regulation of GFR.^{98,99}

We examined the role of kinins in the regulation of renal blood flow distribution by using a laser-Doppler flowmeter.⁹⁴ The kinin antagonist lowered papillary blood flow without altering outer cortical blood flow, suggesting that intrarenally formed kinins are important in regulating blood flow in the inner medulla. This study also showed that renin plays an important role in the regulation of papillary blood flow, because after kinins were blocked, enalaprilat increased flow significantly. When we inhibited both ACE and neutral endopeptidase-24.11 (NEP-24.11), papillary blood flow increased by 50%, as compared with 25% when they were inhibited separately. These increases were blocked by the kinin antagonist, indicating that the augmented papillary blood flow induced by both ACE and NEP-24.11 inhibitors is mediated by increased kinin concentrations in the interstitial space. We observed no consistent effect on water or sodium excretion; however, water excretion tends to decrease in animals treated with a kinin antagonist.

In anesthetized rats, blocking kinins decreased renal blood flow.⁹⁵ In dogs, when kallikrein excretion was stimulated by sodium deprivation, a kinin antagonist (given intrarenally) partially blocked the effect of enalaprilat on renal blood flow.¹⁰⁰ This suggests that although blockade of the renin-angiotensin system accounted for a significant portion of the increase in renal blood flow caused by the ACE inhibitor, a substantial component was contributed by endogenous kinins. Similar results were reported in rats in which the kallikrein-kinin system was stimulated by deoxycorticosterone.¹⁰¹

In the kidney, kinins normally play a minor role in the regulation of blood flow. However, when the kallikrein-kinin system is stimulated by low-sodium intake or mineralocorticoids, or when endogenous kinin degradation is inhibited, kinins appear to participate in the regulation of renal blood flow. In addition, the data suggest that kinins play an important role in the regulation of papillary blood flow and that during reduction of renal perfusion pressure, kinins may aid in regulation of the GFR.

KININS IN THE REGULATION OF WATER AND ELECTROLYTE EXCRETION

Renal kallikrein is located in the connecting cells of the connecting tubule; it is released in significant amounts in this segment of the nephron and excreted in the urine (Figure 20-3).^{37,102,103} Kallikrein releases kinins into the lumen of the distal nephron, either from filtered kininogen or kininogen produced in the principal cells of the distal nephron.^{104,105} Kinin receptors are also present in the collecting duct.¹⁰⁶ In addition, kallikrein is released on the basolateral side of the nephron, where it may liberate kinins from plasma kininogens.¹⁰⁷ The renal interstitial fluid contains a high concentration of kinins.¹⁰⁸ The role of kinins in the regulation of water and sodium excretion has been studied by

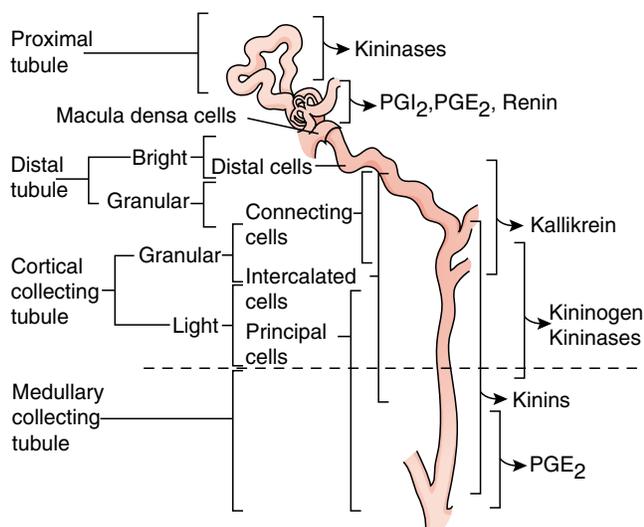

Figure 20-3 Localization of the kallikrein-kinin system, renin, and prostaglandin in the nephron (right brackets); anatomical subdivisions of the nephron (outer left brackets); and type of cells found in the distal nephron (inner left brackets). PGE₂, prostaglandin E₂; PGI₂, prostacyclin.

either increasing intrarenal kinins or blocking kinins. Infusion of kinins into the late proximal nephron doubled excretion of simultaneously administered²² Na,¹⁰⁹ and that part of this effect was mediated by prostaglandins,¹¹⁰ whereas infusion of a kinin antagonist into the late proximal nephron reduced²² Na recovery significantly.¹¹¹ After systemic administration of phosphoramidon, an inhibitor of NEP-24.11 (a major kininase in the nephron), urinary excretion of kinins doubled; diuresis increased by 15%, and natriuresis increased by 37%.⁵⁵ These data support the hypothesis that increased kinins in the nephron participate in intrarenal control of water and electrolyte excretion, but it is also possible that the effect of this peptidase inhibitor is mediated by blocking hydrolysis of other peptides such as atrial natriuretic factor (ANF).¹¹²

The infusion of aprotinin inhibited the enzymatic activity of urinary kallikrein but did not affect acute water or electrolyte excretion in euvoletic and sodium- or water-expanded rats.¹¹³ A transient decrease in sodium excretion has been observed during aprotinin administration in mineralocorticoid-treated rats.¹¹⁴ Infusion of kinin antibodies into saline-expanded rats decreased sodium excretion.¹¹⁵ Caution should be used in interpreting this finding, because antibodies may stimulate release of histamine, cause an anaphylactoid reaction, or form a high-molecular-weight complex with kininogen that is then deposited in the nephron, any of which might alter water and sodium excretion. To avoid these problems, we use Fab fragments of kinin antibodies, which are rapidly distributed in the extracellular fluid and excreted by the kidney; moreover, they do not form high-molecular-weight complexes or activate complement and other proteolytic systems in plasma, thus reducing the risk of anaphylactoid reactions. In unanesthetized rats, the Fab fragments blocked 70% of the effect of an injection of 100 ng bradykinin on blood pressure and appeared rapidly in the urine, suggesting that they block the

effect of kinins not only in the vascular and interstitial spaces but also in the lumen of the distal nephron. Using these Fab fragments and a kinin antagonist, we studied a model in which the renal kallikrein-kinin system is stimulated—namely, DOCA-salt-treated rats.¹¹⁶ Both the Fab fragments and kinin antagonist significantly decreased urine volume and increased urinary osmolarity; however, only the Fab fragments significantly lessened urinary sodium excretion. Neither altered blood pressure, renal blood flow, or GFR. The antidiuretic effect of the Fab fragments and kinin antagonist may be due to blockade of kinins in the vascular interstitial space of the kidney, since the antagonist is likely hydrolyzed in the proximal tubule and does not reach the lumen of the distal nephron. On the other hand, the antinatriuretic effect of Fab fragments of kinin antibodies on sodium excretion may be due to blockade of kinins in both the vascular/interstitial and urinary compartments or only in the latter compartment, because the antibody appeared in the urine and the antidiuretic effect was not observed with the antagonist. Thus kinins may aid in the regulation of water and sodium excretion when the kallikrein-kinin system is stimulated. In normal nonanesthetized rats, inhibition of kinin release in the lumen of the nephron by Fab fragments of monoclonal antibodies to kallikrein causes urinary PGE₂, UV, and U_{Na} V to decrease. The changes in UV and U_{Na} V mimic those of PGE₂, suggesting that the natriuretic and diuretic effects of kinins are mediated in part by PGE₂.¹¹⁷

In vitro, stimulation of the release of EDRF from endothelial cells by bradykinin or acetylcholine increases cGMP content and inhibits Na⁺ transport by cortical collecting duct cells.¹¹⁸ In vivo, stimulation of EDRF release by bradykinin results in natriuresis and diuresis without affecting the GFR.¹¹⁹ In conclusion, kinins acting as local hormones play a role in the regulation of renal hemodynamic and excretory function, either directly or via the release of PGE₂ and EDRF.

KININS AS REGULATORS OF BLOOD PRESSURE AND THE PATHOGENESIS OF HYPERTENSION

The development of antibodies to kinins and kallikrein, kinin antagonists, and kininase inhibitors—as well as gene knockout (KO) models of the kallikrein-kinin system and the discovery of kininogen-deficient rats and humans with various spontaneous mutations of the system—has allowed us to study the role of kinins in various physiologic and pathologic conditions. The role of the kallikrein-kinin system in the pathogenesis of hypertension has been studied by (1) measurements of the various components of the system, (2) the use of bradykinin B₂ receptor antagonists, (3) the use of mice in which the B₂ receptor has been deleted by homologous recombination, (4) deletion of the kallikrein gene, and (5) use of rats deficient in kininogen. Decreased activity of the kallikrein-kinin system may play a role in hypertension. Low urinary kallikrein excretion in children is one of the major genetic markers associated with a family history of essential hypertension, and children with high urinary kallikrein excretion have less probability of a genetic background of hypertension.¹²⁰⁻¹²³ A restriction fragment length polymorphism for the kallikrein gene family in spontaneously hypertensive rats has been linked to high blood pressure,¹²⁴ and

urinary kallikrein excretion is decreased in several models of genetic hypertension. Urinary and/or arterial tissue kallikrein are also decreased in renovascular hypertension and genetically hypertensive rats.¹²⁵⁻¹²⁸ Although these reductions may be secondary to increases in blood pressure, urinary kallikrein is decreased in normotensive children of patients with essential hypertension and in genetically hypertensive and Dahl salt-sensitive rats before the development of hypertension,¹²⁹⁻¹³³ suggesting that these decreases may be primary abnormalities.

Kinins circulate in concentrations of approximately 5 to 50 pg/ml of blood.⁶ These concentrations need to be increased to at least 100 pg in humans¹³⁴ and 1000 pg in rats¹³⁵ to cause acute decreases in blood pressure. Although blood kinin concentrations may increase in some physiologic and pathologic situations, they seldom reach levels that could explain changes in blood pressure, save for exceptional experimental conditions such as stimulation of the sympathetic nerve of the submandibular gland in animals treated with ACE inhibitors (see section on blood flow regulation). Thus kinins must act as paracrine hormones, regulating local vascular resistance and organ function.

In early studies, acute administration of a kinin antagonist at high doses increased blood pressure in most rats tested, while a vasodepressor effect was observed in some.¹³⁶ Using a more potent antagonist,¹³⁷ also at high doses, we found that it produced a transient biphasic response: first a small pressor effect, followed by a depressor effect.¹³⁸ At lower doses, although still sufficient to block exogenous bradykinin, the same antagonists did not alter normal blood pressure. These studies are compatible with the hypothesis that kinins play a role in the regulation of blood pressure. However, to demonstrate the pressor effect, the kinin antagonist has to be used at much higher doses than those needed to block the vasodepressor effect of exogenous bradykinin. High doses may be needed to displace kinins bound to tissue receptors. We must be cautious in interpreting these data, because we cannot rule out the possibility that these kinin antagonists have a vasopressor effect that is unrelated to kinin-blocking activity. Studies by our group using kinin antibodies or their Fab frag-

ments showed that although they partially block the vasodepressor effect of kinins, they do not cause acute changes in blood pressure.

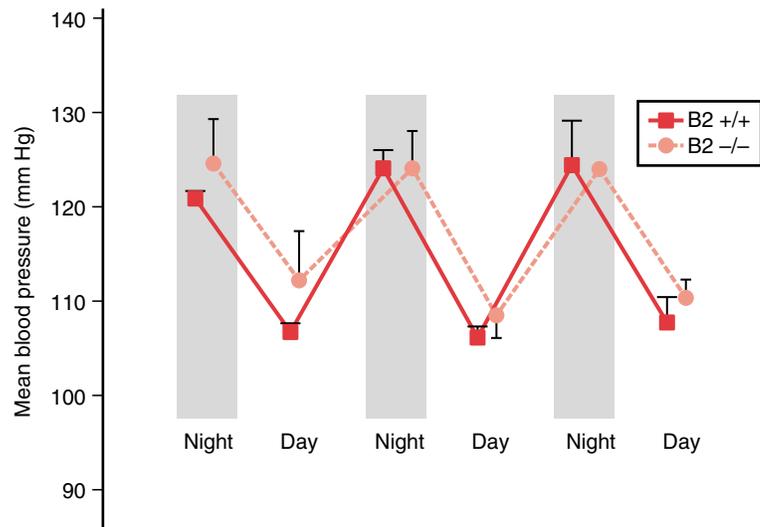

Chronic blockade of B₂ kinin receptors with a potent and selective B₂ antagonist, icatibant, did not increase blood pressure under normal conditions or under conditions that favor the development of hypertension in rats such as (1) chronic infusion of a subpressor or pressor dose of angiotensin II, (2) a high-salt diet, or (3) mineralocorticoids and salt.^{139,140} However, these results are not universal.¹⁴¹⁻¹⁴⁴

Mice with the bradykinin B₂ receptor deleted by homologous recombination (gene knockout) have normal blood pressure (Figure 20-4). However, they develop hypertension when fed a high-sodium diet (8%) for at least 2 months.^{145,146} Thus, low kinin activity may be involved in the development and maintenance of salt-sensitive high blood pressure. However, in these mice, mineralocorticoid hypertension was not exacerbated.¹⁴⁷ It has been reported that as these mice grow older, they also develop hypertension and left ventricular hypertrophy (LVH) even on a normal sodium diet.¹⁴⁸ However, we were unable to demonstrate that ablation of B₂ kinin receptors renders mice spontaneously hypertensive.¹⁴⁹ Others were also unable to confirm the hypothesis that B₂ kinin receptors are major components in the maintenance of normal blood pressure and cardiac structure.^{146,147,150,151} Mice deficient in kinin B₂ receptors or tissue kallikrein had blood pressure similar to wild-type controls, confirming that kinins are not an important determinant of blood pressure.¹⁵¹

In kininogen-deficient Brown Norway Katholiek rats (BNK), administration of mineralocorticoids and salt or angiotensin II reportedly causes blood pressure to increase similarly to rats with a normal kallikrein-kinin system.¹³⁹ This contradicts other reports.¹⁴¹⁻¹⁴³

These studies suggest that kinins do not play an important role in the regulation of normal blood pressure or in the pathogenesis of hypertension, although they may be involved in the pathogenesis of salt-induced hypertension. Overall, chronic blockade of the kallikrein-kinin system does not appear to cause hypertension or potentiate hypertensinogenic stimuli, although the data are inconsistent.

Figure 20-4 Diurnal and nocturnal mean blood pressure of bradykinin B₂ receptor knockout (-/-) and wild-type (+/+) mice. Blood pressure was measured over 24 hours by a telemetric system. (Rhaleb N-E and Carretero OA, unpublished data.)

ROLE OF KININS IN THE ANTIHYPERTENSIVE EFFECT OF ACE INHIBITORS

Inhibition of kinin and degradation of other oligopeptides may contribute to the antihypertensive effect of ACE inhibitors. Although blockade of angiotensin II formation appears to be important in this regard, the role of kinins is less well established. Orally active ACE inhibitors are effective antihypertensive agents, not only in high-renin hypertension but also in clinical and experimental models in which the renin-angiotensin system has not been pathogenetically implicated.^{152,153} Thus, some effects of ACE inhibitors may be mediated by a local renin-angiotensin system, kinins, or some other undetermined mechanism, because ACE can hydrolyze other peptides (Figure 20–5). ACE inhibitors may also potentiate the effect of kinins by a direct interaction with the kinin B₂ receptor.⁸⁰

Blood kinins are unchanged or moderately increased after administration of ACE inhibitors.^{1,154,155} (For review, see references 156–157.) Kinins in the urine reportedly increase more consistently after administration of ACE inhibitors, indicating that their concentration in renal tissue likewise increases.^{55,158–161} This may contribute to the antihypertensive effect of ACE inhibitors by altering renovascular resistance and increasing sodium and water excretion.

Many studies have assessed the role of kinins in the acute antihypertensive effect of ACE inhibitors. In various experimental models of hypertension, the acute antihypertensive effect of ACE inhibitors is attenuated by blocking kinins with either high titers of kinin antibodies^{162–165} or with a B₂ kinin receptor antagonist.^{154,155,166} Kinin antagonists also partially reverse the antihypertensive effect of ACE inhibition in rats with renovascular hypertension.¹⁶⁵ We assessed the influence of kinins on the acute antihypertensive effect of enalaprilat in rats with severe hypertension induced by aortic ligation between the renal arteries.¹⁵⁵ In this model, renin plays an important role in the pathogenesis of hypertension.¹⁵² Acute and severe hypertension can produce endothelial damage that may lead to activation of plasma kallikrein and increased kinin formation. We found that enalaprilat lowered mean blood pressure by 48 ± 6 mm Hg in the controls and 21 ± 4

mm Hg in the kinin antagonist group (*p* < .01). However, kinin concentrations in arterial plasma were not significantly altered by the ACE inhibitor (41 ± 10 vs. 68 ± 20 pg/ml) (Figure 20–6). As indicated earlier, if mean arterial pressure in the unanesthetized rat is to be decreased, kinins in arterial blood must reach at least 1000 pg/ml.¹³⁵ Thus the effect of the ACE inhibitor may be due to an increase in tissue kinins, which could act as a paracrine hormonal system regulating vascular resistance. Cachofeiro et al.¹⁵⁴ demonstrated that pretreatment with either a bradykinin antagonist or an NO synthesis inhibitor attenuated the acute antihypertensive effects of both captopril and ramipril in SHR, but pretreatment with a prostaglandin synthesis inhibitor failed to alter the effects of ACE inhibitors, suggesting that this acute antihypertensive effect is due to bradykinin acting via the release of NO. However, in the dog, kinins may play a role in the acute hypotensive effect of ACE inhibitors through the release of prostaglandins.¹⁶⁷

In humans, an ACE insertion (I)/deletion (D) polymorphism in intron 16 of the ACE gene could be an important determinant of bradykinin metabolism¹⁶⁸; ACE activity is higher in subjects with ACE D and is associated with a high rate of bradykinin degradation. In normotensive persons and hypertensive persons with low and normal renin, aprotinin (an inhibitor of kallikrein and other proteases) blocked part of the acute blood pressure–lowering effect of captopril.¹⁶⁹ The influence of aprotinin could be due to inhibition of kinin formation or other effects. However, when using a specific B₂ kinin receptor antagonist (icatibant), the short-term blood pressure effects of ACE inhibitors were attenuated in both normotensive and hypertensive persons.¹⁷⁰ These studies suggest that part of the acute effect of ACE inhibitors on blood pressure is mediated by kinins, which affect local and peripheral vascular resistance either directly or through release of prostaglandins and NO.

The contribution of kinins to the chronic antihypertensive effects of ACE inhibitors is more controversial. In renovascular hypertension (2K1C), chronic blockade of kinin receptors interferes with the blood pressure–lowering activity of ramipril.¹⁷¹ In mineralocorticoid hypertension, in which kallikrein-kinin and ACE activity are reportedly increased,¹⁷² chronic ACE inhibition has a small but significant antihypertensive effect; blocking the B₂ receptor with icatibant blunted

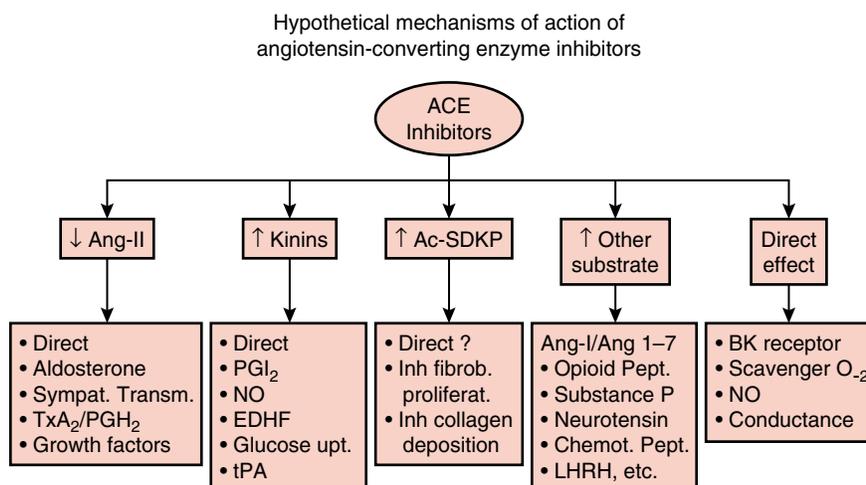

Figure 20–5 ACE has multiple substrates, and inhibition of their hydrolysis may explain the cardioprotective effect of ACE inhibitors.

this chronic antihypertensive action,^{139,173} suggesting that in this model, kinins may play a role in the antihypertensive effect of ACE inhibitors. However, they do not appear to contribute to the chronic antihypertensive effect of ACE inhibitors in SHR¹⁷¹ or in hypertension induced by aortic coarctation.^{154,174,175} Therefore the role of kinins in the long-term antihypertensive effect of ACE inhibitors depends on the model. To our knowledge, no studies of chronic blockade of the kallikrein-kinin system have been conducted in humans.

ROLE OF KININS IN THE CARDIAC ANTIHYPERTROPHIC EFFECT OF ACE INHIBITORS

ACE inhibitors have been shown to reverse LVH in essential hypertension and in various experimental models. This decrease is partly due to reduced afterload, but it has been postulated that it may be partially independent of the decrease in blood pressure. A decrease in angiotensin II, which stimu-

lates various protooncogenes and growth factors, may participate in the antihypertrophic effect of ACE inhibitors acting independently of their effect on blood pressure. The cardiac kallikrein-kinin system may also participate in the effect of ACE inhibitors on the heart. Doses of ACE inhibitors that do not decrease blood pressure reverse LVH in rats with hypertension caused by aortic coarctation.¹⁷⁶ To be certain that blood pressure does not decrease, direct 24-hour measurements are needed. The antihypertrophic effects of ACE inhibitors have been reported to be reversed by a kinin antagonist.¹⁷⁷ However, using a very similar protocol, we have not been able to confirm this.¹⁷⁵ Further studies are needed to determine whether doses of ACE inhibitors that do not decrease blood pressure (24-hour blood pressure monitoring) reverse cardiac hypertrophy and whether kinins participate in this process.

Capillary length and density increase in hearts of SHR treated with an ACE inhibitor at both “antihypertensive” and “nonantihypertensive” doses. There is strong evidence that angiotensin II also has significant angiogenic effects.¹⁷⁸ However, the effect of an ACE inhibitor on capillary growth cannot be attributed to inhibition of angiotensin production alone, because it is blocked by concomitant treatment with the selective B₂ receptor antagonist, icatibant, suggesting that it may be due to kinins.¹⁷⁹

ROLE OF KININS IN MYOCARDIAL ISCHEMIA AND IN THE PROTECTIVE EFFECT OF ISCHEMIC PRECONDITIONING AND ACE INHIBITORS

Both human and animal studies have demonstrated that kinins are released from the heart and that their release is increased during ischemia. This release of kinins could have a cardioprotective effect.^{180–182} Indeed, experimental studies have shown that intracoronary infusion of bradykinin significantly limited infarct size, reduced the incidence of ventricular arrhythmias, improved cardiac performance and normalized myocardial metabolism.^{183–185} It has also been suggested that kinins are important mediators of ischemic preconditioning, in which repeated brief coronary occlusions render the myocardium more resistant to injury from subsequent prolonged ischemia. In patients undergoing angioplasty, balloon inflation for 1 minute (which mimics ischemic preconditioning) increased kinin concentrations in the coronary sinus 50-fold as compared with preinflation values.² Preconditioning almost doubled cardiac interstitial kinin concentrations as compared with nonpreconditioned hearts subjected to ischemia.¹⁸² The role of kinins in ischemic preconditioning was further demonstrated in our laboratory with animals genetically lacking B₂ kinin receptors or deficient in kinins. We found that in B₂ kinin receptor KO mice, as well as in rats deficient in HMWK, the cardioprotective effect of preconditioning was abolished or significantly blunted.³

During myocardial ischemia followed by sympathetic nerve stimulation, kinins in coronary sinus blood increase significantly.¹⁸⁶ An ACE inhibitor was shown to reduce myocardial infarct size after ischemia/reperfusion, whereas an angiotensin II antagonist (losartan) did not.¹⁸⁷ In nephrectomized dogs in which infarction was induced by occlusion of the coronary

artery for 90 minutes, blockade of local angiotensin II formation with protease inhibitors had no significant effect on myocardial infarct size despite decreased angiotensin II release. Captopril did not alter local angiotensin II formation but did increase bradykinin and reduce infarct size, suggesting that kinins were responsible for the effect of the ACE inhibitor on infarct size.¹⁸¹ Similarly, when low doses of the ACE inhibitor ramiprilat (which had no systemic effect) were infused into the left coronary artery in dogs, they reduced the size of the infarction caused by ligation of the descending branch of the left coronary artery.¹⁸³ This cardioprotective effect of ramiprilat was mimicked by bradykinin and abolished by coadministration of a kinin antagonist.

ACE inhibitors have been shown to reduce ischemia/reperfusion injury, including infarct size and reperfusion arrhythmias. The cardioprotective effect of ACE inhibitors is due to inhibition of both angiotensin II formation and kinin degradation.^{4,5,187-190} In animal models of ischemia/reperfusion injury, we and others have shown that ACE inhibitors reduced infarct size and ventricular arrhythmias and that these effects of ACE inhibitors were abolished or attenuated by coadministration of a B₂ kinin antagonist.^{183,187,191} We further showed that the infarct-limiting and antiarrhythmic effects of ACE inhibitors were blocked by inhibition of NO or prostaglandin synthesis¹⁹¹ and diminished in eNOS gene KO mice.¹⁹²

The cardioprotective effect of kinins may be mediated in several ways. Release of NO from the endothelium may be stimulated either directly or via prostaglandins. It has been shown that myocardial ischemia increases kinin release, accompanied by increased release of cGMP (an indicator of NO production) and 6-keto-PGF₁ (a metabolite of prostacyclin),^{193,194} whereas inhibiting NO or prostaglandin synthesis diminishes or blocks the cardioprotective effect of kinins.^{195,196} Kinins improve cardiac metabolism by increasing high-energy phosphate production and glucogen content in the heart, which could be mediated by facilitating translocation of intracellular glucose transporters (GLUT1 and GLUT4), thereby increasing glucose uptake.^{197,198} This is important because during ischemia, the source of energy production is shifted from oxidation of fatty acids to glycolysis. Also, activation of protein kinase C (PKC) has been shown to be involved in the protective mechanism of preconditioning.¹⁹⁹⁻²⁰¹ Activation of kinins causes further phosphorylation of a secondary effector, presumably the adenosine triphosphate (ATP)-sensitive potassium channels (K_{ATP}). Kinins have been shown to activate PKC, thereby stimulating the opening of K_{ATP} and leading to cardioprotection.^{202,203} Such responses may favorably influence functional and metabolic events during ischemic episodes and protect against ischemia/reperfusion injury.

ROLE OF KININS IN THE CARDIOPROTECTIVE EFFECT OF ACE INHIBITORS IN HEART FAILURE AFTER MYOCARDIAL INFARCTION

ACE inhibitors reduce morbidity and mortality, improve cardiac function, regress left ventricular remodeling, and prolong life in patients with heart failure. We showed that in a rat model of heart failure caused by surgically induced myocardial infarction (MI), ACE inhibitors improved cardiac function and attenuated remodeling, as evidenced by increased

ejection fraction and decreased left ventricular dilation, myocyte hypertrophy, and interstitial fibrosis. These beneficial cardiac effects of ACE inhibitors were diminished by blockade of kinins.¹⁹⁰ The role of kinins in the cardioprotective effect of ACE inhibitors was confirmed by the fact that in B₂ kinin receptor KO mice and kininogen-deficient rats after MI, the effect of ACE inhibitors was significantly diminished or absent.^{5,189} Although the precise mechanism by which kinins protect the heart is not yet well defined, accumulated evidence suggests that kinin-stimulated release of NO and/or prostaglandins may be largely responsible. Bradykinin stimulates release of NO from the mouse myocardium and decreases myocardial oxygen consumption; these effects are blocked by a B₂ kinin antagonist and absent in B₂ receptor KO mice.²⁰⁴ We have shown that in eNOS KO mice with heart failure after MI, the effect of the ACE inhibitor was almost abolished.²⁰⁵ Considered together, these findings may suggest that kinins acting on the B₂ receptor play an important role in the cardioprotective action of ACE inhibitors via the release of NO.

In patients with heart failure, ACE inhibitors have been shown not only to improve cardiac function and increase survival but also to decrease the rate of myocardial reinfarction.²⁰⁶ The mechanism of this decrease is not known, but because ACE inhibitors may block kinin degradation in the coronary circulation, one hypothesis is that kinins stimulate the release of EDRF and PGI₂, important inhibitors of platelet aggregation. Because kinins are potent stimulators of the release of tPA,^{62,207} it is also possible that this potentiation of tPA release may activate plasmin and fibrinolysis. Although the exact mechanism of action of ACE inhibitors in reinfarction is not known, these hypotheses open up an exciting new area of cardiovascular research.

ROLE OF KININS IN THE CARDIOPROTECTIVE EFFECT OF ANGIOTENSIN RECEPTOR BLOCKERS

Two subtypes of angiotensin II receptors, AT₁ and AT₂, have been identified. Most biologic actions of angiotensin II are mediated by the AT₁ receptor, whereas little is known about the function of AT₂ receptors. In cultured endothelial cells, angiotensin II stimulates the release of NO. This effect is blocked by either an AT₂ or B₂ receptor antagonist, indicating that angiotensin II-stimulated NO release is mediated via activation of the AT₂ receptor and a kinin-dependent mechanism.²⁰⁸ Mice overexpressing the AT₂ receptor were reported to have increased kininogenase activity in the vasculature.²⁰⁹ Because blockade of the AT₁ receptor increases angiotensin II levels, which in turn may activate the AT₂ receptor, it is rational to hypothesize that the cardioprotective effect of ARBs is mediated in part by kinins via activation of the AT₂ receptor. In fact, we found that ARBs improved cardiac function and ameliorated remodeling in rats with congestive heart failure after MI and that these effects were significantly attenuated by an AT₂ or B₂ receptor antagonist¹⁹⁰ or in mice lacking the AT₂ receptor.²¹⁰ Using B₂ kinin receptor KO mice and kininogen-deficient rats, as well as eNOS KO mice, we confirmed that a lack of kinins or endothelium-derived NO diminished the cardioprotective effect of ARBs,^{4,5,205} indicating that increased release of kinins and NO cause by activation of the AT₂

receptor is an important mediator of the cardioprotective effect of ARBs.

Because angiotensin II also plays a critical role in the regulation of blood pressure and in the pathogenesis of many models of hypertension, the interaction of the renin-angiotensin-aldosterone system and the kallikrein-kinin system and their contribution of these two systems to the effects of ACE inhibitors and ARBs should not be underestimated. Figure 20–7 illustrates some of these interactions. The AT₁ receptor and the bradykinin B₂ receptor form stable heterodimers, causing increased activation of G[alpha]_q and G[alpha]_i (the two major signaling proteins triggered by AT₁). Also, the endocytotic pathways of both receptors change with heterodimerization. This appears to be the first reported example of signal enhancement triggered by heterodimerization of two different vasoactive hormone receptors.⁸¹ Interaction of the AT₁ and B₂ receptors potentiates the pressor effect of angiotensin II. On the other hand, angiotensin-(1-7) interacting with bradykinin has emerged as an endogenous antihypertensive/antitrophic mechanism, opposing many of the actions of angiotensin II that are mediated by the AT₁ receptor.^{211–213} It has been demonstrated that angiotensin-(1-7), acting via receptors other than AT₁ or AT₂, induced bradykinin-mediated hypotension in SHR and normotensive rats²¹⁴ and dilation of porcine coronary arteries.^{215,216} Angiotensin I and II are cleaved to angiotensin-(1-7) by various endopeptidases.^{217,218} This constitutes another mecha-

nism by which kinins could contribute to the beneficial effects of ACE inhibitors or ARBs. Bradykinin also appears to play an important role in mediating the counterregulatory protective effect of AT₂ receptors, which oppose the effect of the AT₁ receptor.^{190,210,219} Thus there is a close interaction between kinins and angiotensins in the regulation of cardiovascular and renal function.

Kinins appear not to play a fundamental role in the pathogenesis of hypertension, because humans, rats, and mice with a deficiency of one component of the kallikrein-kinin system or with chronic blockade of the kallikrein-kinin system do not have hypertension. In the kidney, kinins participate in the regulation of papillary blood flow and water and sodium excretion. B₂-KO mice appear to be hypersensitive to the hypertensinogenic effect of salt. Kinins participate in the acute antihypertensive effect of ACE inhibitors but in general are not involved in their chronic antihypertensive effects, save for mineralocorticoid-salt-induced hypertension. Kinins acting via NO participate in the vascular protective effect of ACE inhibitors during neointima formation. In MI produced by ischemia/reperfusion, kinins play an important role in the reduction of infarct size induced by preconditioning or ACE inhibitors. In heart failure secondary to infarction, the therapeutic effects of ACE inhibitors are partially mediated by kinins via the release of NO. The therapeutic effect of ARB in heart failure is partly due to activation of AT₂ receptors that act via kinins and NO. Thus kinins play an important role in

Figure 20–7 The renin-angiotensin and kallikrein-kinin systems. In both systems, a substrate is cleaved by an enzyme of restricted specificity, releasing a peptide that is either already active (lys-bradykinin, bradykinin) or inactive (angiotensin I). On further processing by a specific peptidase, angiotensin I is converted to a vasoactive peptide (angiotensin II). In turn, vasoactive peptides are inactivated by peptidases. Angiotensin-converting enzyme is common to both systems but has different roles: it processes angiotensin I to angiotensin II and is the main kinin-inactivating peptidase. From Liu Y, Yang X, Sharov VG, et al. Effects of Angiotensin-converting enzyme inhibitors and Angiotensin II Type I receptor antagonists in rats with heart failure. *J Clin Invest* 99:1926-1935, 1997.

the regulation of cardiovascular and renal function as well as in many of the beneficial effects of ACE inhibitors and ARBs.

SUMMARY

Autocrine, endocrine, and neuroendocrine hormonal systems are important factors that regulate cardiovascular and renal function. Alteration of the balance among these systems may result in hypertension and target-organ damage. Changes in this balance could be due to (1) genetic factors and/or (2) environmental factors. Endocrine and neuroendocrine vasopressor hormonal systems—such as the renin-angiotensin system, aldosterone, and catecholamines—play a well-established and important role in the regulation of blood pressure and the pathogenesis of some forms of hypertension and target-organ damage. The role of vasodepressor autacoids such as kinins is less well established. However, there is increasing evidence that vasodepressor hormones not only play an important role in the regulation of blood pressure and renal function but may also oppose remodeling of the cardiovascular system. This chapter reviews the role of kinins, oligopeptides containing the sequence of bradykinin. They are generated from precursors known as *kininogens* by enzymes such as glandular (tissue) enzymes and plasma kallikrein. Some of the effects of kinins are mediated via autacoids such as eicosanoids, NO, EDHF, and/or tPA. Acting via these mediators, kinins play an important role in the regulation of cardiovascular and renal function as well as some of the cardiovascular and renal effects of ACE and ARBs. A study of Utah families revealed that a dominant kallikrein gene expressed as high urinary kallikrein excretion was associated with a decreased risk of essential hypertension. Also, a restriction fragment length polymorphism (RFLP) that distinguishes the kallikrein gene family in one strain of SHR from normotensive Brown Norway rats has been identified; in recombinant inbred substrains derived from these SHR and Brown Norway strains, the RFLP marking the kallikrein gene family of the SHR cosegregated with an increase in blood pressure. However, humans, rats, and mice with a deficiency of one component of the kallikrein-kinin system or chronic blockade of the kallikrein-kinin system do not have hypertension. In the kidney, kinins participate in the regulation of papillary blood flow and water and sodium excretion. Mice with homologous deletion of the gene for the B₂ receptor for bradykinin appear to be more sensitive to the hypertensinogenic effect of salt.

Kinins participate in the acute antihypertensive effect of ACE inhibitors; however, in general they are not involved in the chronic antihypertensive effects of ACE inhibitors save for mineralocorticoid-salt-induced hypertension. Kinins acting via nitric oxide NO participate in the vascular protective effect of ACE inhibitors during neointima formation. In MI produced by ischemia/reperfusion, kinins play an important role in the reduction of infarct size induced by preconditioning or ACE inhibitors. In heart failure secondary to infarction, the therapeutic effects of ACE inhibitors are partially mediated by kinins via the release of NO. The therapeutic effect of ARB in heart failure is partly due to activation of angiotensin type 2 receptors via kinins and NO. Thus kinins could play an important role in the regulation of cardiovascular and renal function as well as in many of the beneficial effects of ACE inhibitors and ARB.

Target Organ Damage/ Cardiovascular Events

Chapter 21

The Concept of Total Risk

William J. Elliott, Henry R. Black

RISK—DEFINITIONS AND TYPES

Webster's New Pocket Dictionary defines *risk* as “the chance of harm, injury, etc.” Risk, however, has many different meanings, depending on the context and the background and training of the user or audience. In the discipline of surgery, a person who is a “poor surgical risk” is an individual whose likelihood of death or other adverse outcome during the perioperative period is high, compared with the chance of a desirable outcome. In commerce, risk comes in at least three varieties: “Business risk” can be loosely defined as the chance that something will go wrong with an individual company, resulting in a loss. “Systemic risk” includes potential threats to an area’s financial structure, which could make the entire region suffer economically. “Market risk” quantitates the probability that when one wishes to sell an asset, the proceeds will be less than expected. When the term *risk factor* was first added to the medical vocabulary by the Framingham Heart Study, its heritage, in fact, came from the financial world.

In medicine (and epidemiology, the basic science that forms the foundation for evidence-based medicine), risk is most easily defined as the proportion of previously unaffected individuals who, on average, will acquire the disease of interest during a defined period of time. Because risk is given as a proportion, it typically has no specific units, although the time period of interest is usually given in academic discussions. For short-term changes in health status (e.g., intensive-care unit medicine), the time period of interest is usually minutes, hours, or days. For longer-term evaluations of disease emergence, the time period of interest is often measured in years or decades.

Risk comes in two basic types: *absolute risk*—the definition of which is essentially the same as risk, as given previously, except that the time frame is *always* included; and *relative risk*, which is essentially a ratio of the risks for a group of interest, compared with another “control” group. A variant of relative risk is *attributable risk*, which is the amount or proportion of disease that can be said to be associated with exposure to a particular factor; its use is more common if there are “competing risks” (more than one factor being evaluated, to be discussed shortly).

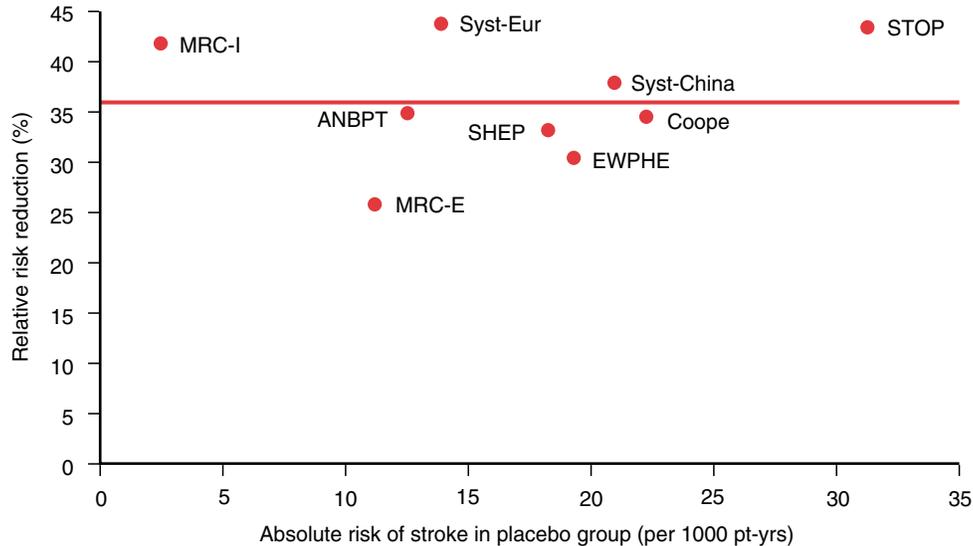

Perhaps the easiest way to illustrate the difference between absolute and relative risk is in the context of a clinical trial. In

the 1980s, there was still debate as to whether older people with “isolated systolic hypertension” (defined, at that time as systolic blood pressure [SBP] ≥ 160 mm Hg, but a normal diastolic blood pressure [DBP], < 90 mm Hg) should be given antihypertensive medications. There was concern not only that there would be few, if any, benefits, but also that the side effects of the drugs would be more troublesome to older people, in whom the typical elevation in SBP may be only a result of “stiffer” arteries. The Systolic Hypertension in the Elderly Program (SHEP) therefore enrolled 4736 people aged 60 years or older, in normal sinus rhythm, with blood pressures (BPs) in the range of 160 to 209/ < 90 mm Hg, and randomly allocated 2365 of them to treatment, beginning with 12.5 mg/day of chlorthalidone.¹ The other 2371 people received placebo tablets, but were allowed to begin open-label treatment during follow-up if one of several prespecified criteria was met. The primary outcome measure was fatal or nonfatal stroke, but other cardiovascular endpoints, including coronary heart disease (CHD) and heart failure, were also collected. The study, on average, lasted 4.5 years. At the completion of the study, there were 106 fatal or nonfatal strokes in the treatment group, as compared with 159 in the group originally assigned placebo.¹ The absolute risk of fatal or nonfatal stroke, therefore, in the placebo-treated group was 159 strokes/2371 people allocated to placebo treatment/4.5 years of follow-up, or approximately 1.5% per year. The absolute risk of fatal or nonfatal stroke in the actively treated group was, analogously 106 strokes/2365 people allocated to active treatment/4.5 years of follow-up, or approximately 1.0% per year. The relative risk of fatal or nonfatal stroke for the actively treated group, compared with those who were initially given placebo, can be estimated as the ratio of these two absolute risks: $106/2365:159/2371$, or 0.668. The relative risk reduction in fatal or nonfatal stroke, calculated by this method, would therefore be 0.332, or 33.2%. This simple estimate compares rather favorably with the 36% calculated by the more complex proportional hazards model (which takes into account the incidence of stroke over the entire time of follow-up that is ignored in the simple risk ratio calculated previously).¹

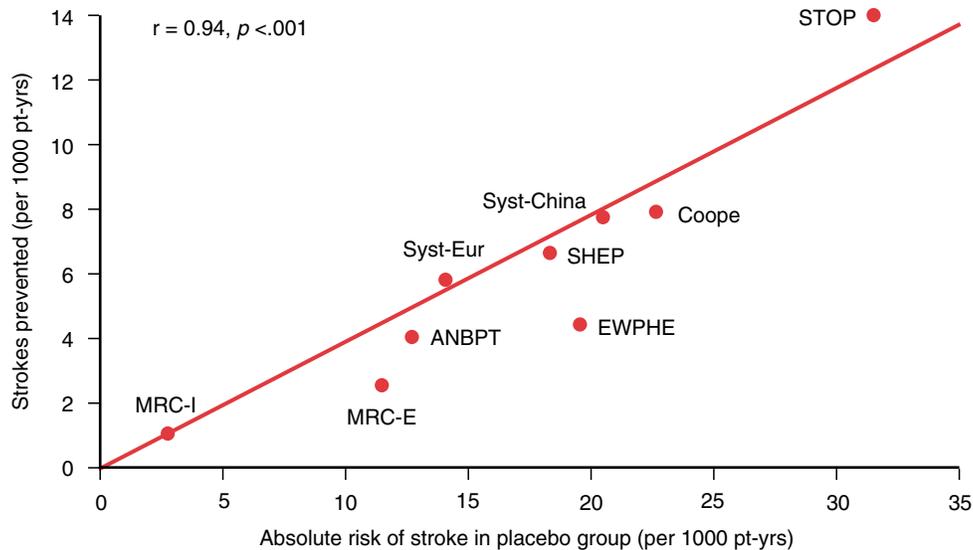

It is interesting and important to contrast estimates of absolute and relative risk reduction. In the previous example,

the relative risk reduction in stroke, for actively treated versus placebo-treated people in SHEP, was about 33% to 36% (depending on the method used for its calculation). The *absolute risk reduction*, however, was the difference between the two groups' absolute risk estimates: 1.490% to 0.996% per year, or about 0.494% per year. Headline writers and many

physicians are much more easily impressed with relative risk reduction estimates, because these are somewhat better understood by most lay people, and are often easier to remember.² However, there are good reasons to consider, and perhaps even to prefer, absolute risk reduction estimates. Because relative risk estimates always require reference to a specific "con-

A

B

Figure 21-1 Relationships between absolute risk of stroke (calculated as the stroke rate per 1000 patient-years in the control group, either placebo or no treatment) and **(A)** the relative risk reduction of stroke with active treatment compared with control; and **(B)** the absolute risk difference between active treatment and control (equivalent to the number of strokes prevented per 1000 patient-years by antihypertensive drug therapy). Each circle represents a single clinical trial.

Abbreviations: MRC-I, Medical Research Council Trial in Mild Hypertension⁸; MRC-E, Medical Research Council Trial in Older Adults⁷²; ANBPT, Australian National Blood Pressure Trial⁷³; Syst-Eur, Systolic Hypertension Trial in Europe⁷⁴; SHEP, Systolic Hypertension in the Elderly Program¹; EWPHE, European Working Party on Hypertension in the Elderly⁷⁵; Syst-China, Systolic Hypertension Trial in China⁷⁶; Coope, Coope and Warrender⁷⁷; STOP, Swedish Trial in Old Patients with Hypertension.⁷ (Updated from The sixth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI). Arch Intern Med 157:2413-2446, 1997 and Lever AF, Ramsay LE. Treatment of hypertension in the elderly. J Hypertens 13:571-579, 1995).

tol group,” such estimates tend to be somewhat less useful across time, particularly as the science of medicine evolves. For example, the relative risk estimate for drug treatment of “isolated systolic hypertension” is not of great interest today, because most physicians, an important meta-analysis,³ and all guidelines since 1993 agree that such treatment is desirable and should be routine. Additionally, neither group in SHEP received intensive drug treatment for dyslipidemia, despite the fact that most eligible people with isolated systolic hypertension today would be recommended to receive it. Such treatment would likely decrease the relative risk reduction for stroke that could be attributed to antihypertensive drug treatment, because a meta-analysis of 3-hydroxy-3-methylglutaryl-coenzyme A reductase treatment suggests a relative risk reduction of about 24% in primary stroke prevention.⁴

A further positive attribute of absolute risk is that it can be easily compared across studies; this is particularly easy and appropriate when all studies are placebo-controlled. Figure 21–1, A, shows a plot of the relative risk reduction for stroke (on the y-axis) across many clinical trials in hypertension, indexed to the absolute risk of stroke (on the x-axis) for the population studied.

These data show that the relative risk reduction for stroke for nearly all trials was typically about $36\% \pm 6\%$ (mean \pm standard deviation). Although this is perhaps useful and interesting, a meta-analysis would probably provide a more precise assessment of the pooled point estimate. Alternatively, focusing on the absolute risk difference, Figure 21–1, B, shows the number of strokes prevented (on the y-axis), indexed as before to the absolute risk of stroke (on the x-axis). This graph illustrates the very powerful effect of “risk stratification” for individual patients,⁵ and also shows why estimates of risk are very important to decisions regarding therapy.⁶ For example, giving antihypertensive drug therapy to the much older patients in the Swedish Trial of Old Patients with Hypertension (STOP-Hypertension)⁷ prevents approximately 14 strokes per 1000 patient-years of treatment. This would be a much more cost-effective use of medications than giving similar antihypertensive drug therapy to the much younger patients (age 35–64 years old) in the first Medical Research Council (MRC-I)⁸ trial, which observed approximately one stroke saved for every 1000 patient-years of therapy. This observation is also consistent with the adage, “One cannot prevent a stroke that isn’t likely to occur.”

Another major advantage of the absolute risk estimate (over relative risk) is that it can easily be tied to the “NNT” (number needed to treat), which provides an overall estimate of the effectiveness of an intervention.⁵ Simply put, the NNT is an estimate of the number of people who would need to be treated with the studied regimen to prevent a *single* outcome of interest. The NNT is simply the reciprocal of the absolute risk difference: For SHEP, the 1-year NNT is $1/0.494$ or about 202. This suggests that one fatal or nonfatal stroke would be prevented by the antihypertensive drug treatment regimen used in SHEP for each 202 individuals treated for 1 year. Because most antihypertensive drug studies (and indeed SHEP) gathered data for nearly 5 years, it is more traditional to present the 5-year NNT data; for SHEP, the 5-year NNT shrinks to 40.

Another variant of risk that is most useful in large populations where there are competing risk factors is *attributable risk*. For example, many conditions influence the future risk of stroke, including the presence or absence of atrial fibrillation, hypertension, smoking habit, dyslipidemia, and possibly over-

weight/obesity. The relative importance of each of these factors can be most easily apportioned using a completely untreated population (e.g., the Framingham Heart Study). Discerning a significant risk reduction can be difficult in treated populations, because the overall risk for the event of interest can be reduced by therapy, leading to an incorrect estimate of the risk attributable to one or more other risk factors. Perhaps the best recent example of this was the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT), in which (in a 2×2 factorial design) two active antihypertensive treatment regimens were compared, while simultaneously atorvastatin was compared with placebo, in the prevention of fatal or nonfatal myocardial infarction (MI).⁹ Fortunately, the degree of BP lowering was not significantly different across the two randomized groups (atorvastatin vs. placebo). This allowed the investigators to estimate the relative risk reduction for fatal or nonfatal MI attributable to atorvastatin at 36% (95% confidence interval: 17%–50%, $p = .0005$), without interference from the effect of BP lowering.¹⁰ Most studies are not as fortunate, and therefore most estimates of attributable risk must be understood in the context of the degree of treatment of other risk factors, and the potential interaction of the two or more risk factors and their treatment. Within a given large population, the population-attributable risk (PAR) takes into account not only the relative risk for an endpoint, but also the prevalence of the potential risk factor within the population (or proportion of cases with the endpoint exposed to the factor). For example, a recent publication from the Framingham Heart Study suggested that the PAR for overweight, as a possible risk factor for stroke, in men was significant, at about 15%.¹¹

TOTAL RISK

Statistical evaluations of risk factors must necessarily consider *only* clearly defined endpoints, for example, stroke, CHD, end-stage renal disease (ESRD), or “cardiovascular events” (which has been variably defined). As a result, what constitutes “total risk” depends somewhat on one’s perspective. Because medicine tends to be fragmented, with specialists usually focusing on one specific organ or disease, little attention is routinely given to statistical evaluations that encompass *all* diseases commonly associated with common interdisciplinary conditions, such as hypertension. Thus, hypertension is a well-known risk factor for stroke, CHD, heart failure, and ESRD. Because stroke tends to be the province of neurologists, CHD is studied most intensively by cardiologists, and ESRD is of greatest interest to nephrologists, these hypertension-associated endpoints tend to be segmented when statistical evaluations of risk factors and risk assessments are performed.

As with attributable risk, population-based data often help define total risk. Projections were that, in the United States in 2003, a first diagnosis of CHD would be made in more than 650,000, stroke in more than 500,000, and ESRD in nearly 100,000 people.¹² Preliminary national vital statistics data (derived from death certificates) from 2001 show that heart disease accounted for 28.9%, stroke for 6.7%, and nephritis (a category that includes many types of renal disease) for about 1.6% of the 2,4017,798 deaths,¹³ but these data probably underestimate mortality resulting from renal disease, because dialysis patients most often die from heart disease.¹² In the Framingham Heart Study, in participants younger than 75

years, CHD consistently accounted for more than half of the cardiovascular events from 1948 to 1998, whereas stroke incidence markedly decreased during this time period. Framingham cannot provide meaningful information about ESRD, because their original population included only 5209 people. Even using the 1999 nationwide incidence of ESRD, fewer than two of their original participants should have required dialysis or renal transplantation.

There is increasing interest in the use of risk equations to guide public policy, which depends not only on the rates of disease emergence, but the cost of each episode. U.S. national data estimate the per-patient cost of therapy for ESRD (\$54,917/year for dialysis, \$51,096/year for renal transplantation)¹⁴ much higher than for heart disease (\$11,273 per hospitalization for MI, and \$5501 per hospitalization for heart failure) or stroke (\$5955 per hospitalization for stroke).¹² Because the incidence of ESRD has grown steadily while the rates for heart disease and stroke have declined since 1980, there is much interest from federal and other authorities to find quantitative methods for estimating the risk for combined cardiovascular and renal disease. Some authors have concluded that, on an economic basis, risk assessment is too labor- and laboratory-intensive for application to the entire population, and should be limited to demographic groups with an inherently higher risk (e.g., older people).¹⁵ The National Institutes of Health is currently exploring ways to combine other longitudinal data (from sources such as the Cardiovascular Health Study¹⁶ and the Atherosclerosis Risk in Communities study¹⁷) with those from the Framingham Heart Study (which included no minority participants) to provide a more universally accepted risk equation for the U.S. population.

Rather than generating a single risk equation that encompasses both cardiovascular and renal endpoints, most recent efforts have focused on risk prediction scores for cardiovascular events (which include MI, heart failure, stroke, and other cardiovascular disease-related deaths).¹⁸ There are many reasons for this, including the fact that many risk factors other than hypertension impact the risk of both cardiovascular and renal endpoints, but with different weights. Probably the two best examples are the degree of microalbuminuria and/or proteinuria,^{19,20} and serum creatinine concentration, which is probably the best single predictor of ESRD, but a relatively insensitive and nonspecific predictor of cardiovascular events.²¹ Estimated glomerular filtration rate (which incorporates serum creatinine concentration²²), however, has been shown to be a powerful predictor of both renal and cardiovascular endpoints.²³

COMPETING RISKS

One of the basic tenets of modern statistical methods is the strict minimization of bias. In general, individuals who have already suffered an endpoint (e.g., a first MI) are at significantly higher risk for a second endpoint of a similar nature (e.g., a second MI, which is about 2 to 4 times more likely than in individuals without such a prior history). The best and most widely accepted way to avoid this sort of bias in risk assessment is to simply use the time-to-first event methodology (e.g., Kaplan-Meier life-table analyses) and “censor” (or ignore) all events that occur subsequent to the first one. Although this has a major advantage in statistical modeling, it leads to underestimates of the incidence of major adverse events, especially

cardiovascular events. Whereas ESRD is typically encountered only once in any given person’s lifetime, MIs, strokes, and hospitalizations for heart failure can (and do) recur.

The issue of “competing risks” is particularly important when attempting to integrate cardiovascular and renal event data into a single risk equation. As noted previously, there are multiple risk factors that are shared by the two types of events, including age, gender, and BP. Serum creatinine concentration, probably the best predictor of the need for renal replacement therapy, has been associated with a significantly higher risk of cardiovascular events in several datasets.^{21,24-27} Some of this association can be attributed to the elevated creatinine being a result of poorly controlled hypertension, which itself increases cardiovascular risk.²⁸ In addition, ESRD itself is an independent risk factor for cardiovascular events and cardiovascular death: ESRD patients have an 80% 1-year mortality after MI, compared with about 10% in the non-ESRD population.²⁹ People on dialysis or who have had a kidney transplant have an increased propensity to infection, a predisposition to cancer inherent to immunosuppressants, and a continued risk of the disease that brought them to renal replacement therapy (most commonly diabetes in the United States). Despite these risks, nearly half of the Americans with ESRD disease die of cardiovascular disease (CVD). In the 2001 death registry maintained by the U.S. Renal Data Systems (which includes all individuals in the United States whose ESRD treatment is funded through Medicare or Medicaid), 43.7% died from a cardiac cause, and another 5.2% succumbed to a stroke.¹⁴

A further confounder of any attempt to integrate both cardiovascular and renal risk into a single equation is potential differential effects of treatment. Theoretically, any treatment that delays a fatal MI or stroke is likely to increase the chance that the patient will live long enough to develop ESRD. Similarly, a therapy that delays the time to ESRD may lengthen life sufficiently so that an MI or stroke may occur. Another potential concern is the possibility of a treatment that may significantly decrease the risk of ESRD, but increase the risk of cardiovascular events. This phenomenon may have been observed in the Irbesartan Diabetic Nephropathy Trial (IDNT), in which the angiotensin II receptor antagonist irbesartan significantly reduced the primary renal endpoint (doubling of serum creatinine, ESRD, or death) compared with amlodipine, by 23% ($p = .006$).³⁰ There were no significant differences between these two randomized treatment groups in the composite secondary outcome that included cardiovascular events, but the nonsignificant trends favored amlodipine over irbesartan for cardiovascular death (relative risk reduction of 26%), MI (35%), and stroke (35%).³¹

INTERRELATION OF TYPES OF CARDIOVASCULAR RISK

Probably the simplest type of quantitative risk assessment should be based on cardiovascular death as the endpoint, because this would preclude some of the issues related to competing risks discussed previously. A method for calculating the 5-year risk of cardiovascular death has been derived from eight clinical trials involving 47,088 patients followed for a mean of 5.2 years, and resulting in 1639 deaths.³² The small proportion of people who die (which limits statistical power) can be overcome by longer follow-up.³³ Although

cardiovascular death is gaining favor as the preferred endpoint among European epidemiologists, health economists and policymakers (especially in the United States) object, because it would ignore any and all expensive and debilitating events that precede death.

A second logical endpoint is all cardiovascular events, which include CHD events and stroke. Some authors prefer to include heart failure among the CHD events, but others restrict it to fatal and nonfatal MI. This endpoint is particularly favored (over CHD alone) by many groups interested in hypertension treatment, because BP lowering reduces stroke more (in terms of relative risk, about 36%) than CHD (about 18%-21%) in nearly all clinical trials. In most Western hypertension clinical trials, CHD events account for about 75% of the cardiovascular events; in most studies performed in China and older studies in Japan, stroke comprises a higher proportion of the total events. Several recent comparisons of various risk estimators suggest that a cutoff of CVD risk $\geq 20\%$ over 10 years is roughly equivalent to a CHD risk $\geq 15\%$ over 10 years.^{34,35}

The most common endpoint for Western risk assessment has become CHD events. Although this endpoint ignores stroke, it lends itself readily to a discussion not only of the

potential benefits of antihypertensive drug therapy, but also aspirin and lipid-lowering agents. An obvious disadvantage of using this method is the fact that CHD displays wide (but predictable) variability across regions and countries that is not easily explained by differences in the prevalence of the usual CHD risk factors.³⁶ Thus a person with the same set of risk factors will typically have markedly different risk for CHD in Italy compared with Finland³⁷; this has proven to be a major challenge for groups trying to develop a single overall risk estimator for all of Europe.^{6,38-40}

CURRENT CARDIOVASCULAR RISK ASSESSMENT TOOLS

Perhaps because of the difficulty in integrating both cardiovascular and renal risk in a single risk equation, most recent authors have focused on developing, testing, and comparing risk assessment algorithms for cardiovascular (most especially cardiac) events. The algorithms that have been used vary in complexity from simply counting the existing risk factors⁴¹ to complex equations (derived from a Weibull accelerated failure

Table 21-1 Some Methods of Estimating Risk

Model	Population Studied	Risk Factors Included	Validated?
Framingham Heart Study*	About 11,332 residents of Framingham, MA	Age, gender, SBP and DBP; total, LDL and HDL cholesterol; diabetes; smoking	Widely
Cardiovascular Disease Life Expectancy Model	3700 men and women from USA and Canada, aged 35-74 (from Lipid Research Clinics follow-up cohort)	Age, gender, mean BP, total and HDL cholesterol, diabetes, smoking, cardiovascular disease	Yes
Munster Heart Study	4400 German men and women, aged 40-65 (workplace-based)	Age, SBP, total and HDL cholesterol, diabetes, smoking, family history, angina symptoms	Not in women
British Regional Heart Study Risk Function	7735 men aged 40-59 (general practitioner-based)	Mean BP, total cholesterol, diabetes, smoking, family history, angina symptoms	No
Dundee Coronary Risk Disk	5203 men aged 40-59 (UK Heart Disease Prevention Project)	Total cholesterol, SBP, smoking	Not in women
New Zealand Guidelines*	Based on Framingham equation	Age, gender, diabetes, smoking, SBP, DBP, total:HDL cholesterol ratio	No
Joint British Societies Risk Tables*	Based on Framingham equation, modified with epidemiologic data from Britain	Age, gender, diabetes, smoking, SBP, total:HDL cholesterol ratio, family history	Yes
European Society of Cardiology Tables*	Based on Framingham equation, modified with epidemiologic data from Europe	Age, gender	Yes
Sheffield Tables*	Based on Framingham equation, modified with epidemiologic data from Scotland	Age, gender, total:HDL cholesterol ratio, hypertension, smoking, diabetes, LVH on ECG, family history of CHD	Yes

*Denotes models that are discussed more fully in text. SBP, systolic blood pressure; DBP, diastolic blood pressure; BP, blood pressure; LDL, low-density lipoprotein; HDL, high-density lipoprotein; LVH, left ventricular hypertrophy; ECG, electrocardiogram; CHD, coronary heart disease.

regression model).⁴² Some of these, and the populations from which they have been derived, are summarized in Table 21–1.

Counting Risk Factors

The simplest type of risk assessment is probably the one recommended by the sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI).⁴¹ In this scheme, people were divided into three broad categories of risk (A, B, or C). Risk Group A, which is defined without mention of any threshold of absolute risk, are those without any of the traditional cardiovascular risk factors, target organ damage related to hypertension, or concomitant CVD. These very-low-risk individuals include only premenopausal women and comprised only 9% of the hypertensive population in the National Health and Nutrition Examination Survey (NHANES) I Epidemiological Follow-up Study.⁴³ The majority (nearly 72%) of the hypertensive population had one or more risk factors for CVD, but no diabetes, target organ damage, or concomitant CVD, and were placed in Risk Group B. The highest-risk group (Risk Group C) with either diabetes, evidence of target organ damage, or concomitant CVD, accounted for 19.2% of the NHANES sample. After correcting for regression-dilution bias, Ogden et al. calculated that the number of people needed to be treated for 10 years to prevent a CVD death ranged from 34 to 486 (Risk Group A) to 11 to 21 (Risk Group C), with the higher numbers associated with the lower levels of BP.

JNC VI recommended using this simple system to decide on the intensity and type of initial treatment for high-normal and high BP. Unless the initial BP exceeded 180/110 mm Hg, only lifestyle modifications were recommended for people in Risk Groups A and B; the latter were to receive them for a shorter time before drugs should be started. Both antihypertensive drug therapy and lifestyle modifications were initially recommended for people in Risk Group C.

The obvious advantage of this simple system was that it is easy to use. It did not require a computer or access to complex figures or tables. The authors of JNC VI were not concerned with making precise estimates of cardiovascular risk, but instead focusing attention on hypertensive individuals whose overall risk was very low or very high, independent of the BP level. However, the specificity of the JNC VI risk stratification system, when compared with the most recent Framingham risk equation, in a group of 202 people representative of a Scottish population, was only 9%.³⁵ This would presumably lead to drug treatment for a high number of people, many of whom are unlikely to benefit from it (in terms of cardiovascular event protection). Another potential disadvantage of the JNC VI risk stratification system was the inclusion of age (the most important risk factor for cardiovascular events) only as a dichotomous variable (older or younger than 60 years); this probably accounted for much of the low specificity. The JNC VI scheme is still the only risk stratification system that includes postmenopausal status as a cardiovascular risk factor for women. As with the World Health Organization/International Society of Hypertension (WHO/ISH) guidelines discussed next, JNC VI counted a family history of premature CVD (first-degree female relatives younger than age 65, or men younger than age 55); this is mentioned only as a footnote in other risk estimators.

The risk stratification scheme published in 1999 as part of the WHO/ISH guidelines included more detail than, but was similar to, the JNC VI risk stratification method.⁴⁴ One major difference was that there were four categories of risk: low, medium, high, or very high. These corresponded rather generally to categories of absolute risk of CVD over 10 years: <15%, 15% to 20%, 20% to 30%, and >30%, respectively. Low-risk people included men younger than 55 years of age and women younger than 65 years of age with grade 1 hypertension (140–159/90–99 mm Hg) and no other cardiovascular risk factors, target organ damage, diabetes, or associated clinical conditions (existing CVD). Medium-risk individuals included grade 1 hypertensives with one or two other risk factors, or grade 2 hypertensives (160–179/100–109 mm Hg) with zero to two other risk factors, but again no target organ damage, diabetes, or associated clinical conditions. High-risk people had either grade 3 hypertension ($\geq 180/\geq 110$ mm Hg) and no other risk factors, or grade 1 or 2 hypertension and three or more risk factors, or target organ damage or diabetes. People with associated clinical conditions were all very high risk, as were grade 3 hypertensives with one or more risk factors, target organ damage, or diabetes. The WHO/ISH risk stratification system therefore went somewhat beyond a simple counting of risk factors, but relied heavily on the counted number to categorize hypertensive people according to their need for therapy. Not surprisingly, this slightly more complex method was superior to the simple JNC VI stratification scheme, especially in correctly estimating risk for low-risk hypertensives.³⁵ Two potential disadvantages of the WHO/ISH risk stratification system were its complexity and unclear relationship to treatment; even today, most practicing doctors do not take the time to count the risk factors and classify individual patients, before starting antihypertensive drug therapy.

The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) does not provide much information about formal risk assessment of hypertensive patients.^{45,46} It does recommend a thiazide-type diuretic for most patients with stage 1 hypertension, and a two-drug combination for most patients with stage 2 hypertension, but it omits a discussion of examining a patient's BP in the context of other risk factors and the global cardiovascular risk. Perhaps the most important reason for this was previous recommendation of the National Cholesterol Education Panel's III Adult Treatment Panel for physicians to use, in everyday clinical practice, a modified Framingham equation to estimate absolute risk of CHD.⁴⁷ The Executive Committee also wished to focus attention on hypertension per se and to avoid potential differences of opinion with other guidelines committees for the United States, including a proposal to consolidate recommendations across many healthcare advocacy groups (including the National Heart, Lung, and Blood Institute; National High Blood Pressure Education Program; National Cholesterol Education Program; American Diabetes Association; and National Kidney Foundation). A second important reason for omitting a discussion of risk stratification was that only when stratification leads to differential treatment strategies does it really impact on clinical practice. Because JNC 7 recommends antihypertensive drug treatment for all hypertensives ($\geq 140/\geq 90$ mm Hg) and all those with "compelling indications" for a specific drug or drug class, there was little to be gained by refocusing attention on global

cardiovascular risk assessment that would not change the existing treatment plan.

The 1999 risk stratification system of the WHO/ISH has been updated by the European Society of Hypertension (ESH) and European Society of Cardiology (ESC).⁴⁸ This extensive document now provides five levels of risk, based on an interaction of the untreated BP level and the presence or absence of risk factors, target organ damage, or associated clinical conditions. The “average risk” individual has either “normal” (120-129/80-84 mm Hg) or “high-normal” (130-139/85-89 mm Hg) BPs and no other risk factors (which now include both abdominal waist circumference and C-reactive protein⁴⁹). “Low added risk” includes individuals with no other risk factors and grade 1 hypertension (140-159/90-99 mm Hg) or one to two risk factors and either normal or high-normal BPs. “Moderate added risk” includes people with grade 2 hypertension (160-179/100-109 mm Hg) and no other risk factors; grade 1 or 2 hypertension with one to two risk factors; or normal BPs and three or more risk factors, tar-

get organ damage, or diabetes. Individuals with “high added risk” include grade 3 hypertension ($\geq 180/\geq 110$ mm Hg) and no other risk factors; three or more risk factors, target organ damage, or diabetes and either high-normal BP or grade 1 or 2 hypertension; and normal BP and established CVD. Everyone with established CVD with a BP $>130/85$ mm Hg is at “very high added risk,” according to the new ESH/ESC guidelines. The need for immediate drug treatment of hypertension is tied loosely to the risk category. Individuals at high or very high added risk begin drug treatment promptly; those at moderate added risk are to be monitored closely for at least 3 months and treated if the individual so desires or remains persistently hypertensive. Interestingly, and perhaps uniquely, the new ESH/ESC guidelines recommend withholding antihypertensive drug therapy for at least 3 months from a 64-year-old female smoker with dyslipidemia (or any other individual with two risk factors) and a BP of up to 179/109 mm Hg. Because the ESH/ESC risk stratification system is so new, formal evaluations of its predictive value have not yet been undertaken.

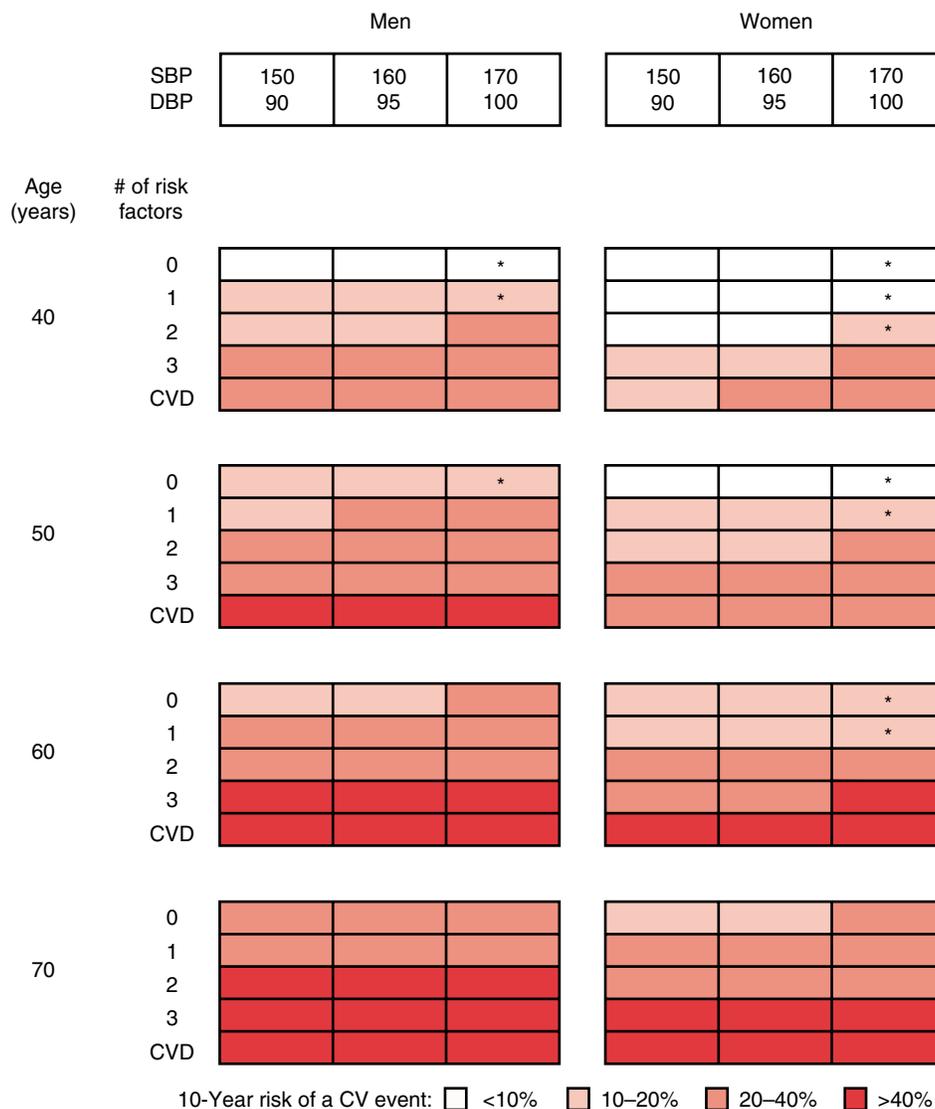

Figure 21-2 Risk stratification algorithm proposed for New Zealand in 1993, adapted from Jackson et al.⁴⁹ CV, cardiovascular; CVD, (existing) cardiovascular disease. The asterisk (*) indicates groups with low absolute risk for whom treatment is nonetheless recommended.

Counting Risk Factors and Stratification by Age

In 1993, a group of physicians in New Zealand broke new ground in considering risk for hypertensive patients and recommended that treatment generally be initiated only for hypertensive individuals (defined then as BP \geq 150/90 mm Hg) whose absolute cardiovascular risk exceeded 20% in 10 years (Figure 21–2).⁵⁰ They suggested that the threshold for hypertension treatment should not be based only on the level of BP, but instead on absolute risk of CVD. These novel proposals, as intended, have been debated widely, but have resulted in several refinements (discussed in the following paragraphs) that have been generally widely accepted in Europe, and to a lesser extent in the United States; they have been updated in 2000.⁵¹

The original New Zealand treatment guidelines departed somewhat from their intended goal, in that they recommended antihypertensive drug therapy for all with initial BPs higher than 170/100 mm Hg. According to their calculations, 40- to 59-year-old men with zero to one risk factor(s) and 40- to 60-year-old women with zero to two risk factor(s) have an absolute risk lower than the recommended threshold ($>$ 20% risk of CVD in 10 years), yet these individuals should still receive drug therapy (see asterisks in Figure 21–2). The New Zealand authors chose cutpoints for BP that were different from other guidelines: 150/90, 160/95, and 170/100 mm Hg. Epidemiologic data indicate that cardiovascular risk increases continuously, from a BP $<$ 115/75 mm Hg,⁵² but the New Zealand guidelines ignore these lower levels of BP. Like the Framingham group, the New Zealand authors prepared separate risk tables for each gender, a practice that has become common. Unlike American guidelines, the New Zealand group included obesity (body mass index $>$ 30 kg/m²) and the ratio of total:high-density lipoprotein (HDL) cholesterol ($>$ 6:1) as risk factors. Their definition of a positive family history is somewhat more conservative than that used in JNC VI, because both male and female relatives must have had a CVD event before age 55.

Despite these differences from simpler risk estimators, the New Zealand guidelines still merely *count* cardiovascular risk factors, without giving each one a specific weight. For example, diabetes and a family history of premature cardiovascular events are equivalent in this strategy, which may account for its poorer performance compared with other, more complex risk estimators.^{35,53} The major contribution of the New Zealand group was to stratify the risk calculation by age and gender and to recommend treatment only for those whose absolute CVD risk exceeded a given threshold. Their approach of displaying the various levels of risk using different colors or patterns has been followed by many other groups, to simplify the results of sometimes complex calculations.

There is some reluctance, particularly in the United States, to rely on these (more complex) estimates of cardiovascular risk as a guide to treatment. First, it takes time and effort to compile the required data for each patient and to perform the calculation, even with web-based resources or personal digital assistants. Unless it was linked to reimbursement, busy practitioners would likely find this exercise to be an inconvenience and a waste of time for patients' return office visits. A second challenge derives from biologic variability and medicolegal risk. Although today's risk estimators can provide a reason-

able "guess" of an individual's absolute risk of a CVD or CHD event, there is sufficient variability in the estimate that even complex equations may result in an inexact and incorrect prediction.⁵⁴ There is a finite possibility that an individual with a calculated "low-risk" of a cardiovascular event, who avoids treatment, will suffer such an event. If the decision not to treat is based solely or primarily on the risk score, it will be difficult to mount a successful defense about the withholding of anti-hypertensive treatment, if the prevailing local standard is to treat every hypertensive person with drug therapy.

Tables Using Weighted Coefficients for Risk Factors

Several different groups have issued tables that are similar to those of the New Zealand guidelines. The most important and most heavily studied of these are from the ESC, the Joint British Societies (JBS), and Sheffield, England.

The ESC has published a set of guidelines for prevention of CHD.⁵⁵ These guidelines include a risk estimator that is based on prior work of the Framingham Heart Study, but which uses weightings for each of the risk factors that are derived from epidemiologic data from Europe (especially Northern Europe). The ESC risk estimator uses total serum cholesterol and assumes a constant HDL cholesterol of 1.0 mm/L (39 mg/dl). As might be expected, this model gives overall results that are similar to those provided by the Framingham risk equation, with perhaps slightly less specificity for American patients.⁵⁶

In 1998, the JBS (Cardiac, Hyperlipidaemia, Hypertension, and Diabetes) met and agreed on a set of recommendations for prevention of CHD.⁵⁷ Their risk estimator, a modified Framingham risk equation that weighs each risk factor according to British national data, has several forms, which originated at the University of Manchester. For the practicing physician, the equations are "simplified" into a set of colored tables. Unlike other similar tables, in which every box in the table (corresponding to a set of risk factors) has a single risk level (and color), the JBS tables often have boxes that contain two colors. This is presumably useful in identifying individuals with risk that is intermediate between the cutoff levels ($<$ 15%, 15%-30%, or $>$ 30% risk of CHD over 10 years). There are two separate tables, one for diabetics and another for non-diabetics. The age groups are categorized as 35 to 44, 45 to 54, 55 to 64, and 65 to 74 years. The other major risk factors included are smoking habit ("which should reflect lifetime exposure to tobacco and not simply tobacco at the time of risk assessment"⁵⁷), SBP, and total:HDL cholesterol ratio. A somewhat more complex "Cardiac Risk Assessor" (which includes DBP and left ventricular hypertrophy [LVH] by electrocardiogram [ECG]) has also been developed at the University of Manchester and is available on the Internet.⁵⁸ The JBS tables³⁵ and computer program⁵⁹ have been tested against other risk estimators, with reasonably good results.

Investigators from Sheffield, England have published and been very active in testing a series of tables, the most recent of which is based on the Framingham equations, supplemented by data from the 1995 Scottish health survey.⁶⁰ Their new tables (one for men, another for women) use age and total:HDL cholesterol ratio (with 22 choices for men, 18 for women), and dichotomize hypertension (defined as \geq 140/90 mm Hg, or taking treatment), smoking, and diabetes. With a few modifications (e.g., doubling of risk with LVH on ECG,

increasing age by 6 years if family history of premature CHD), these tables have been reasonably well validated.^{34,35} Some physicians and nurses have found the Sheffield tables difficult to use,⁶¹ and they do not address levels of risk different from the 15% and 30% risk of CHD over 10 years.⁵⁹ Surprisingly, the Sheffield investigators indicated that the actual level of BP (treated or untreated) affected overall risk of CHD only slightly; this is why their tables dichotomize hypertension as being present or not. This approach differs, in this respect, from many others, and from the data on more than 1 million people in 61 observational studies indicating that the risk for coronary and cerebrovascular mortality doubles for each 20/10-mm Hg increase in BP over 115/75 mm Hg.⁵²

Framingham Risk Equations

The Framingham Heart Study has published several equations that are useful in risk estimation, but are, of their very nature, quite complex.^{42,62} Although derived from 5541 men and 5791 women, mostly white, who lived in Framingham, Massachusetts (the original Framingham cohort who survived until 1971, and their spouses or offspring, aged 35 to 74 years), the Framingham equations have been found to be useful in other populations, including minorities and people from other countries.^{17,56,63-65} The Framingham risk score has also been used to standardize cardiovascular risk (as a single baseline covariate) across randomized treatment groups in the LIFE (Losartan Intervention for Endpoint reduction) study.⁶⁶

The Framingham risk equations have been greatly simplified by means of a scoring system that allows each risk factor to be rated and a composite score to be calculated, which is proportional to the 10-year risk of CHD.⁴² This was the approach chosen by the National Cholesterol Education Program's Adult Treatment Panel III, which included an even more simplified version of this scoring system as the final page of its Executive Summary.⁴⁷

Box 21-1 Tests That May Improve Prediction of Risk for Cardiovascular Disease

Serum Markers

High-sensitivity C-reactive protein, homocysteine, fibrinogen, lipoprotein(a)

Imaging Studies

Electron-beam computed tomography of the coronary arteries; magnetic resonance imaging of heart, brain, and major blood vessels; B-mode ultrasound of carotid arteries

Physiologic Studies

Pulse-wave velocity in radial artery, treadmill and other types of exercise testing, ankle-brachial index

Blood Pressure Specific

Ambulatory blood pressure (BP) monitoring data; nocturnal versus daytime BPs, urinary albumin:creatinine ratio

FUTURE METHODS FOR RISK ESTIMATION

As epidemiologists continue to identify new risk factors for CVD, these may be incorporated into newer equations that improve the accuracy of (and maybe even simplify) such calculations.⁶⁷ Box 21-1 is a partial list of these, some of which (e.g., high-sensitivity C-reactive protein^{48,49}) have already been incorporated into risk stratification systems. It is likely, however, that new equations will not ignore the "classical" risk factors, including hypertension.⁶⁸ Two papers have reexamined the decades-old allegation that less than half the people hospitalized with an acute coronary syndrome have even one established risk factor; both studies have shown that the true prevalence of "risk factor-free" individuals who develop coronary events (including coronary death) is probably 5% to 15%.^{69,70}

SUMMARY

Although the concept of "total risk" is attractive, there are few well-validated methods of estimating a composite of both cardiovascular and renal risk in hypertensive patients. Many methods exist for computing short-term (e.g., 10-year) risk for CHD (typically defined as fatal or nonfatal MI and new-onset angina pectoris). The most well-known of these is the Framingham risk score. Whether any of these risk estimators (with all their complexity), novel genetic markers, and/or risk equations based on genomic techniques will lead to more cost-effective risk stratification and better use of limited healthcare resources remains to be seen.

New Interpretations of Blood Pressure: The Importance of Pulse Pressure

Stanley S. Franklin

The traditional epidemiologic definition of hypertension as a cardiovascular risk factor is based on two components of the arterial pulse wave—the peak systolic blood pressure (SBP) and end-diastolic blood pressure (DBP)—as measured from the brachial artery by means of the sphygmomanometer. More recently, attention has been directed toward the pulse pressure (PP) as a pulsatile component of cardiovascular risk. PP, the difference between SBP and DBP, is due to the force imparted to the arterial blood column by left ventricular contraction, which produces a pressure increment over and above the existing DBP. There is abundant evidence that the increase in PP after the sixth decade of life is a surrogate risk marker for central artery stiffness.¹⁻³ There is also evidence that central artery stiffness is an independent risk factor for cardiovascular disease.¹⁻³ Still unsettled, however, is whether PP is superior to SBP or to mean arterial pressure ($MAP = \frac{1}{3} SBP + \frac{2}{3} DBP$) as a predictor of cardiovascular risk. The objective of this chapter is to review the clinical usefulness of PP as a predictor of cardiovascular risk.

HISTORICAL PERSPECTIVE

Our understanding of the relationship between the various blood pressure (BP) indices and cardiovascular risk has undergone considerable change since the introduction of the sphygmomanometer at the beginning of the twentieth century. Initially, elevated DBP was thought the best measure of cardiovascular risk because it was equated to the resistance that the heart had to overcome, whereas elevation in SBP was largely ignored because it was equated with the maximum force of the heart.⁴ Indeed, interventional studies between the 1960s and 1980s invariably defined the severity of hypertension solely on the basis of DBP. However, since publication of data from the Framingham Heart Study in 1971, more weight has been given to SBP in defining hypertensive cardiovascular risk.⁵⁻⁷ Nevertheless, it was only after the benefits of antihypertensive therapy in isolated systolic hypertension (ISH) were clearly demonstrated in the 1990s that national and international guidelines first recommended therapy for elevated SBP in the absence of associated diastolic hypertension. Although the current guidelines acknowledge that both SBP and DBP define hypertensive cardiovascular risk,^{8,9} they contain a number of limitations. SBP and DBP represent only the two extremes of the propagated arterial pulse wave that is measured by sphygmomanometry at the brachial artery. Since the late 1980s, new evidence suggests that the relationship of BP components to cardiovascular risk is surprisingly more complex than initially thought. Part of this complexity involves the effect of ageing on BP indices and the possible role of PP in predicting cardiovascular risk.

AGE-RELATED CHANGES IN BLOOD PRESSURE

Population studies,^{10,11} including those from Framingham,¹² demonstrate that SBP rises from adolescence, whereas DBP, although initially increasing with age, levels off at ages 50 to 55 and decreases after ages 60 to 65 years. Thus PP increases after ages 50 to 55: a change that is accelerated from the ages of 60 to 65 and beyond. The rise in SBP and DBP up to ages 50 to 55 can best be explained by the dominance of peripheral vascular resistance (Table 22–1). In contrast, after the fifth decade of life (1) increasing PP and decreasing DBP are surrogate measurements for central elastic artery stiffening. Indeed, the fall in DBP with increasing aortic stiffness is explained by a diminished hydraulic buffering system, leading to greater peripheral run-off of stroke volume during systole. Thus, with less blood remaining in the aorta at the beginning of diastole, and with diminished elastic recoil, DBP decreases with increased steepness of diastolic decay. (2) After age 60, central arterial stiffness overrides increased systemic vascular resistance and becomes the dominant hemodynamic factor in both normotensive and hypertensive individuals, as manifested by an increase in SBP, a decrease in DBP and hence a rise in PP. (3) Hypertension, left untreated, may accelerate stiffening of elastic arteries, which, in turn, may set up a vicious cycle of worsening hypertension and further increases in elastic artery stiffness.¹²

The Third National Health and Nutrition Examination Survey¹³ (NHANES III) showed that three of four adult persons with hypertension are 50 years of age or older. Moreover, 80% of untreated or inadequately treated persons with hypertension in this age group have ISH, which by definition consists of elevated PP. In addition to ISH being the predominant form of geriatric hypertension, there is evidence that widened PP may complement SBP as a predictor of cardiovascular risk.

USEFULNESS OF PULSE PRESSURE IN PREDICTING CORONARY HEART DISEASE RISK

Using almost the same Framingham cohort as in the previous study, 1924 men and women between 50 and 79 years of age at baseline with no clinical evidence of coronary heart disease (CHD) and free from antihypertensive drug therapy, were followed for up to 20 years (Figure 22–1).¹⁴ In this population, CHD risk was inversely correlated with DBP at any level of SBP greater than 120 mm Hg, suggesting that PP was an important component of risk. There was a far greater increase in CHD risk with increments in PP for a given SBP than with increments in SBP with a constant PP. The Framingham study

Table 22-1 Hemodynamic Patterns of Age-Related Changes in Blood Pressure

Age (years)	DBP (mm Hg)	SBP (mm Hg)	MAP (mm Hg)	PP (mm Hg)	Hemodynamics
30-39	↑	↑	↑	→↑	R > S
↑	→	↑	→	↑↑	R = S
≥60	↓	↑	→↑	↑↑↑↑	S > R

Adapted from Franklin SS, Gustin W, Wong ND, et al. Hemodynamic patterns of age-related changes in blood pressure. The Framingham Heart Study. *Circulation* 96:308-315, 1997; with permission. DBP, diastolic blood pressure; SBP, systolic blood pressure; MAP, mean arterial pressure; PP, pulse pressure; ↑, increase; ↓, decrease; →, no change; R, small-vessel resistance; S, large-vessel stiffness.

supports the findings of earlier workers¹⁵⁻¹⁷ that PP may be useful as an adjunct to SBP in predicting risk and that CHD events are more related to the pulsatile stress of elastic artery stiffness during systole (as reflected in a rise in PP) than the steady-state stress of resistance during diastole (as reflected in a parallel rise in SBP and DBP). Seven additional publications, including a total of 12 different databases from around the world, have clearly shown an inverse relation of risk with DBP, so that PP becomes superior to the reference SBP in predicting total and cardiovascular mortality¹⁸⁻²⁴; three additional studies have shown the same relation for predicting CHD risk.²⁵⁻²⁷ Furthermore, the value of PP in predicting risk in the elderly has been confirmed by 24-hour conventional²⁸ and intraarterial²⁴ ambulatory BP monitoring.

PP may predict cardiovascular risk when SBP is normal or low as a result of ventricular dysfunction. This has been described in postmyocardial infarction,²⁹ end-stage renal disease

(ESRD) on hemodialysis,³⁰ and frank heart failure³¹ and is consistent with “reverse causation,” expressed as an increased cardiac mortality in association with a falling SBP. In the presence of compromised myocardial function, DBP decreases at a more rapid rate than SBP, so that the rise in PP rather than the fall in SBP becomes the stronger predictor of future cardiac events, including cardiac death.

USEFULNESS OF PULSE PRESSURE IN PREDICTING BENEFIT OF THERAPY

The benefit of effective antihypertensive therapy may be related to the extent of increased PP. There is evidence from a meta-analysis of eight intervention trials involving elderly individuals with ISH (defined by a SBP ≥160 and DBP <95 mm Hg) that fewer patients had to be treated to prevent one cardiovascular death if the PP at baseline was 90 mm Hg or greater.²³ The importance of a wide PP in ensuring a robust therapeutic outcome was confirmed in the Losartan Intervention for Endpoint Reduction (LIFE) trial of patients with hypertension and left ventricular hypertrophy (LVH). The therapeutic benefit of losartan was compared with that of atenolol in persons with ISH (SBP ≥160 and DBP <90 mm Hg) enrolled in LIFE, and that benefit was compared with the benefit achieved in LIFE participants with combined systolic-diastolic hypertension (SDH, defined as a SBP ≥160 and DBP ≥90 mm Hg). There was a 46% decrease in cardiovascular mortality from losartan over atenolol therapy in the ISH group as compared with no difference between treatments in the SDH group, although SBP was reduced almost equally in both arms of the study.³² The most logical interpretation of this analysis is that effective therapy with an angiotensin II antagonist resulted in a significant benefit over atenolol in reducing cardiovascular mortality in the group with the highest PP and hence the greatest risk.

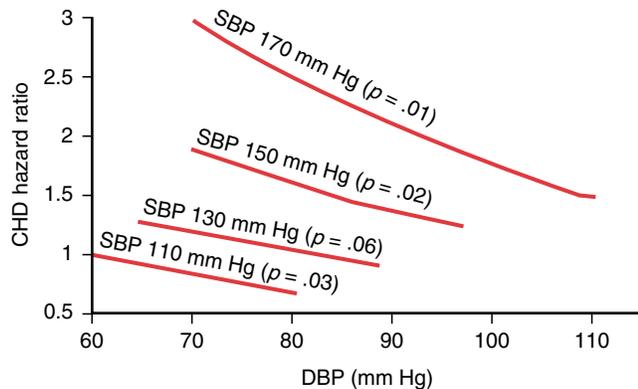

Figure 22-1 Joint influences of systolic blood pressure (SBP) and diastolic blood pressure (DBP) risk. Coronary heart disease (CHD) hazard ratios were determined from the level of DBP within SBP groups. Hazard ratios were set to a reference value of 1.0 for SBP of 130 mm Hg and DBP of 80 mm Hg and plotted for SBP values of 110, 130, 150, 170 mm Hg, respectively. The p-values were for the β coefficients for model. All estimates were adjusted for age, sex, body mass index, cigarettes smoked per day, glucose intolerance, and total cholesterol:high-density lipoprotein. (Adapted with permission from Franklin SS, Khan SA, Wong ND, et al. Is pulse pressure useful in predicting risk for coronary heart disease? The Framingham Heart Study. *Circulation* 100:354-360, 1999.)

PULSE PRESSURE AS A MARKER FOR CENTRAL ARTERY STIFFNESS: PATHOLOGIC CONSEQUENCES

Increased PP may be a surrogate marker for several possible pathologic mechanisms, all originating from the underlying increased central arterial stiffness and contributing to disorders of the myocardium.³³ Increased aortic pulsatile load elevates left ventricular wall stress, decreases coronary flow reserve, impairs left ventricular relaxation, and may lead to

diastolic dysfunction. Increased aortic pulsatile load is the major factor in the development of LVH with increased coronary blood flow requirements. Simultaneously, the decrease in DBP that characterizes ISH further compromises the oxygen supply:demand ratio by reducing coronary blood flow. In addition, increased pulsatile stress leads to endothelial dysfunction with a greater propensity for coronary atherosclerosis and for rupture of unstable atherosclerotic plaques.

HOW DOES AGE INFLUENCE THE CUFF PRESSURE ASSESSMENT OF CHD RISK?

The Framingham Heart Study examined the relationship between BP and CHD risk as a function of age (Figure 22–2).³⁴ From the ages of 20 to 79 years there was a continuous, graded shift from DBP to SBP and eventually to PP as predictors of CHD risk. From age 60 onward, when considered with SBP, DBP was negatively related to CHD risk, so that PP emerged as the best predictor.³⁴ All three BP indices in the Framingham study³⁴ were equally predictive of CHD risk in the transitional ages of 50 to 59 years, whereas in the younger group (<50 years of age), DBP was a more powerful predictor of CHD risk than SBP; PP itself was not predictive. Evidence favoring DBP over SBP in predicting CHD risk in young adults was also noted in a number of earlier large observational studies^{35–37} and in a later study utilizing intraarterial BP measurements.²⁴ These findings are consistent with the NHANES III study, which showed that there were twice as many hypertensive persons younger than age 50 up-staged by DBP as compared with SBP.¹³ The bias toward DBP over SBP by earlier generations of physicians may be, in part, due to the emphasis on hypertension as a young person's condition. However, with the ageing of the population over the past half-century, hypertension has become largely a condition affecting older persons with ISH.

Figure 22–2 Difference in coronary heart disease prediction between systolic blood pressure (SBP) and diastolic blood pressure (DBP) as function of age. Difference in β coefficients (from Cox proportional-hazards regression) between SBP and DBP is plotted as function of age, obtaining this regression line: $\beta(\text{SBP}) - \beta(\text{DBP}) = -1.49848 + 0.0290 \times \text{age}$ ($p = .008$). (From Franklin SS, Larson MG, Khan SA, et al. Does the relation of blood pressure to coronary heart disease risk change with aging? The Framingham Heart Study. *Circulation* 103:1245-1249, 2001; with permission.)

Curiously, the underlying hemodynamics that favor DBP as the predominant predictor of CHD risk in young hypertensive subjects are poorly understood.

THE IMPORTANCE OF PULSE WAVE REFLECTION

Conventional hemodynamic mechanisms do not explain why cuff DBP is superior to cuff SBP and PP in predicting CHD risk in young adults. The studies of Elzinga and Westerhof³⁸ showed that increased peripheral resistance was associated with a nearly parallel rise in aortic SBP and aortic DBP (or a greater rise in SBP than DBP in conjunction with some increase in arterial stiffness), whereas increased arterial stiffness alone was associated with a rise in aortic SBP and a fall in aortic DBP.³⁹ Thus the concept that increased peripheral vascular resistance alone is responsible for a greater rise in cuff DBP than SBP is a myth; an additional hemodynamic factor—wave reflection—must be present to explain these findings (Figure 22–3).

In young subjects the reflected pressure waves return to the ascending aorta in diastole and serve to elevate mean DBP, thus boosting coronary artery perfusion.⁴⁰ In addition, the summation of the incident pressure wave with the reflected wave in young adults produces a normal phenomenon of pressure amplification of PP and SBP from the aorta to the brachial artery.⁴⁰ In contrast, as arteries stiffen with advancing age, a larger reflected pressure wave returns to the ascending aorta earlier during late systole and increases or “augments” the central SBP and PP, thus decreasing pressure amplification and simultaneously contributing to increase cardiac afterload.⁴¹

Studies by Wilkinson et al.,⁴² using radial artery waveforms recorded noninvasively by applanation tonometry, have shown that peripheral amplification of PP and SBP decreases significantly as peripheral DBP increases in persons younger than 50 years of age; however, only a small, nonsignificant further decrease in amplification occurs in older subjects, largely because there is already increased early wave reflection within a stiffened arterial tree. In contrast, peripheral and central DBP and MAP track in a near parallel manner at all ages. Thus as peripheral vascular resistance rises in younger subjects, there is less change in peripheral SBP because of reduced pressure amplification. This explains why DBP is a better predictor of CHD risk in younger subjects. Further support for this concept comes for the studies of Millasseau et al.,⁴³ who showed that pulse wave velocity, as a surrogate measurement for aortic stiffness, was more closely correlated with peripheral DBP than SBP in subjects older than age 50 but not in those age 50 or younger.

SPURIOUS SYSTOLIC HYPERTENSION

Peripheral amplification, when exaggerated in tall, fit young men with highly elastic central arteries, may produce spurious upper limb systolic hypertension.^{44,45} This normal variant represents extreme pressure amplification of the brachial and radial systolic cuff pressures. Characteristically, these young men have normal central SBP and DBP and normal peripheral DBP and heart rates. The frequency of this form of pseudosystolic hypertension is unknown. This exaggerated

Figure 22–3 Pressure wave recorded along the arterial tree from the proximal ascending aorta to the femoral artery in three subjects aged 24, 54, and 68 years. (From Nichols WW, et al. *In* O'Rourke MF, Safar ME, Dzau V (eds). *Arterial Vasodilation: Mechanisms and Therapy*. London, Edward Arnold, 1993; with permission.)

peripheral amplification in some young, tall individuals with highly elastic central arteries represents a second example of why DBP is superior to SBP in predicting cardiovascular risk.

PARADIGM SHIFT IN THE INTERPRETATION OF BLOOD PRESSURE MEASUREMENTS

Paradoxically, the heart only “sees” SBP in the ascending aorta, and pressure wave amplification distorts the relationship between central and peripheral systolic pressure, as measured at the brachial artery by the sphygmomanometer. Therefore, central and not peripheral SBP, regardless of age, determines cardiac afterload and hence CHD risk. The changing pattern of age-related brachial artery BP components that predict CHD risk results from altered peripheral resistance, aortic stiffness, and early wave reflection, all acting in concert to raise SBP, decrease DBP, and abolish pressure amplification; this leads to an age-related shift from sphygmomanometric-determined DBP to SBP and ultimately to PP in the prediction of CHD risk. Overall, these findings validate the hemodynamic factors associated with aging and hypertension that were described more than 20 years ago by O'Rourke and Nichols.^{46,47} In addition, these findings represent a significant paradigm shift in our understanding of how we use brachial artery cuff BP components to predict CHD risk.

CLINICAL IMPLICATIONS

The reliance on DBP in the young and on SBP in the middle-aged to predict CHD risk appears straightforward, but there are questions regarding the best clinical approach for using PP as a predictor of CHD risk in the older patient. Cuff PP cannot replace SBP as a single measure of CHD risk, because it significantly underestimates peripheral vascular resistance.⁴⁸

Furthermore, MAP or DBP consistently underestimates peripheral resistance, central artery stiffness, and early wave reflection in this older age group.⁴⁸ In contrast, elevation in cuff SBP fully represents increased peripheral vascular resistance and partially represents increased central elastic artery stiffness and early wave reflection. Of the four BP indices, SBP is usually the single best predictor for middle-aged and older persons with systolic-diastolic hypertension (SBP ≥ 140 and DBP ≥ 90 mm Hg). However, evaluation of SBP and DBP jointly allows the assessment of the total cardiac load (i.e., the full influence of resistance, stiffness, and reflection) and therefore provides the best estimation of cardiovascular risk. Thus, the best strategy for assessing risk in this age group is to determine the level of SBP elevation, and then adjust risk upward in the presence of discordantly low DBP and hence high PP ISH.⁴⁸

The greatest prognostic value of a wide PP in this older age group may be in the categories of high-normal (higher half of the prehypertensive classification) SBP and stage 1 systolic hypertension (i.e., from SBP of 130 to 159 mm Hg), a BP span that encompasses almost two thirds of all adult CHD events.⁴⁹ The concurrent presence of wide PP in either of these two BP groups could shift an individual into a higher risk category and therefore possibly dictate a change in therapy. In addition, a wide PP could be helpful in identifying high-risk persons who may profit from more aggressive therapy for control of their BP.

CAVEATS IN EQUATING PULSE PRESSURE WITH CARDIOVASCULAR RISK

If PP is a surrogate for central artery stiffness, it is the stiffness that is the cardiovascular risk factor; strictly speaking, PP is a risk marker of stiffness. There are certain caveats to consider when using PP as a predictor of cardiovascular risk.

First, in middle-aged, healthy populations or older individuals with both systolic and diastolic hypertension, SBP and

MAP may be equal or superior to PP as predictors of cardiovascular risk⁵⁰⁻⁵²; in this population, there is such high colinearity between SBP and PP that it often becomes impossible to show an advantage of one index over another in predicting risk. Only when SBP increases and DBP decreases, as described in most observational studies, does the superiority of PP over SBP as a predictor of cardiovascular risk become apparent in uncomplicated hypertension.

Second, with advanced age and after adjustment for cardinal risk factors, PP becomes an independent predictor of CHD risk. Therefore, despite the high colinearity between SBP with PP, the latter predominates as the single best predictor of CHD risk because of the contribution of pulsatile stress in a minority of subjects with discordantly low DBP values. It should be noted that the MAP equation ($\frac{1}{3}$ SBP + $\frac{2}{3}$ DBP) grossly underestimates vascular resistance after ages 50 to 60 as DBP levels off and even falls.¹² Hence, beyond middle-age, PP becomes a better predictor and the MAP a poorer predictor of cardiovascular risk. Paradoxically, the value of MAP has been highlighted with the recent publication of meta-analyses by the Prospective Studies Collaboration (PSC)⁵³ and the Asian Pacific Cohort Studies Collaboration (APCSC),⁵⁴ using 61 and 37 cohort studies, respectively. These investigators concluded that MAP, in both the young and old, was a far superior predictor of CHD risk than was PP. Their conclusions are in total disregard of the proven importance of arterial stiffness and early wave reflection as important risk factors in middle-aged and elderly individuals with ISH. A meta-analysis of a smaller number of well-performed, observational studies, rather than the multiple diverse studies included in the PSC and APCSC, might have provided a different picture of the importance of PP in predicting cardiovascular risk.

PP becomes an even stronger predictor of cardiovascular risk (1) when combined with a cluster of risk factors⁵⁵; (2) in the presence of target organ damage, such as LVH⁵⁶ or albuminuria⁵⁷; (3) in association with diabetes⁵⁸; and (4) in the presence of prior cardiovascular complications that lead to ventricular dysfunction.²⁹⁻³¹

The totality of evidence supports PP as a surrogate risk marker for arterial stiffness, although at times an imperfect one. Despite high colinearity of PP with SBP, PP can be a more useful predictor of cardiovascular risk above and beyond the predictive power of MAP, SBP, or DBP. Clearly, these findings call into question the prevailing belief that elevation of SBP and DBP contribute equally to cardiovascular risk. However, there is as yet scanty evidence supporting the reduction of PP instead of SBP as a therapeutic goal. In addition, we have little information on the utility of using PP and SBP together, rather than SBP alone, to classify hypertensive risk. Furthermore, a public health recommendation that focuses on PP may detract from the importance of SBP in the diagnosis and treatment of hypertension. At present, it would be premature to modify current guidelines on the basis of prevailing data.

FUTURE FRONTIERS OF NONINVASIVE ASSESSMENT OF CENTRAL BLOOD PRESSURE

Although the use of cuff PP as a prognostic guide to cardiovascular risk may have some utility in older persons, this may not hold true under all circumstances. Aortic PP is the result of integration of three principal factors (i.e., stroke volume,

arterial stiffness, and the intensity and timing of wave reflections). Each of these factors can influence PP independently, but usually they act in concert. However, individual changes in pressure amplification, heart rate, stroke-volume and cardiac contractility may distort the relation between PP and arterial stiffness. Because central artery stiffness is established early, noninvasive assessment of arterial stiffness may allow better assessment of cardiovascular risk before hypertension develops, and long before the onset of cardiovascular complications.⁵⁹⁻⁶⁴ In addition, assessment of aortic stiffness may allow targeted primary prevention of cardiovascular disease and may be a useful tool for monitoring the success or failure of antihypertensive therapy. Thus noninvasive assessment of arterial stiffness and central BP appears to be a promising area for further investigation. There is hope that physicians of the twenty-first century will have a simple office method of measuring central pulse waveforms that will supplement or possibly replace the sphygmomanometer.

Coronary Atherosclerotic Sequelae of Hypertension

William B. Kannel

Hypertension is a highly prevalent predisposing condition for the development of cardiovascular disease (CVD) in the United States, and one of the major contributors to coronary heart disease (CHD) the leading cause of cardiovascular death from this cause. Hypertension affects about 50 million persons in the United States and is destined to increase further as the population ages.¹ Framingham Study data indicate that 90% of 50-year-old normotensive persons can expect to develop hypertension in their lifetime.² Persistent elevation of blood pressure (BP) is a critical element in the evolution of atherosclerotic cardiovascular morbidity and mortality. Animal experiments indicate that hypertension accelerates lipid-induced atherosclerosis and that lowering the BP retards the pathology.³ Also, low-pressure segments of the human circulation such as the pulmonary arteries or veins are virtually immune to atherosclerosis, despite exposure to the same lipid-laden blood as the systemic arteries supplying the heart, brain, and limbs. Atherosclerotic vascular pathology has now replaced the fibrinoid necrosis of malignant hypertension as the chief outcome of poorly controlled hypertension. However, the relation of hypertension to atherosclerosis is complex, interacting with other major risk factors that greatly influence its potential to enhance atherogenesis in the coronary arteries and elsewhere. The continuing high prevalence of hypertension in the general population, its great impact on cardiovascular morbidity and mortality rates and our ability to treat and control it, give it a high priority among measures to prevent CVD in general and CHD in particular. Treatment of hypertension and the CVD it promotes, account for a large portion of our health care expenditures.

PREVALENCE AND INCIDENCE

Hypertension (BP >140/90 mm Hg) is a dangerously prevalent condition afflicting one in four American adults. About 4% of persons younger than age 30 years have this condition and it increases in prevalence with age, reaching 65% in persons age 80 years and older.⁴ Each year about 2 million individuals are added to the pool of hypertensive persons requiring evaluation and treatment. The seventh Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) has designated systolic blood pressures (SBPs) of 120 to 139 mm Hg or diastolic blood pressures (DBPs) of 80 to 89 mm Hg as *prehypertension*.¹ These patients are at twice the risk for developing *hypertension* as those with lower values.⁵

Over 26 years of follow-up, 25% to 50% of the normotensive segment of the Framingham Study cohort developed

hypertension.⁶ Those with high-normal pressures developed “hypertension” at a twofold to threefold higher rate than those with strictly normal pressures.⁵⁻⁷ The incidence of new onset of hypertension increased threefold and eightfold from the third to the fifth decade of age in men and women, respectively.⁶

OPTIMAL BLOOD PRESSURE

It is difficult to specify at what BP a significant excess risk of hypertensive atherosclerotic cardiovascular sequelae *begins* to occur. Epidemiologic investigations report an excess risk of such events at BPs well below those often designated to define hypertension.^{1,8,9} To assess accurately the incremental risk of CVD at BPs in the nonhypertensive range, it is necessary to have huge population samples. A reasonably precise assessment of the risk of mortality at relatively low BPs can be obtained from the more than 350,000 men screened for eligibility in the Multiple Risk Factor Intervention Trial (MRFIT).⁹ Ten-year mortality rates in relation to baseline BP in that study increased stepwise from the lowest SBP (<110 mm Hg) on up. Compared with this lowest pressure, those with SBPs of only 120 to 129 mm Hg had an 18% higher overall and 35% higher cardiovascular mortality.⁹ Thus the optimal SBP appears to be less than 110 mm Hg because 40% of all deaths and 35% of cardiovascular deaths occurred in the “normotensive” range of 110 to 139 mm Hg. Based on these data, it appears that the majority of the population have higher than optimal SBPs, because only 6% of MRFIT screenees had pressures less than 110 mm Hg. A report based on another large population sample also shows a continuous relationship between CVD and BP in 40- to 70-year-old persons. Each 20-mm Hg increment in SBP or 10-mm Hg increase in DBP confers a doubling of the risk of CVD across the range of BPs from 115/75 to 185/115 mm Hg.¹⁰ Framingham Study data also suggest a continuous graded influence of BP on myocardial infarction (MI) occurrence in particular, beginning below 120 mm Hg systolic and 75 mm Hg diastolic, in men younger than age 65 years. For men older than age 65 years, an even steeper gradient of risk is noted throughout the SBP range. For DBP, incremental risk is noted as pressures increase above 75 mm Hg (Figure 23-1).

The population-attributable risk statistic provides the best indication of the population impact of hypertension because it takes into account both the prevalence of designated stages of hypertension and their risk ratios. Based on Framingham Study data, this indicates that, together, all grades of hypertension account for 28.5% of atherosclerotic cardiovascular events in men ages 35 to 64 years; 18.1% is attributed to JNC VI stages I and II hypertension. In women, the corresponding

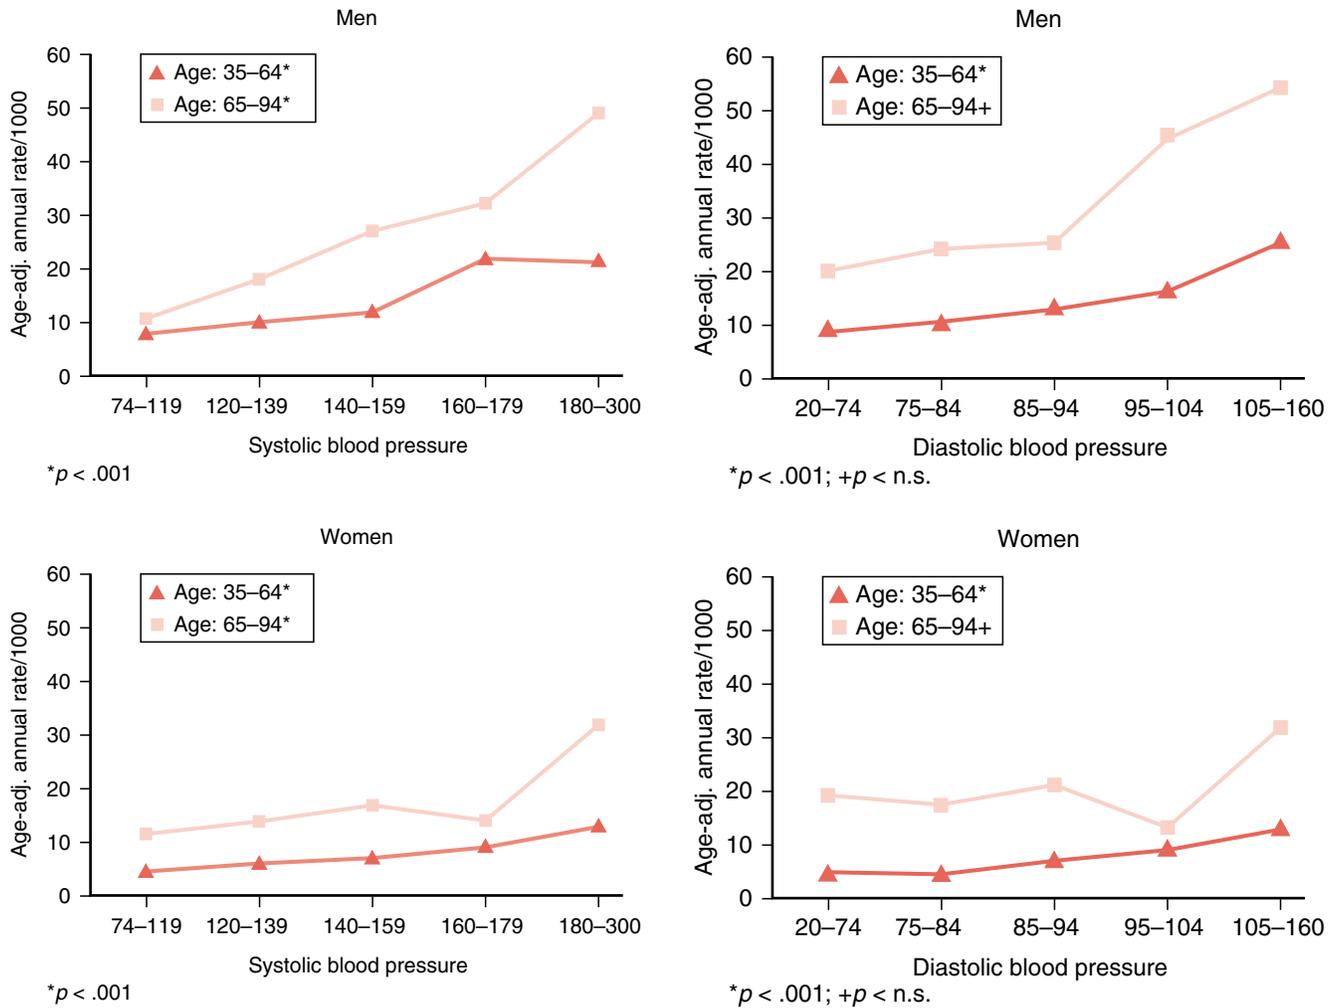

Figure 23-1 Risk of coronary heart disease by level of systolic blood pressure (SBP) and diastolic blood pressure (DBP) in each sex at specified ages. Framingham Study: 30-year follow-up. (From Vokonas PS, Kannel WB. Epidemiology of coronary heart disease in the elderly. In DD Tresh, WS Aronow (eds). *Cardiovascular Disease in the Elderly*, 2nd ed. New York, Marcel Dekker, 1999; pp 139-164.

attributable risk figures are 29.6% and 14.2%. Similar proportions of cardiovascular events are attributable to hypertension in the elderly. The relative and absolute risk of CHD to the individual increases sharply with the degree of BP elevation, but the population impact, signified by the population-attributable risk, is greatest for JNC VI stages I and II hypertension.

Control of existing hypertension remains far from complete and the incidence of newly acquired hypertension has not declined, indicating a need for primary prevention by weight control, salt restriction, and exercise, targeted at persons with a strong family history of hypertension, Blacks, and the obese.¹¹ Because there is a high prevalence in the population of persons with high-normal prehypertensive pressures who are at increased risk of developing more severe grades of hypertension, these nonpharmacologic approaches to control the discretionary environmental determinants of elevated BP need greater attention. The goal for hypertension control in the general population is to shift the BP distribution down to a more acceptable average value by hygienic measures, as well as treating those with already elevated pressures.

For physicians using medication to control BP, somewhat higher pressures are recommended as thresholds for treatment. However, it is important to recognize that the average pressure at which atherosclerotic cardiovascular events occur is not extremely elevated. The average BP at which men aged 30 to 62 years in the Framingham Study developed CHD was only 146/91 mm Hg; and for women, 161/94 mm Hg (Table 23-1). The median BP at which cardiovascular events occurred tended to increase with age, and has declined over succeeding calendar decades, both in those untreated and those under treatment. By the 1980s, half the cardiovascular events in Framingham Study men not on treatment occurred at pressures below 135/81 mm Hg, and in women, at pressures below 136/80 mm Hg.

ATHEROSCLEROTIC SEQUELAE

Hypertension is clearly a major contributor to the occurrence of atherosclerotic CVD in the general population, imposing

a twofold to fourfold increased risk of a major atherosclerotic cardiovascular event in persons ages 35 to 64 years and about a twofold risk in the elderly (Table 23–2). Thus it contributes to the risk of such events at all ages in either sex. The risk ratios are largest for heart failure and stroke, but CHD is the most common and lethal sequela for individuals younger than age 65 years, equaling in incidence all the other adverse outcomes combined. Although the absolute and excess risk of atherosclerotic CVD imposed by hypertension in women is less than in men, the relative risk is just as high for women as for men older than and younger than age 65 years (see Table 23–2).

Coronary Hazards

The less-than-expected efficacy of antihypertensive therapy to reduce the risk of coronary morbidity and mortality in early trials led to some unjustified questioning of the importance of BP in the development of CHD. Prospective epidemiologic investigation has in fact shown that hypertension is a powerful independent risk factor for the occurrence of coronary events.¹² In the Framingham Study, risk of every clinical manifestation of CHD was increased in persons with antecedent hypertension (Table 23–3). Although the CHD incidence rates of hypertensive women are substantially lower than those of men, the risk ratios comparing rates in hypertensives

with nonhypertensives are higher in women than men. Hypertension increases the risk of an MI almost twofold in men younger than age 65 years and threefold in such women (see Table 23–3).

For reasons that are unclear, hypertension predisposes disproportionately to MIs that go unrecognized, and the more severe the hypertension, the greater the proportion unrecognized (Table 23–4). This association persists even after excluding persons on therapy that might mask symptoms, persons with electrocardiogram (ECG) evidence of left ventricular hypertrophy (LVH) that might be confused with anterior MIs, and persons with coexistent diabetes who are known to be more prone to silent MIs. Unrecognized MIs are surprisingly common in general and particularly so in hypertensive persons. In hypertensive men, 35% of MIs go unrecognized, and in hypertensive women, 48%. This propensity to silent or unrecognized MIs makes periodic ECG surveillance of hypertensive patients for evidence of an MI mandatory.

As for CVD in general, risk of coronary events increases with the BP in a continuous graded fashion with no indication of a critical value where normal pressure leaves off and abnormal ensues (see Figure 23–1). It has been suggested that there is an excess risk of CHD at very low DBPs. However, in the Framingham Study of healthy persons taken as a whole, there was no indication of a J-curve relation of DBP to the occurrence

Table 23–1 Mean Initial Blood Pressure of Those Developing Coronary Heart Disease (CHD) Versus Those Remaining Disease Free for 14 Years in the Framingham Study

of coronary mortality.¹³ Only in persons with elevated SBP and those who already had an MI was an upturn in coronary mortality seen at DBPs below 75 mm Hg. The reason for this excess of mortality at low DBPs is at present unclear, but it is likely that it is confined to those with an increased pulse pressure.

It has been suggested that increased coronary mortality at low DBPs is a reflection of ill health, poor left ventricular function, or overtreatment.¹⁴⁻¹⁶ Overtreatment does not appear to be a likely explanation, because the J-curve BP relationship has been observed in both treated and untreated persons who have sustained an MI in the Framingham Study and elsewhere.^{13,17} Because low DBP appears to be associated with a poor outcome in patients with overt CHD and not in those free of such disease, it is possible that the presence of a low pressure, whether induced by treatment or not, is potentially lethal in the presence of a severely compromised coronary circulation. Although the Framingham Study took into account the fall in pressure that may result from an extensive MI and excluded persons with heart failure, it remains possible that the low DBP following MI is a manifestation of the extent of myocardial damage sustained.

Reinfarction and Death

A wide range of clinical, demographic, and biochemical risk factors have been investigated for prognostic value following an MI, but only a few studies have assessed the outlook beyond 5 years, as the Framingham Study has done. Assessment of the influence of BP on the outlook following MI is complicated because the BP can fall as a result of the infarction, so its association with the prognosis may depend on when the BP was measured with respect to the time of

occurrence of the infarction.^{13,14} Hypertension appears to confer a poor prognosis after an MI only when the BP is assessed after it has stabilized from the drop in pressure that often occurs postinfarction.^{15,16} Patients whose BPs fall as a result of an MI have a worse outlook than those whose pressures remain stable.^{13,14,17} Framingham Study data indicate that after excluding those who had a significant (i.e., 10 mm Hg) fall in BP immediately post-MI, there is a distinct relationship of the post-MI BP to mortality (Figure 23-2).

In the Framingham Study, where BPs were measured about 1 year after surviving the MI, and patients were followed for reinfarction or coronary death up to 30 years, both SBP and DBP were found to be important risk factors.¹⁸ Mean SBP

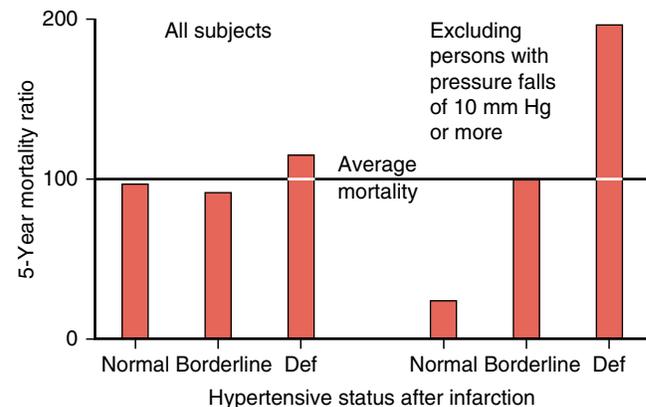

Figure 23-2 Mortality following myocardial infarction (MI) according to blood pressure status after interim MI. Framingham Study.

and DBP were higher in persons who experienced a reinfarction or coronary fatality. Each 25-mm Hg increase in SBP conferred a 53% increase in propensity to reinfarction and a 42% increased likelihood of coronary mortality adjusted for age and other risk factors for CHD.¹⁸ This strong association of postinfarction SBP with reinfarction and coronary mortality is in agreement with the findings of others.^{19,20}

COMPONENTS OF BLOOD PRESSURE

For most of the past century arterial hypertension was regarded as an arteriolar disease leading to increased resistance and hence increased mean arterial pressure (MAP). Because MAP is closer to the DBP than SBP, elevation of the diastolic component of the BP was considered the hallmark of arterial hypertension.²¹ DBP was considered a clinical measure of arteriolar tone and SBP, a measure of cardiac strength.

The increase in BP with age was regarded as a natural phenomenon. Although challenged by Framingham Study investigators in relation to risk of both stroke and heart attack many decades before,²² the idea that the increase in SBP with age is innocuous persisted until the Systolic Hypertension in the Elderly Program (SHEP) trial.²³

Clinical decisions and trials concerned with the efficacy of treating hypertension emphasized the diastolic component of the BP for too long because high DBPs were believed to be more pathologic than SBP elevations. However, epidemiologic data from the Framingham Study^{22,24} and elsewhere⁹ do not suggest that the DBP has a greater impact than the SBP on the occurrence of CVD in general or CHD in particular. SBP has a significantly greater impact than DBP on the rate of development of cardiovascular sequelae of hypertension, including CHD.^{9,22}

Current staging of hypertension is based on the levels of both SBP and DBP. Franklin et al. have examined whether the

pulse pressure adds useful information for estimating the risk of initial coronary events in the population-based Framingham Study²⁵ (see Chapter 22). They found that when SBPs and DBPs were jointly entered into multivariable analysis, CHD risk was positively associated with SBP and inversely for DBP. Cross-classification examination of CHD risk by SBP and DBP confirmed this result (Table 23–5). These findings suggested that the pulse pressure is an important determinant of the BP-related risk of CHD. For any level of SBP, persons with higher pulse pressure (i.e., lower DBP) had a substantial increase in risk (Figure 23–3). Risk of CHD increased in a continuous graded fashion with the pulse pressure at all levels of SBP.

These results support the prior Framingham Study data indicating that in persons whose DBPs had not exceeded 90 mm Hg, the risk of cardiovascular events increased steeply with the SBP (and hence pulse pressure) at all ages in both sexes.²⁴ In the Framingham Study, the age-adjusted incidence of CHD was substantially greater for isolated systolic than isolated diastolic hypertension in both sexes. Age-specific analysis of Framingham Study data indicates that this conclusion may need to be modified because of an observed variable impact of the BP components according to age. An examination of the relative importance of systolic, diastolic, and pulse pressure as CHD predictors in different age groups suggests that there is a gradual shift with advancing age from diastolic to systolic and finally to pulse pressure as dominant predictors of CHD. In younger (<50 years) persons, DBP and to a lesser extent SBP, predict CHD, whereas in older individuals SBP and pulse pressure are superior predictors of the risk.²⁶

RISK FACTOR CLUSTERING

A tendency for hypertension to cluster with other major coronary risk factors has long been noted in the Framingham

Table 23–5 Risk of Coronary Heart Disease According to Systolic and Diastolic Blood Pressure: 20-Year Follow-up in the Framingham Study of Persons Ages 50–79 Years

Study and elsewhere, and many of the risk factors with which it tends to cluster also predict the occurrence of the hypertension.^{1,27} It has become increasingly apparent that the magnitude of the risk of CHD associated with any degree of BP elevation is markedly influenced by the associated burden of other risk factors (Figure 23-4).²⁷ Only 20% to 24% of the elevated (upper quintile) BP (>138 mm Hg in men and >130 mm Hg in women) that occurred in the Framingham Study was accompanied by other risk factors (upper quintiles of total cholesterol, body mass index [BMI], triglycerides, glucose,

or lower-quintile high-density lipoprotein [HDL] cholesterol). Clusters of two or more of these additional risk factors occurred in 49% of men and 54% of women, a rate greatly exceeding that expected by chance. The bulk of CHD events—63% in men and 78% in women—occurred in those hypertensives with two or more additional risk factors (Table 23-6).

The tendency for elevated BP to cluster with other risk factors suggests that hypertension may be a reflection of some more fundamental process that accelerates atherogenesis²⁸ (see Chapter 13). Abdominal obesity promotes insulin resistance and abnormal sympathoadrenal activity and has been postulated as an underlying mechanism.²⁹ Abnormalities of lipoprotein metabolism, insulin resistance, and glucose tolerance are commonly encountered in persons with essential hypertension and their close relatives.³⁰ These abnormalities do not cluster with secondary hypertension. Hyperinsulinemia, signifying insulin resistance, is found in both obese and nonobese persons with hypertension and may persist despite antihypertensive therapy.²⁸ However, insulin resistance and hyperinsulinemia are more severe and more closely associated with hypertension in obese than nonobese persons. Also, weight gain worsens all the elements of the insulin resistance syndrome and weight loss improves them. In the Framingham Study the extent of risk factor clustering increased stepwise with the degree of obesity: A 5-pound increase in weight imposed a 30% increase in the extent of risk factor clustering with hypertension. Persons with elevated BP characteristically have elevated triglycerides and reduced HDL cholesterol. Such persons also tend to have atherogenic small-dense low-density lipoprotein particles.³¹ It is uncertain what percentage of hypertensive persons have the insulin resistance syndrome; it has been estimated that about half may have it.

In the Framingham Study, BP-related risk of developing CHD increased stepwise with the extent of risk factor clustering (see Table 23-6). Among persons with elevated BP it is estimated that about 40% of coronary events in men and 68% in women are attributable to clusters of two or more additional risk factors.

Total			72 (100%)	
Women				
0	1.0 (referent)	18%	2 (5%)	—
1	2.05 (0.41, 10.18)	28%	7 (18%)	0.23
≥2	4.93 (1.14, 21.27)	54%	31 (78%)	0.68
Total			40 (100%)	

High blood pressure defined as SPB ≥138 mm Hg (men) and ≥130 mm Hg (women). Other risk factors included the top quintiles of other factors (total cholesterol, BMI, triglycerides, glucose) and bottom quintile for HDL cholesterol. CI, confidence interval; CHD, coronary heart disease; BMI, body mass index; SBP, systolic blood pressure; HDL, high-density lipoprotein.

Whatever the cause of the risk factor clustering in persons with elevated BP, it is clear that it should be anticipated and routinely screened for. Also, when three or more of the specified risk factors—increased waist girth, elevated triglycerides, reduced HDL cholesterol, elevated blood sugar, and BP—are found, it seems reasonable to suspect the presence of the insulin resistance or metabolic syndrome.¹

GLOBAL RISK ASSESSMENT

Because of the tendency of risk factors to cluster with hypertension and the variable risk depending on the amount of clustering that accompanies the hypertension, it is advisable to undertake a global coronary risk assessment in all hypertensive patients. To facilitate this, CHD risk factor prediction charts were developed based on Framingham Study multivariate risk formulations (Table 23–7). Using this scoring system it is possible to conveniently estimate the global CHD risk of hypertensive patients, taking the associated burden of other risk factors into account. To an extent, designation by the JNC 7 guidelines of the *metabolic syndrome* as one of the “special situations” to consider in evaluation and treatment of hypertension invokes multivariable risk assessment. However, most of the ingredients of the syndrome are components of the Framingham Study risk profile; the value of detecting persons with the syndrome has greater implications for the choices of therapy than risk assessment.

Renin

Hypertension is heterogeneous in its pathophysiology and clinical sequelae. Much research has been directed at determining and understanding the pathophysiology of the factors that increase the risk of CHD in hypertension. In this connection, the role of the renin-angiotensin system (RAS) has been the focus of attention for some time.³² An activated RAS has been postulated to be another risk factor for CHD in hypertension.³³ In addition to causing vasoconstriction and sodium retention, angiotensin II increases vascular smooth muscle cell growth and promotes neointima formation after vascular injury.³² Experimentally, angiotensin-converting enzyme (ACE) inhibitors reduce myocardial ischemia, decrease atherosclerosis, prevent restenosis after arterial injury, and prevent ventricular dilation.³² However, it is not yet clear whether high renin plays a causal role in the risk of an MI in hypertension or is only a marker for an activated sympathetic or neurohormonal state.³² High renin with respect to the level of sodium excretion has been reported in a case-control comparison and a prospective epidemiologic investigation to be another predictor of MI in patients with hypertension.^{33,34} A retrospective study similar to the earlier retrospective study that claimed to show a relationship of renin to heart attacks and strokes failed to confirm this claim.^{34,35} It is possible that hypertensive patients with high renin profiles could benefit more than those with low renin from treatment with β -blockers or ACE inhibitors to prevent CHD, but this remains to be demonstrated.

Left Ventricular Hypertrophy

LVH, whether manifested by ECG, chest radiograph, or echocardiogram, is an ominous feature of hypertension. ECG

LVH, particularly when accompanied by repolarization abnormality, is a harbinger of impending clinical CHD in the hypertensive patient. It further escalates the risk of all the major sequelae of elevated BP; most commonly CHD (Table 23–8). Framingham Study participants with higher baseline voltages and more severe repolarization abnormalities had higher BPs, and serial changes in these ECG parameters were accompanied by corresponding changes in BP. The risk of CVD increases over a threefold range in relation to the size of the R-wave on the ECG and, compared with normal, severe repolarization abnormality increases the risk almost sixfold for men and 2.5-fold for women.³⁶ Framingham Study participants observed to have a decrease in voltage over time had only one half the risk of cardiovascular events of those with no change.³⁶ Because ECG LVH carries as serious a prognosis as an MI detected by routine ECG examination, it is appropriate to regard hypertensive persons with this condition as seriously as if they have diagnosed CHD.⁸ LVH on radiograph is not as ominous as the ECG version, but adds to risk when it accompanies ECG hypertrophy.⁸ Echocardiography is a more sensitive and more easily quantifiable detector of hypertensive LVH, and hypertrophy detected by echocardiogram has also been shown to be associated with an increased risk of developing CHD.³⁷ Risk of coronary events is related to the left ventricular mass observed in hypertensive persons in a continuous graded fashion, with no critical value that separates compensatory from pathologic hypertrophy (Figure 23–5).³⁷

Heart Rate

Hypertensive persons tend to have higher heart rates than normotensive people, and persons with more rapid heart rates tend to develop hypertension at a greater rate.^{38,39} Hypertension with a rapid heart rate is also more dangerous. The Framingham Study observed an independent effect of the heart rate that accompanies hypertension on the rate of subsequent mortality from CHD (Table 23–9). The observed effect was stronger for the occurrence of fatal than nonfatal coronary events, and particularly for acutely fatal attacks, consistent with a direct effect of heart rate, mediated through the autonomic nervous system. Apparently as hypertension exacts its toll on the myocardium, the heart rate must increase to compensate for a decreased stroke output.³⁹

The Elderly

The impact of hypertension on the development of CHD is perceived to weaken in advanced age.^{11,40} In the very old, it has been claimed that hypertension may actually protect against mortality.⁴⁰ This has resulted in a reluctance to treat hypertension aggressively in the aged.¹¹ The risk ratio for clinical CHD in hypertensive participants in the Framingham Study decreases slightly with advance in age, but this is offset by a distinctly higher absolute, excess, and attributable risk, owing to the high incidence of CHD in the elderly, the high prevalence of hypertension in this age group, and the significant risk ratio in older persons (Table 23–10). Because there is a disproportionate rise in SBP compared with DBP with advancing age, isolated systolic hypertension (ISH) is the predominant type of hypertension in the elderly. ISH is clearly a risk factor for the development of CHD in

the elderly, possibly more so than in the middle aged (Figure 23-6). The high SBP and pulse pressure in the hypertensive elderly appears to be a direct cause of the excess CHD rather than only a sign of a diseased rigid artery, because the systolic hypertension persists as a risk factor when the associated arterial rigidity is taken into account.⁴¹ The chief determinant of ISH in the elderly appears to be an elevated BP in middle age.⁴²

Whether predominantly systolic, diastolic, or combined, hypertension is a hazard for CHD in the elderly. However, SBP elevation is a more reliable predictor of CHD in the elderly than the DBP, and reliance on the DBP to assess risk can be misleading in the aged with systolic hypertension.⁶ Although their absolute risk of developing clinical CHD is lower than in men, the relative risks are higher in women than men for all clinical events other than sudden death.

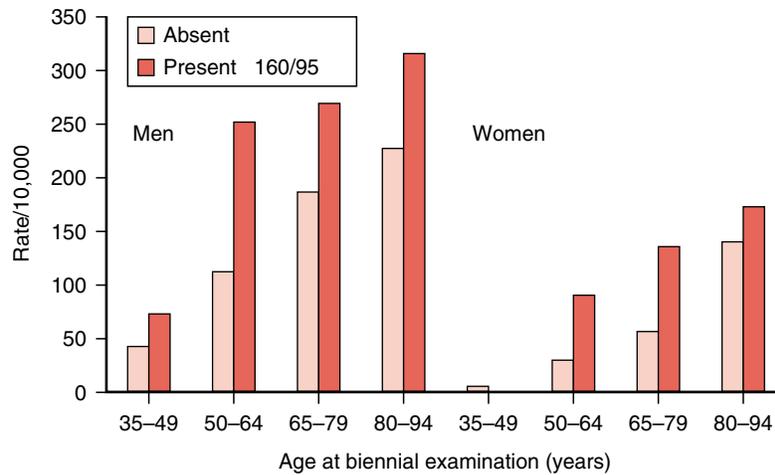

Figure 23-6 Average annual incidence of myocardial infarction associated with isolated systolic hypertension by age and sex. (Framingham Study.)

Table 23-11 Percent Prevalence of Associated Cardiovascular Conditions in Hypertensive Elderly: Framingham Study (1970-1982), Persons Aged 65-94 Years

Associated Cardiovascular Conditions	Men	Women
Angina	12	16
Myocardial infarction	12	5
Cardiac failure	3	5
Stroke	10	5
Peripheral artery disease	9	6
Any cardiovascular disease	31	27

Hypertension in the elderly is likely to be accompanied by overt CHD. In the Framingham Study, 24% of hypertensive elderly men also had angina or an MI. In elderly hypertensive women, 21% had these manifestations of CHD (Table 23-11). Stroke, heart failure, and peripheral artery disease are also commonly present. Some 31% of men and 27% of women in this age group will have one or more of these cardiovascular conditions. These greatly increase the hazard of the hypertension and must be taken into account in treatment decisions.

PREVENTIVE IMPLICATIONS

In the 1950s there was limited knowledge about the long-term outlook of what was called “essential hypertension,” and the condition was considered benign. Physicians were unimpressed with the hazards of such hypertension and, even if they were concerned, could do little about it. Over the past four decades we have come to recognize that idiopathic hypertension is an insidious and long-term promoter of accelerated atherogenesis and lethal cardiovascular events. Also, during this period effective, tolerable, and safe antihypertensive medications were produced that made it possible to control elevated BP and determine the effects of BP control on CVD outcomes.

BPs obtained routinely in the office predict the rate of development of CVD in general and CHD in particular.

Although there is some evidence that home BPs and 24-hour monitoring of BP may be useful refinements (see Chapters 27 and 28), risk assessment and treatment can be based on the average of several office BPs. Treatment should not be initiated on the basis a single casual office BP elevation, nor should the efficacy of treatment be judged from less than the average of multiple BP measurements. The lowest of a series of BPs should not be used to determine either the need for, or efficacy of, antihypertensive therapy.

In evaluating the hazard of hypertension and the need to treat it, more attention needs to be given to the SBP. For too long there has been an overemphasis on the diastolic component of the BP. Risk of CHD has been consistently shown to be more strongly related to the SBP than the DBP. ISH is not an innocuous accompaniment of advanced age. Treatment based on the SBP in patients with ISH has been shown to be at least as effective as that based on the DBP in preventing cardiovascular morbidity and mortality.^{23,43}

Coexistent risk factors that cluster with hypertension exert a greater influence on the cardiovascular and coronary hazards of hypertension than the character of the BP elevation. Hypertension seldom occurs in isolation of other major risk factors to which it is metabolically linked. This makes it mandatory to test for the other risk factors and to conceptualize hypertension as a component of a cardiovascular risk profile. This avoids the possibility of either overreacting to an isolated moderate BP elevation or being falsely reassured by a return of BP to high-normal levels. Accompanied by multiple abnormalities of other risk factors, a seemingly innocuous degree of hypertension can be dangerous. When hypertension is accompanied by elevated triglycerides, reduced HDL cholesterol, and abdominal obesity, insulin resistance is likely and treatment should be modified accordingly. Prevention of CHD is more likely to be effective if in addition to lowering the BP, a more favorable coronary risk profile is achieved. Not uncommonly, elderly hypertensive patients when first encountered may already have overt angina, an MI, peripheral artery disease, or cardiac failure. These associated conditions must be taken into account in judging the urgency for treatment and in choosing the optimal therapeutic agents.

Antihypertensive therapy has been shown to regress LVH in hypertensive patients.⁴⁴ Although it is not yet established by controlled trials whether this regression consistently reduces the formidable increase in CVD risk imposed by LVH, Framingham Study data indicate that when improvement in the ECG evidence of hypertrophy is observed, there is a substantially lower risk of cardiovascular sequelae compared with those in whom there is no change or progression (Table 23–12).³⁶ Thus, therapy that eliminates or slows progression of LVH may improve the outlook of the hypertensive patient with this dangerous condition. When LVH accompanies hypertension, there should be a greater urgency for aggressive antihypertensive therapy.

Because heart rate appears to directly influence the coronary mortality rate associated with hypertension, antihypertensive medications that lower the heart rate may have an advantage over those that accelerate it. In an analysis of β -blocker trials, a strong relationship between the reduction in heart rate achieved and the reduction in mortality was found.⁴⁵ Analysis of the Norwegian Multicenter Timolol Trial found that the postinfarction resting heart rate predicts later cardiac mortality and that the benefit of treatment was a result of the achieved reduction in heart rate.⁴⁶ Treatment with β -blockers has been reported to reduce silent ischemic events in relation to the reduction in heart rate achieved.⁴⁶

Because hypertension predisposes to the occurrence of silent or unrecognized MI, hypertensive persons should be periodically monitored by ECG for such an occurrence. These unrecognized MIs must be detected and dealt with aggressively because they impose a long-term outlook that is little different from that of overtly manifest MIs.⁴⁷

The greatest burden of hypertension-related CHD occurs in the elderly, in whom ISH predominates. In contrast to earlier reports, meta-analysis of the efficacy of antihypertensive therapy in the elderly indicates a significant 25% decrease in coronary mortality.^{48,49} Practitioners caring for elderly ambulatory hypertensive patients should attempt to control elevated BP of any variety. Reduction of SBP in the elderly with ISH resulted in substantial decreases in coronary events.^{39,46} In the

very oldest and most ill and frail, further trials are needed before well-founded recommendations can be made (see Chapter 55).

The elderly with a favorable risk profile and only mild hypertension can be managed with weight control, a moderate exercise program, salt and alcohol restriction, and advice against smoking. These measures help reduce the dosage of antihypertensive medication required to control hypertension and also help to control other often-associated risk factors. Polypharmacy may be a significant problem in managing hypertension in the elderly, who often take nonsteroidal antiinflammatory drugs for arthritis. There is much to be gained in treating hypertension in the elderly because their risk of disabling cardiovascular events is so high. However, despite convincing evidence of the benefit of treating ISH, the third National Health and Nutrition Examination Survey found that only about half of hypertensive patients receive therapy and only 27% of those under treatment are adequately controlled.¹

ISH is the least likely form of hypertension to be treated, and even when treated, it is seldom controlled. Examination of the rates of control to goal SBPs and DBPs in the Framingham Study indicates that among those receiving antihypertensive therapy, only 49.0% are controlled to the systolic goal of <140 mm Hg compared with 89.7% to the diastolic goal of <90 mm Hg, and only 47.8% to both goals.⁴⁹ Older age, LVH, and higher BMI are associated with poor SBP control. Because ACE inhibitors both lower BP and improve arterial distensibility, they seem a logical choice for treating ISH. However, diuretics and calcium antagonists have been shown to reduce coronary events in ISH.^{39,46}

Prevention of CHD requires more than reduction of the BP. Excess risk is concentrated in those who have other risk factors or evidence of target organ involvement, such as proteinuria, cardiomegaly, vascular bruits, or ECG abnormalities. Optimal preventive management should include reduced saturated fat, cholesterol, and salt intake; increased physical activity; smoking cessation; and avoidance of excessive alcohol intake. Inducing the hypertensive cigarette smoker to quit can promptly reduce the risk of CHD to half that of those who continue to smoke, a risk reduction greater than that expected from reduction in the BP per se.

The benefits of treating hypertension, particularly for ISH in the elderly, are now better appreciated.^{23,43} Low-dose combination therapy using antihypertensive agents with different modes of action can substantially reduce the BP, virtually eliminate unpleasant side effects, and maintain a good quality of life in those under treatment.

SUMMARY

Over the past two decades the percentage of hypertensive persons who have become aware of their problem and have come under treatment has improved substantially. Concomitant with these improvements, major declines in coronary and stroke mortality have occurred. Because of the large population-attributable risk for hypertension as a risk factor for CHD and stroke, it is inferred that the improved detection and control of hypertension in the general population contributed substantially to these declines.

Epidemiologic investigation has shown the importance of elevated BP as a contributor to cardiovascular morbidity and

mortality in general and CHD in particular. It has demonstrated that BP exerts a continuous graded influence, so the concept of an acceptable BP has changed from that which is usual in an apparently healthy population to that which confers the greatest freedom from its cardiovascular sequelae. Risk of developing the cardiovascular consequences of hypertension increases linearly over a sixfold range with each increment of BP, even within the range of pressures usually considered high-normal. The bulk of cardiovascular events, including coronary events, occur in persons with stage 1 and stage 2 hypertension. Three times as many cardiovascular events are attributable to this less severe hypertension than stage 3 hypertension. The odds of developing CVD in stages 1 and 2 hypertension is double that of persons with normal BPs.

Epidemiologic investigation has also shown that the adverse consequences of hypertension are more closely related to elevation of SBP than DBP. It is now evident that hypertension seldom occurs in isolation and that high-risk hypertension is concentrated in those with a cluster of other metabolically linked risk factors. Hypertension is often one component of an insulin resistance syndrome.

Epidemiologic investigation has established the importance of hypertension as a risk factor for CHD in the elderly and clinical trials have shown the efficacy of treating both systolic and diastolic hypertension at all ages. The ominous significance of LVH is now well documented and the potential benefit of causing it to regress shown.

Physicians now have a good deal more information to guide them in their efforts to delay or prevent the sequelae of hypertension than was available only a decade ago. However, this increase in information has made clinical decisions and therapeutic choices in managing hypertension more complex. Evaluation and management of hypertension is no longer based solely on determining the height of the BP, and lowering it to a more acceptable level. New classification schemes place more emphasis on SBP, lesser BP elevations, and the presence of other associated risk factors.¹ The number of available antihypertensive agents, with different modes of action, suitable for monotherapy and combined therapy, has grown. There is controversy about first-choice agents and whether therapy should necessarily be tailored to take into account the associated dyslipidemia, glucose intolerance, LVH, and insulin resistance commonly present.

The goal of antihypertensive therapy is to prevent cardiovascular morbidity and mortality rather than simply to bring the BP under control. BP control must be achieved in the least intrusive way, and use of low dose combinations of agents is preferred over resorting to high doses of single drugs to achieve goal BPs. Trials have clearly shown that treatment reduces stroke and heart failure events, but some question the efficacy of antihypertensive treatment, without concomitantly improving the multivariate risk profile in reducing CHD. There is some interest in cautious step-down therapy for patients whose BPs have been well controlled over time.

Maintaining long-term compliance with treatment remains a problem. There is continuing concern about the safety of drastic lowering of the BP in hypertensive persons with concomitant CHD. For those with stage 1 hypertension, optimal treatment requires improvement in the patient's global risk by serious attention to the often-associated cluster of atherogenic risk factors. Only in this way can we target mildly hypertensive

persons for cost-effective treatment without needlessly alarming or falsely reassuring them.

Despite potent antihypertensive therapies and clinical trial evidence that treatment reduces cardiovascular and renal sequelae, more than one fourth of the 50 million hypertensive persons in the United States remain unaware that they have the condition, and three fourths of those known to have it are poorly controlled.¹ Most cases of uncontrolled hypertension are in persons with elevated SBP.^{50,51} This is regrettable because it is in these persons that antihypertensive therapy has been shown to be most effective in reducing the incidence of MI, overall mortality, stroke, and heart failure.^{23,43} Poor control of hypertension is attributable to adverse effects of drugs, medication costs, patients' knowledge and beliefs, and physicians' knowledge and attitudes.⁵² Approximately one half of patients prescribed medication discontinue it by the end of 1 year (see Chapter 37). Physicians are often reluctant to treat systolic hypertension for fear of doing harm by lowering the DBP too much. The validity of the J-curve phenomenon and fear of impairing cognitive function by excessive reduction in BP are not supported by clinical trial data.⁵³ Dementia incidence in the Syst-Eur trial was actually 50% lower in the treated than in the control group.⁵³ Intensified efforts to modify BP and its often-associated risk factors must become a national priority if we are to continue to decrease death and disability from CHD.

Left Ventricular Hypertrophy, Congestive Heart Failure, and Coronary Flow Reserve Abnormalities in Hypertension

Joseph A. Diamond, Robert A. Phillips

Hypertensive heart disease is a result of a complex interaction of genetic and hemodynamic factors inducing structural and functional adaptations that lead to increased left ventricular (LV) mass, diastolic dysfunction, congestive heart failure (CHF), arrhythmias, and abnormalities of blood flow due to microvascular disease. These changes increase the risk of coronary heart disease, CHF, stroke, and sudden death. Echocardiographically determined left ventricular hypertrophy (LVH) is defined as LV mass in the upper 2.5% to 5% of the adult population. It occurs in 15% to 20% of hypertensive patients.¹ Considered as a discrete, categorical variable, LVH significantly increases the risk of coronary artery disease, CHF, cerebrovascular accidents, ventricular arrhythmia, and sudden death.²⁻⁴ LVH increases the relative risk of mortality by twofold in persons with coronary artery disease and by fourfold in those with normal epicardial coronary arteries.^{5,6} In addition, when LV mass is considered as a continuous variable, a direct and progressive relationship exists between cardiovascular risk and absolute LV mass³ (Figure 24-1). This chapter covers the following areas:

- Causes of LVH and CHF
- Myocardial and structural alterations in LVH
- Identification and treatment of LVH in clinical practice
- LV mass regression—does the choice of antihypertensive matter?
- Diastolic dysfunction and CHF: mechanisms and treatments
- Coronary microcirculation in patients with hypertension

CAUSES OF LEFT VENTRICULAR HYPERTROPHY AND CONGESTIVE HEART FAILURE IN PATIENTS WITH HYPERTENSION

Genetic Factors in the Development of Left Ventricular Hypertrophy and Congestive Heart Failure

It is estimated that up to 60% of the variance of LV mass may be due to genetic factors independent of blood pressure (BP).⁷ Epidemiologic evidence for genetic influence on LV mass includes offspring studies that generally, but not uniformly, demonstrate that LV mass in children of hypertensive parents is elevated independently of BP and other known determinants of LVH.^{8,9} In the Framingham Heart Study, there are significant parent-child and sibling correlations of LV mass after adjustments for age, height, weight, and systolic blood

pressure (SBP). However, the overall contribution of heredity to LV mass is small.^{9,10} Furthermore, one twin study, in which monozygotic twins had only minimally less intertwined variation in wall thickness than dizygotic twins or sibling pairs, indicates that genetic influences on LV mass can be modified by environmental factors.¹¹

Additional evidence for a genetic influence on LV mass is that race appears to be a determinant of ventricular structure. Studies over the past three decades suggest that for equal levels of BP, Blacks have increased relative wall thickness and LV mass compared with whites. In the Evans County, Georgia Study, conducted between 1960 and 1962, electrocardiographic evidence of LVH was twofold to threefold higher in Blacks at any given level of BP.¹² In the early 1980s, Dunn et al., using M-mode echocardiography, showed that for the same level of BP, Blacks had greater LV mass.¹³ Hammond et al. showed that for the same BP and LV mass, relative wall thickness (concentric remodeling) was greater in Blacks.¹⁴ Similarly, in the Treatment of Mild Hypertension Study (TOMHS), even though BP and LV mass were the same, Blacks had greater wall thickness than whites.¹⁵ Similarly, a study from London showed that for equal levels of previously untreated BP, Blacks had greater LV mass and relative wall thickness than whites.¹⁶ Hinderliter et al. showed that even in the absence of hypertension, young adult Blacks tend to have greater relative wall thickness than whites, suggesting that differences in ventricular structure may be independent of hemodynamic factors.¹⁷ The increase in LV mass and relative wall thickness observed in Blacks may in part be due to a greater total hemodynamic burden as compared with whites, due to a more blunted fall in nocturnal BP.¹⁸ This altered BP pattern begins in adolescence.

One of the first and most studied genetic factors in the development of LVH in hypertensive humans is an insertion/deletion polymorphism of a 287 base-pair marker in intron 16 (noncoding region) of the gene for the angiotensin-converting enzyme (ACE). It is estimated from population studies that the ACE gene contributes 3% to 4% to the variation of BP in the general population. The homozygous genotype for the deletion (DD) is associated with electrocardiographic evidence of LVH.¹⁹ The association was strongest in men who were normotensive, supporting the concept that this association is independent of hemodynamic factors. However, the Framingham study did not find a relation between echocardiographically measured LV mass and ACE genotype.^{19,20} An Italian study showed that the DD genotype was a risk factor for increased echocardiographically determined LV mass.²¹ Furthermore, a study in an ethnically diverse New York City population found that the DD genotype was associated with

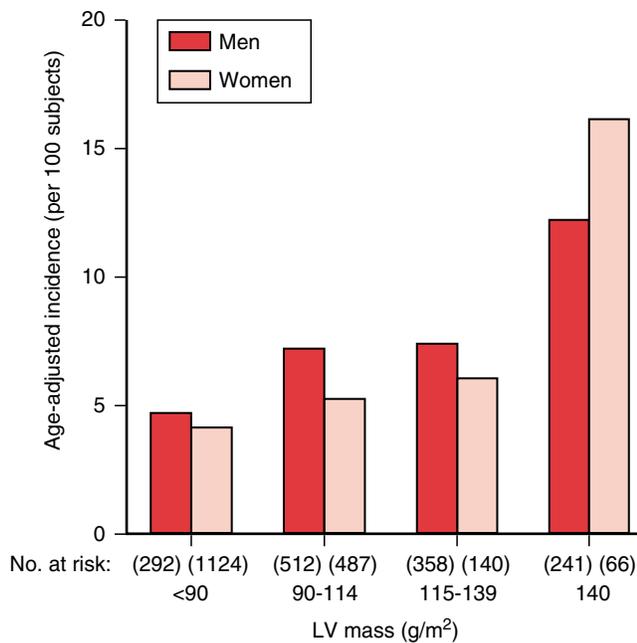

Figure 24-1 Effect of left ventricular (LV) mass on age-adjusted incidence of cardiovascular disease over a 4-year period in the Framingham Heart Study. (Adapted with permission from Levy D, Garrison RJ, Savage DD, et al. Prognostic implications of echocardiographically determined left ventricular mass in the Framingham Heart Study. *N Engl J Med* 322:1561-1566, 1990. Copyright © 1990 Massachusetts Medical Society.)

concentric remodeling of the LV, a geometric pattern associated with increased cardiovascular risk.²²

In addition to the ACE gene, there is strong evidence that other genes affecting the renin-angiotensin system are influential in the development of LVH. A polymorphism (344C/T) in the promoter region of the aldosterone synthase gene on chromosome 8, resulting in increased intracardiac aldosterone production (independent of adrenal synthesis) has been associated with increased LV mass in individuals with mild to moderate hypertension.^{23,24} The angiotensinogen gene (on chromosome 1) also contributes to the development of LVH in hypertensive individuals. In the Hypertension Genetic Epidemiology Network (HyperGEN) study, two polymorphisms of the angiotensinogen gene have been associated with LVH. The M235T polymorphism on exon 2 of the angiotensinogen gene appears to be a marker for a functional variant, the G-6A polymorphism, which is tightly linked to the marker (6 base pairs away) and affects the transcriptional rate of the gene.²⁵ Additional studies applying the principles of physiologic genomics are assessing the effect of the ACE and angiotensinogen genes on hypertensive heart disease. This is accomplished by altering expression levels via transgenics, knockouts, and gene targeting in animal models.²⁶ In spontaneously hypertensive rats (SHR), antisense targeted to angiotensinogen mRNA delivered by an adeno-associated virus produced sustained reduction in BP and reduction in LVH.²⁷ This suggests a potential future gene therapy approach for the treatment of hypertension and regression of LVH.

In addition to the renin-angiotensin system, other studies are focusing on genes with different physiologic mechanisms that

could contribute to hypertensive heart disease. For example, Nakayama et al. identified an insertion/deletion mutation in the human type A natriuretic peptide receptor gene (hNPRA) on chromosome 1 that appears to result in LVH in a population of Japanese hypertensive subjects.²⁸ Another gene under study is the G-protein β_3 -subunit gene (CNB3) on chromosome 12 that encodes the β_3 subunit of G proteins. A single base substitution (C → T) at position 825 of the gene results in a change in the splicing of exon 9, resulting in the loss of 41 amino acids in the resulting altered, but functioning, protein. Enhanced G-protein activation has been demonstrated and is thought to be the cause of the phenotypic observation of enhanced Na^+ , H^+ exchanger activity, which has been associated with hypertension and LVH. Poch et al. showed increased LV mass by echocardiography in Spanish individuals with the 825T allele.²⁹ However, this was not confirmed in other population studies.³⁰ Table 24-1 summarizes the genes that appear to contribute to LVH.

In addition to genes that contribute to the development of LVH, studies have also identified genes that affect LV contractility in individuals with hypertensive heart disease. One study implicates a gene on the short arm of chromosome 11. This gene is likely involved in the production of myosin-binding protein C (MyBP-C), a protein with several important structural and regulatory functions in the contractility of myocytes.³¹ It may play a particularly important role in LV contractility in Blacks. Another gene on chromosome 22 may play a less important though significant role in regulating LV contractility. This gene may regulate the production of β -adrenergic receptor kinase (β ARK), which with elevated expression, attenuates β -adrenergic signaling and contributes to contractile dysfunction.^{32,33}

Hemodynamic Factors and Left Ventricular Hypertrophy

The effect of BP, as well as virtually every factor known to influence BP, has been investigated for its independent effect on LV mass (Table 24-2). There is very strong evidence for a causal relationship between BP and absolute LV mass. This was first reported 70 years ago³⁴ and led to the view that myocardial hypertrophy is an adaptive cardiac response that reduces wall stress and allows the ventricle to maintain mechanical efficiency.^{35,36} In the Framingham Heart Study, 10% of the variation in LV mass among persons was accounted for by differences in SBP averaged over 30 years.³⁷ Similarly, average BP obtained during awake hours in hypertensive subjects accounts for 10% to 25% of LV mass variation,³⁸⁻⁴⁰ whereas a blunted nocturnal fall in BP is associated with increased LV mass.⁴¹ Ambulatory BP monitoring (ABPM) correlates more closely than clinic BP with LV mass and carotid artery intimal-medial thickness, and may more accurately predict the risk for cardiovascular disease than clinic BP measurements.^{39,42-46} (see Chapters 27 and 28).

In hypertensive persons, approximately 40% ($r = 0.66$, $p < .001$) of the variance in LV mass is accounted for by total LV load or peak meridional wall stress.⁴⁷ In normotensive persons, enhanced augmentation of SBP by reflected waves, a process associated with aging of the arterial tree, elevates wall stress and is associated with increased LV mass.⁴⁸ Other hemodynamic factors associated with increased mass are volume, which obviously directly increases LV mass, and intrinsic contractility of the ventricle. An intrinsically hypercontractile

Table 24-1 Genes Implicated in the Development of Left Ventricular Hypertrophy in Essential Hypertension

Gene	Location	Physiologic role
ACE gene ^{19,22,374}	Insertion/deletion polymorphism of 287 base pair marker in intron 16 on chromosome 17	Production of angiotensin II
X-linked angiotensin II type 2 receptor gene ³⁷⁵	Intronic polymorphism (-1332 G/A) on the X-chromosome	Oppose the effects of AT ₁ receptor
Angiotensinogen gene ³⁷⁶	G-6A polymorphism in exon 2 on chromosome 1	Production of angiotensinogen
Aldosterone synthase gene ²⁴	-344C/T polymorphism in the promoter region of the aldosterone synthase gene on chromosome 8	Production of intracardiac aldosterone
G-protein β_3 -subunit gene ^{29,377}	Single base substitution at position 825 of exon 9 on the short arm of chromosome 12	Enhanced Na ⁺ ,H ⁺ exchange due to enhanced G-protein activation
Type A human natriuretic peptide receptor gene ²⁸	Deletion mutation of the 5' flanking region on chromosome 1	Elevated BNP due to decrease in natriuretic peptide receptors

ACE, angiotensin-converting enzyme; AT₁, angiotensin II type I; BNP, brain natriuretic peptide.

Table 24-2 Association Between Left Ventricular Mass, Hemodynamic Factors, and Nonhemodynamic Factors

Factor	Strength of Evidence Supporting a Causal Role in LV Mass
Blood pressure/ wall stress	Very strong ^{34,37-41,47,378}
Stroke volume	Very strong ^{47,379}
Obesity	Very strong ^{62,70,71,73,74}
Growth hormone and IGF-1	Strong ^{89,90}
Gender	Strong ^{65,69,380,381}
Race	Strong ^{12,15-17,382}
Age	Strong (women only?) ⁶⁰⁻⁶⁴
Intracellular [Ca ²⁺]	Strong ^{51,75}
Insulin resistance	Strong ^{70,92,93}
Angiotensin II	Strong ^{80,383}
Alcohol	Needs confirmation ³⁸⁴
Intrinsic myocardial contractility	Needs confirmation ⁴⁷
Blood viscosity	Needs confirmation ³⁸⁵
Parathyroid hormone	Needs confirmation ⁷⁸
Aldosterone (collagen synthesis)	Needs confirmation ^{82,383,386}
Sodium intake	Needs confirmation ³⁸⁷
Na ⁺ ,H ⁺ exchanger and Na ⁺ ,K ⁺ ,Cl ⁻ cotransport system	Needs confirmation ³⁸⁸
Polymorphism of the ACE gene	Controversial ^{19,21}
Plasma renin activity	Controversial ⁷⁷⁻⁷⁹
Norepinephrine	Controversial ^{11,77,85,86,88}
Na ⁺ ,Li ⁺ exchanger	Controversial ^{388,389}
β ARK	Controversial ^{32,33}

ACE, angiotensin-converting enzyme; β ARK, β -adrenergic receptor kinase; IGF-1, insulin-like growth factor-1; LV, left ventricular.

ventricle requires less wall thickening to overcome wall stress. Thus, an inverse relation exists between degree of LV mass and intrinsic myocardial contractility.⁴⁷

The sequence of events that leads from increased wall stress to cellular hypertrophy is only beginning to be elucidated.⁴⁹ Because failure to hypertrophy in response to increased wall stress would result in a mechanical disadvantage and decreased LV function, it is likely that there are redundant systems that translate wall stress into cardiac myocyte hypertrophy. Increased wall stress may activate a stretch receptor, which, through a series of cellular and subcellular events, activates fetal cardiac and growth genes, such as *c-myc* and *c-jun*, to up-regulate myocardial cell protein synthesis. Shear stress has been shown to activate these growth genes in endothelial cells by stimulating the production of several mitogen-activated protein kinases (Figure 24-2).⁵⁰ The molecular mechanisms that couple hypertrophic signals at the cell membrane to the reprogramming of cardiomyocyte gene expression are beginning to be elucidated. Intracellular calcium release may be an early response to myocyte stretch and other humoral stimuli, including angiotensin II (Ang II), phenylephrine, and endothelin. The increase in intracellular calcium results in activation of the phosphatase calcineurin, which then dephosphorylates transcription factor NF-AT3, resulting in its translocation to the nucleus. In the nucleus, NF-AT3 interacts with another transcription factor, GATA4, to initiate transcription of genes that lead to myocyte hypertrophy,⁵¹ such as β -myosin heavy chain and β -skeletal actin (Figure 24-3). In the hypertrophic response, other genes, such as those for atrial natriuretic peptide and phospholamban, are also up-regulated.⁵²

Calcineurin appears to be both necessary and sufficient to induce hypertrophy. Pharmacologic inhibition of calcineurin activity with cyclosporine blocks development of hypertrophy in several circumstances: (1) mice prone to LVH because they are genetically engineered to produce high levels of calcineurin,⁵¹ (2) mice genetically predisposed to develop hypertrophic cardiomyopathy,⁵³ and (3) rats whose aorta was banded to produce a pressure stimulus for hypertrophy.⁵³ Although cyclosporine is not clinically useful in the nontransplant population, it is likely that new classes of calcineurin inhibitors

Figure 24–2 The sequential events of signaling and gene expression in endothelial cells in response to shear stress or mechanical strain. Tyrosine kinases in the focal adhesion site of endothelial cells such as FAK and c-SRC are involved in the mechanochemical transduction. Through the Src homology 2–containing adaptor Grbe, the small GTPase Ras is activated by Sos, a guanine nucleotide exchange factor that converts the inactive GDP-Ras to the activated GTP-Ras. As a result, JNK and ERK in the cytoplasm are activated to phosphorylate, respectively c-Jun and p62^{TCF}/c-Fos, which are components of the transcription factor AP-1. In the nucleus, the action of the activated AP-1 on its target sequence (e.g., the TRE site in the promoter of the MCP-1 gene) causes an up-regulation of gene expression. Concurrently, NFκB/Rel is activated by eliminating its inhibitor IκB so that genes with a shear stress–responsive element or κB site (e.g., PDGF-B can be activated). (Reproduced with permission from Chien S, Li S, Shyy YJ. Effects of mechanical forces on signal transduction and gene expression in endothelial cells. *Hypertension* 31:162-169, 1998.)

(e.g., tacrolimus [FK506]) that regulate transcription will become available to modulate responses such as hypertrophy.⁵⁴ It is likely that the ACE inhibitors and angiotensin receptor blockers (ARBs) also attenuate the development of cardiac hypertrophy by preventing angiotensin from up-regulating the production of factors that stimulate fetal-type genes, particularly calcineurin. Nonantihypertensive doses of the ARB candesartan suppress calcineurin production and subsequent LVH and fibrosis in salt-sensitive hypertensive Dahl (DS) rats.⁵⁴

Two large community-based studies indicate that hypertension is the most common risk factor for CHF, both with and without systolic dysfunction.^{55,56} In the Framingham study, after adjusting for age and other risk factors in proportional hazards regression models, the risk for developing CHF due to systolic dysfunction (CHF-S) in hypertensive compared with normotensive persons was nearly twofold in men and threefold in women. Hypertension was the highest risk factor for CHF-S by multivariate analysis, accounting for 39% of cases in men and 59% in women.⁵⁵ Another population-based study of CHF in Olmsted County, Minnesota showed similar findings. Of 216 persons studied, 52% presented with hypertension. Of these patients, 137 underwent evaluation of LV systolic function. Hypertension was the underlying risk factor in 53% of persons with LV ejection fraction (LVEF) <50% and was present in 58% of those with LVEF ≥50%. Of note, long-term survival was not significantly different between persons with normal or low LVEF.⁵⁶ The prognosis for hypertensive patients with newly diagnosed CHF-S was poor in both studies (≤35% survival by 5 years).

BP control effectively prevents the development of CHF. In the Systolic Hypertension in the Elderly Program (SHEP)

study, patients with isolated systolic hypertension (ISH) and a prior history of myocardial infarction (MI) (by electrocardiogram [ECG]) who were treated with diuretic-based therapy with BP lowering to <150 mm Hg systolic had only a 2% to 3% chance of developing CHF over a 4-year period. By contrast, those patients treated with placebo had an 8% to 10% chance of developing CHF.⁵⁷ Meta-analysis of randomized placebo-controlled antihypertensive therapy trials demonstrated that adequate BP control decreases the incidence of CHF by half.⁵⁸

Nonhemodynamic Factors and Left Ventricular Hypertrophy

LV mass is not significantly different in boys and girls during infancy and childhood, but a difference becomes evident at puberty, when sex-specific hormonal influences occur.⁵⁹ With aging, LV mass increases in both genders, but this effect may be more pronounced in women than men.^{60–64} Women have less LV mass for the same level of office-determined BP,⁶⁵ but whether this difference is biologic or an artifact of the method of BP measurement or indexation of LV mass is controversial. For similar levels of clinic BP, women often have lower ambulatory BPs than men. This results in less hypertrophy in women for the same level of clinic pressure.^{66–68} Additionally, some of the gender difference is accounted for by less lean muscle mass in women than in men.⁶⁹ When LV mass is indexed by the lean body mass (obtained by bioelectrical impedance), the gender difference in LV mass disappears.

Determinants of LV mass may also differ between men and women. In the Tecumseh study of normotensive adults, LVH

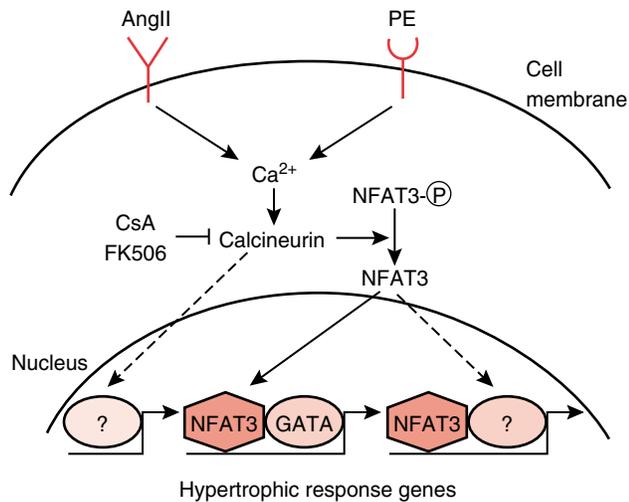

Figure 24-3 A model for the calcineurin-dependent transcriptional pathway in cardiac hypertrophy. Angiotensin II (Ang II), PE, and possibly other hypertrophic stimuli acting at the cell membrane lead to elevation of intracellular Ca^{2+} and activation of calcineurin in the cytoplasm. Calcineurin dephosphorylates NFAT3, resulting in its translocation to the nucleus, where it interacts with GATA4 to synergistically activate transcription. Whether all actions of NFAT3 are mediated by its interaction with GATA4 or whether there are GATA4-independent pathways for activation of certain hypertrophic responses remains to be determined. *Solid arrows* denote pathways that are known. *Dotted lines* denote possible pathways that have not been demonstrated. (reproduced with permission from Molkentin JD, Lu JR, Antos CL, et al. A calcineurin-dependent transcriptional pathway for cardiac hypertrophy. *Cell* 93:215-228, 1998.)

in men was associated with evidence of increased sympathetic nervous system activity and hyperinsulinemia, whereas in women, obesity was the major determinant of LVH.⁷⁰ In a study by De Simone et al., obesity was the predominant factor determining LV mass in women, whereas in men, hemodynamic factors, age, and degree of obesity all contributed.⁷¹ The association of obesity with LVH may account for the increased risk of morbidity and mortality associated with LVH in Black women. In one study of 163 Black men and 273 Black women, after adjusting for age, BP, and ejection fraction, the relative risk for total mortality in individuals with LVH versus those without LVH was 2.0 (0.8-5.0, 95% confidence interval [CI]) for men and 4.3 (1.6-11.7, 95% CI) for women.⁷²

In the Framingham study, obesity was associated with increased LV mass in elderly men and women.⁶² The greater incidence of LVH in obese persons is accounted for by increased wall thickness and often by increased LV internal dimension.^{71,73,74} These changes are reversible with weight loss.⁷⁴

Several hormones have been related to the hypertrophic process.^{49,75,76} The role of the renin-angiotensin-aldosterone axis in hypertensive target organ pathophysiology has been extensively explored (see Chapters 8, 9, 10, and 72). Experimental and human studies^{77,78} have linked plasma renin activity to degree of LVH, but this is not universally accepted.⁷⁹ The product of renin activity, angiotensin I (Ang I), is the substrate for ACE. Expression and regulation of the ACE gene and thus

Ang II levels, may modulate development of LVH. This is supported by in vitro studies in which local release of Ang II in response to the mechanical stretch is a necessary permissive factor for induction of the hypertrophic growth response.⁸⁰ Although there is ample evidence that Ang II is involved in the hypertrophic response, it is apparently not necessary. This was shown in a study in which LVH developed in mice in response to pressure overload despite homologous deletion of the Ang II type 1 (AT_1) receptor.⁸¹ Aldosterone, the synthesis of which is partially controlled by Ang II levels, appears to regulate cardiac fibroblast metabolism and growth.⁸² These observations may explain why elevated plasma renin levels confer a greater risk for MI in patients with hypertension.⁸³

Several lines of evidence suggest that norepinephrine may influence LV mass. Regression of LVH in SHR is enhanced by drugs that inhibit adrenergic stimuli.⁷⁷ Elevated plasma norepinephrine levels in the absence of hypertension cause LVH in dogs⁸⁴ and significant increases in LV mass are induced by several weeks of diet-induced elevated endogenous catecholamine levels in normotensive offspring of hypertensive parents.⁸⁵ These observations may be explained by the stimulatory effect of norepinephrine on the renin-angiotensin-aldosterone axis, and by evidence in cell culture that, through α_1 receptors, norepinephrine can activate growth promoting oncogenes.⁸⁶ However, the importance of adrenergic stimuli in development of LVH has been questioned.⁷⁹ Cardiac and vascular structural changes, seen in renovascular hypertension and hyperaldosteronism, are not observed in patients with essential hypertension or pheochromocytoma.⁸⁷ Furthermore, only a minority of patients with pheochromocytoma have LVH despite extraordinarily high levels of norepinephrine.⁸⁸

Hormones and growth factors that regulate general growth may also be involved in myocardial hypertrophy. For example, marked increases in LV mass may occur in persons with acromegaly as a result of elevated growth hormone and insulin-like growth factor 1 (IGF-1).⁸⁹ IGF-1 levels are higher in hypertensive patients with LVH.⁹⁰ In utero, insulin is a trophic factor that causes macrosomia.⁹¹ Insulin levels and the degree of insulin resistance may independently modulate LV mass in normotensive and borderline hypertensive subjects.^{70,92,93} This may be because insulin resistance leads to increased levels of intracellular calcium, possibly as a result of decreased Na^+ , K^+ -ATPase activity.⁹⁴ Elevated intracellular calcium, which appears to be caused by calcineurin, may be an important stimulus for myocardial actin and myosin synthesis.⁷⁵ This ionic hypothesis⁹⁵ may also explain the association between parathyroid hormone levels and LV mass in hypertensive persons.⁷⁸

MYOCARDIAL COMPOSITION IN LEFT VENTRICULAR HYPERTENSION AND CORONARY HEART FAILURE

Increases in myocyte and interstitial mass that occur as the heart hypertrophies adversely alter ventricular and vascular performance, creating a substrate for increased cardiovascular morbidity and mortality. The heart is composed of several different cell types and an extracellular matrix. Myocytes constitute approximately 75% of the heart mass (Figure 24-4); the remaining 25% is cardiac interstitium that is composed of the coronary vasculature, fibroblasts, macrophages, and mast cells. In hypertensive heart disease, myocytes hypertrophy and

Figure 24-4 Schematic representation of the cellular composition of the myocardium. The heart is composed of several different cell types and an extracellular matrix. Monocytes constitute approximately 75% of the heart mass. The remaining 25% is the cardiac interstitium, which is composed of the coronary vasculature, fibroblasts, macrophages, and mast cells. (Reproduced with permission from Weber KT, Brilla CG. Pathological hypertrophy and cardiac interstitium. Fibrosis and renin-angiotensin-aldosterone system. *Circulation* 83:1849-1865, 1991.)

interstitial components undergo hyperplasia, hypertrophy, and remodeling.^{34,82} Excess collagen production by fibroblasts increases total interstitial and periarteriolar fibrosis. This reduces ventricular compliance. Echocardiographically derived parameters (pixel intensity, skewness, kurtosis, and the broad band of echoes about the distribution) have been shown to correlate with histologically assessed collagen volume in patients with hypertension and LVH.⁹⁶ Vascular smooth muscle cells undergo hyperplasia and hypertrophy, resulting in medial hypertrophy, coronary artery wall remodeling, and increased coronary wall:lumen ratio.⁹⁷ These structural changes decrease vasodilator capacity.

Although the precise structural changes that lead to decompensated systolic and diastolic function from compensated LVH are not currently known, myocardial fibrosis likely plays an important role. As part of the hypertrophic response, cardiac fibroblasts undergo a phenotypic change, assuming a myofibroblast configuration. Stimulated myofibroblasts proliferate and increase production of extracellular matrix proteins, including fibronectin, laminin, and collagen I and III. This results in progressive fibrosis. Many of these processes are controlled by integrins, which are cell surface receptors that mediate the cell's ability to interact with its environment.⁵²

Progressive fibrosis of the heart is a major component of the remodeling process in hypertensive heart disease and leads to LV systolic dysfunction (CHF-S) through impaired myocyte contractility, oxygenation, and metabolism. Several studies, including a study of hypertensive patients that showed that AT₁ receptor blockade with losartan results in decreased plasma levels of growth factors including endothelin-1, basic fibroblast growth factor, and platelet-derived growth factor, suggest that this process may be reversed.⁹⁸ This may help explain the posi-

itive survival impact of ACE inhibitors and may suggest positive benefits of ARBs in patients with CHF-S.^{99,100}

Myocyte hypertrophy may decrease the efficiency of excitation-contraction coupling, leading to decreased efficiency of contraction and development of CHF.¹⁰¹ Normally, depolarization triggers influx of calcium through dihydropyridine receptors (L-type Ca²⁺ channels), leading to local cytoplasmic increases in Ca²⁺ concentration. This local increase "sparks" the release of Ca²⁺ from the sarcoplasmic reticulum (SR) through activation of ryanodine receptors (RyRs). The efflux of Ca²⁺ from the SR causes myocyte contraction by activating the troponin-actin-myosin complex. Physical alteration of the hypertrophied myocyte in LVH increases the distance between the voltage-dependent Ca²⁺ channels and the RyRs on the SR, resulting in failure of the local Ca²⁺ to trigger sarcoplasmic Ca²⁺ release.

MEASUREMENT OF LEFT VENTRICULAR HYPERTROPHY AND USE IN CLINICAL TRIALS AND PRACTICE

M-Mode Echocardiography

M-mode echocardiography is the most widely used, anatomically validated method for determining LV mass.¹⁰² Most laboratories acquire M-mode tracings with two-dimensional (2D) directed imaging.¹⁰³ To obtain a technically adequate study, the patient is imaged in the parasternal short-axis view from the highest possible interspace. This increases the likelihood of achieving an image plane orthogonal to the LV anatomic long axis, yielding a "round" LV image in the parasternal view. The M-mode cursor is then directed through the center of the 2D parasternal short axis, just distal to the mitral valve leaflets, and the M-mode gains are adjusted to optimize endocardial and epicardial interfaces. To measure walls and prevent inclusion of right- and left-sided chordal echoes in the septal and posterior wall, several guidelines are helpful. The M-mode tracing should be recorded with simultaneous viewing of the 2D image, measuring interfaces that show continuous motion throughout the cardiac cycle and discarding tracings that show abrupt posterior motion of the septum in midsystole. The latter finding reflects an incorrect angle beam from a low parasternal window. In research studies, interfaces are usually measured using the Penn convention, which excludes endocardial and epicardial surfaces in measurement of wall thickness and includes endocardial surfaces in the LV dimension measurement.¹⁰² Measurements are made in diastole on the R wave of the QRS complex. LV mass is calculated according to the following formula:^{*}

$$1.04[(ivs + pwd + lvid)^3 - lvid^3] - 13.6$$

Comparable LV mass values can be obtained with measurements made according to the American Society of Echocardiography (ASE) convention using the following formula¹⁰⁴:

$$0.8 (\text{ASE mass}) + 0.6 \text{ g}$$

ASE measurements are made at the onset of the QRS and are based on the leading-edge method.¹⁰⁵ It is important to note that many large multicenter epidemiologic studies are now

*ivs, interventricular septum; pwd, posterior wall dimensions; lvid, left ventricular internal dimension (diastole).

measuring wall thickness from still-frame 2D images when the M-mode is inadequate. This is in recognition of the fact that many clinical echocardiographic laboratories where these studies are performed are not sufficiently expert at obtaining research-quality M-mode images.

No uniform method is available for indexing LV mass measurements by body size or composition. The method of indexing may be irrelevant; a study comparing different methods of indexing LV mass suggested that prediction of mortality is similar for various indices, including those based on height or body surface area.¹⁰⁶ Most published studies index mass by body surface area, expressed as g/m^2 .⁶⁹ De Simone et al. suggested that indexing LV mass by height to the 2.7 power avoids underestimation of LVH in obese subjects.¹⁰⁷ Until late 1994, most publications from the Framingham Heart Study indexed LV mass by the person's height in meters,¹ but Framingham now recommends indexing mass by the person's height to the second power.¹⁰⁸ Partition values for LVH based on different indexing methods are listed in Table 24–3.

Despite careful attention to the technical points noted previously, several studies indicate considerable variability in an individual measurement of LV mass.^{109,110} In TOMHS, the width of the 95% confidence interval for a single replicate measurement of LV mass was 60 g, or approximately $35 \text{ g}/\text{m}^2$.¹¹¹

This raises the issue of whether 2D-directed M-mode echocardiography should be used to guide decisions about initiation or intensity of antihypertensive therapy in the patient with borderline or stage 1 hypertension. Most of the data on reduction of cardiovascular events have been derived from trials that focused on treatment of a single risk factor. If the only risk for cardiovascular disease is diastolic BP $>110 \text{ mm Hg}$, then more than 100 patients must be treated with antihypertensive therapy to prevent one event in 5 years.^{112,113} However, patients present to the physician with varying degrees of risk based on absence or presence of multiple risk factors. Because of this variability, the concept is emerging that deciding whether to treat, or determining intensity of treatment, should be based on the aggregate of risk factors, that is, “absolute” risk^{112,114} (see Chapter 21). LVH is a major risk factor for future cardiovascular events, but it is unclear how to integrate information from echocardiography into a treatment algorithm when the echocardiographic measurement has such great intrinsic variability.

A statistically based resolution of the problem of inherent variability in the measurement of LV mass is needed. We derived an estimate of the probability that LVH is present for any given value of LV mass (Figure 24–5). This calculation is based on the Z-statistic, using methodology similar to that employed to determine the probability that hypertension is present for any given level of ambulatory BP.¹¹⁵ If the cutoff for LVH is $125 \text{ g}/\text{m}^2$ (95th percentile for LV mass), then a person with an LV mass index $\geq 110 \text{ g}/\text{m}^2$ has at least a 20% chance of having LVH. Because of the prognostic implications of LVH, we propose that intensive treatment for LV mass reduction begin when there is at least a 20% probability that LVH is present. Similarly, if LV mass is $<110 \text{ g}/\text{m}^2$, the risk of a cardiovascular event in a patient with stage 1 hypertension is low; therefore, initiation or intensity of treatment would be determined by presence or absence of other risk factors.

Role of 2D Echocardiography, Magnetic Resonance Imaging, Computed Tomography, and 3D Imaging

Two-dimensional measurements of LV mass using Simpson's rule and the area-length method have been standardized and may be reproducible.^{116,117} However, acceptance of these measurements is limited by several factors. These include lack of anatomic validation of the technique, which may be a result of incorrect assumptions about ventricular geometry in unusually shaped ventricles, and technical difficulties in obtaining endocardial and epicardial interfaces, especially of the lateral wall.¹⁰⁴

Newer techniques focus on more accurate visualization of the LV. Many of these are less dependent on calculations based on geometric assumptions about the shape of the ventricle.¹¹⁸ Magnetic resonance imaging (MRI), for example, may give highly reliable and anatomically validated LV mass measurements.^{119–121} Transverse slices are obtained and the endocardial and epicardial contours are determined. Computer summation of all the pixels in the circumscribed muscle area of each slice may then be determined. The multiple of slice thickness and number of slices, and the specific gravity of $1.06 \text{ g}/\text{ml}$, is then calculated to obtain LV mass. There are no assumptions regarding the shape of the ventricle in this method.

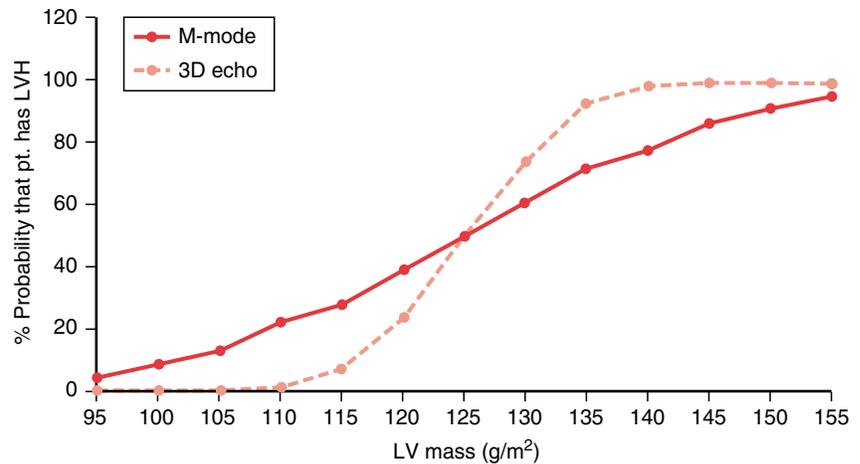

A similar technique may be used in ultrafast computed tomography (CT) images.¹²² Although significantly more costly than echocardiography, MRI may be an effective tool

This is based on a standard deviation for M-mode 17.4 g/m² and for 3D = 6.8 g/m² (assumption that body surface area = 1.7).

for monitoring changes in LV mass for an individual patient or for groups of patients in a research protocol.^{118,121} Less expensive and technically less demanding methods of assessing LV mass have used computer-automated algorithms with technetium-99m-sestamibi single-photon emission CT myocardial perfusion imaging.^{123,124} These techniques rely on determining counts per pixel of myocardium and thus do not depend on assumptions about the shape of the ventricle. Early studies are promising; however, this technique is still in development.¹²⁵

New techniques in echocardiography are allowing noninvasive, accurate assessments of LV mass. Three-dimensional echocardiography eliminates problems of the geometric assumptions used in M-mode and 2D echocardiographic techniques, allowing for more accurate assessment of LV mass. In vitro correlation of 3D-determined LV mass and weight of fixed animal hearts is high, and in vivo correlation with MRI measurement in humans is also very good over a wide range of weights.¹²⁶⁻¹³⁰ A new generation of intravenously administered ultrasound contrast agents (microbubbles) capable of consistent and persistent detection within the LV cavity and myocardium now allows easier visualization of the endocardial and epicardial edges, permitting more accurate measurements for conventional M-mode- and 2D-determined LV mass. In experimental studies, 3D echocardiography performed with new echocardiographic contrast agents has been used to display myocardial mass and the mass of infarcted myocardium.¹³¹

LEFT VENTRICULAR MASS REGRESSION

Regression of LV mass with effective BP reduction has been demonstrated in more than 400 clinical studies, but fewer than 10% have been double-blind and placebo-controlled.¹³² Data indicate that LV mass regression improves survival in hypertensive patients. In one small trial that followed hypertensive patients for more than 10 years, the cumulative incidence of nonfatal cardiovascular events was significantly higher among patients without regression of LVH as compared with those with significant reduction of LV mass.¹³³ Verdecchia et al. showed decreased risk of cardiac events with LV mass regression independent of the baseline LV mass, baseline clinic and ambulatory BP, and the degree of BP

reduction.¹³⁴ Similar findings were reported in a prospective study of 172 patients with essential hypertension, in whom the absence or presence of LVH on follow-up echocardiogram was the strongest predictor of subsequent morbid events.¹³⁵ Total cardiovascular events were also reduced in TOMHS, in which there was LV mass regression.¹³⁶ A mechanism that might explain these findings is that midwall fractional shortening, a sensitive measure of intrinsic myocardial systolic performance, appears to improve with LV mass regression, as does Doppler assessed stroke volume.^{137,138}

BP reduction with all classes of antihypertensive agents reduces LV mass, with the possible exception of pure vasodilators such as minoxidil and hydralazine.⁷⁷ A meta-analysis of more than 100 studies yielded a moderately strong relationship between BP reduction and LV mass regression.¹³⁹ This confirms the hemodynamic contribution to LV mass.

It is not clear, however, whether antihypertensive agents can regress LV mass independent of their effect on BP. In animal studies, low-dose ACE inhibitors can reduce LV mass without lowering BP.¹⁴⁰ The Losartan Intervention for Endpoint Reduction (LIFE) study showed a significant and progressive decrease in LV mass over a 3-year treatment period, despite only a small reduction in BP after the first year of blinded therapy with atenolol or losartan.^{142,143} However, one meta-analysis suggested that for equal levels of BP reduction, β -blockers, ACE inhibitors, and calcium channel blockers (CCBs) cause the same degree of LVH regression, whereas diuretics reduce chamber dimension but do not lead to regression of hypertrophied muscle.¹³² This conclusion has been challenged in two randomized trials that suggest that diuretics are as effective if not more effective than other drug classes for reducing LV mass. In TOMHS, BP was reduced by a combination of weight loss plus either placebo or one of five antihypertensive drug classes (β -blocker, α -blocker, CCB, ACE inhibitor, or diuretic).¹³⁶ At 1 and 4 years, all groups showed LV mass regression, confirming that weight loss in conjunction with BP reduction reduces LV mass. Surprisingly, only participants receiving chlorthalidone had greater LV mass regression than those undergoing weight loss and receiving placebo. Reduced internal dimension as well as reduced wall thickness accounted for this finding. The Veterans Administration (VA) Cooperative Study Group reported similar results: For equal levels of BP reduction, hydrochlorothiazide had a greater effect on LV

mass regression than other antihypertensive agents.¹⁴¹ In this trial of 493 patients who completed 1 year of maintenance antihypertensive therapy, LV mass was not reduced despite hemodynamic improvement in patients taking prazosin, clonidine, or diltiazem, but ACE inhibition was nearly as beneficial as diuretic-based therapy. In the LIFE trial, LV mass regression (by Cornell ECG voltage criteria) occurred with both atenolol and the ARB losartan, but the reduction was significantly more pronounced with losartan.¹⁴² Additional data (not analyzed by drug assignment) from a subset of patients who underwent serial echocardiograms ($n = 754$) showed significant regression in LV mass after 1 year of treatment (despite small overall reduction in BP) and continued regression of LV mass by 2 years with sustained BP reduction.¹⁴³ (See Chapter 31 for a more complete discussion of the LIFE trial.)

Although the patient with hypertension and LVH is typically treated with more than one agent, few studies have evaluated the effect of combination therapy on LV mass regression. However, the 4E-LVH study (Effects of Eplerenone, Enalapril, and Eplerenone/Enalapril) reported that the combination of eplerenone (an aldosterone antagonist) with the ACE inhibitor enalapril was more effective in reducing LV mass than either treatment alone.¹⁴⁴

NEW PHARMACOLOGIC APPROACHES FOR LEFT VENTRICULAR MASS REGRESSION

Targeting Structural, Functional, and Genetic Adaptations That Lead to Increased Left Ventricular Mass

The factors that predict why some patients respond to anti-hypertensive treatment with LV mass regression and others do not, have not been identified. It is likely that genetically based differences may account for heterogeneity of response.

“Nonantihypertensive” medications may interfere with the pathways that lead to cellular (and therefore cardiac) hypertrophy. In addition to providing cardiovascular benefit by their cholesterol-lowering actions, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors may also reduce cardiac morbidity and mortality by preventing cardiac hypertrophy. The activation of fetal cardiac and growth genes such as *c-myc* and *c-jun* to up-regulate myocardial cell protein synthesis is accomplished by stimulating the production of several mitogen-activated protein kinases (e.g., the *Ras-Raf1-ERK1* kinase cascade). HMG-CoA reductase inhibitors disrupt the proper plasma membrane localization of GTP-binding proteins such as Ras. Thus in animal models of LVH (aortic-banded Wistar rats), simvastatin has been shown to limit the development of cardiac hypertrophy by inhibiting Ras signaling.¹⁴⁵ In aortic banded mice, rapamycin attenuated the development of hypertrophy.¹⁴⁶ Rapamycin inhibits the mammalian target of rapamycin (mTOR), a component of the phosphoinositide 3-kinase pathway, which is also thought to be an important determinant of cell size. Rapamycin also appears to affect the mitogen-activated protein kinase pathways by inhibiting JNK1.

DIASTOLIC FUNCTION IN HYPERTENSION

Clinical Presentation and Etiology

The clinical presentation of diastolic dysfunction in hypertensive heart disease is variable, ranging from asymptomatic findings on noninvasive testing to overt CHF despite normal systolic function.¹⁴⁷⁻¹⁵² The prevalence of asymptomatic LV filling abnormalities in adults without hypertrophy and with ambulatory awake BP >130/85 mm Hg may be as high as 33%.⁴⁰ Once LVH or ischemia develops, these asymptomatic abnormalities may cause decreased exercise ejection fraction and blunt the expected rise in exercise cardiac output.¹⁵³ An estimated 30% to 45% of patients with CHF have normal systolic function but abnormal diastolic function (CHF-D).¹⁵² In the Olmsted County study, the prognosis for patients with CHF-D was poor. Survival at 3 months, 1 year, and 5 years was 86%, 76%, and 48%, respectively (Figure 24–6).⁵⁶ In a cohort of patients with CHF-D and underlying coronary artery disease, 7-year cardiovascular mortality approached 50%. Many

Congestive heart failure in the community: A study of all incident cases in Olmsted County, Minnesota, in 1991. *Circulation* 98:2282-2289, 1998.)

of these patients were also hypertensive.¹⁵⁴ Symptoms in CHF-D are accounted for by prolonged LV relaxation or decreased compliance, which causes shifts in the diastolic LV pressure-volume relation that result in elevated left atrial and LV filling pressures.¹⁵⁵

Factors Affecting Diastolic Function

Genetic,¹⁵⁶ structural, metabolic, and hemodynamic factors can affect diastolic function under resting conditions and during states of increased demand or ischemia (Figure 24–7).

Genetic Factors

Using E and A Doppler mitral inflow velocities as a phenotype for diastolic filling, the Hypertension Genetic Epidemiology Network study performed linkage analyses that identified two potentially significant genes on chromosome 5 that contribute to diastolic dysfunction in hypertension.¹⁵⁷ One is a calcium-modulating cyclophilin ligand (CAMLG), an integral membrane protein involved in the regulation of Ca²⁺ ion signaling. This protein is expressed in multiple tissues, and may play a role in Ca²⁺ transport in myocardial contraction/relaxation. The other is the α -1B adrenergic receptor (ADRA1B) gene, which is expressed in myocardium and may indirectly stimulate intracellular Ca²⁺ release and protein kinase C activation. Other genes likely involved in diastolic dysfunction include the SR-Ca²⁺ ATPase pump, which is up-regulated in CHF, and phospholamban, which is overexpressed in rats with prolonged isovolumic relaxation and increased LV end-diastolic pressure. In addition, abnormal diastolic filling parameters have been associated with ACE I/D and G-protein β_3 -subunit C825T gene polymorphisms.

Structural Factors

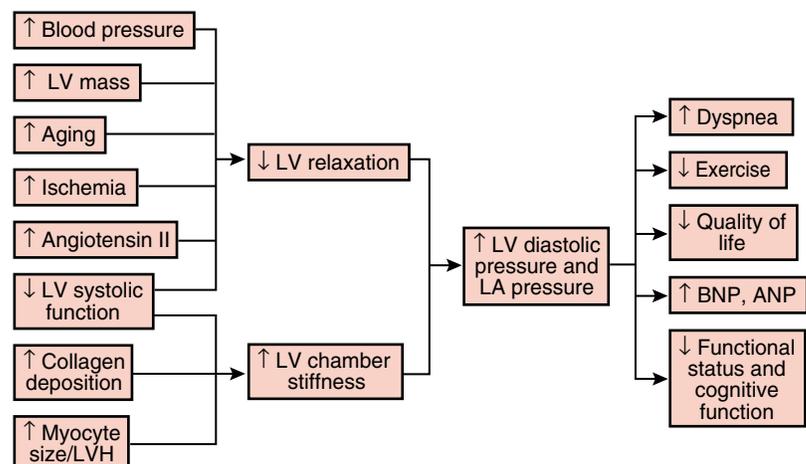

Reports in the late 1980s and early 1990s suggested that diastolic abnormalities occur early in the course of hypertension and precede detectable hypertrophy.^{40,148,158–160} Later studies challenged the notion that diastolic abnormalities are the first sign of hypertensive heart disease; they suggest that diastolic abnormalities do not precede structural changes, but rather occur simultaneously. In general, diastolic function is inversely related to LV mass in patients with hypertension^{148,149,161–163}

and regression of LV mass with CCBs, β -blockers, and ACE inhibitors is often,^{164–169} but not always,¹⁷⁰ associated with improved LV diastolic function. In the Hypertension and Ambulatory Recording Venetia Study (HARVEST), an Italian study comparing young (age 18–45 years) patients with stage 1 hypertension with matched normotensive controls, the former had significantly greater LV mass and more concentric remodeling.¹⁷¹ However, there was no significant difference in Doppler mitral inflow velocity (E/A) ratio, a marker of diastolic dysfunction. Experimental data suggest that a diastolic abnormality in the absence of frank hypertrophy indicates that the heart is beginning to hypertrophy in response to hemodynamic or nonhemodynamic stimuli. For example, dogs with aortic banding simultaneously develop abnormalities of LV filling and increased LV mass.¹⁷² This early change appears to be dependent on increased myocyte size rather than increased fibrosis.¹⁷³ However, there is also strong evidence that abnormal filling is partially accounted for by interstitial collagen deposition that occurs with LVH and aging, leading to passive structural changes that result in increased chamber stiffness.^{82,174,175}

Ischemia

Ischemia has pronounced effects on diastolic function, and these are exacerbated in even the minimally hypertrophied heart.¹⁷⁶ Several metabolic/biochemical factors, which are not fully elucidated, help slow inactivation of the actin-myosin complex and delay relaxation. Baseline adenosine triphosphate (ATP) levels in the pressure-overload hypertrophied heart are similar to or slightly lower than those in control hearts.^{177,178} Although it may be normal in the resting state,¹⁷⁹ the rate of sarcoplasmic uptake of Ca²⁺, an energy-dependent and ATP-requiring step, is markedly reduced by hypoxia.¹⁸⁰ However, diastolic dysfunction in the hypertrophied ventricle may not be fully explained by depletion of high-energy phosphates. In one study, when the isolated buffer-perfused rat heart was subjected to hypoxia, significantly more ischemia developed in hypertrophied hearts than in control hearts at equivalent rates of coronary flow and with similar rates of ATP depletion.¹⁷⁷ This led the authors to conclude that hypertrophy-induced alterations in Ca²⁺ handling, such as changes in the calcium transient that are abnormal even at rest,¹⁸¹ might contribute to ischemia-induced diastolic dysfunction in LVH. In the intact

Figure 24–7 Causes of left ventricular (LV) diastolic dysfunction and its clinical consequences. ANP, atrial natriuretic peptide; BNP, brain natriuretic peptide; LA, left atrial; LVH, LV hypertrophy.

dog, however, under conditions of increased oxygen demand, there was decreased conversion of phosphocreatinine to ATP in the hypertrophied heart,¹⁷⁸ suggesting that high-energy phosphate metabolism is impaired by hypertrophy. Differences in results between the isolated heart and the intact heart may be due to failure of the intact heart to deliver adequate blood flow because of decreased coronary flow reserve.

Hemodynamic Load

Increased hemodynamic load affects diastolic performance. In isolated hearts, increases in afterload early in systole impair relaxation.¹⁸² Wall stress in untreated hypertensive persons is inversely related to diastolic function.¹⁶³ When studied with ABPM, previously untreated borderline and mild hypertensive patients demonstrate a linear relation between BP and abnormal LV filling.^{40,183} The degree to which an acute reduction in BP per se improves LV diastolic performance is not known, and studies are difficult to interpret because the agents used can themselves affect performance.^{184,185}

CHF-D may be characterized by a higher pressure/volume ratio at end-diastole in comparison with normal individuals, but no difference in the ratio at end of systole. This appears on the pressure-volume loop curve as a shift upward and to the left, thus indicating an abnormality of passive diastolic relaxation with decreased capacitance (a decrease in filling volume at any specified filling pressure). Kawaguchi et al.¹⁸⁶ invasively compared LV pressure-volume relationships in patients with CHF-D versus age-matched and young controls. They showed an elevation of end-diastolic pressure:volume ratio (EDPVR) in patients with CHF-D. However, they also showed changes in systolic-ventricular and arterial stiffening and suggested that CHF-D may be due to an adverse coupling of diastolic relaxation abnormality with systolic-ventricular and arterial stiffness.¹⁸⁶ Some investigators have even proposed that CHF-D is not a disease of abnormal LV relaxation, but is a complex of different pathophysiologic processes that produce the clinical scenario of CHF-D.¹⁸⁷

Systolic Function

Systolic function, as measured by ejection fraction, does not appear to decrease during episodes of severe hypertension with pulmonary edema.¹⁸⁸ However, systolic and diastolic dysfunction are closely linked. Midwall fractional shortening, a more sensitive measure of intrinsic myocardial systolic function than endocardial fractional shortening, is abnormal in a substantial portion of asymptomatic hypertensive persons.^{189,190} Schussheim et al. found that depressed midwall fractional shortening and diastolic dysfunction occur simultaneously in asymptomatic hypertensive persons with normal endocardial fractional shortening.¹⁹¹ Conversely, those with normal midwall fractional shortening tend to have normal Doppler indices of mitral inflow. In the Hypertension Genetic Epidemiology Network Study, impaired LV relaxation, measured by prolonged isovolumic relaxation time, was associated with lower midwall fractional shortening, but not with lower fractional shortening.¹⁵⁷ The prognostic implications of these findings were illustrated in the Cardiovascular Health Study, a population-based study of 5201 men and women ≥ 65 years. Those at highest risk for CHF were those with the highest LV

mass index and lowest stress-corrected midwall fractional shortening.¹⁹²

Aging

Aging has profound effects on diastolic function, reflected in a reduced rate of LV relaxation and increased diastolic stiffness. This effect has been confirmed by various noninvasive measurements of diastolic function.^{40,61,193-198} Among normal persons in the Framingham Heart Study, age was the predominant factor affecting Doppler indices of diastolic function, with a Pearson correlation coefficient of -0.80 between age and the E/A ratio.¹⁹⁹ Hypertension, including ISH, further depresses diastolic function in older subjects,^{159,200,201} but this finding has been questioned.²⁰²

The effect of exercise on age-related changes in diastolic function is also controversial. A prospectively designed exercise program in men between the ages of 60 and 82 demonstrated reversal of depressed LV diastolic function with aging.²⁰³ However, a cross-sectional study of younger (52-76 years) male athletes demonstrated similar impairment of diastolic LV filling similar to sedentary peers.²⁰⁴ In contrast, a study of healthy persons in all age ranges showed that diastolic function improved with regular modest use of alcohol or regular aerobic exercise.²⁰⁵

Hormones and Paracrine Factors

Catecholamines are believed to favorably affect diastolic performance by improving systolic performance.^{206,207} Other studies suggest that Ang II adversely affects diastolic function by impairing LV relaxation and stimulating aldosterone-mediated myocardial fibrosis.⁸² In an echocardiographic study of 84 nonhypertensive Finnish men and women age 36 to 37 years, polymorphism in the gene encoding aldosterone synthase (CYP11B2), an enzyme catalyzing critical steps in aldosterone synthesis, was linked to diastolic dysfunction and LV mass. Persons with the $-344TT$ polymorphism in the promoter region of this gene had mean early:late peak velocity (A/E) ratios and LV mass significantly greater than individuals with $-344CT$ and $-344CC$ genotypes.²³ In contrast, a later study of hypertensive persons showed the opposite finding, with higher LV mass in individuals with the $-344CC$ variant.²⁴ Clinical studies of aldosterone antagonists appear to demonstrate improvement of echocardiographic parameters of diastolic dysfunction and LV mass independent of the degree of BP lowering.^{144,208}

Noninvasive Measurement of Diastolic Function

Diastolic function can be evaluated by several methods. The rate of isovolumic pressure decay, early and late LV filling, and pressure-volume relations can be derived from cardiac catheterization.²⁰⁹⁻²¹¹ Although these measurements are the most accurate indices of diastolic function, they require an invasive procedure. Inferences regarding the diastolic properties of the ventricle can be obtained noninvasively with radionuclide angiography²¹² and M-mode²¹³ or Doppler echocardiography²¹⁴ and acoustic quantification.²¹⁵ These techniques yield information on all phases of diastole, including isovolumetric relaxation, early and late LV filling,^{40,159,216}

and temporal differences in regional filling (regional nonuniformity).²¹⁷

Radionuclide angiography was one of the first noninvasive techniques for assessment of LV filling properties. It is based on analysis of the LV time-activity curve. The time-activity curve represents relative volume changes throughout the cardiac cycle. Several parameters of diastolic function can be computed from the time-activity curve, including the peak rate of rapid diastolic filling, time to peak filling rate and the relative contributions of the rapid filling period and of atrial systole to total LV stroke volume. In addition, the duration of the isovolumetric relaxation period may be computed in approximately 80% of patients. Decreased peak filling rate, increased time to peak filling rate, and decreased third and one-half filling fractions are reported.

Hypertensive patients with LVH and impaired diastolic filling at rest also have decreased exercise-induced augmentation in end-diastolic volume, leading to reduced stroke volume and impaired exercise ejection fraction.¹⁴⁸ Attention must be given to technical details of data acquisition and analysis for evaluation of diastolic events using radionuclide angiography. In particular, the effects of cycle length variability (in gated studies), temporal resolution, temporal smoothing, and normalization parameters must be considered. For diastolic studies, high-count double-buffered, left anterior oblique 32-frame images are used.

Doppler echocardiographic evaluation of LV inflow is the most widely used noninvasive measure of diastolic function.²¹⁸ The LV diastolic flow velocity profile obtained with Doppler echocardiography correlates well with radionuclide angiographic variables in the evaluation of LV diastolic function.²¹² However, Doppler echocardiographic assessment is easy and convenient and does not add much time to data acquisition. Furthermore, significant prognostic information may be obtained from Doppler determined mitral inflow. The Strong Heart Study evaluated the prognostic significance of abnormal mitral inflow as a measure of diastolic dysfunction in a population-based sample of middle-aged and elderly American Indians. In this population, a restrictive pattern of inflow with mitral E/A ratio >1.5 was associated with a three-fold increase in cardiac mortality independent of other covariates.²¹⁹ A low E/A ratio (i.e., <0.6), indicative of delayed LV relaxation, was also associated with increased cardiovascular mortality, but not as an independent variable. A younger Italian population was evaluated in the Progetto Ipertensione Umbria Monitoraggio Ambulatoriale (PIUMA) study. They did not observe a J-shaped pattern as noted in the Strong Heart Study. There was, however, significantly increased cardiovascular mortality associated with a low E/A ratio, with a 21 % higher risk of cardiovascular events for each 0.3 decrease in age-adjusted E/A ratio below the median value for the group (0.98).²²⁰

In the setting of normal ventricular relaxation, immediately after mitral valve opening LV pressure is significantly lower than left atrial pressure, and therefore the gradient between the left atrium and LV is relatively high. This results in a high peak velocity of early filling (E) and significant emptying of the blood in the left atrium in early diastole. As a result, the peak velocity of the late filling wave (A) is low. If LV relaxation is prolonged, the LV pressure decline after mitral valve opening is delayed, so the gradient between the left atrium and LV in early diastole is reduced, and equilibration of pressure between the two chambers may be delayed. In the setting

of normal LV function, this is reflected on the Doppler recording as a reduced E and higher A/E ratio and/or a prolonged deceleration time of the early filling wave²²¹⁻²²³ (Figures 24–8 and 24–9). The enhanced A wave may be a result of two factors: (1) LV pressure is lower than normal just before the atrial contraction due to decreased LV filling, and (2) the delayed atrial emptying causes a rise in atrial pressure. These two factors lead to a higher gradient between the left atrium and LV at atrial systole and, hence, an enhanced peak A wave.

Using Doppler echocardiography, one group studied normal persons between the ages of 20 and 50 years (mean 35 ± 9 years), with heart rates ≤ 90 beats/min and no evidence of coronary artery disease. The average value peak A/E ratio was 0.67 ± 0.16 ; an A/E ratio of 0.99 was 2 standard deviations (SDs) above this mean value.⁴⁰ These data have been corroborated by others, who have shown that an A/E ratio ≥ 1 in persons younger than 50 years of age is significantly higher than the range for normal subjects.¹⁹⁶ Framingham Heart Study data, however, suggest that an A/E ratio of 1 may be in the upper range of normal for a 40- to 50-year-old, and is clearly abnormal only in persons younger than age 40 years (Figure 24–10).²²⁴ Studies using Doppler echocardiography show that approximately 20% of untreated prehypertensive or stage 1 hypertensive persons have diastolic filling abnormalities in the absence of LVH.^{40,225} In addition, there may be a threshold of average awake ambulatory BP, 130/85 mm Hg, below which neither diastolic abnormalities nor LVH is detected (Figure 24–11).⁴⁰

Pitfalls in Interpretation of Noninvasive Measurements

Information derived from Doppler echocardiography should be interpreted in the context of the many dynamic factors that can affect Doppler variables. These include changes in afterload, systolic performance, heart rate, and cardiac filling pressures.^{221,226} For example, the peak velocity of late LV filling (peak A) is directly related to heart rate.²²⁷ Therefore, a pharmacologic intervention that simultaneously increases heart rate and the height of the A wave could be incorrectly interpreted as adversely affecting diastolic function. Conversely, a pharmacologic intervention that raises LV end-diastolic pressure could be misinterpreted as beneficial if it simultaneously lowers the A wave and raises the E wave (i.e., “pseudonormalization” of the Doppler profile). This was demonstrated in a study in which verapamil was given to patients with coronary artery disease.²²⁸ This intervention resulted in an increased early filling velocity (E wave) and a shortening of isovolumetric relaxation. Invasive studies, however, showed that these seemingly beneficial changes were in fact associated with a prolongation of the time constant of relaxation and an increase in LV end-diastolic pressure. Thus, increased LV end-diastolic pressure and left atrial filling pressures—not improved LV relaxation—caused a pattern of Doppler “pseudonormalization” characterized by a higher E wave, lower A wave, and shortened isovolumetric relaxation time.

Emerging Techniques to Measure Diastolic Function

A challenge in noninvasive evaluation of diastolic function is to devise methods by which LV end-diastolic pressure can be serially evaluated. One group suggested that plasma atrial

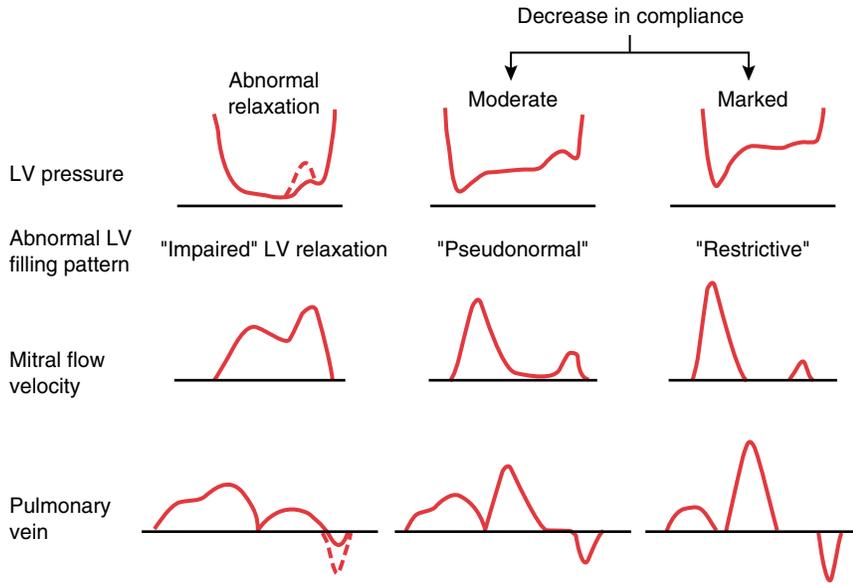

Figure 24-8 The three basic abnormal left ventricular (LV) (mitral flow velocity) filling patterns together with representative LV pressure recordings and pulmonary venous flow velocity recordings. (Reproduced with permission from Appleton CP. Left ventricular diastolic function. In Murphy JG, (ed). Mayo Clinic Cardiology Review. Armonk, NY, Futura, 1997; pp 43-56.)

natriuretic peptide, a measure of LV filling pressures, be used to interpret changes in noninvasively derived LV filling parameters. Plasma atrial natriuretic peptide levels increase when the atria are stretched as a result of increased filling pressures²²⁹⁻²³¹ and fall as LV end-diastolic pressure decreases. This knowledge was exploited to interpret a Doppler evaluation of diastolic function in severely hypertensive persons treated for 1 year with nifedipine.¹⁶⁹ Over the year, the Doppler early filling (E wave) increased while the A wave decreased. Atrial natriuretic peptide levels fell, suggesting that LV end-diastolic pressure had decreased. The investigators concluded that it was likely that the increased velocity of early filling and decreased A wave were due to improved LV relaxation.

Several merging Doppler techniques may allow for serial noninvasive interpretation of LV end-diastolic pressure. Among these is measurement of pulmonary venous inflow.²³²⁻²³⁴ During atrial contraction, flow into the pulmonary veins reverses as the pulmonary veins become a “low-pressure sink” for the contracting atrium. Increased LV end-diastolic pressures create more “afterload” for the atrium, leading to increased height and duration of the “reverse flow” wave. Furthermore, the difference in pulmonary venous and mitral flow velocity duration during atrial contraction is related to the increase in LV end-diastolic pressure.²³³ Therefore, prolonged pulmonary venous velocity duration during atrial contraction, coupled with a shortened duration of the mitral A wave, suggests increasing LV end-diastolic pressure.

Conversely, a shorter pulmonary venous velocity duration coupled with a lengthened transmitral A wave during atrial contraction suggests decreasing LV end-diastolic pressure (see Figure 24-8).

Another promising Doppler technique to assess LV end-diastolic pressure rests on the observation that diastolic flow is initially directed toward the ventricular apex (transmitral A wave) and then wraps around and enters the LV outflow tract just before ejection.^{235,236} This “preejection wave,” termed the *Ar wave*, can be identified on recordings of the LV outflow tract. The time from peak of the transmitral A wave to peak of the Ar wave (A-Ar interval) is inversely related to LV chamber stiffness and LV end-diastolic pressure²³⁵ (i.e., the stiffer the ventricle or the higher the LV end-diastolic pressure, the shorter the A-Ar interval).

Color M-mode assessment of LV filling expands on this concept. It is based on the interval from color M-mode peak velocity at the mitral leaflet tips to peak velocity in the apical region of the LV. A first wave propagates from the left atrium to the LV apex, corresponding to early filling, and a second wave follows atrial contraction. The magnitude of these velocities is highest above the mitral tips and decreases as flow approaches the apex. The velocity at which flow propagates within the ventricle (V_p) is given by the slope of the color wavefront. The time delay of the first wave of early filling from its appearance at the mitral leaflets to its appearance in the LV apex (TD) is also measured and is directly related to the time constant of isovolumetric relaxation.

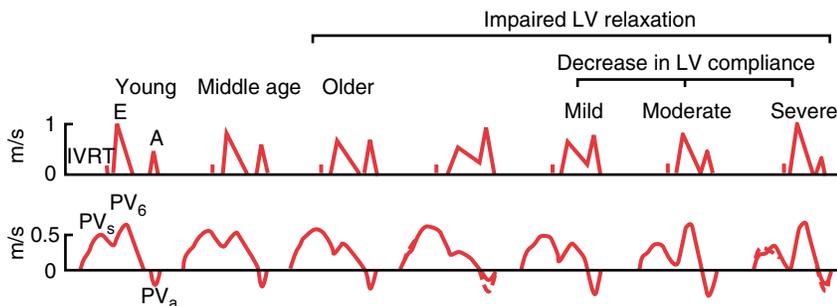

Figure 24-9 Natural history of left ventricular (LV) filling patterns. Left ventricular diastolic function. In Murphy JG, (ed). Mayo Clinic Cardiology Review. Armonk, NY, Futura, 1997; pp 43-56.)

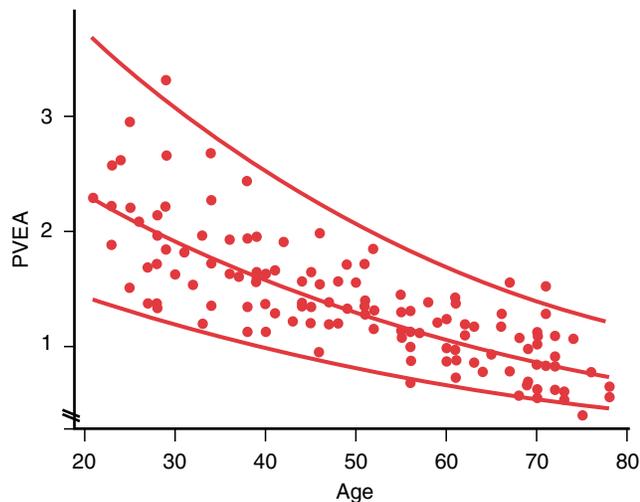

Figure 24-10 Predicted value of ratio of peak velocity of early filling/late filling (PVEA) ratio in normal subjects studied in the Framingham Heart Study. *Solid outer lines* represent the 95% confidence intervals. At approximately age 40, a PVEA ratio below 1 is outside of the 95% confidence interval. (From Benjamin EJ, Levy D, Anderson KM, et al. Determinants of Doppler indexes of left ventricular diastolic function in normal subjects (the Framingham Heart Study). *Am J Cardiol* 70:508-515, 1992, with permission from Excerpta Medica.)

In hypertensive patients with abnormal relaxation, and in patients with restrictive heart disease, there is reduced V_p and prolonged TD.²³⁷ These variables may be independent of heart rate and LV end-diastolic pressure. Thus, this technique may become extremely useful in serial assessment of LV relaxation.

Tissue Doppler imaging (TDI) is an ultrasound technique based on color Doppler imaging principles. It allows quantification of intramural myocardial velocities by detection of consecutive phase shifts of the ultrasound signal reflected from contracting myocardium. Large Doppler signals obtained from the ventricular wall can be selectively displayed as a color or pulsed Doppler images by eliminating small Doppler signals produced by the blood flow.^{238,239} There are significant correlations between early and late myocardial velocities obtained by TDI and the invasively determined time constant of LV pressure decay during an isovolumetric diastole (τ).²⁴⁰ This suggests that TDI variables are load and heart rate independent reflections of intrinsic diastolic function. As a result, and because of the availability of TDI on most new commercially available ultrasound equipment, TDI will probably emerge as the measure of choice for assessing diastolic function.

Ultrasonic backscatter is an echocardiographic technique in which quantitative characterization of myocardial texture is obtained by analysis of ultrasonic reflectivity. The amount of backscatter produced when ultrasound interacts with components of tissue appears to correlate with the degree of myocardial fibrillar collagens type I and type III. An association between myocardial ultrasonic reflexivity and extent of diastolic dysfunction defined by traditional ultrasound Doppler methods has been demonstrated.²⁴¹

Effect of Treatment on CHF-D

Although CHF-D has been recognized for nearly two decades, treatment of hypertensive patients with symptoms of CHF-D is guided by relatively few studies. Topol et al., in a landmark study, analyzed the effect of treatment on morbidity and mortality in 21 elderly hypertensive patients with marked concentric hypertrophy, supernormal LV systolic function, and depressed LV diastolic function. These patients were treated with a variety of antihypertensive and cardioactive agents because of CHF, angina, stroke, or syncope.¹⁵¹ Of the 12 patients who received vasodilators (nitrates, hydralazine, prazosin, or captopril), 6 had a severe hypotensive reaction and 1 died. In contrast, all 9 patients who received β -blockers or calcium antagonists improved, and 4 had less dyspnea after discontinuation of digoxin and furosemide. In a study of 144 patients with CHF and Doppler evidence of restrictive LV diastolic filling as measured by a shortened deceleration time of early mitral filling, cardiac mortality was assessed after 2 years of unblinded oral therapy. Various combinations of digoxin, diuretics, ACE inhibitors, nitrates, and β -blockers were used. Survival was significantly better in patients with prolongation of the deceleration time over the treatment period compared with patients with no change in deceleration time.²⁴² The latter group used more digoxin. No other significant difference in medication use was noted. Thus, although reversing diastolic dysfunction may relieve symptoms and prolong survival, the optimal regimen is still not clear.

Systematic studies of various agents on CHF-D are few, and the paucity of the resulting data have formed the basis for conflicting recommendations by authorities on the optimal treatment of CHF-D. This suggests a need for a randomized controlled trial utilizing drug classes whose efficacy in treatment of CHF-D has not been proved.

ACE Inhibitors and Angiotensin Receptor Blockers in the Treatment of CHF-D

Three studies have evaluated the efficacy of ACE inhibitors in CHF-D. In one study, 10 persons with hypertension, LVH, and CHF-D were treated in a nonrandomized, uncontrolled study with the ACE inhibitor enalapril and a low-sodium diet.¹⁶⁸ After an average of 9 months of treatment, CHF symptoms resolved in all subjects, without use of diuretics. Diastolic function as measured by Doppler echocardiography did not change after the initial decrease in BP, but improved significantly (decreased A/E ratio and deceleration time) after LV mass regression. Another study compared treatment with an ACE inhibitor to standard therapy without enalapril in 21 elderly patients with CHF-D, prior non-Q-wave MI, and normal ejection fraction.²⁴³ In the enalapril group, BP and LV mass were significantly reduced with treatment, and this was accompanied by a significant improvement in New York Heart Association functional score (decrease from 3.0 to 2.4, $p < .01$), increased exercise time on a treadmill, and an improvement in diastolic function as measured by Doppler echocardiography. In the third study, 35 patients with hypertension and LVH underwent endocardial biopsy after 6 months of treatment with lisinopril.²⁴⁴ There was evidence of significant regression of myocardial fibrosis as evidenced by collagen volume fraction and myocardial hydroxyproline concentration, irrespective of the degree of LVH regression. This was accompanied by echocardiographic signs of improved LV

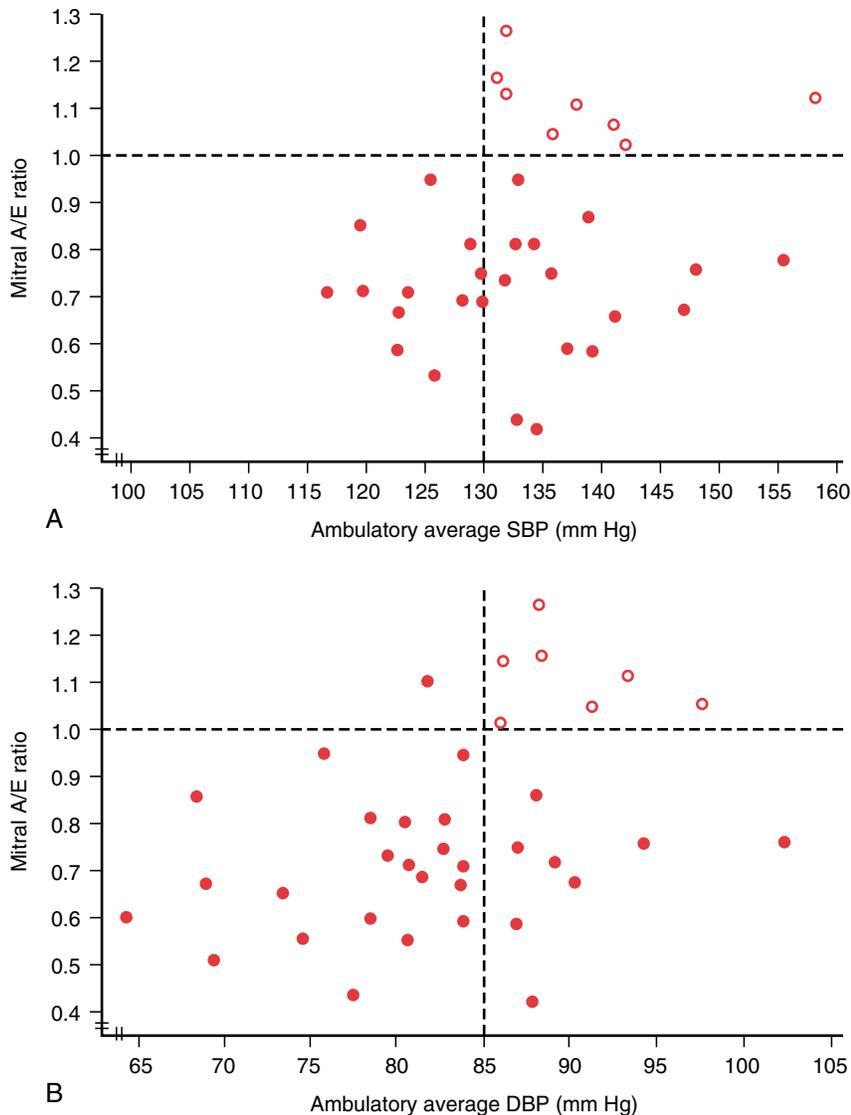

Figure 24-11 Ratio of late (A) to early (E) left ventricular inflow velocity (A/E ratio) in 37 persons (<50 years old) plotted against (*panel A*) average ambulatory awake systolic blood pressure (SBP) and (*panel B*) average awake ambulatory diastolic blood pressure (DBP). All subjects were untreated and had no evidence of coronary disease and were referred for evaluation borderline hypertension. Horizontal hatched lines indicate A/E ratio ≥ 1 is abnormal in this population; vertical hatched lines indicate BP above which abnormal A/E ratio was detected. All subjects (eight, open circles in upper right quadrant of panel **A**) had SBP >130 mm Hg. In upper left quadrant of panel **B**, only 1 of 22 subjects (closed circles) with diastolic pressure <85 mm Hg had abnormal A/E ratio, and this subject had SBP >130; all other subjects with abnormal A/E ratio (seven, open circles in upper right quadrant of panel **B**) had DBP >85. (From Phillips RA, Goldman ME, Ardeljan M, et al. Determinants of abnormal left ventricular filling in early hypertension. *J Am Coll Cardiol* 14: 979-985, 1989, with permission from the American College of Cardiology Foundation.)

diastolic function, including increased E/A and decreased isovolumic relaxation time.

In the Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM)-preserved study, an ARB was assessed in comparison with placebo in 3023 patients with history of classes II-IV CHF, but LVEF >40%. This study showed a significant benefit of the ARB over placebo preventing further hospitalizations for CHF.²⁴⁵ However, these results might be explained by a significantly greater reduction in BP in the candesartan group compared with the placebo group (6.9 mm Hg systolic and 2.9 mm diastolic, $p < .0001$).

Calcium Channel Blockers in the Treatment of CHF-D

Two small, short-term studies have been reported in which CCBs were the mainstays of therapy for CHF. In a prospective study of 20 patients (15 of whom had hypertension), verapamil and placebo were compared in a 5-week crossover design. Compared with baseline, verapamil significantly improved LV filling, decreased symptoms and improved exercise time,²⁴⁶ whereas placebo had no significant effect.

However, possibly because of a “carryover” effect of verapamil-induced improvement into the placebo phase of the crossover design, there was no difference between verapamil and placebo in LV filling. In six severely hypertensive patients followed for 4 months, of whom four received a concomitant diuretic, treatment with nifedipine was associated with symptomatic improvement.²⁴⁷

β -Blockers in the Treatment of CHF-D

There is very limited data regarding the role of β -blockers in isolated CHF-D. A study in patients with idiopathic dilated cardiomyopathy (ejection fraction <25%) evaluated the effect of metoprolol, up to 50 mg three times daily, on diastolic dysfunction.²⁴⁸ Diastolic function improved within 3 months of treatment, and the investigators suggested that better diastolic performance might have allowed for the subsequent observed boost in systolic function. Another study compared atenolol with nebivolol in hypertensive patients with history of CHF-D. After 6 months of treatment, they found significant improvement in E/A ratio with all patients, though somewhat more pronounced with the latter treatment group.²⁴⁹

Diuretics in the Treatment of CHF-D

Although no clinical trial data are available, some investigators recommend cautious use of diuretics to reduce the congested state in CHF-D.^{150,250} Diuretics reduce congestion by lowering LV preload and reducing right ventricular filling pressure, thereby relieving pericardial restraint on the LV.²⁵¹ However, use of diuretics remains controversial because of the lack of clinical trial evaluation of this strategy and the concern that preload may be inappropriately reduced with “overdiuresis.” In fact, the Fifth Report of the Joint National Committee on the Detection, Evaluation, and Treatment of Hypertension (JNC V) considers diuretic therapy in diastolic dysfunction as “relatively or absolutely contraindicated” in patients with hypertensive hypertrophic cardiomyopathy with diastolic dysfunction.²⁵² On the other hand, diuretic-based therapy very effectively prevents development of CHF in patients with hypertension.

Digoxin and Inotropes in the Treatment of CHF-D

Although digoxin may improve LV filling by decreasing heart rate, its ability to increase intracellular calcium may increase LV stiffness.²⁵³ In the National Institutes of Health–sponsored Digitalis Investigation Group trial, with nearly 8000 patients,²⁵⁴ digoxin did not appear to be deleterious in those with abnormal systolic function (CHF-S) and might have improved functional status.

Summary of Treatment of CHF-D

Although 2 million Americans have CHF-D, few have been enrolled in published studies that specifically evaluated the effect of drug therapy on this syndrome. Some authorities recommend that first-line treatment include β -blockers or calcium antagonists.^{250,252} However, until recently, β -blockers were contraindicated in patients with CHF. Others recognize that management of symptoms in these patients often requires use of diuretics,¹⁵⁰ but physicians should prescribe diuretics cautiously in this setting. Still others advocate improvement of diastolic dysfunction by inhibition of the renin-angiotensin system with ACE inhibitors, ARBs, and/or aldosterone antagonists, with the aim of reversing of interstitial cardiac fibrosis.²⁵⁵ The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) recommends ACE inhibitors, β -blockers, ARBs, and aldosterone blockers along with diuretics for patients with symptomatic CHF with either systolic or diastolic ventricular dysfunction. Evaluation for ischemic heart disease is also recommended in these patients.²⁵⁶

Effect of Antihypertensive Treatment on Asymptomatic Diastolic Dysfunction

The effect of antihypertensive treatment on noninvasively derived LV filling abnormalities in asymptomatic subjects has been studied with a variety of agents. No study has reported conversion from asymptomatic to symptomatic status with treatment. Thus, analysis of therapy relies on serial measurements of noninvasively derived measures of LV filling. These studies are difficult to evaluate without data on filling pressures, which are rarely provided. For example, one 8-week

study comparing verapamil with lisinopril suggested that verapamil was superior because treatment resulted in shorter time to peak LV filling, reduced isovolumetric relaxation time, and greater first-half filling. In that study, lisinopril prolonged resting isovolumetric relaxation time.²⁵⁷ An equally compelling alternative explanation is that the effect of verapamil was a result of increased filling pressures²²⁸ and the effect lisinopril was due to decreased filling pressures.

Calcium Channel Blockers in the Treatment of Asymptomatic Diastolic Dysfunction

Many studies suggest that the CCBs verapamil and diltiazem improve diastolic function.^{164,167,169,257-259} Some of these salutary effects are likely pharmacologic, but some studies also suggest that improved filling is dependent on coincident LV mass regression.^{164,167,169} Studies with diltiazem showed no significant benefit, but these were flawed by short duration of treatment¹⁴⁹ or by inclusion of patients whose LV diastolic function was nearly normal at baseline.²⁶⁰

β -Blockers in the Treatment of Asymptomatic Diastolic Dysfunction

β -Blockers are routinely advocated as first-line agents in treatment of CHF-D.^{250,261} However, the effects of β -blocker therapy on diastolic function have been variable. Some studies show improved filling (in association with, but possibly independent of, LV mass regression).¹⁶⁴⁻¹⁶⁶ Two studies, including one in elderly hypertensive patients, failed to demonstrate LV mass regression or improvement in diastolic function.^{167,262} Because β -blockade antagonizes catecholamine-mediated LV relaxation, it has been suggested that β -blockers can improve diastolic function only if accompanied by BP reduction, relief of ischemia, and prolongation of the time for LV filling.^{150,262}

ACE Inhibitors in the Treatment of Asymptomatic Diastolic Dysfunction

Studies of the effects of ACE inhibitors on asymptomatic diastolic function in hypertensive patients have revealed variable effects. Because Ang II has a direct negative effect on myocardial relaxation,²⁶⁴ inhibition of Ang II would be expected to improve LV filling. In one study in which captopril induced significant LV mass regression, Doppler indices of LV filling did not change.¹⁷⁰ However, LV filling was normal at baseline; thus, LV filling would not be expected to improve. Both lisinopril²⁶⁵ and enalapril have been shown to improve Doppler or M-mode derived indices of diastolic function.²⁶⁶

CORONARY MICROCIRCULATION ABNORMALITIES IN THE PATIENT WITH HYPERTENSION

In hypertensive patients with LVH, structural and functional alterations in the small coronary vessels, increasing ventricular wall stress and alterations in the rheologic properties of blood (e.g., increased viscosity) inhibit the ability of the coronary microcirculation to regulate overall coronary blood flow.²⁶⁷ These abnormalities result in diminished coronary flow reserve, the increase in total coronary blood flow that

occurs with maximal vasodilation (Figure 24–12). A better (though less frequently used) term may be *myocardial perfusion reserve*, because this reflects the total circulation of the myocardium rather than just the epicardial coronary arteries. Abnormal coronary flow reserve may predispose the hypertensive patient to ischemic syndromes, which lead to CHF, MI, and sudden death.

Coronary Vessel Pathology in Left Ventricular Hypertrophy

Various vascular abnormalities result in a reduction in the total maximal cross-sectional area of the coronary microvasculature. These include inadequate vascular growth in response to increasing muscle mass, changes in vessel wall composition, vascular remodeling, and vascular endothelial dysfunction.

Rarefaction of Arterioles

Morphometric studies in various animal models suggest that inadequate growth of the coronary microvascular bed is one factor limiting myocardial perfusion in the presence of pressure-overload myocardial hypertrophy.^{268–275} The capacity for coronary angiogenesis decreases over time. Between the ages of 9 to 14 years, heart weight increases fourfold, while capillary density decreases by 28%. Capillary density in the hypertrophied heart is also age dependent. Adults with acquired aortic stenosis have decreased capillary density, whereas children with congenital aortic stenosis maintain capillary density by increasing capillary supply in proportion to myocyte volume.^{273,276,277} As hypertrophy progresses in the adult with hypertension, there is insufficient angiogenesis to compensate for the increasing myocardial mass.

Defective angiogenesis may be a mechanism in the inheritance of hypertension. Higher vascular resistance and lower

capillary density (in the dorsum of the finger) were demonstrated in mildly hypertensive young men with hypertensive parents but not in mildly hypertensive men without hypertensive parents.²⁷⁸ The mechanisms of angiogenesis are complex. Factors released with increased vascular wall tension that influence cell to cell interactions, extracellular matrix molecules, and the inhibition and stimulation of endothelial growth factors may be important.^{279,280} Vascular endothelial growth factor (VEGF) is one such factor that has received much attention in the developing field of cardiac molecular therapy. VEGF promotes the sprouting of new vessels via its effects on angiopoietin. ACE inhibition has in part been thought to promote angiogenesis and thus augment coronary flow reserve by up-regulation of VEGF, as well as other related factors.²⁸¹ Another factor, hepatocyte growth factor (HGF), is a mesenchyme-derived pleiotropic factor that regulates cell growth, cell motility, and morphogenesis of vascular tissue (among other types of cells). Myocardial HGF concentrations are low in SHR and are inversely proportional to LV weight. Concentrations of cardiac and vascular Ang II, a suppressor of HGF, are increased in SHR. In addition, administration of an ACE inhibitor or an ARB results in a significant increase in cardiac HGF concentration.²⁸²

Medial Wall Thickening

Pressure overload with coronary arterial hypertension causes vascular medial hypertrophy with decreased lumen diameter and increased ratio of media thickness to lumen diameter (media:lumen ratio).^{283–285} Comparisons of coronary vascular morphology and coronary resistance in normotensive Wistar-Kyoto (WKY) and SHR showed a nearly twofold increase in medial thickness in the coronary arterioles of the hypertensive rats.²⁶⁷ There was also a significantly increased ratio of medial thickness to vessel radius and increased minimal coronary resistance in the hypertensive

Figure 24–12 Diagram of coronary flow reserve in the presence of hypertrophy. In panel **A**, absolute flow is measured (ml/min). In panel **B**, flow per unit mass (ml/min/g) is measured. A, autoregulated flows; D, pressure flow line during maximal vasodilation; R, flow reserve. Normal are A1, D1, R1, and solid lines. Hypertrophied are A2, D2, R2, R3, and dashed lines. In both scenarios, coronary flow reserve is diminished. R3 represents coronary flow reserve when perfusion pressures are elevated. (Reproduced with permission from Hoffman JI. A critical view of coronary reserve. *Circulation* 75:16-11, 1987.)

animals. The cellular basis for this increase in medial thickness is predominantly rearrangement of smooth muscle cells within the medial layers of the arterial wall, not increases in individual myocyte cell size.²⁸⁶ The factors responsible for this rearrangement are slowly becoming understood.

Endothelin plays a significant role, because blockade of endothelin subtype A (ET_A) receptors inhibits hypertrophic vascular remodeling in salt-sensitive forms of hypertension.²⁸⁷ This factor, as well as other agents important for control of smooth muscle cell hypertrophy and proliferation (endothelial growth factor [EGF], platelet-derived growth factor [PDGF], Ang II, mechanical stretch, and fluid shear stress), induce a series of cellular kinase cascades, known collectively as the mitogen-activated protein (MAP) kinase cascades, which have been implicated in vascular smooth muscle cell proliferation and hypertrophy.²⁸⁸ These kinases lead to activation of the protooncogenes *c-fos* and *c-jun*, which are components of the nuclear transcription factor AP-1. Activation of this transcription factor results in increased gene expression for processes that initiate vascular growth and hypertrophy²⁸⁹ (see Figure 24–2). The magnitude of vascular structural alteration, however, may be independent of the extent of endothelial dysfunction in hypertension.²⁹⁰

Perivascular and Interstitial Fibrosis

In addition to medial hypertrophy, pressure-overloaded cardiac hypertrophy with hypertension causes increased vascular and perivascular deposition of collagen.²⁹¹ Inhibition of collagen deposition in vascular and extravascular myocardial tissue in the Wistar rat shows that coronary flow reserve is mainly determined by medial thickening, independent of collagen deposition. Nevertheless, collagen deposition does affect coronary blood flow, since there is more reversal of coronary flow abnormalities after removing the pressure load on the heart (aortic banding) in the rats with less collagen deposition.²⁹¹

Increased Vascular Water Content

A 10% to 15% increase in the water content of arterial walls occurs in hypertensive patients. A high concentration of vascular water produces thickening of the vascular walls (even in the absence of hypertrophy) and may also cause a reduction in coronary flow reserve.²⁶⁷

Endothelial Dysfunction

In the heart and systemic vessels, nitric oxide (NO) appears to reverse smooth muscle cell hypertrophy and hyperplasia.²⁹² Thus, expression of NO in hypertension may help protect from target end-organ damage. Impairment of endothelial function is an early vascular abnormality resulting in abnormal myocardial blood flow in patients with coronary artery disease, angina pectoris with normal coronary arteriograms, and hypertension with LVH. Although hypertensive patients have appropriate responses to the endothelial-independent vasodilators, most studies demonstrate a blunted response to acetylcholine-stimulated endothelial-dependent vasodilation.^{293–297} Imbalance between endothelial-mediated vasodilation and vasoconstriction may be an early lesion in hypertension. In SHR, impaired endothelial-dependent relaxation occurs before the development of overt hypertension.²⁹⁸

Attention has focused on substance P and bradykinin, native peptides of the coronary endothelium that are extremely potent in triggering endothelium-dependent dilation of small coronary arteries. They contribute to the resting level of coronary blood flow and partially mediate flow-dependent dilation in response to increased myocardial demand.^{299,300} A cytochrome P450 product, not NO, may regulate production of these vasodilators.³⁰⁰

Myocardial Hypertrophy and Wall Stress

Increased wall stress (one factor initiating the development of LVH in hypertensive patients) may directly modulate coronary flow reserve by causing physical compression of blood vessels. Elevated wall stress may stimulate the release of vasoactive substances that alter vascular function and growth.²⁶⁷ Patients with nonhypertensive LVH, without ventricular dilation and increased wall tension (i.e., some cases of aortic stenosis, hypertrophic obstructive and hypertrophic nonobstructive cardiomyopathy with no ventricular dilation) do not have decreased coronary flow reserve. Those with hypertension with similar degrees of LVH, or aortic stenosis with ventricular dilation and increased LV end-diastolic pressures, however, show abnormally decreased flow reserve.^{301,302} This effect is also seen in patients with dilated cardiomyopathy³⁰³ and dilated ventricles due to aortic regurgitation.^{304,305}

Alterations of Coronary Autoregulation and Flow Reserve with Left Ventricular Hypertrophy

The coronary circulation is able to maintain a relatively stable blood supply over a wide range of perfusion pressures.^{306–309} This range varies in different experiments but is generally between 70 and 130 mm Hg in humans.³¹⁰ Coronary flow decreases markedly when perfusion pressure drops below the lower limit of autoregulation.

Proposed Mechanisms of Autoregulation

Both metabolic and myogenic mechanisms may produce autoregulation of coronary flow. Different sites in the microvasculature may have different dominant mechanisms of control.³¹¹ The smallest coronary arterioles are predominantly sensitive to metabolic factors, whereas larger arterioles are more reactive to myogenic stimuli. According to the metabolic theory, a decrease in coronary artery perfusion pressure results in decreased blood flow. Subsequent decreases in myocardial substrate availability, or increases in production of metabolites, produce vasodilation.³¹² Potential mediators include oxygen (myocardial oxygen tension), K⁺ and Ca²⁺ ion concentrations (transmembrane potentials), osmolality, adenosine, prostaglandins, and carbon dioxide (CO₂) and H⁺ concentrations.^{313–315} The endogenous vasodilator NO has been shown to inhibit coronary autoregulation.³¹⁶

Myogenic regulation is an intrinsic mechanism: Application of force to vascular smooth muscle results in contraction.^{317–319} In the coronary circulation, there are difficulties in demonstrating myogenic responses, because these are closely integrated with metabolic factors.³²⁰ These mechanisms result in both microvascular dilation and increased recruitment of arterioles,³²¹ thus resulting in changes in intramyocardial

blood volume. Myocardial contrast echocardiography can quantify autoregulatory increases in intramyocardial blood volume, and thus may provide a noninvasive method for studying coronary autoregulation.³²²

Relationship Between Autoregulated Coronary Flow and Maximal Coronary Flow

Coronary flow reserve is, for any given perfusion pressure, the decrease in coronary resistance over the resting state that occurs after maximal coronary vasodilation. A normal human heart can increase coronary flow by a factor of 4 to 5 times over the resting state.³⁰¹ Coronary flow increases above resting autoregulated levels after transient coronary arterial occlusion (reactive hyperemia), exercise, pacing, or injection of agents such as dipyridamole, adenosine, papaverine, or hyperosmolar iodinated contrast media.³²³ Loss of autoregulation occurs during these events. Coronary flow reserve is a dynamic value that is dependent on coronary perfusion pressure. Because there is no autoregulation during states that produce maximal coronary flow, the relationship between coronary flow and coronary perfusion pressure is linear. Relatively small changes in perfusion pressure produce large changes in coronary flow reserve.

Factors that Confound the Measurement of Coronary Flow Reserve

Increased heart rate, contractility, and afterload all decrease coronary flow reserve and therefore confound its measurement. It is not clear if these factors increase baseline flow, decrease maximal flow, or both.^{324,325} In humans, Doppler measurements of coronary blood flow during pacemaker-induced tachycardia show increases in resting flow velocity, but not in peak velocity with papaverine administration.³²⁵ The use of potent vasodilators to quantify coronary flow reserve may result in a blunted measurement if there is any significant increase in heart rate. Body size may also influence absolute values of maximal coronary blood flow.³²⁶

Elevations in aortic pressure increase myocardial oxygen consumption and blood flow. Consequently, shifts in mean aortic pressure produce alterations in autoregulated (resting) blood flow. By using the relationship between mean aortic pressure, coronary flow reserve, and coronary vascular resistance (coronary flow = mean aortic pressure/coronary resistance), one may calculate a coronary resistance ratio.³²⁷ The resistance ratio may be less sensitive than a flow ratio to changes in arterial pressure.³²³

In addition to external confounding factors, there are intrinsic factors in the definition and measurement of coronary flow reserve that produce confusion. Coronary flow reserve can be measured as either the difference of maximal and resting flow (absolute coronary flow reserve) or the ratio of maximal flow to resting flow (relative coronary flow reserve). It is not clear which measurement is clinically more relevant. In hypertensive patients with LVH, it is possible to have a normal or mildly increased absolute coronary flow reserve with a reduced relative coronary flow reserve.³²³

Many current methods of measuring coronary flow reserve are not sensitive to changes in coronary flow reserve over different layers of myocardium. Coronary flow reserve is lower in subendocardial muscle for all perfusion pressures. Some of the newer noninvasive techniques such as cine-CT and nuclear

magnetic resonance may be able to measure coronary flow reserve in the different layers of myocardium, but data are still very preliminary.

Effect of Hypertension and Left Ventricular Hypertrophy on Coronary Flow Reserve

Coronary flow reserve can be measured as absolute flow (ml/min) or flow per unit muscle mass (ml/min/g) (see Figure 24–12).³¹⁰ Although resting absolute coronary blood flow in the entire LV increases with LVH, resting coronary blood flow per gram of myocardium is unchanged. Total maximal ventricular flow does not significantly change with acquired LVH, whereas total flow per gram of myocardium decreases. This is due to the lack of vascular growth in response to increasing muscle mass. Thus, when absolute flow is measured, resting flow is high and maximal flow is normal (see Figure 24–12, A). If flow per gram is measured, resting flow per gram myocardium is normal but maximal flow per gram myocardium is reduced (see Figure 24–12, B). Consequently, coronary flow reserve is less than normal whether measured as absolute flow (ml/min) or flow per gram (ml/min/gm) of myocardium.

In the presence of hypertension, absolute coronary flow reserve may theoretically be normal or increased, despite higher resting absolute coronary blood flow. This is due to the higher coronary perfusion pressure (shift to the right side of the curve), as shown by R3 in Figure 24–12, A. Nevertheless, in most cases of hypertensive heart disease, vascular abnormalities and increased LV end-diastolic pressure result in reduced maximal flow and thus a decrease in coronary flow reserve.^{302,328–330} Most,^{304,329,331} but not all^{332,333} studies show an inverse linear relationship between the extent of LVH and vascular endothelial function as noted by either forearm blood flow or coronary flow reserve (Figure 24–13).

Other factors (e.g., race, gender, diabetes, cigarette smoking, and prior therapies) also influence coronary flow reserve.^{334–338} Evaluation of endothelial-dependent dilation of the brachial artery has shown that reduced flow-mediated dilation is related to age. Noticeable decline begins in men after age 40 years but is preserved in women until their 50s.³³⁹ This delay in women may be due to protective effects of estrogen, because their decline appears to correlate with the onset of menopause. Estrogen treatment of postmenopausal women improves endothelial-dependent vasodilation.³⁴⁰ This may be a direct effect of estrogen on vascular function or an indirect effect through altered lipid metabolism, because increased high-density lipoprotein appears to improve NO bioavailability.³⁴¹ Tamoxifen acts as a selective estrogen receptor modulator (SERM) in women and has estrogen-like activities on some cardiovascular risk factors (e.g., lipids). In one study, tamoxifen was shown to augment endothelium-dependent forearm flow-mediated vasodilation in men with coronary artery disease.³⁴² In a study of the coronary circulation, age and total serum cholesterol were found to be independent predictors of a blunted vasodilator response to acetylcholine.³⁴² Analysis of SHR and normotensive rats showed that hypertension and aging independently result in structural alterations in coronary resistance vasculature, with a decrease in the ratio of lumen diameter to wall thickness. Aging did not decrease arteriolar density.³⁴⁴ Racial differences were demonstrated in a study showing that Blacks have decreased coronary flow reserve compared with whites, independent of LVH.³³⁴

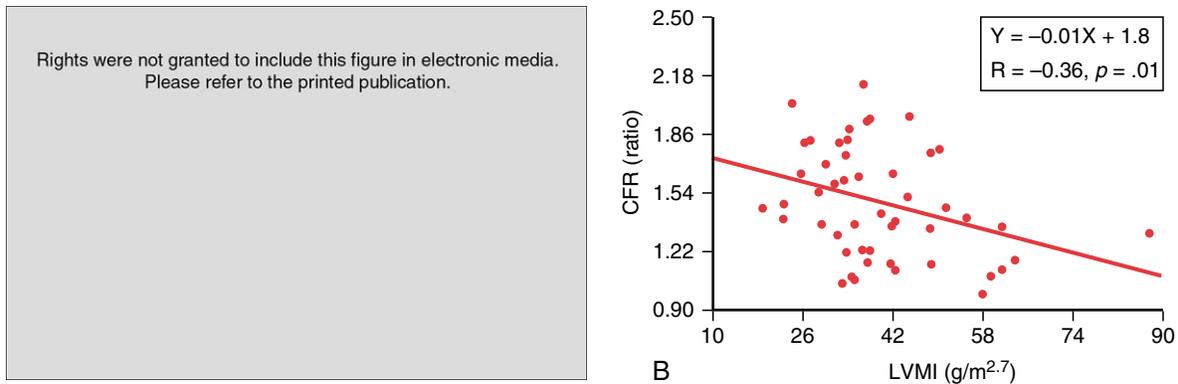

Figure 24-13 Inverse relationship between LV mass and vascular endothelial function. **(A)**, increase in left ventricular mass index (LVMI) is associated with a decrease in the increase in forearm blood flow in response to acetylcholine (ACh) infusion. **(B)**, the same relationship is shown when comparing LVMI with coronary flow reserve (CFR) as determined by “split-dose” Tl-201 single photon emission tomography in subjects with moderate to severe hypertension. (Part A from Perticone F, Maio R, Ceravolo R, et al. Relationship between left ventricular mass and endothelium-dependent vasodilation in never-treated hypertensive patients. *Circulation* 99:1991-1996, 1999. Part B from Diamond JA, Krakoff LR, Goldman A, et al. Comparison of two calcium blockers on hemodynamics, left ventricular mass, and coronary vasodilatory in advanced hypertension. *Am J Hypertens* 14:231-240, 2001, with permission from the American Journal of Hypertension, Ltd.)

Hypertension may alter coronary flow reserve prior to the development of LVH. This was suggested by a cross-sectional analysis of hypertensive and nonhypertensive patients. Although coronary flow reserve was lowest in untreated hypertensive patients with increased LV mass, patients with hypertension and normal LV mass had lower coronary flow reserve than normotensive patients.³⁴⁵ This must be viewed with caution, however, because cross-sectional studies do not allow one to analyze other factors that may influence coronary blood flow, such as duration of hypertension and prior antihypertensive therapies. Whether or not linearly related, most studies suggest that LVH is strongly associated with reduced coronary flow reserve. Thus, abnormalities of coronary flow reserve may partially explain why patients with hypertension and LVH are at increased risk for myocardial ischemia and infarction.³

Effect of Blood Pressure Reduction on Autoregulated Blood Flow and Coronary Flow Reserve

Experimental and clinical studies demonstrate that BP reduction in hypertensive patients with LVH may increase myocardial ischemia. Resting absolute coronary flow is high in these patients, and loss of autoregulated flow occurs at higher perfusion pressures (the autoregulatory curve is shifted upward and to the right). In experimentally induced LVH, although marked reductions in coronary perfusion pressure from 100 to 40 mm Hg have minimal effect on autoregulation in the subepicardium, the ability of the subendocardium to autoregulate is reduced by >50%.³⁴⁶ This may account for the increased size of MI associated with experimentally induced coronary ligation in hypertrophied hearts.^{347,348} Recovery of stunned myocardium (systolic thickening and regional myocardial blood flow) in the period immediately following transient coronary occlusion is delayed in the presence of LVH, and even more so when BP is lowered during this early reperfusion period.³⁴⁹

BP reduction in hypertensive humans without LVH does not significantly change resting coronary blood flow when perfusion pressure is acutely lowered with nitroprusside from 120 to 70 mm Hg. However, LVH accompanies hypertension, there is a marked decline in flow as perfusion pressure decreases from 90 to 70 mm Hg (Figure 24-14).³⁵⁰ This suggests that a reduction of BP to <90 mm Hg in patients with LVH could cause ischemia. This observation may in part explain the limited impact of BP reduction on mortality from coronary artery disease compared with nonfatal and fatal stroke in patients with both systolic and diastolic hypertension. Analysis of several large prospective observational studies suggests that a 5- to 6-mm Hg decrease in diastolic blood pressure (DBP) would cause a 20% to 25% reduction in coronary events. However, this degree of reduction in BP has resulted in only a 14% decrease in coronary events.^{112,351} This finding was confirmed by the Blood Pressure Lowering Treatment Trialists' Collaboration review of 29 major trials, which assessed major cardiovascular outcomes based on class of antihypertensive medication and degree of BP lowering. Overall, larger reductions in BP resulted in the larger reductions in overall cardiovascular risk. The largest impact of BP reduction was on stroke.³⁵²

A J-curve may describe the relation between mortality rate from MI and treated DBP.³⁵³ Traditionally the J-curve does not specifically address hypertensive patients with no coronary artery disease. These patients may benefit from decreasing BP as much as possible. However, those with ischemic disease and a treated DBP of <85 to 95 mm Hg may have an upturn in coronary events. This is presumably a result of inadequate perfusion of coronary arteries. Support for and against this relation is based on differing interpretations and results of retrospective analyses of several large treatment trials or programs.³⁵⁴⁻³⁵⁸ For example, in one retrospective analysis, men with LVH or ischemic patterns on ECG had an increased incidence of MI when treated DBPs were below 95 mm Hg.³⁵⁹ By contrast, in the Systolic Hypertension in the Elderly Program (SHEP) trial, coronary events were decreased in patients with

Figure 24–14 Effect of acute reduction in coronary perfusion pressure on coronary autoregulation in controls with normotension, patients with hypertension without left ventricular hypertrophy (LVH), and patients with hypertension and LVH. The autoregulatory curve for hypertension with LVH is shifted upward and to the right. At coronary perfusion pressure <90 mm Hg, patients with hypertension and LVH have marked loss of coronary autoregulation. (Reproduced with permission from Polese A, DeCesare N, Montorsi P, et al. Upward shift of the lower range of coronary flow autoregulation in hypertensive patients with hypertrophy of the left ventricle. *Circulation* 83:845-853, 1991.)

evidence of LVH by ECG criteria and low treatment DBP.³⁶⁰ Although this may argue against a J-curve, it is important to realize that these patients had low DBPs prior to treatment, and hence their autoregulatory curve was already adjusted to lower pressure. Systolic hypertension in older patients with decreased arterial compliance (increased stiffness) is associated with higher cardiac morbidity and mortality and may explain the association of increased cardiac death in patients with low DBP or increased pulse pressure³⁶¹⁻³⁶³ (see Chapters 15 and 22).

Recommendations for the safest level of BP reduction in patients with LVH can be only speculative at this point. In patients with isolated systolic hypertension, in whom the pre-treatment DBP is already low, SHEP trial data indicate that further reduction to a DBP of 65 mm Hg is safe.³⁶⁴ JNC recommends lowering BP to <130/80 mm Hg in patients with target organ damage, including chronic kidney disease and diabetes, but this is not based on a wealth of data.^{256,365}

Effect of Antihypertensive Treatment on Coronary Flow Reserve

ACE Inhibitors and Angiotensin Receptor Blockers in the Treatment of Coronary Flow Reserve

Few human studies have examined the effects of antihypertensive therapy on coronary flow reserve. Data using the gas chromatographic argon method of quantifying coronary flow reserve showed improvement in hypertensive patients after 12 months of therapy with enalapril.³⁶⁶ By blocking the production of Ang II, ACE inhibitors may be effective in improving coronary flow reserve. This may be due to reduction in perivascular and interstitial fibrosis.³⁶⁷ Akinboboye et al. used ¹⁵O-water positron emission tomography (PET) to quantify myocardial perfusion reserve in a small population (n = 17) of predominantly African Americans with hypertension. This study demonstrated improved myocardial perfusion reserve after treatment with lisinopril for a mean of 11 months,³⁶⁸ but no significant change in myocardial flow reserve after treat-

ment with losartan. Using a modification of traditional TI-201 myocardial perfusion imaging for quantification of myocardial perfusion reserve, Diamond et al. showed modest improvement after 6 months of antihypertensive treatment with the ARB eprosartan.³⁶⁹ However, there was no significant change in myocardial perfusion reserve with the ACE inhibitor enalapril. This may have been due to the short follow-up period in the study.

Calcium Channel Blockers in the Treatment of Coronary Flow Reserve

The effect of CCBs on coronary flow reserve is even less clear. Although they produce favorable hemodynamic effects, with reversal of pressure-overload and regression of LVH, several studies suggest that certain CCBs do not significantly change or may even reduce coronary flow reserve. Theoretically, CCBs may reduce coronary flow reserve by blocking the effect of endogenous vasodilators such as adenosine.³⁷⁰

β-Blockers in the Treatment of Coronary Flow Reserve

Using PET quantification of myocardial perfusion, β-blockers have been shown to augment coronary flow reserve in healthy volunteers. Billinger et al. showed in patients with coronary artery disease that postischemic coronary flow reserve (hyperemic flow) is significantly augmented in patients taking the β-blocker metoprolol.³⁷¹ By augmenting coronary flow reserve, oxygen supply to the heart is enhanced. This may in part explain the benefit of β-blockers in patients with coronary artery disease.

Renal Protection in Chronic Kidney Disease

Donna S. Hanes, Matthew R. Weir

Chronic kidney disease (CKD) has become a major public health problem in the United States and threatens to escalate over the next few decades. In the Third National Health and Nutrition Examination Survey (NHANES III), an estimated 3% of the adult population, or 5.6 million people, were found to have abnormal renal function, as defined by a serum creatinine greater than 1.6 mg/dl.¹ Even more concerning, the number of patients predicted to develop kidney failure by the year 2010 is twofold to threefold higher than the number today and will likely exceed 650,000.² However, even this approximation grossly underestimates the prevalence of kidney disease, because many people have significant proteinuria or other abnormalities that will certainly progress to end-stage renal disease (ESRD) in the face of a normal serum creatinine and normal to reduced glomerular filtration rate (GFR). Extrapolating the estimated number of patients with all stages of kidney failure indicates that more than 11% of the population has kidney disease.

It is commonly accepted that once there is a decline in the GFR, progressive loss of renal function is inevitable. This final common pathway occurs despite the lack of persistent disease activity. Moreover, a heterogeneous variety of insults including diabetes, glomerulonephritis, and hypertension all result in a similar pattern of renal injury. The histologic hallmarks of CKD include glomerulosclerosis, interstitial fibrosis, and renal cell apoptosis. Other morphologic features may include monocytic or macrophage infiltration.

The rate of loss of renal function is determined by the underlying disease process and other factors. The main determinants of renal progression include (1) activity of the primary disease process, (2) intrarenal adaptations, and (3) local and systemic mediators.³ The latter include systemic and glomerular hypertension, proteinuria, metabolic derangements of glucose and lipids, smoking, dietary protein, anemia, race, and gender, many of which cluster together in the same patient⁴ (Figure 25–1).

Therefore intensive efforts are underway to modify the rate of loss of renal function. Over the last few decades, much has been learned about the specific factors that can slow renal disease progression, affording the clinician both a means to treat specific patients and a better understanding of the underlying pathophysiology of renal injury. Currently the most important renoprotective interventions include reduction of blood pressure, inhibition of the renin-angiotensin-aldosterone system (RAAS), and reduction of proteinuria. Many trials have provided insight into the importance of each of these modifiers. By carefully following currently recommended guidelines, the rate of loss of renal function can be slowed and the need for renal replacement therapy can be significantly delayed. Ultimately this will improve patient outcomes, reduce cardio-

vascular morbidity and mortality, and improve quality of life while simultaneously saving millions of Medicare dollars.

This chapter highlights the importance of the known risk factors for renal injury and outlines methods to intervene in these pathways. Emphasis is placed on the interrelationship between kidney and cardiac disease, the importance of blood pressure reduction and RAAS inhibition, and the recently recognized concept of proteinuria reduction independent of changes in blood pressure.

ASSOCIATION BETWEEN NEPHROPATHY AND CARDIOVASCULAR RISK

The link between cardiovascular risk and nephropathy has been well described. In an analysis of the United Kingdom Prospective Diabetes Study (UKPDS), the annual cardiovascular death rate for patients with normoalbuminuria (<30 mg/dl) was 0.7%; in patients who progressed to microalbuminuria (30–299 mg/dl) and macroalbuminuria (>300 mg/dl), the annual death rates rose to 2.0% and 3.5%, respectively. Once a patient developed an increase in serum creatinine or required renal replacement therapy, the annual death rate more than tripled, to 12.1% (Table 25–1).⁵

In 1998, the National Kidney Foundation (NKF) Task Force on Cardiovascular Disease in Chronic Renal Disease issued a report emphasizing the high risk of cardiovascular disease (CVD) in CKD.⁶ In this report it was demonstrated that death caused by CVD was 10 to 30 times higher in dialysis patients as compared with the general population. The task force further recommended that patients with CKD be treated aggressively as the highest risk group for CVD events. In keeping with this strategy, the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) classified patients with kidney disease in the same high-risk category as those with diabetes.⁷ These guidelines recommend a blood pressure goal of <130/80 mm Hg in such patients.

The extent to which traditional risk factors contribute to increased CVD in CKD patients is uncertain. Certainly many patients with CKD have diabetes, older age, and left ventricular hypertrophy. However, the Framingham risk equation appears to be insufficient to capture the extent of CVD risk in patients with CKD.⁸ It has been proposed that the “missing link” that explains the astounding burden of CVD in CKD may be related to nontraditional risk factors.⁹ Patients with kidney failure have an inordinate amount of oxidant stress, dyslipidemia, elevated inflammatory markers, hyperhomocysteinemia, anemia, and other factors that promote atherogenesis¹⁰ (Table 25–2). Although no direct cause-and-effect relationship

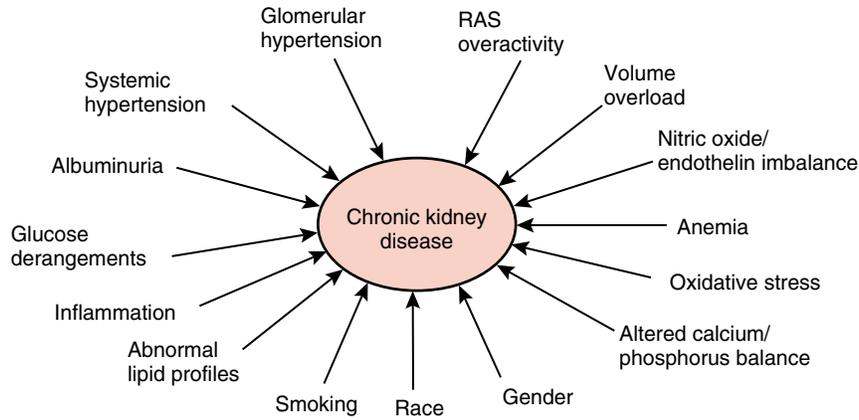

Figure 25-1 Factors contributing to the pathophysiology of CKD.

Table 25-1 Annual Cardiovascular Death Rates in Diabetic Patients with Various Stages of Chronic Kidney Disease

Urinary Albumin Excretion (mg/day)	Annual Death Rate (%)
<150 mg	0.7
150-300 mg	2.0
>300 mg	3.5
>300 mg and requiring renal replacement therapy	12.1

Table 25-2 Traditional and Nontraditional Cardiovascular Risk Factors in CKD

Traditional Risk Factors	Nontraditional Risk Factors
Age	Albuminuria
Male sex	Homocysteine
Hypertension	Lipoprotein (a)
High LDL cholesterol	Anemia
Low HDL cholesterol	Abnormal calcium/phosphate
Diabetes	Volume overload
Smoking	Electrolyte imbalance
Physical inactivity	Oxidative stress
Menopause	Malnutrition
Family history of CVD	Inflammation
L VH	Sleep disturbances
	Altered nitric oxide/endothelin balance

Modified from Oberg BP, McMenamin E, Lucas FL, et al. Increased prevalence of oxidant stress and inflammation in patients with moderate to severe chronic kidney disease. *Kidney Int* 65:1009-1016, 2004.

LDL, low-density lipoprotein; HDL, high-density lipoprotein; CVD, cardiovascular disease; LVH, left ventricular hypertrophy.

has been established between these nontraditional risk factors and CVD events in CKD patients, ongoing clinical trials to reduce the burden of these factors will assess their importance in this patient population.

STAGES OF CHRONIC KIDNEY DISEASE

As shown in Table 25-3, the current classification of CKD is based on the estimated glomerular filtration rate (eGFR). In the Clinical Practice Guidelines published by the NKF, CKD is defined as either kidney damage for ≥ 3 months (defined by structural or functional abnormalities of the kidney) or GFR < 60 ml/min/1.73 m² for ≥ 3 months (with or without kidney damage).¹¹ A GFR of < 60 ml/min/1.73 m² was chosen because it represents (1) the level at which mortality increases significantly, (2) loss of greater than 50% of normal renal function, and (3) the level below which laboratory abnormalities associated with CKD become manifest. Therefore there is a strong impetus to preserve the GFR above the critical threshold of 60 ml/min/1.73 m² from the perspective of both the heart and kidney.

PROTEINURIA AS A MARKER FOR CARDIOVASCULAR DISEASE

Microalbuminuria (defined as a random urine albumin:creatinine ratio [ACR] of 30-300 mg/g) and macroalbuminuria (ACR > 300 mg/g) are increasingly being recognized as independent risk factors for CVD. Large clinical trials have demonstrated that proteinuria is more predictive of a cardiovascular event than any of the traditional risk factors.¹² Microalbuminuria, the hallmark of diabetic nephropathy, is strongly associated with increased cardiovascular risk and strongly predicts renal disease progression. The greater the amount of protein excreted, the greater is the risk for renal disease progression and CVD.¹³

Pathophysiology of Progressive Renal Failure

It is generally accepted that renal injury and loss of glomerular volume result in hyperfiltration and overcompensation by the

Table 25-3 Classification of Chronic Kidney Disease According to the National Kidney Foundation

GFR Stage	Description	ml/min/1.73 m ²	Action
1	Kidney with normal or increased GFR	>90	Diagnosis and treatment Treat comorbid conditions Slow progression CVD risk reduction
2	Kidney damage with mild decrease in GFR	60-89	Estimating progression
3	Moderately decreased GFR	30-59	Evaluate and treat complications
4	Severely decreased GFR	15-29	Preparation for renal replacement therapy
5	Kidney failure	<15	Renal replacement

Increased rates of adverse cardiovascular events occur when patients approach stage 3 CKD.

Adapted from Kidney Disease Outcomes Quality Initiative (K/DOQI). Clinical practice guidelines on hypertension and antihypertensive agents in chronic kidney disease. *Am J Kidney Dis* 43:S1-290, 2004.

remainder of the kidney. Brenner's "remnant nephron" theory postulates that it is this hyperfiltration, or overload, that causes progressive loss of the remaining glomeruli. Once the GFR is <60 ml/min/1.73 m², the remaining nephrons assume the entire filtration load. Consequently, they acquire greater oxygen demands and are then more susceptible to hypoxia and oxidative injury. Other pathophysiologic processes have also been proposed to promote progressive renal injury. In a simplified form, early insult can lead to sodium retention and angiotensin II (Ang II) production, which promote systemic and glomerular hypertension. The result is an increase in glomerulosclerosis and progressive decline in GFR.

Albuminuria has been known for many years to be a marker for kidney disease, but the pathogenic role of proteinuria has been appreciated only recently. Proteinuria frequently precedes the development of glomerulosclerosis even in the absence of glomerular hypertension.¹⁴ Proteinuria has also been shown to have tubulotoxic effects. Remuzzi and Bertani suggest that the first step in renal deterioration is disruption of glomerular permselectivity, which may be mediated by mechanical injury to the capillary wall, or in the absence of increased glomerular capillary pressure, toxins, or immune reactants.¹⁵ Once the permselectivity has been disrupted, the progression to kidney failure is triggered by the exposure of glomerular, mesangial, and tubulointerstitial cells to an abnormal protein load.¹⁶ In keeping with this finding, numer-

ous clinical trials in very diverse kidney diseases have demonstrated that the severity of proteinuria correlated best with the rate of renal function decline.¹⁷

However, some patients do progress to renal failure in the absence of significant proteinuria. Thus, although proteinuria is a key factor in the downward spiral that is CKD progression, it is not critical. Interestingly, Wright et al. have reported that the differences in the rate of progression of kidney disease between the different renal disorders were no longer apparent after correction for proteinuria.¹⁸

Several other factors contribute to progressive decline in renal function. The most important of these include hypertension and the effects of Ang II. Systemic hypertension is the second most common cause of ESRD (the most common being diabetes). For many years, the causal role of hypertension in renal disease progression was not well defined. It was clear that malignant hypertension leads to a rapid loss of renal function, but this is the cause in only about 6% of patients.¹⁹ Milder forms of hypertension have been recognized to be associated with ESRD more recently. One of the first trials to demonstrate the association was the Multiple Risk Factor Intervention Trial (MRFIT).²⁰ In this large epidemiologic study with more than 332,544 middle-aged men, high blood pressure was a strong predictor of increased renal risk (Figure 25-2). The risk of renal injury was seen even at very modest elevations in blood pressure, such as a diastolic and systolic blood pressure of

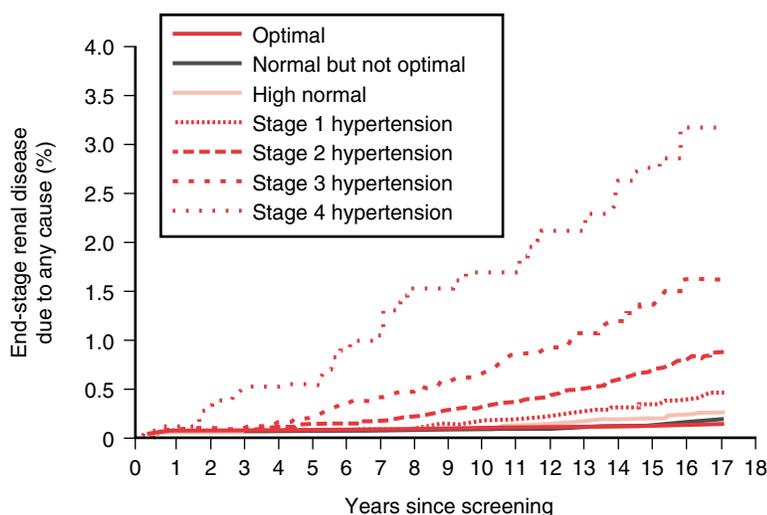

Figure 25-2 High blood pressure and the cumulative risk of end-stage renal disease in men. (From Klag MJ, Whelton PK, Randall BL, et al. Blood pressure and end-stage renal disease in men. *N Engl J Med* 334:13-18, 1996.)

82 mm Hg and 127 mm Hg, respectively. Other studies have confirmed this finding in the general population.^{21,22} Among African Americans, the severity of glomerulosclerosis has been shown to correlate with the level of blood pressure.²³ Perhaps the most striking data come from type 2 diabetics. In a multivariate model of diabetic kidney disease, every 10-mm Hg rise in baseline systolic blood pressure increased the risk of ESRD or death by 6.7%.²⁴ Moreover, patients with the highest pulse pressure, indicating a significant loss of vascular elasticity, had the highest risk for disease progression.

The difficulty with these data is that they do not explain the tremendous variability in the rate of decline of renal function among hypertensive patients. Not all patients with hypertension develop renal disease, and those who do progress toward ESRD at very different rates. Even among normotensives, there is a linear increase in the risk of renal disease as blood pressure rises from optimal to high-normal levels (Figure 25–2). Therefore, other concomitant conditions and individual renal susceptibility to hypertensive renal damage must contribute to the long-term effects of blood pressure on nephron integrity. Nonetheless, as will be discussed, strict control of blood pressure remains the cornerstone of cardiorenal protection.

Role of Angiotensin II

The progression of renal disease is also mediated by Ang II. Ang II raises systemic blood pressure by causing direct vasoconstriction, activation of the sympathetic nervous system, and aldosterone release. This, in turn, causes salt and water retention, further contributing to elevated blood pressure. The increased blood pressure may be transmitted to the glomerulus, promoting intraglomerular hypertension and glomerular capillary damage. This is particularly concerning in the face of diseases that damage renal autoregulatory capacity. For example, in diabetics, the ability of the afferent arteriole to constrict and protect the glomerulus in the setting of systemic hypertension is blunted. This may explain why hypertension in these patients causes an accelerated decline in renal function.

Ang II also contributes to renal injury because of its differential effects on the vasculature of the nephron. It preferentially constricts the efferent arteriole, causing an increase in intraglomerular pressure and perpetuating renal injury.²⁵ Ang II has other detrimental effects on the nephron that are unrelated to elevated blood pressure. Importantly, it stimulates the growth of vascular smooth muscle and mesangial cells, leading to further renal impairment.^{26,27} In diabetics, the tissue RAAS is also a mediator of vascular injury induced by transforming growth factor- β (TGF- β). Uncontrolled and persistent activation of the tissue RAAS with elevated levels of Ang II increases TGF- β , which causes progressive fibrosis. The local production of Ang II directly stimulates TGF- β expression, leading to increased matrix production, decreased degradation, and transformation of cell-surface integrin proteins that facilitate matrix assembly.^{28,29}

Impact of Hyperlipidemia

Hyperlipidemia, either primary or secondary to renal disease, is thought to aggravate renal damage in a number of diverse diseases.³ Dyslipidemia is common in renal disease, particularly in patients with proteinuria. Proteinuria is associated with a distinct form of dyslipidemia, and under experimental

conditions, the glomerular leakage of lipoproteins initiates a sequence of pathophysiologic responses in the kidney, promoting glomerulosclerosis and interstitial sclerosis.^{30–32} The potential of lipids to cause toxic injury to the kidneys is well established. Histologic examination of kidney tissue has demonstrated glomerular deposition of lipids and lipid-laden macrophages.³³ Apolipoprotein (apo) B and apo E often accumulate in mesangial tissue, particularly in association with proteinuria and hyperlipidemia. When hyperlipidemia is present, it is commonly associated with more-severe mesangial hypercellularity and glomerulosclerosis.

Clinical evidence suggests that hyperlipidemia modifies the rate of renal deterioration, at least in some diseases.³⁴ In non-diabetic kidney disease, patients with hyperlipidemia progressed to ESRD more quickly than those without it.³⁵ Specifically, it has been suggested that a high ratio of low-density lipoprotein (LDL):high-density lipoprotein (HDL), elevated levels of apo B or triglyceride-rich apo B, and low HDL levels all contribute to more-rapid renal deterioration.³⁶ However, this relationship has not been demonstrated consistently in all studies, and the effects do not appear to be substantial.

STRATEGIES TO PRESERVE KIDNEY FUNCTION AND DELAY PROGRESSION OF KIDNEY DISEASE

Because the majority of patients with kidney disease are in the early stages of injury, the opportunity to preserve renal function and hence cardiovascular health is of primary importance. In general, the cornerstone of long-term cardiorenal protection involves three major strategies: (1) control of blood pressure, (2) inhibition of the RAAS, and (3) lifestyle modification. It is critically important to emphasize that although angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) are uniquely protective, they must be used in conjunction with other agents such as diuretics, calcium antagonists (CAs), and β -blockers to achieve the recommended blood pressure levels. Currently there is no evidence to suggest that treatment should be determined by race, age, or gender.

Nonpharmacologic Strategies

Lifestyle interventions such as dietary salt reduction, limitation of dietary protein, regular exercise, weight loss, and smoking cessation should be encouraged in all patients with CKD.^{7,37} Reducing dietary salt enhances the blood pressure-lowering effect of virtually all antihypertensive medications and also augments the reduction of proteinuria. Similarly, weight loss to a target body mass index <25 kg/m² can help lower blood pressure and reduce urinary protein excretion independent of blood pressure changes. Exercise for 30 minutes per day, most days a week, should be stressed. Smoking cessation, particularly in diabetics, should always be reinforced, because smoking can independently promote deterioration of renal function and enhance urinary protein excretion in addition to its myriad detrimental effects on overall health. It is imperative to keep in mind that the various lifestyle modifications have more impact in some ethnic groups. For example, dietary salt reduction may be more

important in African Americans, who tend to be more salt sensitive. Women, particularly African Americans, carry the burden of the greatest prevalence of obesity and may benefit the most from weight reduction. Thus the efficacy of lifestyle interventions varies considerably depending on the individual patient. This is not the case with pharmacologic intervention, in that recommendations are much more uniform and effects are much more consistent.

Achieving Target Blood Pressure Pharmacologically

Whether hypertension is the cause or consequence of CKD, numerous clinical trials have demonstrated that achievement of an optimal blood pressure is one of the most important strategies to preserve renal function (Figure 25–3).^{38–40} Optimal blood pressure can be defined as systolic blood pressure <120 mm Hg. This has been demonstrated in all ethnic groups. It is also clear that most patients will require three or more medications to achieve that goal. Furthermore, the higher the baseline systolic blood pressure, the greater will be the relative benefit with drugs that inhibit the RAAS. JNC 7 recommends a goal blood pressure of <130/80 mm Hg in patients with CKD. We are far from reaching that goal. In the NHANES III subgroup that included patients with CKD, only 75% of the patients with hypertension received pharmacologic treatment. Even more alarming is the fact that only 11% of these patients reached the target blood pressure of <130/85 mm Hg and only 27% reached the target of <140/90 mm Hg.¹ Treated hypertensive individuals with elevated serum creatinine levels had a mean blood pressure of 147/77 mm Hg; an astounding 48% of these patients were prescribed only one antihypertensive medication.

Most patients require two or more antihypertensives to achieve these blood pressure goals. If the blood pressure is >20/10 mm Hg above the target, a combination of drugs should be started at the outset.⁷ Because the average number of agents needed to control blood pressure in patients with CKD is 2.6 to 4.3, and the likelihood of these patients having a cardiovascular event is high, therapy should be designed with both diseases in mind.

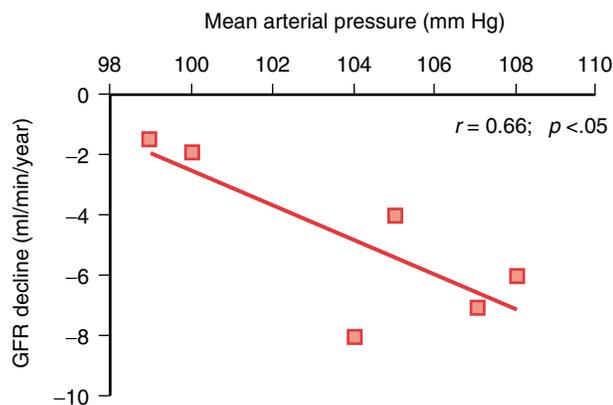

Figure 25–3 Slower decline in renal function with lower blood pressure goals. Results of studies ≥ 3 years in patients with type 2 diabetic nephropathy. (From Bakris GL. *Diabetes Res Clin Pract* 39(suppl):S35-42, 1998.)

DRUG CLASS EFFECTS ON THE KIDNEY

Inhibitors of the Renin-Angiotensin-Aldosterone System: The ACE Inhibitors

There has been considerable interest in the ability of the ACE inhibitors to protect the kidney from the unrelenting deterioration that occurs with hypertension and renal insufficiency. The ACE inhibitors have a number of hemodynamic and non-hemodynamic effects that afford such protection (Box 25–1). In patients with hypertension, ACE inhibitors have the ability to restore the pressure-natriuresis relationship to normal, allowing sodium balance to be maintained at a lower arterial pressure.⁴¹ The mechanism responsible for this effect is direct inhibition of proximal, and possibly distal, tubular sodium reabsorption.⁴² This increase in renal excretory capacity plays a major role in the long-term antihypertensive efficacy of the drugs. Clinically, the increase in sodium excretion is transitory because the reduction in arterial pressure returns sodium excretion to normal. However, the maintenance of normal sodium excretion at lower arterial pressures correlates with increased excretion in the setting of hypertension.⁴² After several days, inhibition of Ang II and aldosterone contribute to the natriuresis.^{43–45}

The long-term effects of ACE inhibitors on water excretion are less certain. ACE inhibitors induce an initial increase in free water clearance, but there are no long-term changes in total body weight, plasma, or extracellular fluid volume.⁴⁶ The decrease in aldosterone caused by ACE inhibition also correlates with decreased potassium excretion,⁴⁵ particularly in patients with impaired renal function. The antidiuretic effect appears to be transient but can be exacerbated by concomitant administration of potassium-sparing diuretics, supplements, and nonsteroidal antiinflammatory drugs and should be monitored rigorously.

Potential renoprotective effects noted in experimental models include attenuation of oxidative stress,⁴⁷ scavenging free radicals, and attenuating lipid peroxidation.⁴⁸ ACE inhibitors also ameliorate the deranged lipid profile in patients with nephrotic-range proteinuria, which may impact the rate of progression of renal failure.^{49,50} The clinical importance of these effects is under investigation.

Insofar as the degree of proteinuria correlates best with the rate of decline of renal function, and a decrease in proteinuria correlates better with renal function outcome than a reduction in blood pressure, reduction of proteinuria has a substantial

Box 25–1 Potential Renoprotective Effects of ACE Inhibitors

- Restore pressure/natriuresis relationship to normal
- Inhibit tubular sodium resorption
- Decrease arterial pressure
- Decrease aldosterone production
- Decrease proteinuria
- Improve altered lipid profiles
- Decrease renal blood flow
- Decrease filtration fraction
- Decrease renal vascular resistance
- Reduce scarring and fibrosis
- Attenuate oxidative stress and free radicals

impact.⁵¹ All ACE inhibitors decrease urinary protein excretion⁵² in normotensive and hypertensive patients with renal disease of various origins.⁵³⁻⁵⁵ Individual response rates vary from a rise of 31% to a fall of 100% and are strongly influenced by drug dose and changes in dietary sodium. There is a clear dose-response relationship between increasing doses and reduction of proteinuria that is not dependent on changes in blood pressure, renal plasma flow (RPF), or GFR. Furthermore, the effect of ACE inhibitors on reduction of proteinuria is abolished with high salt intake.⁵⁶ In normotensive diabetics, studies demonstrate that ACE inhibitors can normalize GFR, markedly attenuate the progression of renal disease, and normalize microalbuminuria.⁵⁷ The effect is noted in the first month of therapy and is maximal at 14 months.

Several mechanisms account for the reduction in urinary protein excretion seen with ACE inhibitors: a decrease in glomerular capillary hydrostatic pressure, a decrease in mesangial uptake and clearance of macromolecules, and improved glomerular basement membrane permselectivity.⁵⁸ ACE inhibitors have superior antiproteinuric efficacy when compared with other classes of antihypertensive agents, with the exception of ARBs. The antiproteinuric effect is additive with the ARBs and does not depend on changes in creatinine clearance, GFR, or blood pressure.^{59,60} Clinical trials also demonstrate a superior renoprotective effect of ACE inhibitor treatment in African Americans, once thought not to benefit from this class. In the African American Study of Kidney Disease and Hypertension (AASK) trial, hypertensive patients with proteinuria >300 mg/day had a much slower rate of progression of kidney disease when treated with an ACE inhibitor when compared with a dihydropyridine CA or β -blocker.⁶¹

Evidence suggests that the majority of vasoconstrictor action of Ang II is confined to the efferent arteriole. ACE inhibitors preferentially dilate the efferent arteriole by reducing the systemic and intrarenal levels of Ang II. The result is a reduction in intraglomerular capillary pressure. ACE inhibitors uniformly increase renal blood flow, decrease filtration fraction, have variable to no effect on GFR, decrease renal vascular resistance, reduce urinary protein excretion, and impair microvascular autoregulation in patients with hypertension. Long-term administration is associated with a decrease in renal perfusion, with a tendency to higher filtration fraction and lower afferent resistances. Marked improvement in GFR occurs and is sustained for up to 3 years.^{62,63}

Many patients with impaired renal function exhibit a reversible fall in GFR with ACE inhibitor therapy that is not detrimental. Numerous studies demonstrate that the GFR declines initially because of the hemodynamic changes, but the long-term reduction in perfusion pressure is renoprotective. In fact, patients with the greatest initial decline in GFR have the slowest rate of loss of renal function over time.⁶⁴ It should be emphasized that ACE inhibitors should not be withdrawn immediately if an increase in serum creatinine is noted; a 20% to 30% decline in GFR can be expected, and close monitoring is warranted. Inappropriate, early withdraw of ACE inhibitors for reductions in GFR is one of the most common mistakes made when treating patients with renal disease.

In patients with an activated RAAS, ACE inhibitors cause a decrease in GFR and can precipitate acute renal failure. Patients with severe bilateral renal artery stenosis, unilateral renal artery stenosis of a solitary kidney, severe hypertensive nephrosclerosis, volume depletion, congestive heart failure,

cirrhosis, or a transplanted kidney are at high risk for renal deterioration with ACE inhibitors.^{65,66} These patients typically have a precipitous drop in blood pressure and deterioration of renal function when treated with ACE inhibitors. In these states of reduced renal perfusion caused by low effective arterial circulating volume or reduced flow through an obstructed artery, the maintenance of renal blood flow and GFR is highly dependent on increased efferent arteriolar vasoconstriction mediated by Ang II. Interruption of the increased tone causes a critical reduction in perfusion pressure and can lead to dramatic reductions in GFR and urinary flow, as well as worsening of renal ischemia, and in select cases, anuria.⁶⁷ Therefore a reduction of GFR greater than 30% should prompt an evaluation for renal artery stenosis.

Renoprotective Effects of Angiotensin II Type 1 Receptor Antagonists

Intrarenal Ang II receptors are widely distributed in the afferent and efferent arterioles, glomerular mesangial cells, inner stripe of the outer medulla, and medullary interstitial cells and on the luminal and basolateral membranes of the proximal and distal tubular cells, collecting ducts, podocytes, and macula densa cells.⁶⁸ The majority of receptors are of the AT₁ subclass. Ang II, predominantly produced locally but also delivered in the systemic circulation, interacts with its receptors to exert its effects. Ang II may work at the cell surface through a second messenger pathway or the receptor ligand complex in the intracellular compartment following internalization of and release of Ang II into the intracellular fluid. Studies suggest that the majority of renal interstitial Ang II is formed at sites not readily accessible to ACE inhibition or is formed via non-ACE pathways.⁶⁹ ARBs antagonize the binding of Ang II to the AT₁ receptor and cause a number of intrarenal changes. The renal hemodynamic responses to AT₁ receptor blockade are variable depending on the counteracting influences of the decrease in arterial pressure.⁷⁰ Decreases in systemic arterial pressure caused by ARBs may be associated with compensatory activation of the intrarenal sympathetic nervous system, resulting in decreased renal function.⁷¹ This effect is more pronounced in sodium-depleted states in which activation of the RAAS helps maintain arterial and renal pressure.⁷²

In contrast, direct intrarenal infusions of ARBs cause an increase in sodium excretion.⁷³ This has been shown to be by direct inhibition of sodium reabsorption in the proximal tubules but may also be due to hemodynamic changes in medullary blood flow and tubular absorption in distal nephron segments.⁷⁴ Because Ang II blockade enhances the ability of the kidneys to excrete sodium, sodium balance can be maintained at lower arterial pressures. Ang II blockade also reduces tubuloglomerular feedback sensitivity by decreasing macula densa transport of sodium chloride to the afferent arteriole.⁷⁵ This leads to an increased delivery of sodium chloride to the distal segments for excretion without compensatory changes in GFR.

A unique property of the ARB losartan is its ability to lower serum uric acid in a dose-dependent manner. It appears to inhibit urate reabsorption in the proximal tubule, resulting in a reduction of serum urate by approximately 0.4 mg/dl.⁷⁶ The clinical implications of this effect are unknown, but it may be beneficial, because it has been suggested that hyperuricemia is a risk factor for renal disease progression and coronary artery

disease.³ It has been suggested that some of the cardiovascular and renal benefits of losartan are a direct result of its uricosuric effect.⁷⁷

ARB treatment of hypertensive patients with normal or impaired renal function elicits renal responses similar to or slightly greater than those elicited by ACE inhibitor treatment.^{78,79} In addition to decreases in systolic and diastolic blood pressure, patients demonstrate increases in renal blood flow, decreases in filtration fraction and renal vascular resistance, and no substantial changes in GFR.⁸⁰ These effects are likely a result of combined decreases in both preglomerular and postglomerular resistances. It has been suggested that elevated intrarenal Ang II levels in the face of AT₁ receptor blockade stimulate AT₂ receptors, which can increase preglomerular vasodilator actions of bradykinin, cyclic guanosine monophosphate, and nitric oxide.^{81,82} ACE inhibitors can potentiate this effect.⁸⁰ The clinical importance of this finding has yet to be established.

Ang II blockade may significantly reduce GFR in underperfused kidneys, and patients with low perfusion pressures, dehydration, or renal artery stenosis may experience severe decreases in GFR but less severe than with ACE inhibitors.^{83,84}

Under conditions of overperfusion, such as hypertension associated with glomerulosclerosis and nephron loss or diabetes, Ang II blockade is protective. Such patients often have a suboptimal suppression of the RAAS. The lowering of efferent arteriole resistance reduces intraglomerular hydrostatic pressure, attenuating the progression of renal injury, and increases renal sodium excretory capacity. In concert with the reduction in systemic arterial pressure, these actions provide more renal protection with the ARBs than with other classes of antihypertensive agents in the presence of equivalent reductions of blood pressure.^{13,85-87}

Urinary protein excretion is significantly decreased with ARBs and parallels findings with ACE inhibitors. Antiproteinuric effects have been described in diabetic and nondiabetic patients and those with renal transplants.⁸⁸ Interestingly, in individual patients, the course of long-term renal function correlates with the antiproteinuric response to therapy.⁸⁹ The antiproteinuric effect has a slow onset. The dose-response curves for the antiproteinuric effects differ from those of the antihypertensive effects. The maximal effect occurs at 3 to 4 weeks, and the peak of the dose-response curve has not been determined.⁹⁰ Whether

the antiproteinuric effects of the ARBs are equivalent to, or better than, those of ACE inhibitors remains to be determined. ARBs and ACE inhibitors appear to have additive and similar hemodynamic and antiproteinuric effects.⁵¹ In a number of trials, ACE inhibitor or ARB therapy reduced proteinuria by up to 40%, whereas combined therapy resulted in a 70% reduction of proteinuria with no further changes in blood pressure.^{91,92} Such findings suggest that the mechanism of antiproteinuric effect may differ between the two classes. Although evidence in support of this approach is limited,¹¹ some authorities recommend that patients on ACE inhibitor therapy with persistent hypertension or proteinuria be treated with additional ARB therapy.⁹³ This combination appears to reduce intrarenal Ang II and TGF-β levels more than high doses of either agent alone.^{94,95} Furthermore, combined ACE inhibitor-ARB treatment has been shown to be more effective than monotherapy with either class of agent in retarding the progression of nondiabetic renal disease (Figure 25-4).⁶⁰

Clinical trials demonstrate superior antiproteinuric effects of the ARBs when compared with conventional antihypertensive treatment. In patients with diabetic nephropathy, ARBs reduce macroproteinuria up to 28% and can revert microproteinuria to normal in 33% of patients (Figure 25-5).^{13,86,87} Long-term renoprotection with these agents substantially retards the progression of renal disease. Patients with diabetic nephropathy and >900 mg/dl protein per day receiving ARBs had a 20% reduction in the risk of composite endpoints (doubling of serum creatinine, developing ESRD, or death).^{13,86} The risk of doubling of the serum creatinine was 33% lower in the ARB arm than in the placebo group and 37% lower than in the amlodipine arm. These effects were independent of changes in blood pressure. Thus, strong clinical trial evidence indicates that ARBs are more effective than other drug classes in slowing the progression of kidney disease.^{11,96} Studies currently underway will assess whether very-high-dose ARBs and/or ARB/ACE inhibitor combinations will provide even more protection. Remarkably, analyses of the results of currently available trials have demonstrated for the first time that the reduction in proteinuria with ARBs correlates with a reduction in cardiovascular morbidity and mortality (Figure 25-6).^{97,98}

Like the ACE inhibitors, ARBs have multiple nonhemodynamic effects that may contribute to renoprotection. These include antiproliferative actions on the vasculature and

mesangium, inhibition of TGF- β ,^{95,99} inhibition of atherogenesis^{100,101} and vascular deterioration,¹⁰² reduced superoxide production and increased nitric oxide bioavailability,^{103,104} reduced collagen formation, reduced mesangial matrix production, improved vascular wall remodeling, decreased vasoconstrictor effects of endothelin-1, improved endothelial function,¹⁰³ reduced oxidative stress, and protection from calcineurin inhibitor injury. The clinical importance of these effects is currently under investigation.

An important consideration when using ACE inhibitors or ARBs is the potential for the development of hyperkalemia. This complication occurs in up to 10% of patients and is more common in diabetics and those with impaired renal function.¹⁰⁵ Serious hyperkalemia is found in only 1% to 2% of patients. Hyperkalemia often results from one or more of three disturbances that impair the excretion of potassium: decreased delivery of sodium to the distal nephron, aldosterone deficiency,

and abnormal functioning of the collecting duct.¹⁰⁶ These abnormalities can result from the effects of other drugs, from underlying disease, or from both. Management of hyperkalemia is outlined in Box 25-2.

β -Blockers

β -Adrenergic receptors in the kidney mediate vasodilation and increase renin secretion. β -Adrenergic blockers might be expected to influence renal blood flow and GFR through their effects on cardiac output and blood pressure in addition to their direct effects on intrarenal adrenergic receptors. β_2 Receptors predominate in the kidney; thus the specificity of a β -blocker will influence its effect on the kidney. Acute administration of β -blockers usually results in a reduction in GFR and effective RPF.¹⁰⁷ Chronic administration is associated with a 10% to 20% decrement in RPF and GFR.¹⁰⁸ This modest reduction in GFR is probably not of great clinical importance. In contrast to the effect with RAAS inhibitors, the reduction in GFR with β -blockers does not seem to correlate with the stabilization of renal function.¹⁰⁸

Renoprotective Effects of Calcium Antagonists

The potential benefits of CAs in acute and chronic kidney disease have been well described. There are multiple mechanisms whereby they alter or protect renal function, notably as natriuretics, vasodilators, and antiproteinuric agents. All CAs exert natriuretic and diuretic effects. Experimental and clinical studies in hypertension indicate that the increase in sodium excretion is, in part, independent of vasodilation or changes in GFR, renal blood flow, or filtration fraction.^{110,111} This effect likely is the result of changes in renal sodium handling that can potentiate the antihypertensive effects of CA on the vasculature. In normotensive subjects, CAs increase sodium excretion from 10% to 240%, often in the absence of changes in blood pressure.¹¹²

The natriuretic effect appears to persist long term. Chronic administration of CAs to hypertensive patients results in a

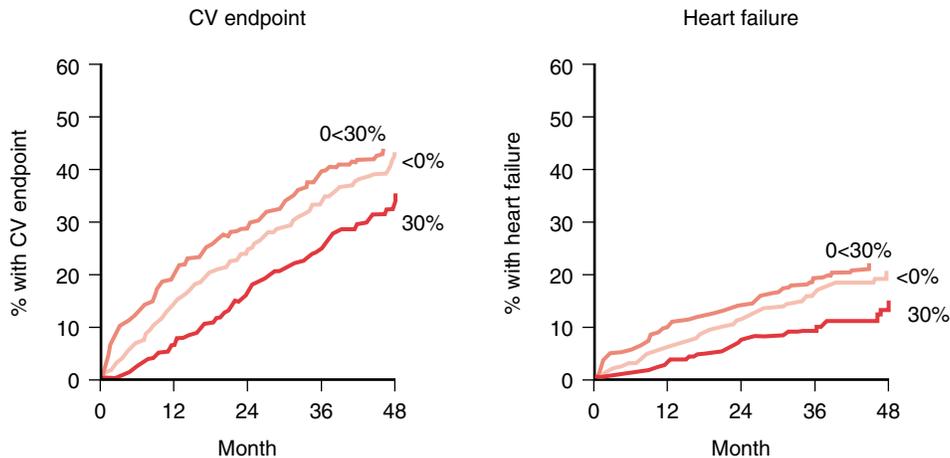

Figure 25-6 Kaplan-Meier curves for the cardiovascular and heart failure endpoints stratified by 6-month changes in albuminuria. Percent represents change from baseline proteinuria. (Adapted from de Zeeuw D, Remuzzi G, Parving HH, et al. Proteinuria, a target for renoprotection in patients with type 2 diabetic nephropathy: Lessons from RENAAL. *Kidney Int* 65:2309-2320, 2004.)

Box 25-2 Approach to Patients at Risk for Hyperkalemia Caused by Inhibitors of the Renin-Angiotensin System

Discontinue drugs that interfere with renal potassium excretion, such as nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors, and trimethoprim-sulfamethoxazole.

Inquire about the use of herbal preparations.

Prescribe low-potassium diet; inquire about the use of potassium-containing salt substitutes.

Prescribe thiazide or loop diuretics (loop diuretics are necessary when the creatinine clearance is less than 30 ml/min).

Consider prescribing sodium bicarbonate to correct metabolic acidosis.

Initiate therapy with low-dose ACE inhibitor or ARB.

Measure potassium 1 week after initiating therapy or changing doses.

If potassium increases to >5.5 mmol/L, decrease the dose of the drug; if the patient is taking a combination of ACE inhibitor and ARB, and/or aldosterone-receptor blocker, discontinue one and recheck potassium.

The dose of spironolactone should not exceed 25 mg when used in combination with ACE inhibitors or ARBs and should not be given at all when the creatinine clearance is less than 30 ml/min.

If potassium is consistently >5.5 mmol/L despite these steps, discontinue drugs.

Adapted from Palmer BF. Managing hyperkalemia caused by inhibitors of the renin-angiotensin-aldosterone system. *N Engl J Med* 351:585-592, 2004.

cumulative sodium deficit that is abruptly reversed with discontinuation of the drug.¹¹³ Natriuresis commonly occurs 3 to 6 hours after the morning dose^{114,115}; the net negative sodium balance plateaus after the first 2 to 3 days but persists throughout the duration of therapy. There are no significant changes in long-term body weight, potassium, urea nitrogen, catecholamines, or GFR.

Renal Hemodynamic Effects of Calcium Antagonists

The renal hemodynamic effects of CAs are variable and depend primarily on which vasoconstrictors modulate renal vascular tone.¹¹¹ Experimentally, CAs improve GFR in the presence of the vasoconstrictors norepinephrine, Ang II, and others by preferentially attenuating afferent arteriolar resistance.¹¹⁶ The efferent arteriole appears to be refractory to this vasodilatory effect. Patients with primary hypertension appear to be more sensitive to the renal hemodynamic effects of CAs than are normotensives, and these effects are more pronounced with advancing kidney disease.^{117,118} Acute administration of CAs results in little change, or augmentation of the GFR and RPF, no change in the filtration fraction, and reduction of renal vascular resistance. Chronic administration is not associated with significant changes in renal hemodynamics. The response is maximal in the presence of Ang II, which selectively causes postglomerular vasoconstriction. Clinically significant changes are counteracted by the reduction in renal perfusion pressure coincident with the reduction in blood pressure.

The long-term effects of CAs on renal function are controversial and variable. In hypertensive patients, the effects on renal hemodynamics vary. Some patients exhibit no change in GFR, whereas others have an exaggerated increase in GFR and RPF. Normotensive patients with a family history of hypertension also have exaggerated hemodynamic responses.¹¹⁹

Antiproteinuric Effects of Calcium Antagonists

The antiproteinuric effects of CAs are also controversial and variable with respect to the class of drug and the level of blood

pressure reduction achieved.^{120,121} Some dihydropyridines may increase protein excretion by up to 40%. It is not clear whether this is a result of vasodilation of the afferent arteriole, resulting in increased glomerular capillary pressure, because CAs directly impair renal autoregulation. Changes in glomerular basement membrane permeability or increased intrarenal Ang II may also play a role in the increased proteinuria associated with CAs.^{122,123} In contrast, felodipine, diltiazem, and verapamil do not appear to have a proteinuric effect and may lower protein excretion, possibly by decreasing efferent arteriolar tone and glomerular pressure. The clinical implications remain to be determined.

Large clinical trials underscore the controversy. In African Americans with hypertension and mild to moderate renal insufficiency and proteinuria >1 g/day, ACE inhibitor therapy was associated with a renoprotective effect, whereas the dihydropyridine CA amlodipine was associated with deteriorating renal function.¹²⁴ This effect was independent of blood pressure reduction and was more evident in proteinuric patients; it also occurred in patients with baseline proteinuria <300 mg/day. Hypertensive patients with diabetic nephropathy also fare worse with amlodipine therapy as compared with therapy with an ARB.⁸⁶ In one study, patients experienced higher rates of progression of renal disease in the amlodipine and placebo groups as compared with the ARB group. This effect was also independent of blood pressure levels achieved. There were no significant differences in cardiovascular death, myocardial infarction, or stroke between the treatment groups.¹²⁵ Coadministration of amlodipine with an ARB does not abrogate the renoprotective effect of the ARB.¹³ It is postulated that selective dilation of the afferent arteriole induced by CAs favors an increase in glomerular capillary pressure that accelerates renal disease progression.

Additional Renoprotective Effects

CAs possess many nonhemodynamic effects that may afford renoprotection. In addition to lowering blood pressure, they act as free radical scavengers; retard renal growth and kidney weight^{126,127}; reduce the entrapment of macromolecules in the mesangium¹²⁸; attenuate the mitogenic actions of platelet-derived growth factor and platelet-activating factor¹²⁷; block

mitochondrial overload of calcium¹²⁹; decrease lipid peroxidation; decrease glomerular basement membrane thickness; augment the antioxidant activities of superoxide dismutase, catalase, and glutathione peroxidase; inhibit metalloproteinase-1 and collagenolytic activity; suppress the expression of the angiogenic growth factors, vascular endothelial growth factor, β -fibrogenic growth factor, TGF- β , and endothelial nitric oxide synthetase¹³⁰; and prevent renal cortical remodeling and scarring^{131,132} (Box 25–3). The clinical implications of these findings remain speculative at present.

Diuretics

Although diuretics have a mechanism of action centered in the kidney, they have no specific renoprotective effect beyond blood pressure lowering. Moreover, thiazides, the recommended first-line agents in the treatment of uncomplicated hypertension, lose their efficacy in patients with CKD and an estimated GFR of <30 ml/min.¹³³ Thus thiazides are a much less important class of drugs for CKD patients. A loop diuretic is often needed to help control extracellular fluid volume and blood pressure in such patients, but no data suggest that loop diuretics improve cardiovascular or renal survival.

ADDITIONAL STRATEGIES TO DELAY RENAL DISEASE PROGRESSION

Treatment of Hyperlipidemia

Pharmacologic reduction of elevated lipids attenuates the progression of renal disease in experimental animals.¹³⁴ In humans the data are very limited but suggest that the reduction of lipids with drugs can slow the rate of progression of renal disease. For example, Bianchi et al. conducted a prospective, randomized, controlled trial to evaluate the effects of 1 year of treatment with atorvastatin versus no treatment on proteinuria and progression of renal disease in patients with CKD.¹³⁵ The authors concluded that treatment with atorvas-

tatin, added to standard therapy with a regimen of ACE inhibitors or ARBs, may reduce proteinuria and the rate of decline of renal function in patients with proteinuria, CKD, and hypercholesterolemia. Multiple small trials with agents that inhibit hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase have demonstrated similar findings. These agents reduce total cholesterol, LDL cholesterol, and apo B.^{136–138} In these trials, a reduction in proteinuria was achieved but no significant changes in the course of renal disease were noted. It has been suggested that the time course of the trials was not sufficient to detect such changes, because the antiproteinuric effects may not be manifest for up to a year.¹³⁹ A meta-analysis of the results of 13 clinical trials of antihyperlipidemic drugs on renal function showed a tendency toward renal preservation with lipid reduction.¹⁴⁰

Because CKD is considered a coronary heart disease equivalent, the NKF Task Force on Cardiovascular Disease recommends aggressive management of all risk factors in patients with CKD. The Kidney Foundation Kidney Disease Outcomes Quality Initiative developed guidelines for the management of dyslipidemias in CKD patients. The Working Group recommended that LDL cholesterol levels should be targeted to <100 mg/dl in patients with CKD.¹¹

Management of Anemia

Interstitial fibrosis plays a critical role in the progression of renal disease by reducing the ability of the kidney to synthesize erythropoietin. Consequently, anemia is perpetuated and the remaining functioning tissue, with a higher metabolic demand than normal, becomes more susceptible to ischemic injury and further fibrosis. Analyses of the biologic effects of erythropoietin and the pathophysiology of interstitial fibrosis suggest that treatment with recombinant human erythropoietin (epoetin) may slow the progression of CKD.¹⁴¹ Exogenous epoetin both decreases interstitial fibrosis and protects against its consequences (Figure 25–7). Clinical trial evidence supports this theory. In one trial, the investigators compared 20 patients with CKD who were treated with epoetin with 43 patients who had a similar degree of renal failure but who were less anemic and thus did not receive epoetin. The rate of decline of creatinine clearance did not change over time in the control group, whereas in the treated group, it was significantly slower after epoetin therapy had been started.¹⁴²

Box 25–3 Renal Protective Mechanisms of CAs

- ↓ Blood pressure
- ↓ Proteinuria
- Scavenge free radicals
- ↓ Kidney growth
- ↓ Mesangial molecule entrapment
- Attenuate antigenic PDGF and PAF
- Block mitochondrial calcium overload
- ↓ Lipid peroxidation
- ↓ Glomerular basement membrane thickness
- Augment antioxidant effects of superoxide dismutase/catalase and glutathione peroxidase
- Inhibit collagenolytic activity
- Suppress angiogenic growth factors
- Prevent renal cortical remodeling
- Ameliorate cyclosporine A toxicity
- Block thromboxane- and endothelin-induced vasoconstriction

PDGF, platelet-derived growth factor; PAF, platelet-activated factor.

SUMMARY

The importance of recognizing early kidney disease is now becoming evident in clinical practice. Major advances have allowed us to better understand renal disease progression, and the last decade has been marked by important discoveries that can slow the rate of decline in renal function. Although several dietary and lifestyle changes may help, by far the most important strategies to delay renal disease progression include strict blood pressure control and inhibition of the RAAS.

Because the reduction of proteinuria predicts long-term renal and cardiovascular protection, proteinuria cannot be overlooked. Proteinuria is not only a determinant of renal risk but also of the benefit that can be attained by pharmacologic intervention. Promising trials are now underway to assess the effects of high-dose RAAS inhibition. In the future we may be

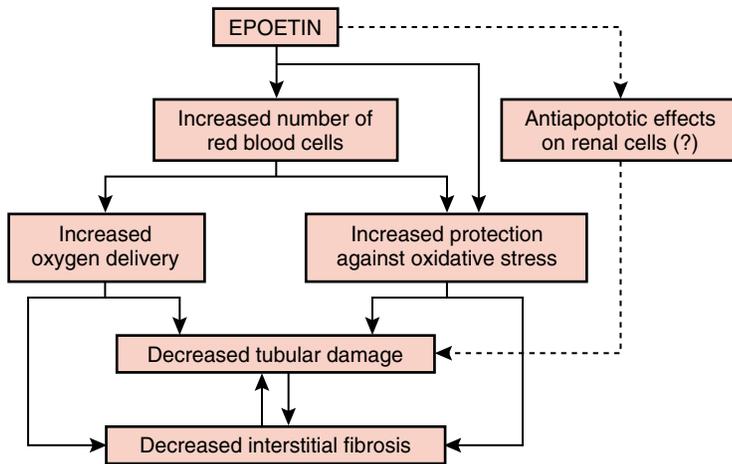

Figure 25-7 Schematic representation of the potential beneficial effects of epoetin treatment. (Adapted from Rossert J, Fouqueray B, Boffa JJ. Anemia management and the delay of chronic renal failure progression. *J Am Soc Nephrol* 14:S173-S177, 2003.)

titrating the dose of RAAS inhibitors to the degree of proteinuria rather than to blood pressure. For the present, any potential intervention that may benefit a patient with early nephropathy should be started.

Diagnosis

Chapter 26

Initial Evaluation and Follow-Up Assessment

Lawrence R. Krakoff

High arterial pressure, hypertension, is a highly prevalent disorder of the adult population in the United States and other nations with “Western” cultures. Hypertension is one of the most common reasons for a patient to visit a physician’s office or clinic. The initial evaluation or work-up for hypertension and its follow-up assessment is quite different from that for acute disease processes. For those disorders with sudden onset, the initial evaluation or work-up is often considered as a definitive assessment that reveals the likely cause, needed diagnostic tests, and appropriate treatment. After the acute disease is successfully treated, follow-up in the clinics may not be needed or may be limited to a few visits.

The initial assessment of hypertensive patients differs from the evaluation for acute illnesses in large part because the diagnostic focus is less on finding a cause (secondary hypertension) than on determining the overall risk status of the patient. Staging comes first, and cause a distant second. Furthermore, the management of hypertensive patients takes place over an extended period of time, many years or decades. During this long interval, many changes can be anticipated as the patient’s status becomes the result of treatment, evolution of related or unrelated disease states, and aging. Hence, periodic reevaluation of hypertensive patients is a necessary part of their management.

In the past few years there has been increasing recognition that in adults, and to some extent in adolescents and children as well, high blood pressure (BP) occurs in many individuals who have other predictors and risk factors for future cardiovascular disease. Smoking, overweight, abnormal serum lipid patterns, and diabetes mellitus (usually type 2) in varying combinations, often accompany hypertension. In addition, hypertensive individuals often have target organ damage (TOD) that has already led to symptoms or impairment, but also predicts likelihood of additional disease in the future. The absolute risk of future cardiovascular disease is then a composite of reversible risk factors and target organ pathology involving the heart, brain, kidneys, and arteries. Aging adds irreversibly and inexorably to the absolute risk of cardiovascular disease. Figure 26–1 is a schematic to summarize these complex relationships. The diagnostic process must combine reasonable completeness, efficiency, and practicality for the limited time and resources available to busy clinicians. This will be the guiding approach summarized in this chapter.

WHEN IS HYPERTENSION PRESENT?

Arterial Pressure and Risk

The risk of future cardiovascular disease increases in a direct and somewhat linear relationship to systolic and diastolic arterial pressure.¹ For systolic blood pressure (SBP), this relationship continues into older age groups.^{2,3} The relationship between diastolic blood pressure (DBP) and risk of cardiovascular disease in older groups is more complex because the pulse pressure (systolic-diastolic pressure) assumes more importance.⁴ In those older than 50 years of age, for equally high SBPs, a lower DBP (wider pulse pressure) confers a worse prognosis.^{5,6} In a similar manner, the risk of future end-stage renal disease (ESRD) increases significantly when BP is only minimally elevated above the normal range, but increases steeply when the pressure is very high.⁷

For practical diagnostic purposes, ranges of BP were grouped into “high-normal pressure” and stages 1 to 3, in the Sixth Report of the Joint National Committee on Detection, Prevention, and Treatment of Hypertension (JNC VI)⁸ and generally accepted by international guidelines.⁹ The most recent guideline from the United States, the Seventh Report of the Joint National Committee on Prevention, Detection, and Treatment of High Blood Pressure (JNC 7) adds a new term, “prehypertension,” referring to those who have BPs above 120/80 mm Hg and below 140/90 mm Hg.¹⁰ The rationale for this classification is based on the very high lifetime risk of hypertension found in the Framingham Heart Study for those with pressures above the ideal level for minimum risk.¹¹ Whether prehypertension, as a diagnosis, is a helpful tool for getting those younger patients to adopt a better lifestyle and prevent hypertension¹² is uncertain. A modified version of the BP classification is given in Table 26–1 as a basis for considering levels of BP in relation to diagnosis and treatment.

Some have suggested that the minute-to-minute *variability* in arterial BP also contributes to disease, in addition to average levels. A cross-sectional study of intraarterial pressures suggested that excessive variation in pressure is correlated with TOD.¹³ However, as a predictor of future disease in prospective studies and a basis for treatment, variability per se, has yet to be shown as an independent risk factor when adjusted for other factors.¹⁴

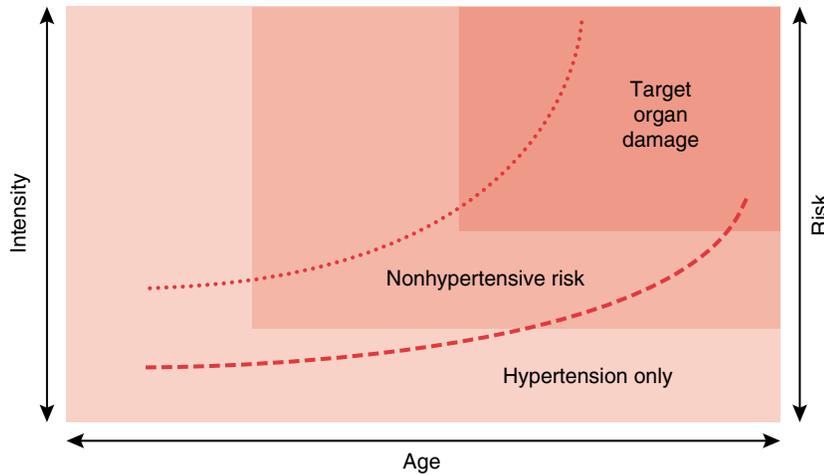

Figure 26-1 A schematic representation for assessing absolute risk of future cardiovascular disease in hypertensive patients. Likelihood of a fatal or nonfatal stroke or myocardial infarction is related to age, the “intensity” of each risk factor (e.g., level of BP or of low-density lipoprotein cholesterol), and absence or presence of target organ damage (TOD) (e.g., left ventricular hypertrophy). The dashed lines indicate that for any combination of risk factors and TOD, age will increase the risk.

Accurate Measurement, Errors, and Bias

Accurate measurement of BP is clearly needed for correct diagnostic classification. When arterial pressure is either well in the normal range (SBP <130 mm Hg and DBP <80 mm Hg) or markedly elevated (SBP >180 mm Hg and DBP >110 mm Hg), even a somewhat inaccurate method of BP measurement will approximate the true average, so the likelihood of a false-positive

or false-negative diagnosis of hypertension is very small.¹⁵ However, many have average or usual pressures that fall in the ranges of 130 to 160 mm Hg for SBP and 80 to 105 mm Hg for DBP. BPs measured by the ordinary clinical method (stethoscope and cuff with either a mercury or aneroid manometer) may be inaccurate or misrepresentative. This can lead to a misclassification that is even more likely when the average pressures are close to one of the dividing points for diagnosis (i.e., high-normal pressure versus JNC VI stage 1).^{15,16} Attention needs to be paid to (1) correct cuff size for the patient, (2) accuracy of the manometer, (3) training and reliability of the observer,¹⁷ and (4) sufficient number of measurements for a reasonable approximation of the average pressure.¹⁵

Table 26-1 Recommended Evaluation and Initial Management for Various Blood Pressure (BP) Levels Found at Initial Clinic Measurement of Asymptomatic Adult Subjects*

BP Levels	Recommended Treatment
Systolic ≥ 220 mm Hg or Diastolic ≥ 115 mm Hg	Rapid evaluation by comprehensive history, physical examination and laboratory tests. Start treatment within 24 hours.
Systolic ≥ 180 mm Hg or Diastolic ≥ 105 mm Hg	Comprehensive evaluation within 1 week. Begin treatment if BP remains at this level.
Systolic ≥ 160 mm Hg or Diastolic ≥ 100 mm Hg	Comprehensive evaluation within 2-4 weeks. Treatment decision depends on overall status.
Systolic 140-159 mm Hg or Diastolic 90-99 mm Hg	Comprehensive evaluation within 1 month. Initiate lifestyle changes. Ordinarily withhold drug treatment for 1-6 months. Supplemental pressure, ambulatory monitoring, or self-measurement may be helpful.
Systolic >120 mm Hg or Diastolic >80 mm Hg	Prehypertension suggesting that hypertension may develop in the future (years). Provide advice regarding diet, exercise, salt intake. Reassess yearly.

*For symptoms or abnormal findings on physical examination, individual decisions are more appropriate. The BP levels approximately correspond to stages 1 to 3 of the JNC VI report,⁸ with the additional classification of “prehypertension” added in the JNC 7 report.¹⁰

Supplemental Pressures

BP measurements obtained outside of the clinic may be helpful to arriving at average pressure and have important prognostic value. The use of either ambulatory BP monitoring¹⁸ or home BPs¹⁹ has gained recognition in this regard. Such measurements may reveal “white-coat hypertension” in which BP elevation is limited to the clinic or office, or its opposite state, in which clinic pressures are lower than average daily pressures.^{20,21} These topics are discussed in Chapters 27 and 28.

NONHYPERTENSIVE RISK FACTORS

Definitions

Hypertension is an unequivocal risk factor for cardiovascular mortality and morbidity. Before clinical trials established the benefit of lowering BP, the term *risk factor* was limited to mean a measurable trait that predicts future disease and is presumed to play a causal role for future pathology. Now that clinical trials have established the effectiveness of antihypertensive therapy, the term *risk factor* includes the implication that reduction of pressure confers benefit. Thus, a cardiovascular risk factor predicts disease, is a cause of pathology, and can be reduced by a treatment that prevents disease.

Some hypertensive patients have no other risk factors to worsen their prognosis. Many, however, have the combination of high BP and other, independent predictors and causes of stroke, coronary heart disease (CHD), and/or renal insuffi-

Table 26–2 Nonhypertensive Risk Factors to be Assessed in the Work-up of Hypertensive Patients

Major Risk Factors	Comment
Smoking status	Cessation of smoking reduces risk of CHD within 2 years by 50%. Stroke and peripheral vascular disease can be prevented.
Diabetes mellitus	More likely in hypertensive groups. Invariably increases risk. Can be treated.
Serum lipid–lipoprotein levels	The benefit of reducing high LDL concentrations is firmly established. Correction of high triglyceride level and low HDL status is likely to be beneficial.
Overweight and increased waist:hip ratio	Overweight and obesity are clearly related to cardiovascular disease. Weight reduction lowers BP and other risk factors.
Excess alcohol use	Clearly associated with increased pressure and likelihood of disease. Low alcohol use may be beneficial.
Reduced aerobic exercise	Evidence supports the value of regular exercise for preventing cardiovascular disease.

CHD, coronary heart disease; LDL, low-density lipoprotein.

ciency. Table 26–2 lists those risk factors that are have strong epidemiologic association with cardiovascular disease. These risk factors are reversible and should be taken into consideration during the initial and continuing evaluation and management of *every* hypertensive patient. A brief review of each of these risk factors now follows.

Smoking

A history of current or recent cigarette smoking nearly doubles risk of stroke and CHD and is well correlated with likelihood of peripheral arterial disease. Furthermore, smoking is related to the occurrence of malignant hypertension.^{22,23} Those who stop smoking can rapidly reduce risk of CHD within a few years.²⁴ Ongoing counseling during follow-up visits may reduce smoking behavior, as demonstrated in the Multiple Risk Factor Invention Trial (MRFIT).²⁵ More recently, pharmacologic options have become available (e.g., nicotine chewing gum, nicotine transcutaneous patches, clonidine, and bupropion). These strategies, together with aggressive public education programs, may achieve a sustained elimination of smoking behavior and thus reduce long-term risk of stroke, CHD, and peripheral vascular disease.

Lipids and Lipoproteins

Many serum lipoprotein patterns have been associated with altered cardiovascular risk and the list of possible candidates is increasing. Increased low-density lipoprotein (LDL) cholesterol or reduced high-density lipoprotein (HDL) cholesterol are well-accepted predictors. The metabolic syndrome, associated with insulin resistance, low HDL cholesterol, and elevated serum triglyceride concentration, appears to be a predictor of CHD.

Randomized placebo-controlled clinical trials carried out in persons with a high risk of future CHD have demonstrated that reduction of serum cholesterol by statin therapy is effective in the presence or absence of hypertension.^{26–28} Statin therapy is effective in preventing coronary events even when baseline cholesterol levels are “normal” (i.e., LDL cholesterol ≤ 100 mg/dl [or ≤ 2.7 mM/L] or total cholesterol ≤ 207 mg/dl [or ≤ 5.6 mM/L]). For those at high risk due to low HDL levels, fibrate therapy

with gemfibrozil may be effective, at least for those with prior CHD.²⁹ Other fibrates have not been studied in outcome trials.

Diabetes, Glucose, and Insulin Resistance

Every hypertensive patient should be assessed for diabetes when first seen and during follow-up. Hypertensives are twice as likely to develop new type 2 diabetes compared with normotensives.³⁰ The importance of overt diabetes, high-normal fasting glucose, or glucose intolerance as adding to potentially reversible risk within the hypertensive population and even in those with high-normal pressure cannot be overemphasized.³¹

Within the hypertensive population, a fraction have normal fasting glucose and glucose tolerance, but the syndrome of insulin resistance (the metabolic syndrome).^{32,33} It is not yet certain that this syndrome, apart from its frequent correlates of obesity and altered serum lipoprotein pattern, confers independent risk. Furthermore, insulin resistance is not easily defined outside of research settings. For a more extensive discussion of insulin resistance in essential hypertension, see Chapter 13.

For ordinary clinical purposes, the fasting serum glucose is all that is needed to define the metabolic state of most patients. However, new definitions of both diabetes and the borderline state of impaired fasting glucose have been reached through an evidence-based process and the consensus of experts and should be used to classify hypertensive patients.³⁴ The diagnosis of diabetes is based on an *average fasting glucose* (two or more separate measurements) of >125 mg/dl (or ≥ 7 mM/L). When the average falls between 100 and 126 mg/dl, impaired fasting glucose is the correct label; such patients should be reevaluated at 1- to 2-year intervals for possible conversion to type 2 diabetes.

If a patient is known to have had either insulin-dependent or non-insulin-dependent diabetes for several years, additional evaluation for complications of the diabetic state including the presence of retinopathy, neuropathy, nephropathy, and evidence of peripheral macrovascular and microvascular disease (i.e., foot ulcers) needs to be undertaken.

Weight, Build, and Overweight

Measurement of weight and height are, or should be, part of the initial assessment of all patients. At a glance, one can tell

if the body build is slim, muscular, mildly overweight, obese, or morbidly obese. It is useful, however, to have a single and simple calculation that gives a numerical counterpart to the clinical impression. The calculated body mass index (BMI) is widely used in clinical studies to convey body build that relates weight to height. The calculation for BMI is weight (kg)/height in meters squared (m^2) or kg/m^2 . For those measuring height in inches and weight in pounds, the formula for BMI, equivalent to using metric units, with a correction factor is $705 \times \text{weight (lbs)}/\text{height in inches}^2$. Generally, desirable BMI is ≤ 25 , mild overweight is 25 to 29, and definite overweight is ≥ 30 or $\geq 20\%$ above desirable weight.

Weight distribution may also predict future cardiovascular disease and the likelihood of hypertension or the tendency to non-insulin-dependent diabetes mellitus (NIDDM). The “apple” shape is relatively incriminated, while the “pear” shape is less so. These adjectives are reflected in a simple measurement, the waist:hip ratio, normally well below 0.9. As the ratio increases in overweight patients, the body build is more of the “apple” or high-risk type.³⁵

Overweight hypertensives may be considered to have a reversible disorder, whose correction (i.e., weight loss) may not only lower their BP, but improve overall risk status (elevated serum LDL cholesterol, impaired glucose metabolism, or NIDDM) as well. National trends suggest that overweight is relentlessly increasing in the United States.³⁶

Exercise Pattern—Fitness

A pattern of regular exercise may lower BP by 4 to 5 mm Hg,³⁷ even reduce left ventricular hypertrophy (LVH)³⁸ and contribute to prevention of future cardiovascular disease.³⁹⁻⁴¹ As part of the initial evaluation, assessment of exercise is advisable along with encouragement to maintain or increase daily physical activity for its benefit.

Alcohol Use or Over Use

Appraisal of day-to-day ingestion of alcoholic beverages should be part of the initial and recurring assessment of hypertensive patients for several reasons. Low-level alcohol intake may be a preventive measure for future cardiovascular disease⁴² and can be encouraged if there is no evidence of harm.⁴³ However, sustained high alcohol intake may contribute to both hypertension and cardiovascular disease,⁴⁴ whereas reduction of high alcohol ingestion may lower BP and even prevent the onset of hypertension.⁴⁵⁻⁴⁷ Those hypertensive patients who continue high alcohol use may be difficult to control because of poor compliance with antihypertensive therapy.

Other Potential Risk Factors

Renin as a Risk Factor and Renin Profiling

The renin-angiotensin-aldosterone system participates in control of arterial pressure and fluid-volume balance. This system can be assessed with widely available clinical measurements. Classification of hypertensive patients into low, normal, and high renin subgroups has prognostic significance in that the low renin subgroup tends to have less CHD, both in an observational study⁴⁸ and a prospective cohort analysis,⁴⁹ in contrast to higher rates of CHD in normal and high renin

groups. Renin profiling may predict response to antihypertensive drug treatment and add useful information for detection of secondary hypertension, especially renal artery stenosis and primary aldosteronism.

As an indirect assessment, an unusually good response to treatment with either an angiotension-converting enzyme inhibitor or angiotensin type 1 receptor blocker (drugs that specifically block the renin-angiotensin system) implies an overactive renin system. In contrast, the lack of any BP response to either of these drug classes suggests a low renin state, as occurs in primary aldosteronism. The sensitivity and specificity of clinical responses to these drugs are, however, not defined.

The use of renin profiling has not become a widespread approach for initial assessment, unless secondary hypertension is suspected. However, renin profiling may have a role for those patients who are resistant to treatment with two to three drugs. Recent studies report high detection rates of primary aldosteronism in patients with refractory hypertension,^{50,51} and the addition of spironolactone or other mineralocorticoid receptor antagonists may be effective in this setting.^{52,53}

Homocysteine and C-Reactive Protein

New candidates as predictors or possible participating causes of cardiovascular disease are often reported. The level of serum homocysteine has been correlated with stroke⁵⁴ and CHD.⁵⁵ Homocysteine levels are partly related to the availability and normal metabolism of folic acid and vitamin B₁₂ via methylation pathways.⁵⁶ An adequate dietary supply of folic acid is needed to minimize homocysteine concentration. Supplementing the diet with folic acid may reduce homocysteine and is potentially beneficial for prevention of cardiovascular disease.⁵⁷

The plasma level of C-reactive protein (CRP), a manifestation of inflammation, is another candidate risk factor for stroke, CHD, and peripheral arterial disease.⁵⁸ It has been suggested that the atherosclerotic process includes a low-grade inflammation, which can elevate CRP.^{59,60} Thus an elevated CRP might be viewed as reflecting TOD, rather than being a candidate risk factor. The overall effect of aspirin in reducing risk of CHD⁶¹ might then include an antiinflammatory effect (on atherogenesis) in addition to an antithrombotic action. It has also been suggested the benefit of statin therapy in preventing CHD is partly mediated by an antiinflammatory effect related to CRP levels. Whether measurement of CRP levels adds enough information to be useful as a screening procedure remains controversial.⁶²

TARGET ORGAN DAMAGE

Treatment of hypertension prevents the development of cardiac, renal, and vascular pathology, (i.e., TOD). Nonetheless, many patients have evidence for TOD when seen initially or during follow-up. Detection of TOD in hypertensive patients is a crucial and necessary diagnostic requirement for initial evaluation and subsequent interval reassessments. Presence of TOD adds to risk of future cardiovascular disease and mortality. Furthermore, treatment may reverse TOD (e.g., regress LVH) or delay progression (e.g., reduce decline in renal function). Both the medical history and pertinent physical examination are clearly useful to detect some forms of TOD. Relevant and cost-effective testing is needed for improving precision in many instances.

Table 26–3 lists the major sites of TOD to be surveyed, how these are to be assessed in the initial medical history and physical examination, and the most often used tests or imaging procedures for confirmation.

INITIAL ASSESSMENT OF HYPERTENSIVE PATIENTS

Hypertension is usually first considered during periodic check-up visits or as part of ordinary screening when patients are seen for unrelated minor illnesses. Hypertension, presenting as an emergency, is rare and will require hospitalization and immediate treatment (see Chapter 78).

Most hypertensives will be managed at clinic or office visits. The initial evaluation should consist of a careful medical history, appropriately comprehensive physical examination, and *necessary* tests. For adult hypertensive patients, the tests that I include, as a minimum, are as follows:

1. Electrocardiogram: Is there evidence for left ventricular enlargement or ischemic disease?
2. Fasting glucose, serum creatinine, and electrolytes (Na^+ , K^+ , Cl^- , HCO_3^-) to assess for diabetes, hypokalemia, and renal function.
3. Serum lipid profile: HDL and LDL cholesterol fractions and triglyceride concentration.
4. Urinalysis: Is proteinuria or an abnormal sediment present?

Once this information is available, the issues addressed in Table 26–4 should be dealt with. The first row of Table 26–4 indicates that the initial assessment should provide the overall absolute cardiovascular risk of each patient, as portrayed in Figure 26–2. Additional tests may be needed to define TOD (see Table 26–3). The second row of Table 26–4 places emphasis on those features derived from the medical history that are often overlooked in overviews and guidelines for patient management and yet are crucial in establishing strategy for long-term management of hypertensive patients. The individual patient's ordinary activities, socioeconomic status, ability to understand his or her risk, comprehension of what may be a complex medical regimen, and support systems are pertinent to management. Will this patient be compliant with medication, and reliable about follow-up visits and reporting symptoms? What financial burdens can he or she deal with for tests and medications? Accurate assessment of these issues may determine whether a patient can be expected to change lifestyle or take medication regularly. The third row of Table 26–4 states that the initial work-up will lead to a plan that will include recommendations for treatment and for appropriate follow-up evaluations, which will be covered in the upcoming sections.

The fourth row in Table 26–4 indicates that an estimate of the likelihood of secondary hypertension should be made. Many forms of secondary hypertension can be detected through a careful history and physical examination. Table 26–5 provides a guide to these disorders and also indicates the

Table 26–3 Assessment of Target Organ Damage (TOD) to be Suspected in Hypertensive Patients with or without Other Risk Factors

Site/Pathology	Detection by History and Examination	Pertinent Additional Tests
Retina: arteriolar thickening, hemorrhage, exudates, papilledema	Ophthalmoscopy	Fluorescein angiography, <i>rarely needed</i>
Carotid artery stenosis	Auscultation for bruits	Carotid ultrasound assessment*
LVH; diastolic and systolic dysfunction	History of dyspnea, fatigue; examination for S_4 , increased S_2 , cardiac enlargement—left ventricular heave	ECG; echocardiogram for selected cases
Coronary artery disease	History of angina, or previous myocardial infarction	ECG, stress tests*
Cerebrovascular disease	History of stroke or transient ischemic attack, screening neurologic examination	Carotid ultrasound assessment*; additional imaging with CT scan or MRI sometimes appropriate
Renal pathology	History of renal disease or diabetes >5 years, unexplained edema	Urinalysis for protein, abnormal sediment; spot urine for microalbumin; albumin: creatinine ratio; calculated creatinine clearance as estimate of glomerular filtration rate
Abdominal aortic aneurysm	History of abdominal mass or discomfort, detection of pulsatile mass on physical examination	Ultrasound of abdomen, * CT scan, MRI, MRA
Peripheral arterial stenosis	History of claudication, reduced pulses on physical examination	Measurement of arm and calf pressures for ankle/arm index*

*Indicated as initial test when history or physical examination reveals positive findings.

LVH, left ventricular hypertrophy; S_4 , fourth heart sound; S_2 , second heart sound; ECG, electrocardiogram; CT, computed tomography; MRI, magnetic resonance imaging; MRA, magnetic resonance angiography.

Table 26-4 Information to be Derived from Initial Assessment of Hypertensive Patients

Assessment	Information Derived
Overall risk status of future cardiovascular disease	Composite of: Average blood pressure level Nonhypertensive risk factors Target organ damage
Assessment for management strategy	Potential for education, change in lifestyle, compliance with medication
Plan for treatment and follow-up	Choice of lifestyle change and/or medication; schedule for follow-up, rescreening
Likelihood of secondary hypertension	Clues provided by history, physical examination, and initial laboratory tests

need for appropriate laboratory assessment as initial screening strategy. Characteristics of many diagnostic tests frequently used to detect secondary hypertension have been calculated with regard to sensitivity, specificity, and predictive value.⁶³ When secondary hypertension is considered likely, on clinical grounds, combinations of tests used judiciously may provide the greatest accuracy.^{63,64}

INITIAL MANAGEMENT

After evaluating hypertensive patients, decisions will be made regarding goals for treatment and strategies for achieving these goals. In general, some combination of lifestyle change and drug therapy will be recommended. When the pressure is higher, drug treatment will be started immediately. For those

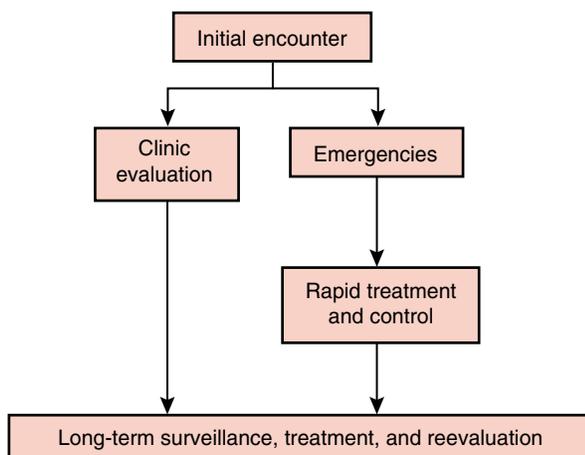

Figure 26-2 A simplified flow diagram for management of hypertensive patients, after their initial detection. The few hypertensive emergencies will be rapidly evaluated and treated. Most patients will be evaluated entirely in clinic or office settings. All should be kept under observation with reevaluation, adjustment in treatment, and appropriate diagnostic assessment for as long as possible.

with pressures in the range of 140 to 150 mm Hg/90 to 100 mm Hg, without TOD, initial nonpharmacologic choices, particularly weight reduction, with or without reduced salt intake may be appropriate. Diets that have high fruit, vegetable, and low-fat dairy product content with low-salt intake such as the Dietary Approaches to Stop Hypertension (DASH)-sodium diet can be recommended as an effective lifestyle change.^{65,66} When smoking, increased LDL cholesterol, or diabetes is found, attention to these may be as important as BP reduction.

Apart from the general advice given in guidelines or consensus documents, there is surprisingly little information in the medical literature about specific strategies for getting each patient to the goal of a reduced overall risk of future cardiovascular disease. The patient's ability to understand and comply with treatment needs attention, as well as his or her various personal, social, and economic characteristics. In setting a plan for management, the time frame for achieving specific goals needs to be discussed with the patient. Trying to do too much in too short a time often leads to frustration and less optimal compliance, compared with a gradual introduction of one intervention at a time over several visits, spaced out over several months.

REEVALUATION AND FOLLOW-UP

After the initial work-up, management of hypertension and cardiovascular risk ought to become a long-term partnership between doctor and patient so that periodic surveillance and reassessment are coupled with continuing motivation and education. The success of randomized clinical trials in demonstrating the efficacy of antihypertensive drug therapy and cholesterol reduction has depended on recruiting and maintaining a high fraction of patients on treatment who are willing to remain enrolled under observation. Whether the same degree of compliance and adherence can be achieved in ordinary clinical settings remains a challenge.

Most patients with well-controlled BP after 6 to 9 months of treatment remain stable for long periods and, in my view can be seen every 6 months thereafter. Even this frequency may be too demanding for many patients who work or have family responsibilities and are free of symptoms, unless a highly convenient medical care system is available. Adjunct resources such as work-site clinics may be helpful.⁶⁷ Self-measurement of BPs at home has the potential for reducing need for office or clinic visits⁶⁸ and may improve control of hypertension.⁶⁹

When hypertension remains uncontrolled despite appropriate multidrug treatment, the terms *refractory hypertension* or *resistant hypertension* apply. Some of these patients have normal pressures by ambulatory BP monitoring⁷⁰⁻⁷² or home monitoring¹⁹ because of a large white-coat effect. Many of those with refractory hypertension probably have reduced adherence to medication and need additional education and counseling to improve use of medication.⁷³ Other considerations should include underdosing of partially effective medications (especially in very obese patients), ineffective drug combinations, use of steroids or nonsteroidal antiinflammatory drugs that may raise pressure, and secondary hypertension (see following paragraphs).

My own suggestions for follow-up evaluations are given in Table 26-6. There are, however, many exceptions or intercurrent changes that warrant highly individual choices. Even when

Table 26-5 Initial Assessment for Secondary Hypertension—Some Examples of More Well-known Forms

Specific Disease	Findings by History and Physical Examination	Usual Screening or Initial Tests
Coarctation of the aorta	Decreased pulsation and pressure in legs, interscapular bruit	Chest radiograph for abnormal aortic contour, chest CT or MRI
Cushing's syndrome	Obesity, "moon" face, "buffalo hump" of cervical fat pad, acne, bruises, purple abdominal striae	24-hour free cortisol and overnight dexamethasone suppression test
Primary aldosteronism, other forms of mineralocorticoid excess	Normal appearance, vague symptoms, fatigue, weakness, rarely tetany	Serum electrolytes, plasma renin, serum or urine aldosterone; measure other mineralocorticoids for rare conditions
Renal artery stenosis	Subcostal bruit, signs of widespread atherosclerotic arterial disease	High renin profile, positive captopril test, duplex Doppler study of renal arteries, MRA of renal arteries
Polycystic kidney disease	History of familial hypertension and renal disease, palpable flank masses	Ultrasound of kidneys
Chronic renal disease	History of abnormal urinalysis, known connective tissues disease (e.g., lupus erythematosus), edema, hematuria, recurrent urinary tract infections or stones	Complete urinalysis; creatinine clearance, urinary protein, appropriate serologic studies
Pheochromocytoma	Highly variable pressure, symptoms of paroxysmal palpitations, anxiety, sweating, headache, constipation or diarrhea, weight loss, family history of endocrine disease or "birthmark" diseases	24-hour urine metanephrine excretion or serum metanephrines; CT scan for detection of tumor
Drug reactions: diet pill overdose, cocaine use, ephedra, other drugs, or alcohol withdrawal	Often abrupt increase in blood pressure with headaches, <i>accurate history is crucial</i> , including <i>recent use</i> of any drugs	Chemical screens for amphetamines, cocaine, alcohol, other drugs
Obstructive sleep apnea	History of snoring or abnormal breathing during sleep, daytime somnolence	Overnight sleep study with O ₂ saturation (somnography)
Hyperthyroidism*	Typical symptoms, tachycardia or atrial fibrillation, wide pulse pressure with normal-low diastolic pressure	Serum TSH with "reflex" test for free thyroxine level
Hypothyroidism*	Typical symptoms, bradycardia, increase in systolic pressure	Serum TSH with "reflex" test for free thyroxine level
Hyperparathyroidism*	Compatible symptoms: renal stones, osteoporosis, intestinal disorders	Serum calcium level, followed by appropriate studies for parathyroid hormone excess

CT, computed tomography; MRI, magnetic resonance imaging; MRA, magnetic resonance angiography; TSH, thyroid-stimulating hormone.

*Whether disorders of thyroid or parathyroid function are specific causes of hypertension remains uncertain. Because hypertension is highly prevalent, these disorders may appear by chance, but patients should be fully evaluated when these disorders are suspected.

hypertension and other risk factors are well controlled over long periods of observation, hypertensive patients remain likely to have cerebrovascular and cardiovascular disease.⁷⁴ Thus clinicians should be aware that the syndromes of cerebrovascular disease or CHD are ever in the background despite effective therapy. This implies that screening tests for arterial disease, particularly cardiac stress tests and ultrasound interrogations of the carotid artery and the abdominal aorta may have value for hypertensives treated for many years, espe-

cially if they are older (>55 years) or have wide pulse pressures or any prior cardiovascular disease. Men older than age 65 may benefit from screening by ultrasound for abdominal aortic aneurysms.⁷⁵ This strategy is not cost-effective for women.⁷⁶

Secondary hypertension may occur, on occasion, in those with essential hypertension during their course of prolonged management. Atherosclerotic renal artery stenosis may develop when there are multiple risk factors for atherosclerosis or carotid or peripheral artery disease. Development of renal

Table 26-6 Suggested Follow-up Assessment for Hypertensive Patients, Based on Level of Absolute Risk and Response to Treatment*

Measurement or Procedure	Comment
Weight	Every visit
Sitting BP	Every visit
Standing BP	Initial visit, if patient dizzy, if tendency to orthostatic hypotension known or suspected; older patients
Listen for carotid bruit, cardiac examination, peripheral vascular assessment	1-2 years, unless new symptoms or abnormalities present in past
For nondiabetic patients: fasting glucose, lipid profile	For stable patients without abnormalities at baseline, every 2 years For overweight patients, or unusual change in weight, recheck glucose and lipids more often
Patients with drug-treated hyperlipidemia	Monitor serum lipids every 6-12 months
Diabetic patients	Glucose, HgbA _{1c} , serum lipids initially as often as necessary for optimal management; once stable, every 6-12 months; check for microalbuminuria annually after 5 years
ECG	Every 2 years unless new symptoms or known abnormalities at baseline
Renal function: creatinine, urine for microalbumin, electrolytes	Every 1-2 years, unless abnormal at baseline or high-dose diuretics prescribed
Echocardiography, cardiac stress test, creatinine clearance	Only for change in status from baseline suspected by new symptoms
Work-up for secondary hypertension	New symptoms, hypokalemia, impaired renal function; consider for some patients with refractory hypertension

*The suggestions are based on several current guidelines and clinical experience, but individual patients may require different kinds of ongoing assessment.
BP, blood pressure; ECG, electrocardiogram.

insufficiency in elderly patients who used to be hypertensive, but now have congestive heart failure with lower arterial pressure, should raise the suspicion of renal arterial disease and ischemic nephropathy.^{77,78}

Refractory hypertension might also raise the question of underlying disease. In addition to renal artery stenosis, hypothyroidism should be considered and is easily detected by measuring thyroid-stimulating hormone (TSH). Primary aldosteronism has recently been reported as a more common cause of drug-resistant hypertension.^{50,51}

Each follow-up visit of a hypertensive patient is not only a reevaluation of medical status, but can be viewed as an opportunity to maintain or enhance the goals of optimal preventive care. Brief and focused emphasis on reinforcing positive changes in lifestyle, education about risk and value of compliance with treatment may contribute to the patient's overall commitment to staying on treatment. The message to be conveyed is that such periodic evaluations are part of the long-range plan for reducing the odds of cardiovascular disease through an effective partnership between doctor and patient.

SUMMARY

The initial and follow-up evaluations of hypertensive patients are, taken together, a complex scheme for preventing or reversing cardiovascular and renal disease over time intervals from

years to decades. The tools available to clinicians for work-up now include a wide spectrum from the most basic skills (the medical history and physical examination) to sophisticated imaging techniques and biochemical assays. It is now possible with reasonable cost and efficiency to predict absolute risk of future cardiovascular disease with far greater precision when many risk factors are taken together, and not rely on BP alone. Such a strategy then can lead to more rational therapy focused on reversible risk factors and pathology, as revealed from clinical trials. Secondary hypertension, although rare, can now be detected with more precise, but less invasive methods because of progress in diagnostic technology. Nonetheless, for most hypertensive patients, it is sustained surveillance and reassessment, coupled with strategies for education and motivation to achieve their active participation in optimal treatment that will be the crucial determinants in reducing the likelihood of stroke, CHD, congestive heart failure, and progression to ESRD.

Prognostic and Diagnostic Value of Ambulatory Blood Pressure Monitoring

Gianfranco Parati, Grzegorz Bilo, Giuseppe Mancia

The currently employed method for blood pressure (BP) measurement in physicians' offices is still based on the auscultatory sphygmomanometric technique, developed by Riva-Rocci¹ and Korotkoff more than a century ago, which has remained the usual approach for the diagnosis and management of hypertension in clinical practice. This technique has provided us with most of the available information on the prognostic consequences of a high BP, and on the protective effect of BP reduction obtained by antihypertensive treatment.

However, over the years a considerable number of problems associated with this time-honored method have been acknowledged. The main limitations of office BP measurements are related to the following:

1. Their inability to provide a large number of BP values (necessary to account for the physiologic variability typical of this parameter).
2. The fact that measurements are usually taken in a health care facility setting, which may cause an alerting reaction in the patient, followed by a BP rise that is frequently of a relevant magnitude (even 30 mm Hg or more), known as the "white-coat effect" (WCE).
3. The often improper application of the auscultatory sphygmomanometric technique (inappropriate conditions of measurement, error in positioning or selecting the arm cuff, wrong arm position, observer's bias and digit preference).
4. The inherent inaccuracy of auscultatory BP readings, mainly for diastolic BP (DBP) measurements, in a number of clinical conditions.
5. The incoming banning of mercury from diagnostic applications and devices, until now routinely used in the clinical setting. The safety issues related to this highly toxic metal may be expected to lead to the disappearance of mercury sphygmomanometers, which have already been banned in some European countries.^{2,3}

The first four issues can be considered responsible for the high degree of between-measurement variability that can be observed both within and between physician's visits, this phenomenon can be explained only in part by physiologic mechanisms.

In the attempt to overcome these limitations, a number of different approaches to BP measurement have been proposed, aimed at obtaining a more precise definition of patients' "true" BP level. Two of them are now widely used in clinical practice, namely self-BP measurement (SBPM) at home and 24-hour ambulatory BP monitoring (ABPM). This chapter focuses on the clinical value of the information obtained by performing ABPM in the management of hypertensive patients.

TECHNIQUE OF AMBULATORY BLOOD PRESSURE MONITORING—ITS HISTORY AND CURRENT ACHIEVEMENTS

The occurrence of pronounced BP fluctuations over time was first observed by Stephen Hales in 1733, when performing his famous experiments on "the arterial pulse" by inserting a glass pipe into the crural artery of mares (Figure 27-1). In the following years, additional information on the occurrence of BP variations with time was obtained in humans, although only through indirect methods aimed at quantifying the arterial pulse, in most cases at the level of the radial artery (Figure 27-2). Further insights into the variations of BP in humans under the effects of exercise, stress, and emotions were later made possible by the introduction of the sphygmomanometric technique by Riva-Rocci¹ and Korotkoff.

A major breakthrough occurred in the last decades of the twentieth century, when a portable intraarterial ABPM system was developed by the Oxford group. This technique, using a catheter placed in the radial or brachial artery and connected with an electronic transducer and a perfusion unit positioned at heart level, was able to yield a detailed recording of beat-by-beat BP changes, stored on an analog tape recorder. The application of this system to ABPM in humans has provided us with the first demonstration that BP is characterized by pronounced oscillations over the entire 24 hours (Figure 27-3).⁴ These include both long-term fluctuations, such as those between wakefulness and sleep, and rapid changes over a time scale of seconds and minutes, due to the cardiovascular effects of emotion, exercise, and behavioral challenges.^{5,6} Application of this technique to subjects characterized by different BP levels has led to the demonstration that BP variability (as quantified by the standard deviation [SD] of average 24-hour BP levels) increases progressively with the increase in 24-hour mean BP levels. It has also allowed a dynamic observation of BP and heart rate changes during the physician's visit, at the time when a sphygmomanometric measurement is performed. Through the application of this technique, we provided the first direct assessment of the magnitude and time course of the WCE and quantification of the differential impact on BP and heart rate exerted by BP measurements performed by a doctor and a nurse, respectively.^{7,8}

The invasive nature of this method has prevented its widespread use in a clinical setting, for which noninvasive approaches are required. This need has been met by progress in technology that led to the development of two alternative approaches to noninvasive BP monitoring. The first consists of a noninvasive system able to yield beat-by-beat BP recordings similar to those offered by the intraarterial technique, but without need of intraarterial catheters. This was achieved

Figure 27-1 The first blood pressure measurement, by Hales, 1733. (Illustration by Elizabeth Cuzzort. From *Medical Times*, Volume 72, 1944.)

through the photo-plethysmographic arterial clamping technique described by Penaz and further improved by Wesseling, based on the application of small cuffs on the middle or ring fingers of the patient's hand.^{9,10} This technique was first applied to the development of a stationary device (Finapres, Ohmeda Inc., Ohmeda, Colorado, USA) now improved, refurbished, and made commercially available with the new name of Finometer (FMS, Arnhem, The Netherlands).

Subsequently, the same technology was implemented in a portable device (Portapres, FMS, Arnhem, The Netherlands), which until now remains the only available approach to non-invasive 24-hour, beat-by-beat ABPM. These devices have been shown to be accurate for tracking of BP changes, but the absolute BP values they yield do not always precisely reflect sphygmomanometric BP obtained at the arm level.¹¹ The accuracy of this system has been improved by implementing a hydrostatic height correction system, able to correct the recorded BP values for the hydrostatic height difference between the finger cuff and heart level, and by applying a mathematical transformation to finger BP waveforms aimed at reconstructing brachial BP waveforms and at approaching arm BP levels¹² (Figure 27-4).

Techniques for continuous BP monitoring have provided us with a large amount of interesting data on the physiologic mechanisms regulating the cardiovascular system and on their derangement in pathologic conditions.¹³ This has been obtained through computer analysis of spontaneous BP and heart rate variations. This approach has yielded new information not only on the magnitude but also on the rapidity of spontaneous BP fluctuations, the latter found to be steeper in hypertensive than in normotensive persons.¹⁴ In spite of their great potential, techniques for continuous BP monitoring have been largely confined to a research setting, mainly because of their high cost and complexity.

The other approach to ABPM is based on the use of portable, noninvasive, discontinuous BP monitoring devices, which have become widely used tools to assess BP changes over the 24 hours in the clinical setting.¹⁵ The first ABPM devices, known as *Remler devices*,^{16,17} were based on semiautomatic techniques. The measurement was started manually by the patient, who was asked to inflate the arm cuff, while the cuff deflation and the BP readings (based on microphonic detection of the Korotkoff sounds) were done automatically. Despite its limitations, including inability to yield information on nighttime BP and the need of an interactive, time-consuming procedure by a technician to individually derive the recorded BP values, this technique made it possible for the first time to obtain evidence on the prognostic relevance of ABPM.¹⁸

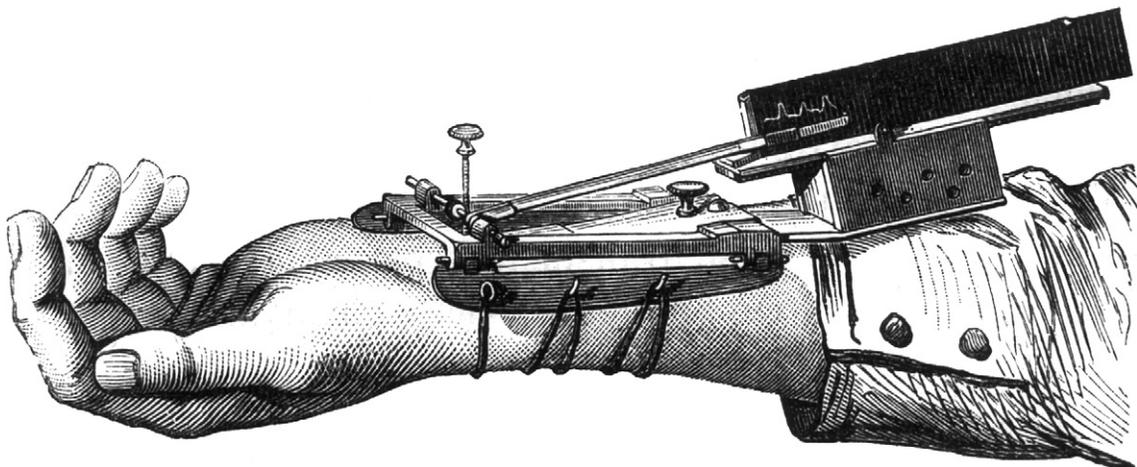

Figure 27-2 The "direct" sphygmograph, by Etienne Jules Marey, 1860. (From Marey EJ. *La circulation du sang*. Paris, Masson, 1881; p 214. Courtesy of The Wellcome Library, London.)

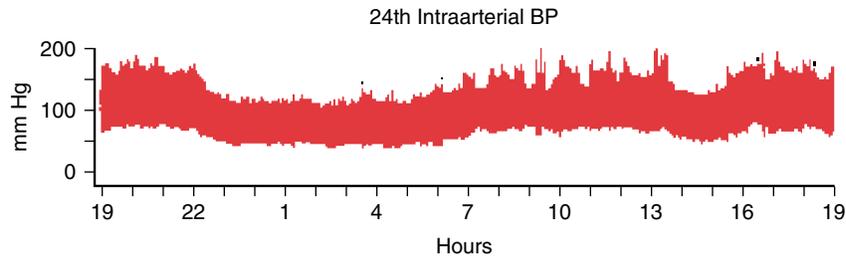

Figure 27-3 An example of 24-hour beat-by-beat intraarterial ambulatory blood pressure (BP) recording documenting the pronounced variability that characterizes BP over day and night periods. (From Mancia G, Parati G, Di Rienzo M, et al. Blood pressure variability. In Zanchetti A, Mancia G (eds). Handbook of Hypertension, Vol. 17: Pathophysiology of Hypertension. London, Elsevier Science BV 1997; pp 117-169: by permission.)

Further technologic development in this field has led to the introduction of fully automated ABPM devices in which BP measurement by the microphonic technique (rather susceptible to interference, especially by external noise) has been progressively replaced by the oscillometric approach. Currently, fully automated oscillometric devices, if validated according to internationally accepted protocols,¹⁹⁻²¹ are the method of choice for performing ABPM.²² The need to focus on validated devices is related to the fact that oscillometric monitors do not directly measure systolic BP (SBP) and DBP, but just mean BP, whereas systolic and diastolic values are derived from mean values through use of proprietary device-specific algorithms. A list of devices validated for clinical application according to the aforementioned protocols is published²³ and is available and regularly updated on a dedicated website (www.dableducational.com).

PROGNOSTIC IMPORTANCE OF AMBULATORY BLOOD PRESSURE

Although most of the available data on the prognostic importance of an elevated BP and on the benefits obtainable by its reduction through effective antihypertensive treatment are based on office readings,²⁴ an increasing number of studies have indicated that ABPM may provide diagnostic and prognostic information that is not only equivalent but probably superior to that yielded by traditional office measurements.²⁵

A number of these studies have focused on the relationship of office and ambulatory BP with target organ damage. They

have almost invariably demonstrated the superiority of ambulatory values in this regard. This was the case in terms of cardiac, renal, cerebral, and vascular changes (both in large and small arteries), as well as in terms of a general organ damage score, in studies specifically focusing on this issue²⁶⁻³⁰ (Figure 27-5),²⁷ and also in analysis of the baseline data of large prospective outcome studies such as the European Lacidipine Study on Atherosclerosis (ELSA—data on macrovascular changes)³¹ (Figure 27-6).

A few longitudinal studies showing that ABPM provides data that are prognostically superior to those obtained by means of office measurement are also available. The first longitudinal data were those of Perloff et al.,¹⁸ followed by data on target organ progression such as those obtained over a 6- to 7-year follow-up of the patients included in our study using intraarterial ABPM³² and those obtained when prospectively focusing on target organ damage reduction by treatment in the Study on Ambulatory Monitoring of Pressure and Lisinopril Evaluation (SAMPLE)³³ (Figure 27-7).

Longitudinal data on the ability of ABPM to provide important prognostic information on the occurrence of cardiovascular events are also available. Such data were provided by the uncontrolled observations by Verdecchia et al. obtained in the cohort of subjects included in the PIUMA (Progetto Ipertensione Umbria Monitoraggio Ambulatoriale) database³⁴ and by Redon et al.³⁵ in patients with resistant hypertension. An important contribution to the demonstration of the prognostic value of ABPM was also provided by analysis of data obtained from the adult population of Ohasama in Japan.

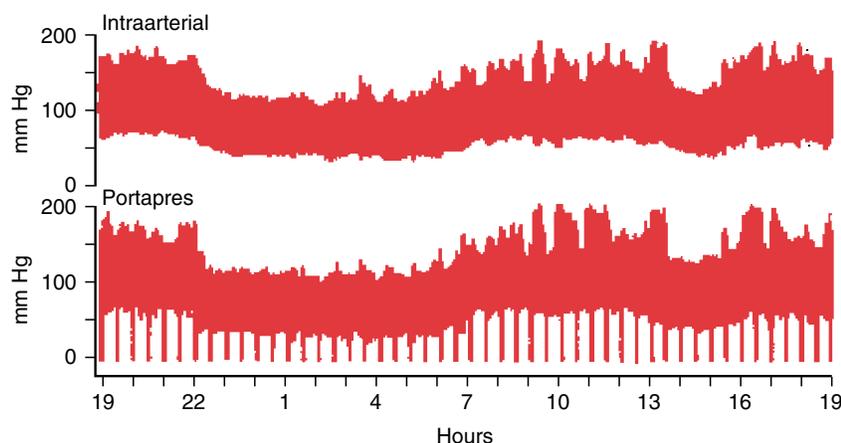

Figure 27-4 Comparison of blood pressure values obtained with invasive technique and with Portapres device.

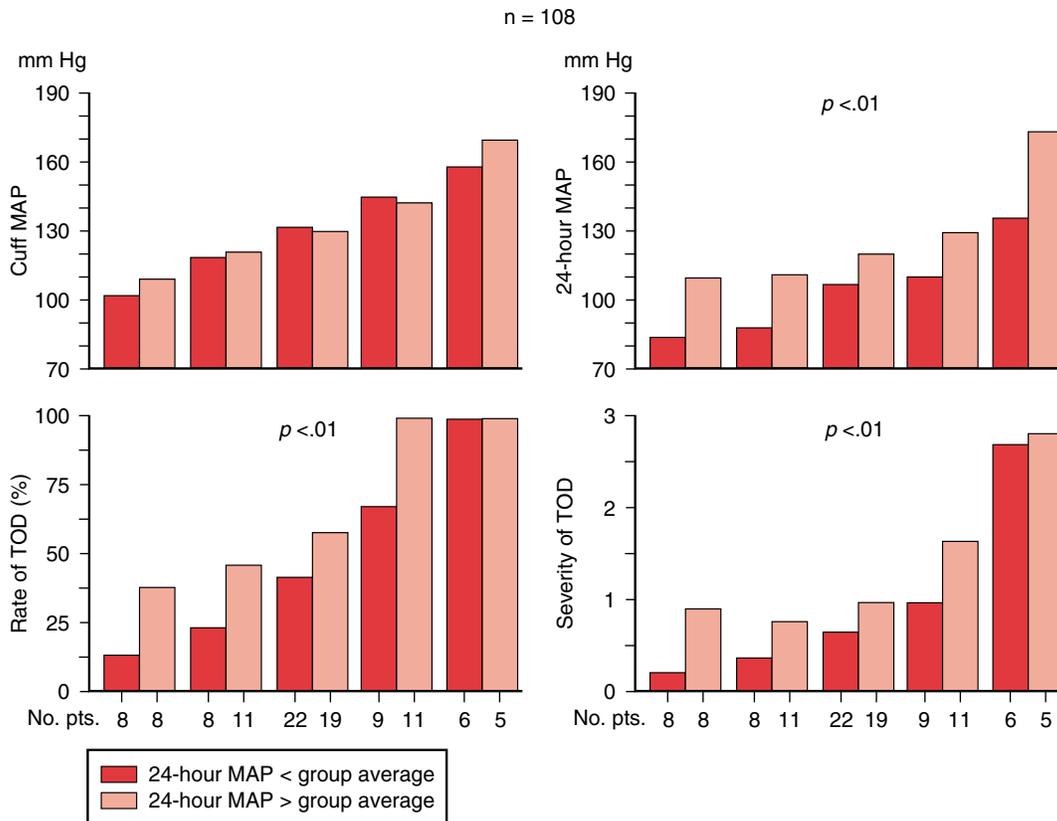

Figure 27-5 A demonstration of additional prognostic value provided by 24-hour blood pressure (BP) in terms of target organ damage (TOD). For every quintile of office BP, the presence of a higher 24-hour mean arterial pressure (MAP) was associated with more severe target organ changes. (From Parati G, Pomidossi G, Alбини F, et al. Relationship of 24-hour blood pressure mean and variability to severity of target organ damage. *J Hypertens* 5:93-98, 1987; by permission.)

After 5 years of follow-up, it was evident that having ambulatory SBP in the highest quintile of the population data distribution was associated with an elevated risk of death from cardiovascular causes, whereas no such close association was found for casual BP values.³⁶ Similarly, in the analysis of data from the Syst-Eur study (Systolic Hypertension in Europe Trial),³⁷ in the group of elderly hypertensives receiving placebo, a 10-mm Hg higher ambulatory SBP (but not office BP) at baseline was an independent predictor of both cardiovascular and total mortality over the follow-up period. The predictive power was stronger for nighttime mean BP (Figure 27-8).³⁷

The prognostic value of ABPM was further confirmed in treated antihypertensive patients in the OvA study (Office versus Ambulatory Blood Pressure Study).³⁸ In this study baseline ambulatory BP (more SBP than DBP) was a powerful significant predictor of risk of cardiovascular events over 5.5 years of follow-up even after correction for differences in office BP had been made (Figure 27-9).

It has to be considered, however, that the superior prognostic value of ambulatory BP and of its reduction by treatment (as shown in the SAMPLE study³³) compared with office BP readings is particularly evident in case of reproducible ambulatory BP data³⁹ compared with “casual” office BP measurements. The difference in predictive power between office and ambulatory BP becomes less pronounced when repeated and carefully performed office BP measures are considered or when, on the other hand, poorly reproducible ambulatory BP

data are taken into account. This has been emphasized in a few studies, including a paper by Fagard et al.,⁴⁰ although another study from this group has demonstrated that even when changes in office BP are significantly predictive of left ventricular mass reduction with treatment, changes in ambulatory BP provide additional prognostic information.⁴¹

Several advantages of ABPM over office readings might explain its greater predictive power^{25,42,43} (Box 27-1). The two most important advantages are (1) the large number of BP readings obtainable with ABPM, which makes the resulting mean values much more stable and reproducible (an observation in line with the previously mentioned demonstration by Fagard et al.⁴⁰ that repeated office BP measurements obtained under standardized conditions may have similar prognostic value to 24-hour ABPM) and (2) the fact that ABPM is devoid of a major confounder in the assessment of BP-related cardiovascular risk (i.e., the WCE⁴⁵; see Chapter 28). Additional factors responsible for the superiority of ABPM over office readings may be the noise introduced in the latter approach by an insufficient quality of office measurements (use of devices in poor technical condition, inappropriate conditions of measurement, observer bias and end-digit preference) and, for the assessment of the effects of antihypertensive treatment, the fact that ABPM is virtually devoid of any placebo effect.⁴⁶

A further advantage of ABPM is related to its ability to provide information not only on average BP values over the 24-hour period, but also on different patterns of BP variation

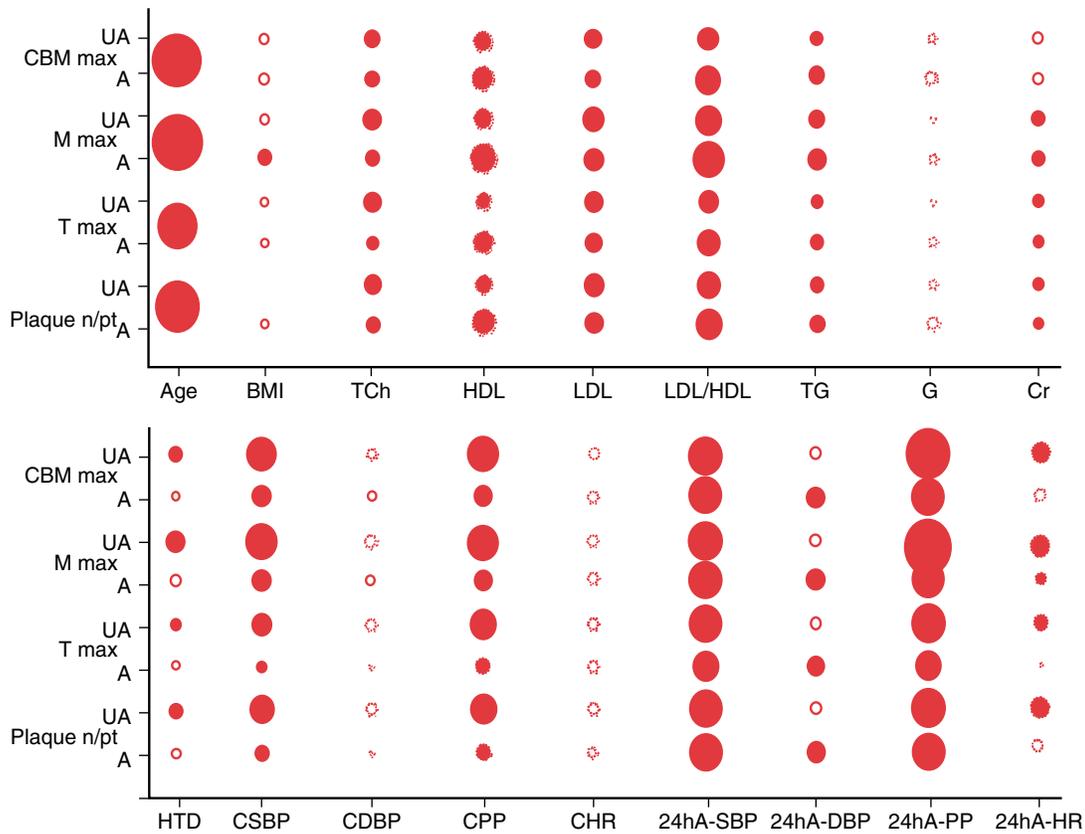

Figure 27-6 The data from ELSA study. The circles represent Spearman correlation coefficients of baseline ultrasonographic variables with a number of possible determinants, including baseline blood pressure (BP) and heart rate. The size of each circle is proportional to the correlation: *full circle*, positive correlation; *dashed circle*, negative correlation; *gray circle*, significant correlation. *Abbreviations:* UA, unadjusted coefficients, A, adjusted coefficients; BMI, body mass index; HDL, high-density lipoprotein; LDL, low-density lipoprotein; HTD, hypertension duration; CSBP, clinic systolic blood pressure; CDBP, clinic diastolic blood pressure; CPP, clinic pulse pressure; CHR, clinic heart rate; 24hA-SBP, 24-hr mean ambulatory systolic blood pressure; 24hA-DBP, 24-hr mean ambulatory diastolic blood pressure; 24hA-PP, 24-hr mean ambulatory pulse pressure; 24hA-HR, 24-hr mean ambulatory heart rate; CBM max, mean of the maximum of intima-media thickness (IMT) of the four far walls of the carotid bifurcations and distal common carotid arteries; M max, changes in the mean thickness of up to 12 different sites (right and left, near and far walls, distal common, bifurcation and proximal internal carotid); T max, overall mean maximum IMT. From 1444 patients in whom complete baseline data were available. (From Zanchetti A, Bond MG, Hennig M, et al. Risk factors associated with alterations in carotid intima-media thickness in hypertension: Baseline data from the European Lacidipine Study on Atherosclerosis. *J Hypertens* 16:949-961, 1998; by permission.)

during the 24 hours. Although the evidence supporting the prognostic value of average 24-hour, daytime or nighttime BP values is extensive and convincing, the prognostic significance of BP variability is still a research issue, even if already supported by several studies.^{27,32,47-52} This is the case for overall BP variability, as quantified by the SD of the average BP values of the 24-hours, the daytime or the nighttime. This is also the case for its different components during 24 hours. The patterns of BP variability that have most commonly been considered to bear a prognostic value are the following.

1. *Nocturnal BP fall (dipping)*. The absence of this physiologic phenomenon in groups of persons at high cardiovascular risk (e.g., patients with diabetes, chronic renal failure, obstructive sleep apnea syndrome, and some forms of secondary hypertension) has raised a question whether it should be considered an independent cardiovascular risk factor. A number of studies have demonstrated that nondipping is associated with more target

organ damage and an increased risk of cardiovascular events,⁵³ but it remains unclear whether this additional risk depends on impaired cardiovascular regulation (as is the case in diabetic neuropathy) or if it is simply the result of an increased BP load at night. In the latter case, the absolute level of BP at night should be prognostically more important than the magnitude of the difference in BP between daytime and nighttime. These possibilities are not mutually exclusive and each may explain the additional risk associated with an alteration of the sleep-wakefulness cycle in BP to a different degree in different patients. The situation is made even more complex by the observations of Kario et al., that in elderly persons also an excessive BP fall at night results in an increased risk of ischemic cerebral damage and stroke.⁵⁴ The issue of the clinical relevance of nocturnal BP dipping needs to be addressed with caution because of the demonstration that this phenomenon is poorly reproducible.⁵⁵ Thus the

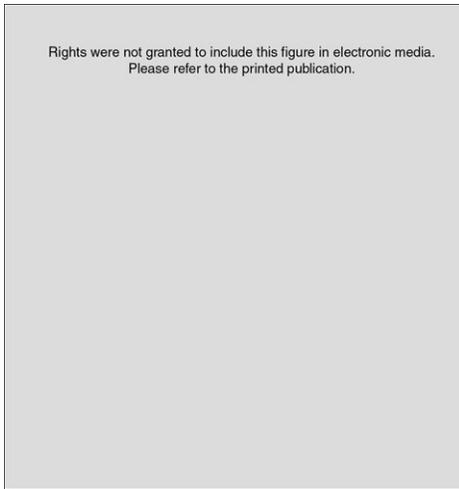

Figure 27-7 SAMPLE study data. Average correlation coefficients between treatment-induced changes in blood pressures (BPs) measured in study and treatment-induced change in left ventricular mass index (LVMI) after 12 months of treatment. Numbers in parentheses refer to subjects used for correlations. (From Mancia G, Zanchetti A, Agabiti-Rosei E, et al. Ambulatory BP is superior to clinic BP in predicting treatment-induced regression of left ventricular hypertrophy. SAMPLE Study Group. Study on Ambulatory Monitoring of Blood Pressure and Lisinopril Evaluation. *Circulation* 95:1464-1470, 1997; by permission.)

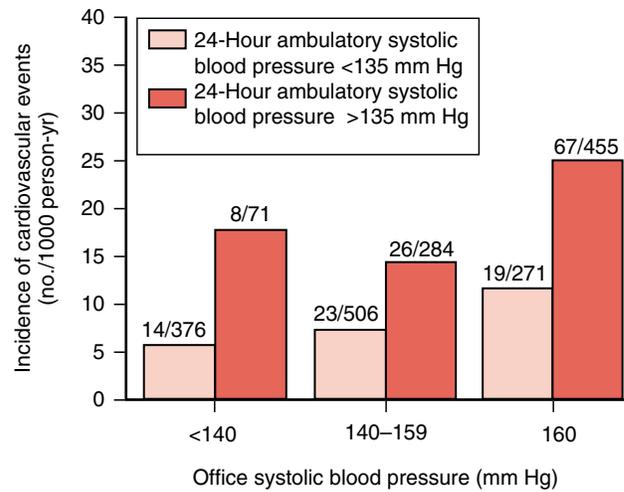

Figure 27-9 Incidence of cardiovascular events in the OvA study according to category of office systolic blood pressure. (From Clement DL, De Buyzere ML, De Bacquer DA, et al. Prognostic value of ambulatory blood-pressure recordings in patients with treated hypertension. *N Engl J Med* 348:2407-2415, 2003. Copyright 2003 Massachusetts Medical Society.)

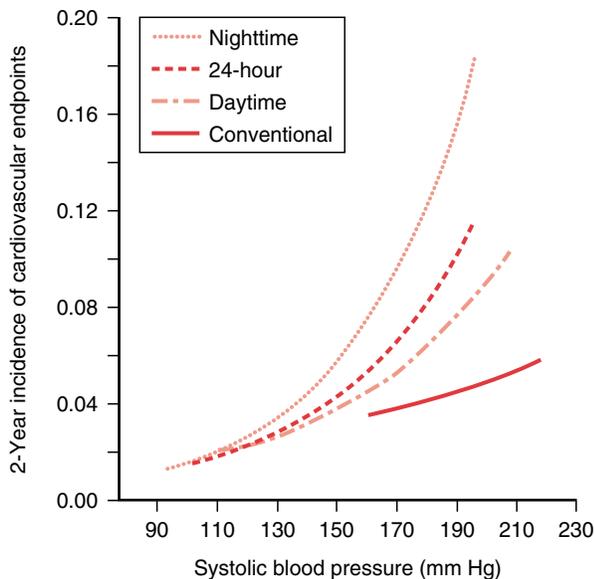

Figure 27-8 Systolic blood pressures on conventional, 24-hour, daytime, and nighttime measurement at entry as predictors of the 2-year incidence of cardiovascular endpoints in the placebo group in the Syst-Eur Study. Incidence is given as a fraction (i.e., 0.02 is an incidence of 2 events per 100 people). Using multiple Cox regression, the event rate was standardized to female sex, 69.6 years (mean age), no previous cardiovascular complications, nonsmoking status, and residence in western Europe. (From Staessen JA, Thijs L, Fagard R, et al. Hypertension in Europe Trial Investigators. Predicting cardiovascular risk using conventional vs ambulatory blood pressure in older patients with hypertension. *JAMA* 282:539-546, 1999; by permission.)

isolated finding of lack of nocturnal BP fall on ABPM should be carefully considered, to avoid the erroneous classification of subjects as “nondippers,” a label that might carry an adverse prognostic meaning, while they might have simply been “nonsleepers.”

- Morning surge of BP.** The rate of cardiovascular events (ischemic cardiac events, sudden death, stroke) is higher in the morning hours,⁵⁶ at a time when increases in BP, heart rate, sympathetic activity, and platelet aggregability occur in association with awakening. It is not clear, however, whether the morning BP surge and the associated increase in event rate are both the result of a common cause (i.e., an increased sympathetic nervous system activity, leading to an increased risk of arrhythmias and BP peaks) or whether there is a causal link between morning BP surge and a higher event rate (a steeper morning BP rise might increase cardiac and vascular stress and thus contribute to the occurrence of events).⁵⁷ Only one study has investigated this relationship directly and has demonstrated that, in fact, an increased morning BP surge is associated with a higher incidence of stroke in the follow-up period.⁵⁸ Importantly, given on one side the aforementioned demonstration that an increased rate of cerebrovascular events may be related to the presence of extreme dipping,⁵⁴ and on the other side the observation that this phenomenon is often associated with a more pronounced morning BP rise, it is not clear which of these two patterns is prognostically more important. In other words, it is not clear whether the adverse prognostic significance of extreme dipping depends on its postulated risk of organ underperfusion or on its association with a resulting steeper morning BP surge.⁵⁸
- Overall BP variability,** including its “erratic,” noncircadian components, which are usually quantified as the SD of average 24-hour, daytime, or nighttime ambulatory BP

Box 27-1 Advantages and Limitations of Ambulatory Blood Pressure Monitoring (ABPM)

values. There are convincing data demonstrating that elevated BP variability is related to target organ damage, as well as to cardiovascular events^{27,32,48,49} (Figures 27-10 and 27-11). The impact of elevated BP variability on cardiovascular mortality has been clearly demonstrated in population studies. In the Ohasama study,⁴⁹ this was particularly evident in case of daytime BP SD values: An increase in daytime SBP variability was associated with increased risk of cardiovascular mortality in this Japanese population. In terms of target organ damage, the predictive value of increased BP variability has been confirmed by data coming from the PAMELA (Pressioni Arteriose Monitorate E Loro Associazioni) study.⁵⁹ In this northern Italian population, the focus was on the so-called erratic component of BP variability, that is, the 24-hour BP variability “purified” from the influence of nocturnal BP fall and of the BP fall associated with siesta (i.e., from its most important cyclic components), identified by means of spectral analysis (Fourier transform). The results showed that in this population only the erratic component of 24 BP SD was significantly correlated with left ventricular mass. All of the aforementioned results differ from those obtained by Verdecchia et al. in the PIUMA study,⁶⁰ where the influence of BP variability on cardiovascular mortality, evident in univariate analysis, became marginally significant after adjustment for confounders. Differences in study design, quality of ambulatory BP recordings, and characteristics of the populations considered might however partly explain this discrepancy. The prognostic value of BP variability has been further supported by additional data from the Syst-Eur study, showing that how SBP variability (only during nighttime in this case) was a significant and independent predictor of stroke in elderly hypertensive patients with isolated systolic hypertension (ISH).⁵¹

It has to be emphasized that, while the first papers demonstrating clinical relevance of BP variability were based on the analysis of continuous intraarterial ambulatory BP recordings, yielding a very accurate assessment of BP variability,^{27,32}

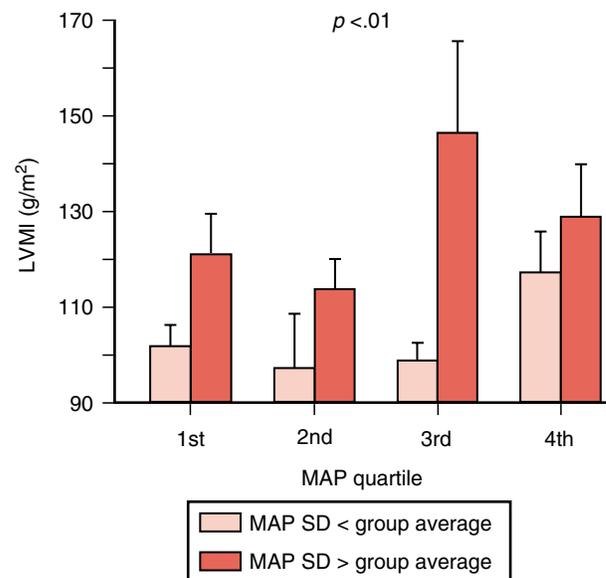

Figure 27-10 A demonstration of additional prognostic value provided by 24-hour blood pressure (BP) variability in terms of target organ damage. For every quartile of baseline 24-hour mean arterial pressure (MAP), the presence of a greater MAP variability (MAP SD) was associated with a higher left ventricular mass index over the follow-up period. (From Frattola A, Parati G, Cuspidi C, et al. Prognostic value of 24-hour blood pressure variability. *J Hypertens* 11:1133-1137, 1993; by permission.)

Rights were not granted to include this figure in electronic media.

Figure 27-11 Kaplan-Meier survival analysis for fatal and nonfatal cardiovascular morbid events in patients with increased (>15 mm Hg) and normal (≤ 15 mm Hg) daytime systolic blood pressure (SBP) variability. (From Parati G, Bilo G, Vettorello M, et al. Assessment of overall blood pressure variability and its different components. *Blood Press Monit* 8:155-9, 2003; by permission.)

all subsequent studies were based on discontinuous noninvasive ABPM, which cannot offer the same accuracy in assessing the magnitude and the frequency of BP variations over time due to loss of information on rapid BP changes.⁶¹

Although the prognostic importance of BP variability over the 24 hours is unquestionable, a number of aspects of the association between different patterns of BP variation and target organ damage/cardiovascular events remain unclear. This is related to a number of yet unsolved problems, such as the definition of “normal” reference values for BP variability; the difficulties in providing a reproducible estimate of this phenomenon; the inaccuracies in estimating BP variability from discontinuous BP samples obtained at a relatively low frequency; and the important interactions between some components of 24-hour BP variability that may raise difficult mathematical and pathophysiologic issues, as exemplified by the reported relation between nocturnal dip and morning BP surge or by the relation between either of these and 24-hour BP SD.

Further evidence is thus needed to evaluate the extent to which alterations in different components of BP variability might cause cardiovascular damage or, on the contrary, to what extent these alterations only constitute a marker of an impairment in cardiovascular control mechanisms associated with a preexisting pathology.

AMBULATORY BLOOD PRESSURE MONITORING IN THE DIFFERENTIAL DIAGNOSIS OF “SUSTAINED HYPERTENSION” AND “WHITE-COAT HYPERTENSION”

Office BP measurements remain the method recommended for the diagnosis of hypertension in daily practice. However, measurements performed in the physician’s office are commonly associated with an alerting reaction induced in the patient by the procedure. This alerting reaction is responsible

for a BP elevation of variable magnitude, often exceeding 20 to 30 mm Hg⁷ (Figure 27-12), which might overestimate the patient’s actual BP levels and/or underestimate the efficacy of antihypertensive treatment. This phenomenon, termed *white-coat effect* (WCE), cannot be easily quantified in clinical practice, because its precise assessment would require continuous BP recordings to be performed before and during the physician’s visit. Because of this difficulty, surrogate measures of WCE are commonly used. The most popular of these is based on the calculation of the difference between office BP and mean daytime ambulatory BP. Based on this approach, *white-coat hypertension* (WCH,⁶² also termed *isolated office hypertension* [IOH]) is defined as the coexistence of elevated office BP values and normal BP levels outside of the physician’s office. Differences in terminology and methodology applied in this context, however, have caused confusion and some discrepancy in the assessment of the clinical relevance of WCH among studies (Box 27-2).⁶³

For this reason, although ABPM is recommended for patients affected by either a pronounced WCE or by WCH (in the United States a suspicion of WCH is the clinical situation in which ABPM is reimbursed by Centers for Medicare and Medicaid Services [CMS]⁶⁴), no standard procedure has yet been defined to identify these patients. In particular, there is still discussion on whether out-of-office BP should be measured by self-BP monitoring at home or by ABPM. There is no general agreement whether ABPM should be performed only in patients with a discrepancy between office and home BP values, or whether ABPM should be adopted anytime a suspicion of WCH is raised based on patient’s clinical evaluation.

Given the limited resources for health care in most countries, the prevailing suggestion is that ABPM should be restricted to selected patients, such as those with a high probability of having WCE. These include patients with SBP values between 140 and 159 mm Hg and DBP between 90 and 99 mm Hg, with no evidence of target organ damage (e.g., normal left ventricular mass); women; nonsmokers; and those with a recent diagnosis of hypertension and with a limited number of office BP measurements available.⁶⁵ Another crucial issue for the diagnosis of WCH is the definition of “normal” out-of-office BP. CMS have proposed out-of-office BP values $<140/90$ mm Hg as a threshold to suspect WCH in patients with elevated office BP readings. However, most current recommendations indicate a level of 135/85 mm Hg as the threshold level to diagnose hypertension when considering either home BP or ambulatory daytime values,^{22,24,66} thus suggesting that, in WCH, out-of-office BP should be lower than this value.

ABPM AND ANTIHYPERTENSIVE TREATMENT

ABPM is commonly applied in the evaluation of antihypertensive drug efficacy. ABPM has several advantages in assessing the BP responses to treatment, for example, the absence of WCE and placebo effects and the possibility of assessing drug coverage over 24 hours, relevant both in clinical practice and in pharmacologic studies^{44,67} (see Box 27-1). The usefulness of ABPM is further emphasized by the observation that assessments of the response to antihypertensive treatment obtained by office readings and ABPM often lead to discrepant conclusions.⁶⁸

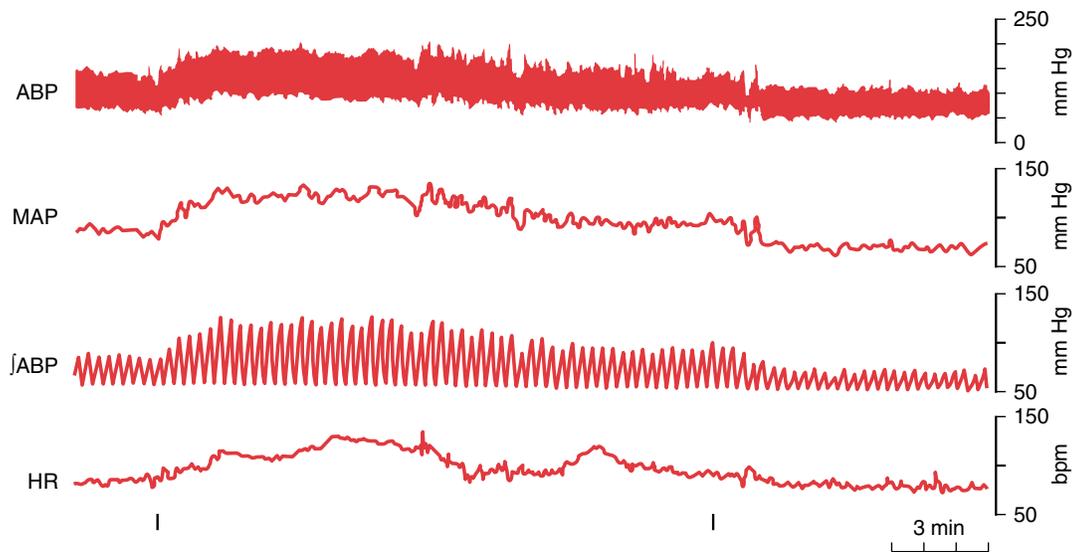

Figure 27-12 Direct assessment of the white-coat effect. Arrows indicate the beginning and the end of a visit by the physician. (From Mancia G, Bertineri G, Grassi G, et al. Effects of blood pressure measured by the doctor on patient's blood pressure and heart rate. *Lancet* 2:695-698, 1983; by permission.)

An additional advantage of ABPM in assessing the BP effects of antihypertensive treatment is its capability to provide a detailed description of both the magnitude and the time distribution of the 24-hour BP reduction related to pharmacologic therapy. Given the contribution of enhanced BP variability to the cardiovascular consequences of hypertension, there is no doubt as to the theoretical advantages of ensuring a consistent and smooth treatment-induced reduction of BP over the entire 24-hour period.⁶⁹ Still, there is no agreement on the best method to assess whether and to what extent this goal has been achieved, either in drug studies or in individual patients. The most commonly used methods proposed include the trough/peak ratio, the morning/evening

home BP ratio, and the smoothness index⁷⁰ (Figure 27-13). There is evidence that the smoothness index may be superior to the trough/peak ratio in predicting regression of cardiac and vascular damage.^{70,71} The value of trough/peak ratio, morning/evening home BP ratio, and smoothness index in assessing the patterns of BP reduction by antihypertensive drug treatment were compared in a study by Stergiou et al.⁷² The authors concluded that although the first two parameters can effectively demonstrate the duration of drug effect but not its magnitude, the smoothness index reflects both the degree and the homogeneity of the antihypertensive effect of a given therapeutic regimen, thus providing information that is complementary, rather than alternative to trough/peak ratio.⁷²

Box 27-2 Terminology of Alerting Reactions to Blood Pressure Measurement and Associated Phenomena

Alerting reaction: A complex, stereotypical reaction to an emotional, potentially threatening stimulus, characterized in the circulatory system by an increase in blood pressure (BP) and heart rate accompanied by vasoconstriction in the skin, splanchnic, and renal circulation, and by vasodilation in the skeletal muscle.

White-coat effect (WCE), direct, "real"; also known as white-coat phenomenon: Alerting reaction and pressor response of the patient to the measurement of BP in the clinic environment; can be quantified by continuous BP monitoring (invasive or noninvasive) before and during the physician's visit.

White coat-effect (WCE), surrogate: Difference between cuff BP measured in physician's office (clinic BP) and a measure of BP outside physician's office (daytime ambulatory BP, home BP); see text for its relation to direct WCE.

Isolated office hypertension (IOH); also known as white-coat hypertension (WCH): Condition characterized by persistently elevated clinic BP in a patient with normal daytime ambulatory or home BP values; 1999 WHO/ISH Guidelines suggest using the term "isolated office hypertension" instead of "white-coat hypertension" because of the evidence of a limited or absent correlation between the office-daytime average or the office-home BP difference and the real white-coat effect.

CLINICAL APPLICATIONS OF ABPM—CURRENT RECOMMENDATIONS AND FUTURE PERSPECTIVES

ABPM, as any other BP measurement technique available in clinical practice, has advantages and disadvantages, the latter including the possibility of artifacts and inaccurate readings, cost, and potential interference with daily life in a working day. In fact, current guidelines still recommend office measurements as the cornerstone for diagnosing high BP^{22,24,66} and suggest that both ABPM and home BP measurement should be regarded as complementary rather than alternative approaches. Identification of situations where these methods might be suitably used in clinical practice is still matter of debate, although there is general agreement on the usefulness of either technique in a research setting.

Self-BP monitoring at home might provide accurate and prognostically relevant information on patients' BP levels by obtaining BP readings over a wide time window. Its main advantage is related to the possibility of offering an inexpensive solution to the need for repeated BP measurements, which are particularly useful in the follow-up of hypertensive patients over long time periods. On the other hand, as concluded by Hond et al., home BP measurements may not be sufficient for diagnosing hypertension and for an initial risk evaluation.⁷³

Although ABPM is not (or at least not yet) recommended as a routine instrument in the clinical evaluation of the hypertensive patient, it is likely to be more and more frequently used, because of its demonstrated ability to more precisely evaluate BP-related cardiovascular risk and to quantify both

the magnitude and distribution of treatment-related BP reduction over 24 hours. If the prognostic value of BP variability and of some of its specific components (e.g., morning rise, nocturnal fall) is confirmed, the ability of ABPM to quantify also these patterns will further emphasize its role in the management of hypertensive patients.

The clinical application of ABPM has been addressed in several sets of guidelines. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) only briefly discusses the indications for ABPM in the evaluation of hypertensive patients, confirming the recommendations contained in the sixth report of the same committee (JNC VI).^{66,74} White-coat hypertension, treatment resistance, hypotension, episodic hypertension, and autonomic failure are all situations in which ABPM should be used according to these guidelines. JNC 7 proposed ambulatory BP levels of 135/85 mm Hg for daytime and of 120/75 mm Hg for nighttime cutoffs for the diagnosis of hypertension. The European Society of Hypertension and European Society of Cardiology joint guidelines emphasize the superiority of ambulatory BP over office BP in terms of prognostic value.²⁴ Situations in which, according to the European guidelines, ABPM may be considered of additional clinical value are WCH, as suggested by excess variability of office BP; high office BP in patients otherwise at low global cardiovascular risk; and marked discrepancy between BP measured in the office and at home. Resistance to drug treatment and research applications are also considered other suitable conditions for ABPM use. Much more liberal are the suggestions for use of ABPM published by the European Society of Hypertension Working

+, recommends; –, does not recommend.

Group on Blood Pressure Monitoring.²² Table 27–1 compares these three sets of recommendations.

SUMMARY

The expanding role of ABPM in clinical practice and in hypertension research is related to its advantages when compared with office readings. These consist in its ability to provide a large number of BP values devoid of any influence from the health care setting and to determine the dynamic changes of BP throughout 24 hours (see Box 27–1). Clearly, ABPM also carries some disadvantages (see Box 27–1), which need to be carefully considered for proper clinical use of this approach. In the light of these advantages and disadvantages, a cautious use of ABPM is recommended, while at the same time recognizing the need for more frequent and accurate office BP measurements. We cannot exclude, however, that an increasing amount of scientific evidence demonstrating the prognostic importance of ABPM might in the near future lead to a more extensive application of this diagnostic tool.

White-Coat Hypertension

George A. Mansoor, William B. White

The almost routine availability of ambulatory, office, and home blood pressure (BP) measurements has generated considerable debate into the relationships of these different measures and clinical outcomes.¹⁻⁸ Although these methods all attempt to obtain a measure of average BP, they do not provide results that are interchangeable. One commonly known disparity between office and ambulatory readings is the transient increase in BP observed in some individuals in the medical care environment. When the disparity persists in an untreated patient, this has been termed *isolated office* or *white-coat hypertension*.¹⁻³ In *treated* hypertensive patients, this increase in office over ambulatory BP has been termed the *white-coat effect* or *white-coat phenomenon*.² This latter group of patients is indeed hypertensive but the office BP readings overestimate their average daily BP.

Although it is accepted that the cause of the higher office than daytime pressure is not identical to the classically described white-coat effect³ using intraarterial measurements, the terminology has taken root. The obvious question to clinical practitioners is whether it is ambulatory or office BP that should be used to diagnose hypertension and guide therapy in these patients. In the patient with untreated white-coat hypertension, should therapy be initiated based on high office readings when ambulatory readings are normal? In the treated patient, which measure of BP should guide changes in therapy?

Other important differences between the various types of BP measurements have also been observed. Office BP averages may be significantly *lower* than ambulatory BP.⁴ This situation leads to possible underestimation of daily BP and can be considered a form of *hidden* or *masked hypertension*, perhaps leading to undertreatment of some patients (Figure 28-1).

These important discrepancies between office and average daily BP raise the question of the preferred indicator of overall BP burden and hence risk for that individual.⁵ The clinical importance of white-coat hypertension has been recognized and most consensus groups recommend ambulatory monitoring for the patient with that diagnosis.⁶ The Centers for Medicare and Medicaid Services, in recognition of the importance of ambulatory BP measurements, now reimburses for ambulatory BP monitoring, the indication of white-coat hypertension.⁷

There are many potential advantages in detecting white-coat hypertension: (1) Patients with white-coat hypertension may not require drug therapy and substantial cost savings may accrue, (2) a better diagnostic and prognostic risk assessment for individual patients may be possible, and (3) clinical drug studies can exclude white-coat hypertensives who may not respond to drug therapy in the same fashion as sustained hypertensive patients.⁸ In patients with masked hypertension, the clinician may be alerted that office BP is an unreliable indicator of daily BP.

In this chapter, we examine the clinical features, prognosis, and treatment of white-coat or office-only hypertension and briefly discuss masked hypertension. The theme suggests that measurement of BP during daily activities more accurately predicts cardiovascular risk than measurement during office visits, and that incorporation of office, and out-of-office BP may optimize patient management.

WHITE-COAT HYPERTENSION

Background and Definition

A higher BP in the physician's presence compared with out-of-office BP was reported more than 60 years ago, but the observation lay dormant for many decades.⁹ Today, clinicians are far more familiar with this concept but uncertainty remains about the optimal management of these patients. Many physicians feel uncomfortable not treating elevated office readings even when ambulatory readings are normal.

As a clinical issue, white-coat hypertension is important. The prevalence is reported to range widely from 10% to 60% of all newly diagnosed hypertensive patients.¹⁰⁻¹⁷ However, the true prevalence is probably closer to 15%, because most studies that reported a higher prevalence used relatively high cut-off levels of ambulatory BP (>135/85 mm Hg) to define white-coat hypertension. The value of ambulatory BP in defining white-coat hypertension was highlighted by the demonstration of a several-fold variation in the prevalence of white-coat hypertension and left ventricular hypertrophy (LVH) with different criteria.¹¹ When conservative criteria are used (e.g., <130/80 mm Hg), the prevalence of white-coat hypertension is 12% and the incidence of LVH is similar to that in normotensive subjects (3%).

To standardize research on white-coat hypertension, analyses should be consistent and follow generally accepted guidelines (Box 28-1). Although it is tempting to use home BP measurements alone to diagnose white-coat hypertension,¹ ambulatory BP remains the ideal method especially in employed subjects who often have higher average BPs at work than at home.¹⁸

The difference between office and daytime BP has been used by most researchers as an indicator of the white-coat effect, but this has been challenged.^{3,19} Although the pathophysiologic cause behind the alerting reaction and the ambulatory-office BP difference may be different, the latter is more commonly available to the clinician. Undoubtedly, factors that lower or raise ambulatory BP will affect the daytime office BP difference, just as factors that elevate office BP will increase the difference.

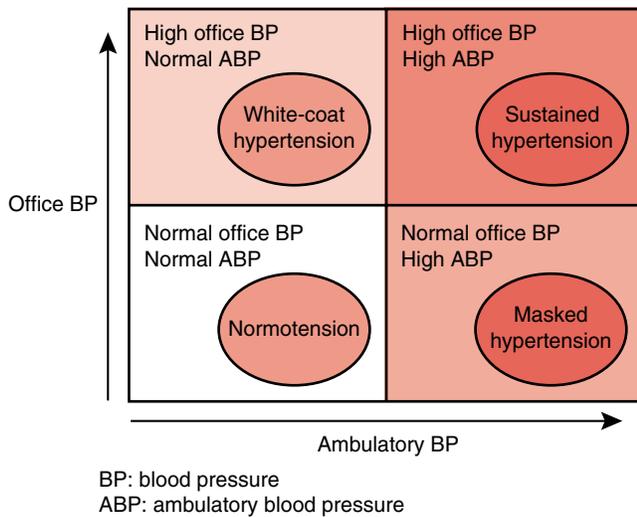

Figure 28-1 Diagrammatic representation of how office and ambulatory BP values for defining hypertension lead to white-coat and masked hypertension.

Pathophysiology of the White-Coat or Alerting Reaction

The pathophysiologic cause of the higher office than ambulatory BP is not certain.²⁰⁻²⁹ It has been customary to use laboratory tests of reactivity^{17,21,23,26} to infer causality of the white-coat effect, but this is likely to be an oversimplification. Suggestions about its etiology have included increased BP reactivity to the stress of clinical visits, as well as a conditioned response to the medical care environment.¹ Several groups could not find any substantial increase in BP variability in white-coat hypertensives compared with essential hypertensives. Furthermore, no consistent psychological or behavioral factors have been identified among white-coat hypertensives.²⁰⁻²⁹ No differences have been found between white-coat

hypertensives and normotensives in a battery of psychometric tests of anger and hostility and anxiety and depression.^{20,24} Smith²⁹ used single and multiunit muscle sympathetic nerve activity to study the sympathetic nervous system in normotensives, white-coat hypertensives, and sustained hypertensives. They found that white-coat hypertensives had activity of the sympathetic system intermediate between that of normotensives and sustained hypertensives. Leary et al.²⁸ reported that increased BP reactivity to physical activity was associated with the white-coat effect. No clear psychological traits are consistently found in white-coat hypertension.

Clinical and Demographic Predictors

Clinical identifiers are needed to be able to target persons with possible white-coat hypertension for ambulatory monitoring. Initial reports suggested that patients with white-coat hypertension were more likely to be young women with a short duration of hypertension.¹⁴ However, subsequent studies have shown that a marked exaggeration of office BP may also occur in older patients irrespective of gender³⁰⁻³² and is common in older patients with isolated systolic hypertension (ISH).³³ Indeed, in a small group of generally older patients, reproducible, spectacular elevations of systolic blood pressure (SBP) were demonstrated in the office.³⁴ For untreated patients with newly diagnosed elevated office readings, ambulatory monitoring may be performed to detect white-coat hypertension in persons with office BP between 140/90 and 159/99 mm Hg, women, and nonsmokers.³² In untreated patients, it is a reasonable strategy to consider the possibility of white-coat hypertension only after repeating the office readings on at least three occasions.

Cross-Sectional Target Organ Studies in White-Coat Hypertension

Because left ventricular mass is reliably determined echocardiographically, this measurement has been used most often in evaluating target organ damage in white-coat hypertension. Other indicators of target organ damage that have been studied include microalbuminuria, arterial compliance, and cerebral white-matter lesions as indicators of silent cerebrovascular damage. Metabolic factors, homocysteine levels, and endothelial function have also been studied in white-coat hypertension.

Left Ventricular Mass

Some studies³⁵⁻³⁹ have found that left ventricular mass index in white-coat hypertensives is similar to that in a group of age- and sex-matched normotensive subjects but lower than that in a group of matched ambulatory hypertensives. One of the first studies in this area³⁵ compared three groups of matched and never-treated hypertensive patients; office hypertensives ($n = 18$, office BP $>140/90$ mm Hg, and awake BP $<130/80$ mm Hg); normotensives ($n = 18$, office BP $<135/85$ mm Hg, and awake BP $<130/80$ mm Hg); and sustained hypertensives ($n = 18$, office BP $>140/90$ mm Hg, and awake BP $>140/90$ mm Hg) with respect to left ventricular mass index and wall thicknesses. Office BP was similar for white-coat hypertensives and sustained hypertensives, and ambulatory BP was similar in normotensives and white-coat hypertensives. Left ventricular

Box 28-1 Considerations in Designing Cross-Sectional Studies of White-Coat Hypertension

- Definition should use both ambulatory SBP and DBP unless a population is studied in which one is obviously preferred (e.g., ISH).
- Define whether 24-hour averages or daytime averages are used.
- Define levels of nighttime BP hypertension.
- Define number of office visits to document high office BP (usually ≥ 2).
- Define normal ambulatory BP using a conservative criterion (e.g., 24-hour BP $<130/80$ mm Hg).
- If surrogate endpoint used, avoid effects of prior antihypertensive therapy and other factors that may influence measured outcome.
- Include both normotensive and sustained hypertensive comparison groups.
- Avoid using home BP alone to define white-coat hypertension.

SBP, systolic blood pressure; DBP, diastolic blood pressure; ISH, isolated systolic hypertension; BP, blood pressure.

mass index was similar in the normotensive and white-coat group and significantly less than in the sustained hypertensive group. However, other researchers⁴⁰⁻⁴⁶ have found that white-coat hypertensives have left ventricular mass higher than normotensives but consistently less than sustained hypertensives, perhaps placing them at intermediate risk. Many of the latter studies used an ambulatory diastolic blood pressure (DBP) of 90 mm Hg as the cut off for white-coat hypertension, a value likely to include many subjects with stage 1 hypertension.

Palatini⁴³ reported data from the Hypertension and Ambulatory Recording Venetia Study (HARVEST), in which 942 never-treated subjects with office BPs of 140 to 159/90 to 99 mm Hg were studied with echocardiography and ambulatory BP monitoring. The authors used three daytime BP criteria for isolated office hypertension: (1) <130/90 mm Hg, (2) <135/85 mm Hg, and (3) <130/80 mm Hg. Irrespective of the criterion used, both left ventricular mass index and wall thickness were higher in both the white-coat and sustained hypertensive group as compared with the normotensive group. There was a gradual increase in left ventricular mass from the normotensive group to the white-coat hypertensive group to the sustained hypertensive group, suggesting that white-coat group is at intermediate risk.

In support of this concept, Grandi⁴⁷ reported that white-coat hypertension based on an ambulatory value of <130/80 mm Hg was associated with higher left ventricular mass and reduced diastolic function indices compared with normotension. Compared with white-coat hypertensives the sustained hypertensives had higher left ventricular mass and lower diastolic function, suggesting an intermediate position of risk for the former group. Sega et al.⁴⁸ described similar findings.

In summary, available studies offer conflicting conclusions regarding cardiac mass in white-coat hypertension. These conflicting results reemphasize the need for prospective studies examining the merits of treating persons with white-coat hypertension.

Renal Indices

Microalbuminuria is indicative of nephropathy in diabetic subjects and hypertensive patients. Hoegholm et al.⁴⁹ compared albumin excretion in 111 patients with white-coat hypertension (daytime DBP <90 mm Hg and office BP >90 mm Hg), 173 with established hypertension (office and daytime ambulatory DBP <90 mm Hg), and 127 normotensive controls (both office and ambulatory DBP <90 mm Hg). There was a graded increase in albumin excretion from normotensives to white-coat hypertensives to sustained hypertensives. These findings were not confirmed by Palatini⁴³ or by Pierdomenico,⁵⁰ who reported that white-coat hypertensives had urinary microalbumin levels similar to normotensives and lower than ambulatory hypertensives.

Vascular Studies

A third target of inquiry has been the vascular system; the rationale being that if white-coat hypertension is indeed innocent, vascular involvement should be much less than in sustained hypertensive patients and similar to normotensive patients. Although the carotid system is amenable to examination by ultrasound, the extent to which properties of the carotid reflect hypertensive damage or the effects of other metabolic factors is not known. The findings from carotid

arterial evaluations mirror other target organ studies, with some authors finding no increase in carotid wall thickness and others finding increases intermediate between those of normotensives and hypertensives.

Several studies^{37,44,45,50} have found no evidence of increased carotid disease in white-coat hypertension. In contrast, Glen³⁶ concluded that both white-coat and sustained hypertensive subjects had abnormalities of elasticity, compliance, and stiffness that were different from normotensive subjects. Similarly, Muldoon⁵¹ found increased carotid atherosclerosis in white-coat hypertension. Landray⁵² cautioned that white-coat hypertension is associated with carotid atherosclerosis. In most of these studies, metabolic risk factors other than high BP were present in the white-coat hypertensive group and possibly contributed to the carotid pathology.

Other studies have focused on noninvasive evaluation of endothelial function. For example, Pierdomenico⁵³ compared brachial artery flow mediated dilation in 22 sustained hypertensives, 22 white-coat hypertensives, and 22 normotensive subjects matched for age, gender, and body mass index. They found that white-coat hypertensives had similar findings to normotensives, and that both had higher levels than sustained hypertensives. Similar results were reported when an older group of patients was studied.⁵⁴

Cerebrovascular Studies

Early effects of hypertension on cerebrovascular structures are difficult to measure, but magnetic resonance imaging (MRI) can detect small vessel occlusive disease. The two most commonly detected abnormalities are lacunae and periventricular white-matter lesions. Lacunae are in essence small infarcts, whereas hypertensive small vessel disease is thought to play a role in the genesis of periventricular white-matter lesions.

Shimada et al.⁵⁵ used these two patterns as indicators of silent cerebrovascular disease and compared their prevalence in elderly patients with sustained and white-coat hypertension with normotensives. The subjects had no history of overt stroke and underwent ambulatory BP monitoring and MRI studies of the brain, as well as office BP measurements. From the overall group of 73 patients, three age-matched groups were defined as follows: (1) sustained hypertensives (n = 26, office BP ≥140/90 mm Hg, 24-hour BP ≥135/80 mm Hg); (2) white-coat hypertensives (n = 14, office BP ≥140/90 mm Hg, 24-hour BP <135/80 mm Hg); and (3) normotensives (n = 28, office BP <140/90 mm Hg, 24-hour BP >135/80 mm Hg). MRI scans were graded by a neuroradiologist unaware of the BP data. The number of lacunae and the grade of periventricular white-matter hyperintensities were similar in the white-coat hypertensive and normotensive groups with both significantly less than the sustained hypertensive group. This was true even though the white-coat hypertensive group had higher ambulatory DBP than the normotensive group.

More recently, Eguchi⁵⁶ examined the effects of ambulatory BP and diabetes mellitus on silent cerebral infarcts. They studied 360 hypertensive patients with a mean age of 67 years with and without diabetes. All participants were studied using ambulatory BP and had brain MRI to quantitate silent cerebral infarcts. As expected, diabetic patients with elevated BP had more silent cerebral infarcts than the group with hypertension but without diabetes. The role of ambulatory BP was examined by stratification into four groups: (1) nondiabetic

with white-coat hypertension, (2) nondiabetic with sustained hypertension, (3) diabetic with white-coat hypertension, and (4) diabetic with sustained hypertension. The most silent cerebral infarcts were seen in the group with combined diabetes and ambulatory hypertension, and the fewest in the white-coat hypertensive group who did not have diabetes mellitus.

Cardiovascular Risk Factors

Additional cardiovascular risk factors are common in the patient with sustained hypertension. Therefore, several authors have measured metabolic parameters likely to confer or be associated with cardiovascular risk in white-coat hypertensives. Pierdominico⁵⁰ and Marchesi⁵⁷ found no metabolic derangements among white-coat hypertensives, but Weber et al.⁴⁰ found that white-coat hypertensives had slightly higher insulin, renin, aldosterone, and norepinephrine levels than did normotensives. Similar metabolic perturbations were also described in the white-coat hypertensive group of the Tecumseh study.⁵⁸ Circulating homocysteine levels have been shown to be similar in white-coat hypertensives and sustained hypertensives.⁵⁹ It is likely that many of the target organ measures used in research studies to assess the risk of white-coat hypertension are affected by these metabolic factors.

Prognosis of White-Coat Hypertension

No randomized intervention study with morbidity and mortality as the endpoint has compared white-coat hypertensives, normotensives, and sustained hypertensives. However, an increasing number of studies in various types of populations have measured ambulatory and office BP at one point in time and then prospectively or retrospectively ascertained cardiovascular outcome several years later. These studies show that ambulatory monitoring of BP is superior to office-based measures of BP in predicting outcomes.⁶⁰⁻⁷⁴ It should be noted that the majority of these studies either evaluated the effects of the circadian BP profile or the comparative effects of ambulatory versus office BP in predicting events. Only two studies using noninvasive ambulatory BP monitoring^{61,67} and one using intraarterial monitoring⁶⁶ have specifically examined the outcome of white-coat hypertension.

Verdecchia⁶¹ attempted to assess the prognosis of white-coat hypertension by initially studying 1187 patients with newly diagnosed essential hypertension compared with 205 healthy normotensive subjects. After a mean of 3.2 years cardiovascular endpoints were assessed retrospectively. They defined white-coat hypertension as daytime ambulatory BP <136/87 mm Hg for men and <131/86 mm Hg for women (the 90th percentiles of same gender normotensive groups). Patients were followed by their own physicians with the goal of reducing their office BP to <140/90 mm Hg. The ambulatory BP data were available to the doctors but probably played a small role in their management. Complete follow-up data were obtained on 99.1% of all participants. Combined cardiovascular morbidity and mortality per 100 patient-years were 0.47 in the normotensive group (4 events in 205 subjects), 0.49 in the white-coat hypertensive group (3 events in 228 subjects), 1.79 in the ambulatory hypertensive group with a dipping BP profile (37 events in 693 subjects), and 4.99 in the ambulatory hypertensive group with a nondipping BP profile (45 events in 266 subjects). Cardiovascular morbidity was

similar in the white-coat hypertension group and the normotensive group by multivariate analysis. A further analysis in which a daytime BP <130/80 mm Hg was used to define white-coat hypertension showed a difference in event-free survival between the two defined white-coat hypertension groups.⁷⁵

The second outcome report of white-coat hypertension involved the data from the ambulatory BP substudy of the Systolic Hypertension in Europe (Syst-Eur) study.⁶⁷ Patients in the Syst-Eur study were 60 years or older and had office SBP between 160 and 219 mm Hg and DBP <95 mm Hg. After randomization, patients were treated either with active medication or placebo. In a subset of 808 patients, ambulatory monitoring was performed at baseline and again at 6 and 12 months. Data were available on 342 patients assigned to active treatment and 353 assigned to placebo. Three groups were defined according to daytime SBP: <140 mm Hg (nonsustained or white-coat hypertension), 140 to 159 mm Hg (mild sustained hypertension), and 160 mm Hg or more (moderate sustained hypertension). Nonsustained hypertensives taking placebo had three to four times lower stroke rates and cardiovascular complications compared with moderate sustained hypertensives. Patients in the mild sustained group were intermediate. Active treatment appeared to reduce outcomes only in the moderate sustained group. No comparison with a normotensive control group was possible. Khattar et al. used intraarterial BP monitoring⁶⁶ and had similar results.

To conduct a large outcome trial to evaluate the possible risks of white-coat hypertension is a complex matter. Event rates are low in this group of patients.⁶⁰ Thus any study would have to be exceedingly large and have long follow-up (>5 years) to show a difference compared with normotensives. Furthermore, pharmacologic therapy of white-coat hypertension may lead to reductions of office but not ambulatory BP,⁷⁶ further complicating the ability to conduct a trial and assess the results.

Blood Pressure Evolution in White-Coat Hypertension

The natural history of persons labeled as white-coat hypertensives is not well studied. One approach has been to follow untreated patients over several years if ambulatory BP increases over time or to see if a surrogate marker of hypertension (e.g., left ventricular mass) changes. If white-coat hypertension is a prehypertensive state, then these persons should evolve into sustained hypertensives over time in excess of an age-matched normotensive group and may show increases of left ventricular mass. Polonia et al.⁷⁷ prospectively evaluated 36 untreated patients with white-coat hypertension (office BP >140/90 mm Hg and awake BP <132/84 mm Hg) and a control group of 52 normotensives (clinic BP <140/90 mm Hg and awake BP <132/84 mm Hg). Patients underwent repeat ambulatory and office BP measurements after a mean interval of 3.5 years. The two groups showed similar rates of evolution to sustained hypertension (22% and 15%, respectively). However, 17 of the original 88 patients studied at baseline had been started on drug therapy, making it difficult to be sure if they had evolved into sustained hypertensives.

White et al.⁷⁸ reported similar results, showing that when a restrictive definition of white-coat hypertension is used (awake ambulatory BP <135/85 mm Hg), the rate of evolution

to sustained hypertension is similar to age-matched normotensives (12% vs 15%). Verdecchia⁷⁹ repeated clinic and ambulatory BP and echocardiographic evaluation of 83 untreated patients defined with white-coat hypertension after a mean period of 2.5 years, and they found that 37% became ambulatory hypertensives. In the group that evolved into sustained hypertension, there was a rise in left ventricular mass of 6.2%, whereas in the group that has persistent white-coat hypertension, there was a small decrease in left ventricular mass. This study had no control group, so that the proportion of age-matched normotensives who evolved into sustained hypertension could not be ascertained. In another study,⁸⁰ a high rate of progression to sustained hypertension was found, but this study used a liberal definition of white-coat hypertension and had no control group.

MASKED HYPERTENSION

In some patients, office-based BP measurements may underestimate average daily BP. Although this phenomenon has not been well studied and many basic questions remain regarding the underlying mechanisms, some data suggest such persons are at high risk. This condition is seen in both young⁸¹ and old patients⁸² and is not rare. A few studies^{48,81} show that masked hypertension is associated with a larger cardiac mass and more carotid atherosclerosis than true normotension. In a recent longitudinal follow-up study of men,⁸² masked hypertension was associated with a twofold to threefold increase in cardiovascular morbidity.

SUMMARY

There is continued uncertainty regarding the prognosis of patients with white-coat hypertension. The fully reported outcome studies suggest a relatively benign prognosis for white-coat hypertensives, and none has shown a worsened cardiovascular outcome compared with normotensives. Nevertheless, most investigators in the field would agree to a few general principles concerning the care of patients with white-coat hypertension. A strict definition using low ambulatory BP averages (e.g., daytime BP <130/80 mm Hg) is necessary to avoid misclassification of patients as white-coat hypertensives when they are actually sustained hypertensives. All coexistent cardiovascular risk factors should be treated. It is prudent to monitor such patients closely and reinforce lifestyle modifications while we await the results of a prospective randomized trial. In the case of masked hypertension, the possibility that out-of-office BP may be higher than office readings should be considered in smokers and in those with excessive target organ damage discordant to levels of office BP (e.g., unexplained LVH). Further study is needed to identify persons at high risk who may benefit from detection of masked hypertension.

Treatment: General Considerations

Chapter 29

The Blood Pressure Lowering Treatment Trialists' Collaboration (BPLTTC)

Fiona Turnbull, Jeffrey A. Cutler

INTRODUCTION

What is the Blood Pressure Lowering Treatment Trialists' Collaboration?

The Blood Pressure Lowering Treatment Trialists' Collaboration (BPLTTC) is an international collaboration of the principal investigators of large randomized trials of blood pressure-lowering regimens (see Appendix). The broad aim of the collaboration is to provide the most reliable evidence about the effects of commonly used blood pressure-lowering regimens on major cardiovascular events by using prospective meta-analyses (overviews) of individual trials.

The overviews are conducted and reported in accordance with a protocol¹ that prespecifies trial eligibility criteria, primary outcomes, and treatment comparisons. The size, scope, and conduct of these overviews generate precise estimates of the effects of different blood pressure-lowering agents that can then be used to inform clinical and health care policy decision making.

The day-to-day activities of the collaboration—including data management, statistical analysis, and report writing—are carried out by a secretariat (Appendix) based at the George Institute for International Health, a department of the University of Sydney, Australia. An executive committee (Appendix), comprising selected members of the collaboration and of the secretariat, oversees these activities. The secretariat takes primary responsibility for securing funding for the project and for coordinating collaborator meetings. These meetings allow investigators to have an active role in decisions about the direction of the collaboration.

Background to the Formation of the BPLTTC

In the late 1970s and 1980s, newer and costlier agents, such as calcium antagonists and angiotensin-converting enzyme (ACE) inhibitors, were developed and approved for use as antihypertensive agents. However, even by the early 1990s, evi-

dence that might justify their use, particularly in preference to older classes of agents (diuretics and β -blockers), remained limited. The few studies that directly compared ACE inhibitors and calcium antagonists with conventional agents²⁻⁵ failed to detect any clear differences, mainly because they were individually and collectively too small to detect any plausibly modest differences in the cause-specific effects of the regimens compared. Similar uncertainty also remained about the effects of different blood pressure-lowering regimens on other groups of patients not identified as being “hypertensive” but otherwise at high risk of cardiovascular events, such as those with diabetes or cerebrovascular or renal disease.

During the latter part of the 1990s, a number of new trials were started in an attempt to elucidate the role of newer agents in the prevention of major cardiovascular morbidity and mortality. However, reliable detection of differences of 15% or less would require an individual trial to record 1000 or more outcome events during follow-up, and few trials were likely to observe this number of events. Detection of such differences would require evidence from randomized trials involving many tens of thousands of patients and 1000 or more outcome events during the scheduled treatment period.

In July 1995, therefore, the principal investigators from many of the large-scale trials that were in progress or in advanced stages of planning met and agreed to collaborate in a program of prospectively planned overviews of randomized trials. The broad goal of the collaboration was to provide highly reliable evidence for the effects of commonly used blood pressure-lowering regimens on major cardiovascular events.

METHODOLOGY

Evidence-Based Medicine and the Value of Systematic Overviews/Meta-Analyses

Evidence-based medicine (EBM) is the “conscientious, explicit and judicious use of current best evidence in making decisions

about the care of individual patients.”⁶ An objective summary of the best available evidence can be provided by a systematic overview or meta-analysis, a statistical procedure that integrates the results of several independent studies that are “combinable.”⁷ Meta-analyses have become increasingly important tools in epidemiologic research because they are capable of assessing small risks⁸ and, as a consequence of including many studies, the findings can be applied to a diverse range of patients.

In combining the results, individual trials are weighted according to size (numbers of clinical events) so that larger trials have more influence than smaller trials. The statistical techniques to combine the estimates of individual trials can be broadly classified into two models. The “fixed effects” model assumes that the variability between trials is entirely due to random variation. The “random effects” model takes into account an additional source of variation by assuming a different underlying effect for each study.⁹ The differences between the models are reflected in the confidence intervals around the point estimate of effect (wider for the random effects model). Neither model is considered “correct,” and substantial differences in the combined effect calculated by each method will be seen only if the findings of the individual, contributing studies are markedly different or “heterogeneous.” Heterogeneity across studies can be formally examined by using statistical procedures. The more significant the

test of homogeneity, the less likely it is that the observed differences in the size of the effect are due to chance alone.¹⁰ A statistically significant test means that significant differences among the studies exist.

There are several different types of meta-analyses, but all share a requirement for a study protocol that clearly describes the research question and the design, including how studies are identified and selected, the statistical methods to be used, and how the results will be reported. Meta-analyses of published data can be performed without the cooperation or even agreement from study investigators. Although this is a relatively simple method for calculating a pooled estimate of effect, these meta-analyses are subject to a number of limitations, including publication bias and differences between contributing studies in their design and definitions of outcomes.⁸ One variation of this type of meta-analysis is the “network meta-analysis,” which combines trials conducting direct comparisons of different treatments with indirect comparisons derived from the use of similar comparator arms in different trials.^{11,12} The Cochrane Collaboration also conducts meta-analyses if data from systematic reviews are of sufficient quality.¹³ Searches for unpublished and non-English records reduce the risk of publication bias, but subsequent meta-analyses remain retrospective and are also subject to differences in the quality of the data from each study.

In meta-analyses using individual data, statistical reanalysis can be performed by using the same inclusion criteria for all studies and unified definitions for all variables. In prospectively designed overviews, the principal research hypotheses, criteria for inclusion of studies, and statistical analyses are all defined a priori in a formal protocol. By specifying these in advance of publication of trial results, retrospective outcome-dependent biases are avoided and the reliability of the estimates of the effects of the individual treatment regimens is increased. Examples of such prospective meta-analyses include the BPLTTC and the Cholesterol Treatment Trialists' (CTT) Collaboration.¹⁴

The BPLTTC Study Protocol

In 1998, the Collaboration published a protocol¹ outlining plans for prospective overviews of major randomized trials of blood pressure-lowering treatments. The following section outlines the major components of this protocol, which guides ongoing work by the Collaboration.

Eligible Trials and Their Identification

Trials are eligible for inclusion in the overviews if they satisfy one of the following criteria: (1) random allocation of patients to regimens based on different blood pressure-lowering agents, (2) random allocation of patients to a blood pressure-lowering agent or placebo, or (3) random allocation of patients to various blood pressure goals. In addition, eligible

trials have to have a planned minimum follow-up of 1000 patient-years per treatment arm and could not have published or presented main trial results before July 1995. Although trials with factorial assignment to other interventions such as cholesterol-lowering treatment are eligible for inclusion, trials in which additional treatments are jointly assigned with blood pressure-lowering treatment are not eligible, because these other treatments act as potential confounders.

Eligible trials are identified by a number of methods, including computer-aided literature searches; scrutiny of the reference lists of trial reports and review articles; scrutiny of abstracts and meeting proceedings; and inquiry among colleagues, collaborators, and industry. Principal investigators of eligible studies are identified and invited to join the Collaboration on an ongoing basis.

Data Collection

Both individual patient data and summary tabular data are sought from each trial. Although most trials provide tabular data in the first instance, individual patient data facilitate data checking and the conduct of more-comprehensive statistical analyses. The data requested include participant characteristics recorded at screening or randomization, selected measurements made during follow-up, and details of the occurrence of all prespecified BPLTTC outcomes during the scheduled follow-up period (Table 29-1). All data are reviewed for accuracy and completeness and, once tabulated, are sent to collaborating investigators for checking.

Table 29-1 Baseline, Follow-up, and Outcome Data Requested from Trials Participating in the BPLTTC

Baseline (At or Before Randomization)	Follow-up (At Annual or Similar Intervals)	Outcomes (All Events in Each Category Recorded during Scheduled Follow-up period)
Patient identifier	Systolic blood pressure	Ischemic stroke
Date of randomization	Diastolic blood pressure	Cerebral hemorrhage
Treatment allocation	Weight	Subarachnoid hemorrhage
Date of birth/age	Serum cholesterol	Other stroke (including unknown)
Gender	Serum creatinine	Myocardial infarction
Ethnicity	Smoking status	Hospitalization for heart failure
Systolic blood pressure	Compliance	Hospitalization for renal disease
Diastolic blood pressure		Hospitalization or transfusion for non-cerebral hemorrhage
Weight		Arterial revascularization procedure
Height		Major cancer (site-specific)
Smoking status		Admission to hospital for any other cause
Serum total cholesterol		Bone fracture
Serum creatinine		Death (cause-specific)
Regular aspirin/antiplatelet drug		Date for each event
Other blood pressure-lowering drug		Date of last follow-up for fatal events
History of:		Date of last follow-up for nonfatal events

Diabetes		
Left ventricular hypertrophy		
Heart failure		
Cerebrovascular disease		
Planned end of scheduled treatment and follow-up		

Prespecified Outcomes

The study outcomes chosen for these overviews represent the main cardiovascular outcomes likely to be affected by blood pressure–lowering treatment regimens and the main noncardiovascular disease (non-CVD) outcomes for which questions about the safety of some agents have arisen. The six prespecified primary outcomes are nonfatal stroke or death from cerebrovascular disease (codes 430-438 in the 9th revision of the International Classification of Diseases [ICD-9]); heart failure causing death or requiring hospitalization (ICD 428); total cardiovascular deaths (ICD 396-459); total major cardiovascular events (stroke, coronary heart disease [CHD] events, heart failure, other cardiovascular death); and total mortality. The secondary study outcomes include hemorrhagic stroke (ICD 431-432); ischemic stroke (ICD 433-434); death or hospitalization for renal disease (ICD 189, 403-404, 580-593); arterial revascularization procedure (ICD 36, 38.0, 38.1, and 38.4); any bone fracture (ICD 800-829); death, hospitalization, or transfusion for any noncerebral hemorrhage (ICD 459, 578.9, but not 430-432); or major site-specific cancer (lung [ICD 162], large bowel [ICD 153-154], breast [ICD 174-175], or prostate [ICD 185]); and admission to hospital for any cause.

Prespecified Comparisons

The comparisons prespecified in the protocol can be broadly divided into two groups. The first group comprises comparisons of active blood pressure–lowering regimens with control regimens: ACE inhibitor–based regimens versus placebo, calcium antagonist–based regimens versus placebo, and regimens targeting different blood pressure goals (more- versus less-intensive blood pressure–lowering regimens). The second group comprises comparisons of different active regimens intended to produce similar blood pressure reductions: ACE inhibitor–based regimens versus diuretic- and/or β -blocker–based regimens; calcium antagonist–based versus diuretic-based or β -blocker–based regimens; and ACE inhibitor–based regimens versus calcium antagonist–based regimens. For each of these comparisons, the null hypothesis of no difference between regimens in their effects on primary outcomes is tested.

At the time of writing the protocol, there were insufficient trials of newer agents such as angiotensin receptor blockers to warrant separate analyses. However, provision was made to include comparisons of these agents as sufficient trials became available.

The protocol also prespecifies secondary analyses with tests of interaction performed to assess the association of any treatment differences with the following patient characteristics: age, sex, diabetes status, preexisting CVD, baseline serum creatinine level, baseline serum cholesterol level, baseline systolic and diastolic blood pressures, and nonstudy blood pressure–lowering treatment at study entry. These subgroup analyses are designed to answer whether there are important differences in the effects of different blood pressure–lowering regimens in younger and older patients, in patients with and without diabetes, and between the other prespecified comparator groups.

Statistical Analyses

Analyses for each primary outcome are based on the first relevant outcome experienced by a participant. Each participant can contribute only one event to the calculation of one outcome analysis but more than one event to separate analyses of

different outcomes. For each study, the relative risk and 95% confidence interval for each outcome are calculated according to the principle of intention to treat. Overall estimates of effect are calculated with a fixed effects model, where the log relative risk for each trial is weighted by the reciprocal of the variance of the log relative risk. The assumption of homogeneity between the treatment effects in different trials is tested with chi-square Q and more recently with the I^2 statistic.¹⁵ If the assumption of homogeneity is rejected, then additional analyses are conducted with a random effects model. Mean levels of baseline characteristics and mean differences in follow-up blood pressure between randomized comparisons are calculated with estimates from individual trials weighted by the number of individuals in the study.

Since publication of the protocol, two cycles of overviews have been reported by the Collaboration. The first cycle, published in 2000, included results from 15 trials and nearly 75,000 individuals. More recently, the second cycle reported on the results from 29 trials and 160,000 individuals (Table 29–2).

FIRST CYCLE FINDINGS: SETTING THE SCENE (FIGURES 29–1 THROUGH 29–6)

By 2000, sufficient data had become available to conduct the first cycle of BPLTTC overviews (Table 29–3).¹⁶ These overviews showed conclusively that the benefits of blood pressure–lowering regimens were not limited to those based on diuretics and β -blockers but extended to newer agents (ACE inhibitors and calcium antagonists) and that these benefits were observed in a heterogeneous population of patients at high risk of CVD.

In the placebo-controlled trials of ACE inhibitors (12,000 individuals and 1800 major cardiovascular events), in which the weighted mean difference between randomized groups was 3/1 mm Hg, there was 20% to 30% reduction in the risk of stroke, CHD, major cardiovascular events, cardiovascular death, and total mortality with active treatment. There was no significant reduction in the risk of heart failure, although the 95% confidence intervals did not exclude a possible moderate advantage for patients receiving ACE inhibitor therapy.

Compared with placebo, calcium antagonist–based regimens producing blood pressure reductions of 9/5 mm Hg conferred clear 30% to 40% reductions in the risk of stroke and major cardiovascular events and nonsignificant trends toward benefits for the remaining outcomes. Although these analyses were limited by rather fewer data (5500 individuals and 380 major cardiovascular events), the estimates of treatment effect largely precluded adverse effects of calcium antagonists in hypertensive patients of the magnitude that had been suggested by earlier reviews in patients with acute myocardial infarction and unstable angina.^{17,18}

Comparisons of regimens targeting different blood pressure goals (20,000 individuals and 1000 major cardiovascular events) showed that patients assigned the lowest diastolic blood pressure goals (75 to <85 mm Hg) experienced lower risks of stroke, CHD, and major cardiovascular events. These reductions in risk were on the order of 20%. However, the exact sizes of the differences remained uncertain because of the wide confidence intervals. There was also evidence of heterogeneity ($p = .02$) among the trials contributing to the more- versus less-intensive comparison, largely attributable to

Table 29-2 Trials Included in Second Cycle of BPLTTC Overviews

trends in opposite directions of the treatment effects for Hypertension Optimal Treatment (HOT)¹⁹ and United Kingdom Prospective Diabetes Study (UKPDS).²⁰

The first cycle overviews of trials comparing regimens based on different active agents showed that where blood pressure differences between randomized groups were small (0-3 mm Hg), there was no evidence of a difference in the risk of composite events, major cardiovascular events, cardiovascular death, and total mortality. However, there was some evidence of moderate but potentially important differences between regimens for the cause-specific outcomes of stroke, CHD, and heart failure. In particular,

compared with regimens based on diuretics/ β -blockers, calcium antagonist-based regimens appeared to afford greater protection against stroke but less against coronary heart disease. These findings were similar for trials of dihydropyridine and nondihydropyridine agents alike. In the comparisons of ACE inhibitor- and calcium antagonist-based regimens, there was a 20% reduction in the risk of both CHD and heart failure with ACE inhibitor-based regimens. However, for the outcome of CHD, there was significant ($p = .01$) heterogeneity among contributing trials, and for the outcome of heart failure, the risk reduction was of borderline significance.

SECOND CYCLE FINDINGS: RESOLVING THE UNCERTAINTY

Although the first cycle of overviews provided many answers to questions they were designed to address, there remained some uncertainty about others—in particular the effects of active treatment with calcium antagonists (compared with none) on the risk of CHD and heart failure and about differences between active regimens in their cause-specific effects.

At the end of 2003, the Collaboration reported its second cycle of overviews.²¹ This second cycle was able to resolve much of this persisting uncertainty. A doubling in the amount of data available for analyses substantially increased the evidence available and resulted in the generation of more-precise estimates of treatment effect, especially for comparisons of different active agents. The substantial increase in the amount of data also provided an opportunity to explore in more detail the association of blood pressure reduction and risk reduction. Furthermore, at the end of 2003, sufficient trials of angiotensin receptor blockers had been completed to warrant separate analyses of this important new class of blood pressure-lowering agent.

Because the second cycle of overviews provides the most recent and reliable evidence for the effects of different blood pressure-lowering agents, they are the major focus for the remainder of the chapter.

Trials and Participants

Nine trials (25,000 individuals and 3500 major cardiovascular disease [CVD] events) provided data from placebo-controlled comparisons of ACE inhibitors and calcium antagonists, and five trials (22,000 individuals and 1200 major CVD events) provided data from trials targeting different blood pressure goals (Table 29-3). Sixteen trials (101,000 participants and 10,000 major CVD events) provided data on comparisons of different active regimens based on ACE inhibitors, calcium antagonists, and diuretics and/or β -blockers. For most trials, patients were selected on the basis of high blood pressure and an additional cardiovascular risk factor such as diabetes, renal disease, or increased age. The overall mean age of participants was 65 years, and just more than half (52%) were men. The mean duration of follow-up for contributing trials ranged from 2.0 to 8.4 years, resulting in more than 700,000 patient-years of follow-up.

Stroke

In keeping with first cycle findings, there were significant reductions (30%–40%) in the risk of stroke with active regimens (ACE inhibitors, calcium antagonists, more intensive) as compared with control (placebo and less intensive) regimens (Figure 29-1, A). In the comparisons of different active regimens, where blood pressure differences between groups ranged from 0 to 2 mm Hg, there were some differences, but these were of borderline statistical significance. There was a trend toward a greater reduction in the risk of stroke associated with calcium antagonists when compared with regimens based on either ACE inhibitors or diuretic/ β -blocker agents (Figure 29-1, B). Similarly, there was also a trend toward a greater protective effect associated with conventional therapy as compared with regimens based on ACE inhibitors. These findings, albeit of borderline significance, had not been apparent in the first cycle of overviews. Furthermore, in this second cycle of overviews based on more than 7500 stroke events, there was no evidence of significant heterogeneity between contributing trials in their estimates of treatment effect (all p homog >.1).

Coronary Heart Disease

More than 10,000 CHD events contributed to the second cycle of overviews. These showed that ACE inhibitor-based regimens reduced the risk of CHD by 20% as compared with placebo (Figure 29-2, A). There was weaker evidence of a reduction with calcium antagonists, and for regimens targeting lower blood pressure goals, there was no clear evidence of benefit. Whereas the first cycle had suggested that there was some evidence of a greater protective effect from regimens based on both diuretics/ β -blockers and ACE inhibitors as compared with calcium antagonists, in the second cycle, there was no evidence of any difference between any of the active regimens for the prevention of CHD. These findings were able to confirm conclusions from earlier reports^{22,23} questioning the validity of claims of large increases in coronary risk in hypertensive patients treated with calcium antagonists. In the specific comparison of regimens based on ACE inhibitors and calcium antagonists for this outcome, there was evidence of heterogeneity among contributing trials, which had also been demonstrated in the first cycle of

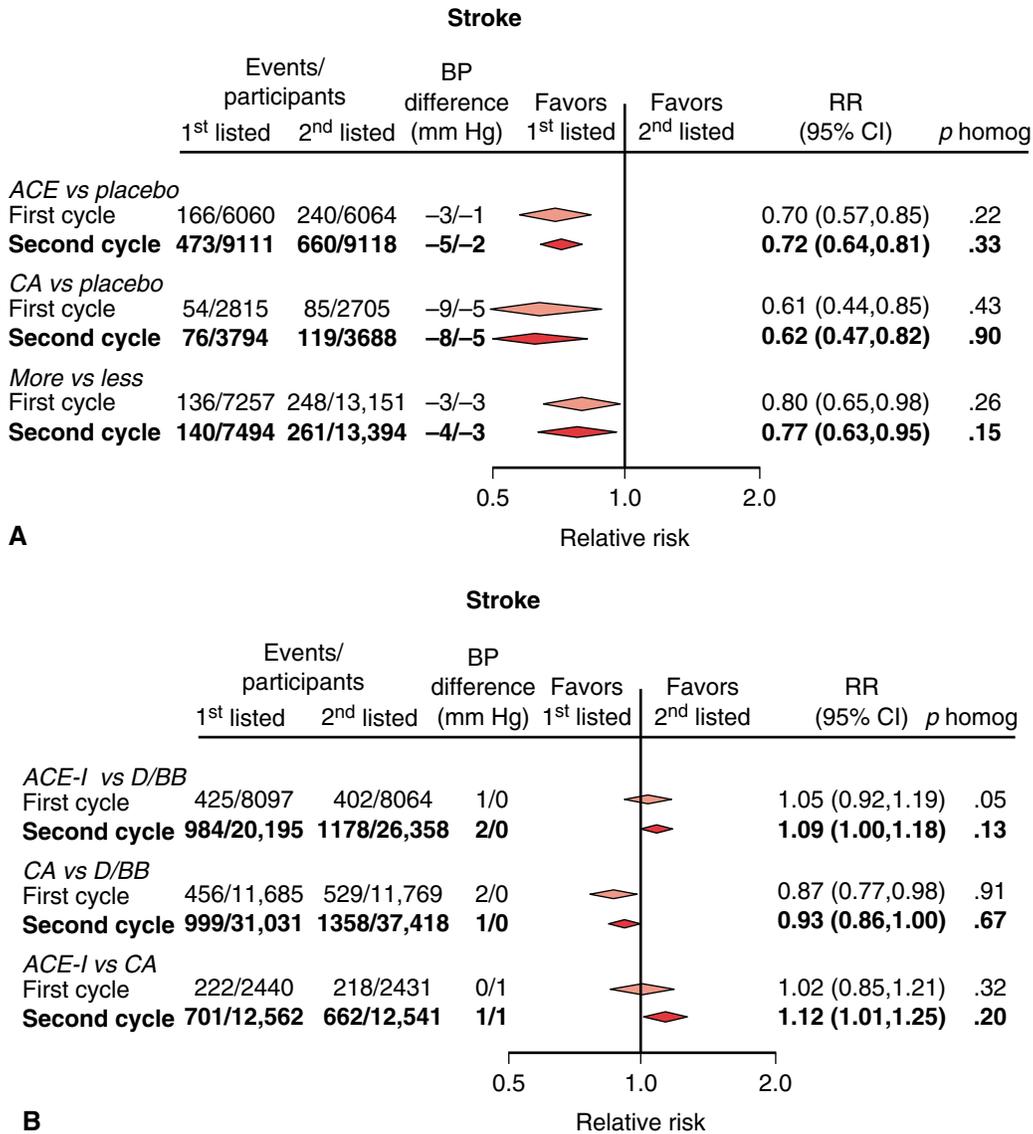

Figure 29-1 Comparisons of active and control regimens **(A)** and comparisons of different active regimens **(B)** for the outcome of stroke. BP, blood pressure; RR, relative risk; CI, confidence interval; ACE, angiotensin-converting enzyme; CA, calcium antagonist; ACE-I, ACE inhibitor; D/BB, diuretic/ β -blocker.

overviews. This heterogeneity was mainly due to one trial²⁴; however, neither exclusion of this trial from the fixed-effects model nor the use of a random-effects model altered the conclusions for this outcome.

Heart Failure

Heart failure events were defined as those resulting in death or admission to hospital. The second cycle of overviews demonstrated a greater protective effect against heart failure from regimens based on ACE inhibitors as compared with placebo but no evidence of a difference between regimens targeting different blood pressure goals. These results were broadly consistent with findings from the first cycle of overviews. Conversely, where first cycle findings indicated a trend toward a greater protective effect against heart failure from regimens

based on calcium antagonists compared with placebo, the second cycle demonstrated a trend in favor of placebo. However, the confidence intervals around the effect estimates for this comparison and for the comparison of more- and less-intensive regimens were wide, reflecting rather fewer data (318 events) available for these analyses.

Compared with regimens based on calcium antagonists, those based on diuretics and/or β -blockers and on ACE inhibitors produced greater reductions in risk of severe heart failure that were not easily accounted for by their comparative effects on blood pressure. Because heart failure events were restricted to those that resulted in death or hospitalization, minor side effects of calcium antagonists, such as peripheral edema, are unlikely to have been responsible for this finding.

The separation of trials that used dihydropyridine agents and those that used nondihydropyridine agents did not result

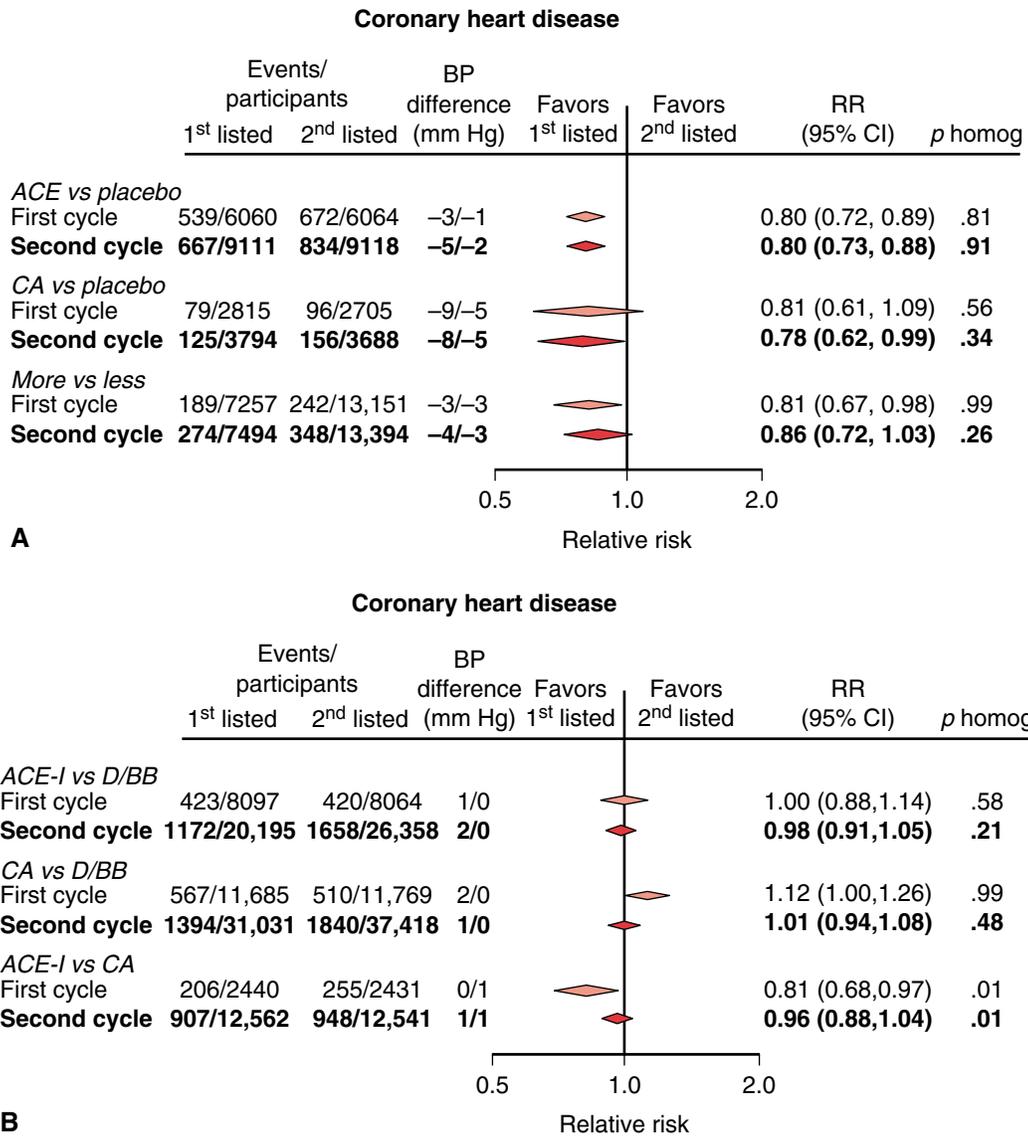

Figure 29-2 Comparisons of active and control regimens (**A**) and comparisons of different active regimens (**B**) for the outcome of coronary heart disease. BP, blood pressure; RR, relative risk; CI, confidence interval; ACE, angiotensin-converting enzyme; CA, calcium antagonist; ACE-I, ACE inhibitor; D/BB, diuretic/ β -blocker.

in any difference in the overall conclusions for this outcome (see Figure 29-3).

Major Cardiovascular Events

A total of more than 17,000 major cardiovascular events (a composite outcome comprising stroke, CHD, and heart failure events plus death from any other cardiovascular cause) contributed to the second cycle of overviews, nearly double the number of events available at the time of the first cycle. In line with first cycle findings, there were significant reductions in the risk of this outcome with active treatment based on either ACE inhibitors (22%) or calcium antagonists (21%) as compared with placebo and for more-intensive as compared with less-intensive regimens (14%). There were no significant differences between regimens based on any of the active

agents (ACE inhibitors, calcium antagonists, or diuretics and/or β -blockers), and confidence intervals were narrow for the estimate for every comparison (see Figure 29-4).

Cardiovascular Death

Compared with placebo, ACE inhibitors reduced the risk of cardiovascular death by 20%. There was a trend toward fewer deaths with calcium antagonist-based regimens but no clear evidence of a reduction in risk with regimens targeting lower blood pressure goals. These findings were comparable with those generated by the first cycle trials, as were the findings for the comparisons of different active agents, in which very precise estimates of effect indicated no difference between regimens based on ACE inhibitors, diuretics or β -blockers, or calcium antagonists (see Figure 29-5).

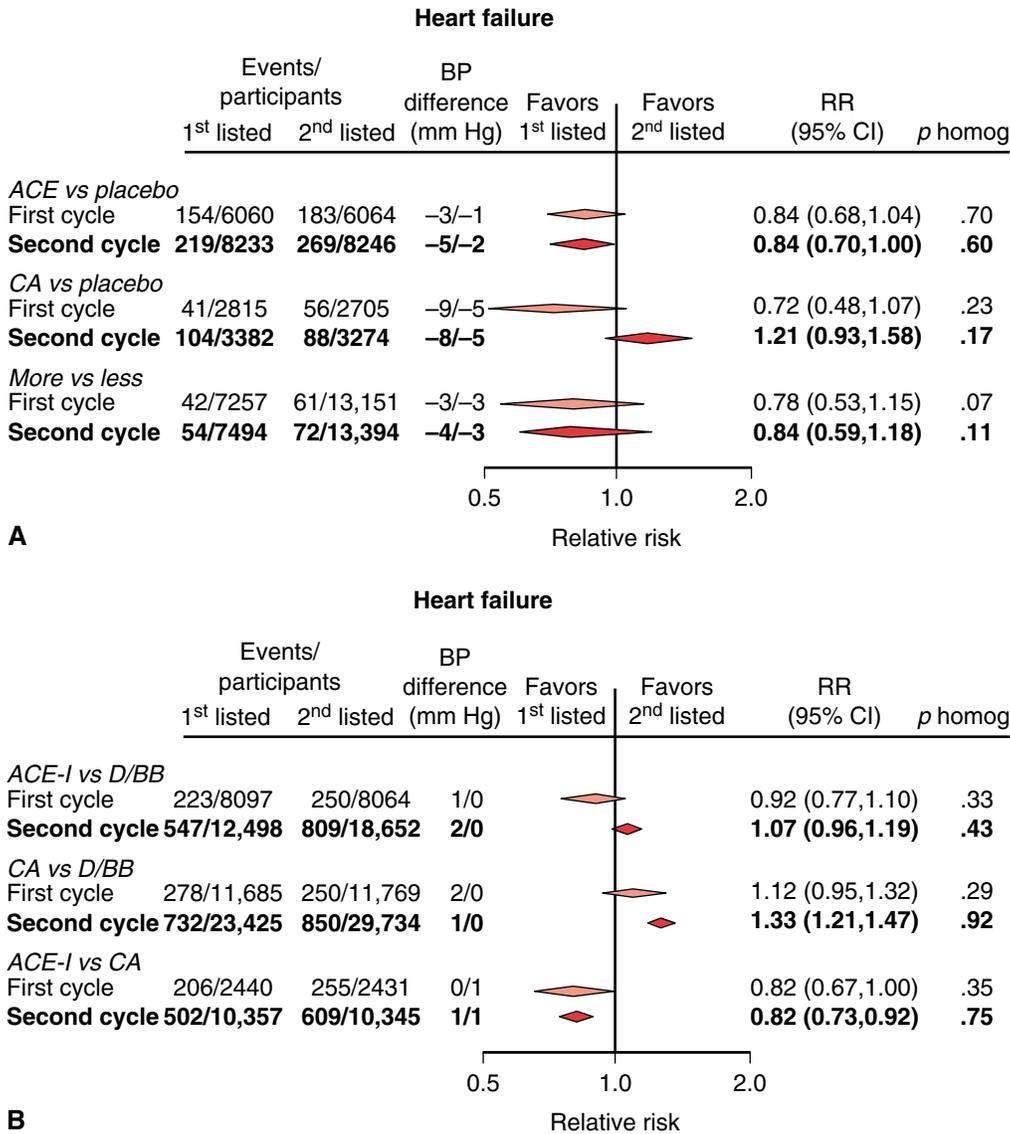

Figure 29-3 Comparisons of active and control regimens **(A)** and comparisons of different active regimens **(B)** for the outcome of heart failure. BP, blood pressure; RR, relative risk; CI, confidence interval; ACE, angiotensin-converting enzyme; CA, calcium antagonist; ACE-I, ACE inhibitor; D/BB, diuretic/ β -blocker.

Total Mortality

Compared with placebo, ACE inhibitor–based regimens reduced the risk of death by 12%. However, there were no significant differences in the risk of death for any of the five other treatment comparisons. There had been evidence of heterogeneity for this outcome in the comparison of more- and less-intensive regimens in the first cycle of analyses. This heterogeneity appeared to reflect a very large reduction in risk of death in favor of more-intensive regimens in the Appropriate Blood Pressure Control in Diabetes (ABCD) trial²⁴ and non-significant trends in the opposite direction from HOT¹⁹ and UKPDS.²⁰ With the addition of two more trials^{25,26} to this treatment comparison, the heterogeneity was less marked. Neither exclusion of the trial with the extreme result nor the use of the random effects model altered the conclusion for this outcome (see Figure 29-6).

Angiotensin Receptor Blocker Trials

At the time of reporting the first cycle of overviews, there were insufficient data from trials of angiotensin receptor blockers (ARBs) to be included in the analyses. However, by 2003, data from four ARB trials were able to be included in the second cycle of overviews. These trials were Irbesartan Diabetic Nephropathy Trial (IDNT),²⁷ Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL),²⁸ Study on Cognition and Prognosis in the Elderly (SCOPE),²⁹ and Losartan Intervention for Endpoint reduction in hypertension study (LIFE).³⁰ As the comparisons of these agents differed somewhat from other treatment comparisons, they were presented separately. Three trials²⁷⁻²⁹ were placebo-controlled trials; however, in SCOPE, active treatment was initiated in a large proportion of the placebo group early in the study, and in IDNT and RENAAL, there was a

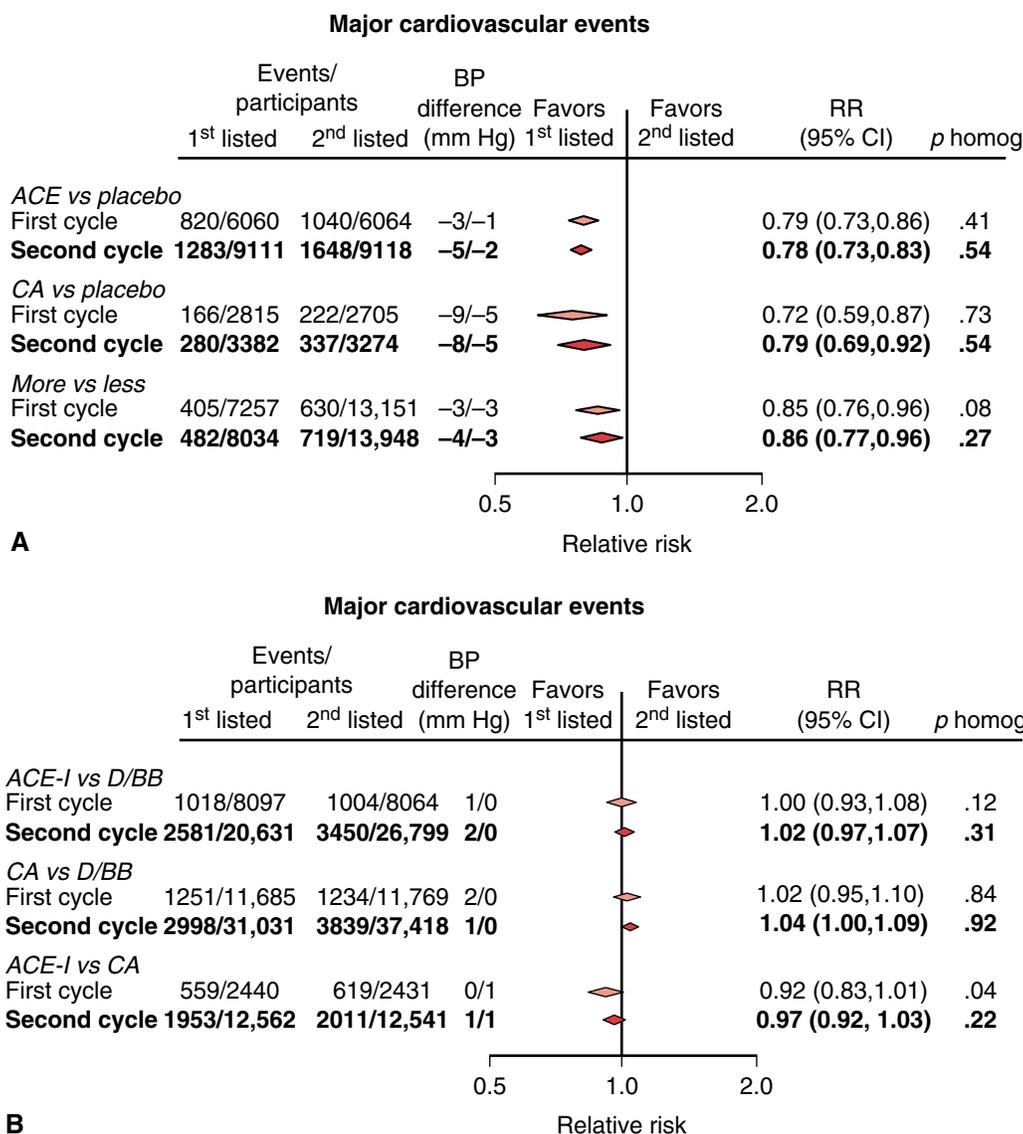

Figure 29-4 Comparisons of active and control regimens (**A**) and comparisons of different active regimens (**B**) for the outcome of total major cardiovascular events. BP, blood pressure; RR, relative risk; CI, confidence interval; ACE, angiotensin-converting enzyme; CA, calcium antagonist; ACE-I, ACE inhibitor; D/BB, diuretic/ β -blocker.

simultaneous attempt to achieve blood pressure reductions in both randomized groups. LIFE was the only trial designed as a head-to-head comparison (a comparison of an ARB and β -blocker). However, because all trials included control arms with active agents other than ARBs, they were analyzed as a single group.

There were significant reductions (10%-20%) in the risk of stroke, heart failure, and total major cardiovascular events with regimens based on ARBs as compared with control regimens (Figure 29-7). However, for the remaining outcomes, there was no significant difference, and it is possible that the differences in certain outcomes can be accounted for by differences in achieved blood pressure levels.

KEY MESSAGES AND IMPLICATIONS FOR CLINICAL PRACTICE

- i These overviews provide clinicians and their patients with uniquely reliable information about the relative benefits and risks of widely used classes of blood pressure-lowering drugs. The results are applicable to a broad population of hypertensive and nonhypertensive individuals at high risk of CVD.
- ii Treatment with any commonly used regimen reduces the risk of total major cardiovascular events, and larger reductions in blood pressure produce larger reductions in risk. Direct evidence of this is provided by overviews of trials that compared more- with less-intensive blood pressure-lowering

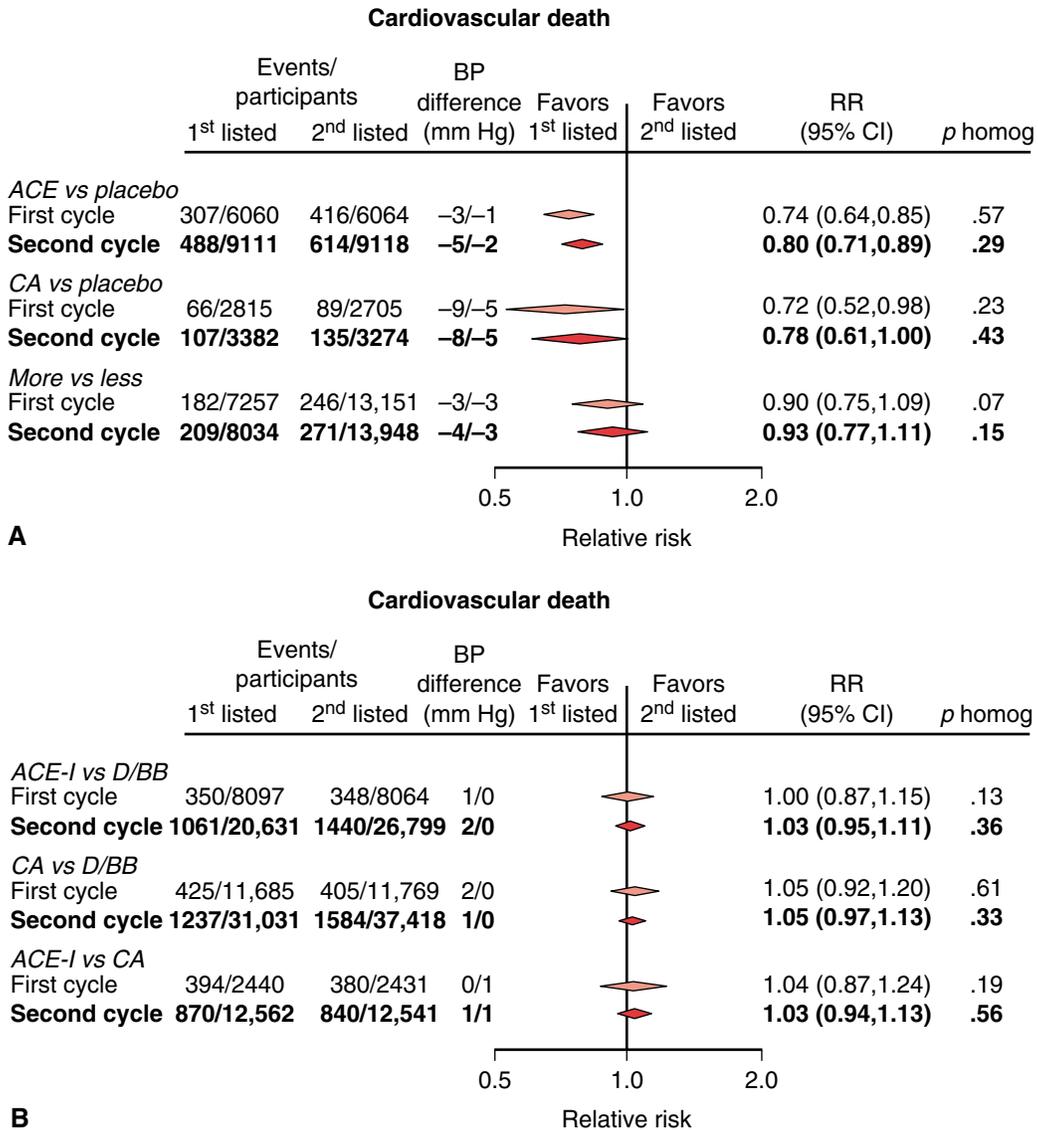

Figure 29-5 Comparisons of active and control regimens (A) and comparisons of different active regimens (B) for the outcome of cardiovascular death. BP, blood pressure; RR, relative risk; CI, confidence interval; ACE, angiotensin-converting enzyme; CA, calcium antagonist; ACE-I, ACE inhibitor; D/BB, diuretic/ β -blocker.

regimens. In these comparisons, the risk of stroke and of total major cardiovascular events was significantly reduced by regimens targeting lower blood pressure goals. Indirect evidence is provided by the association of weighted mean differences in blood pressure between randomized groups with differences in risk of an event (Figure 29-8). This direct association is true for all cardiovascular events except for heart failure.

- iii There are some differences between regimens in their cause-specific effects that appear to be independent of blood pressure. Regimens based on ACE inhibitors and on diuretics and/or β -blockers are much more effective at preventing heart failure than regimens based on calcium antagonists—results that are broadly consistent with trials of both ACE inhibitors³¹ and calcium antagonists³² in heart failure patients. There remains less certainty about possible differences between regimens in their effects on stroke.

THE COLLABORATION AND FUTURE CHALLENGES

Although the BPLTTC has been at the forefront of the field of collaborative overviews of trials and has achieved most of its objectives, it has also faced challenges regarding scope, methodology, logistics, and funding. With regard to scope, the protocol listed eight subgrouping variables, yet because of the complexity of describing results by subgroups, a paper based on one of these—diabetic status—has only recently been completed. To be most useful in informing practice and practice guidelines, it is desirable to report on as many subgroups as possible, because clinicians desire assurance that the broad conclusions are applicable to a variety of patients. The ability to conduct such analyses is enhanced by the fact that early in its evolution the BPLTTC decided to include trials of blood pressure-lowering agents not restricted to hypertensive patients; thus the data set

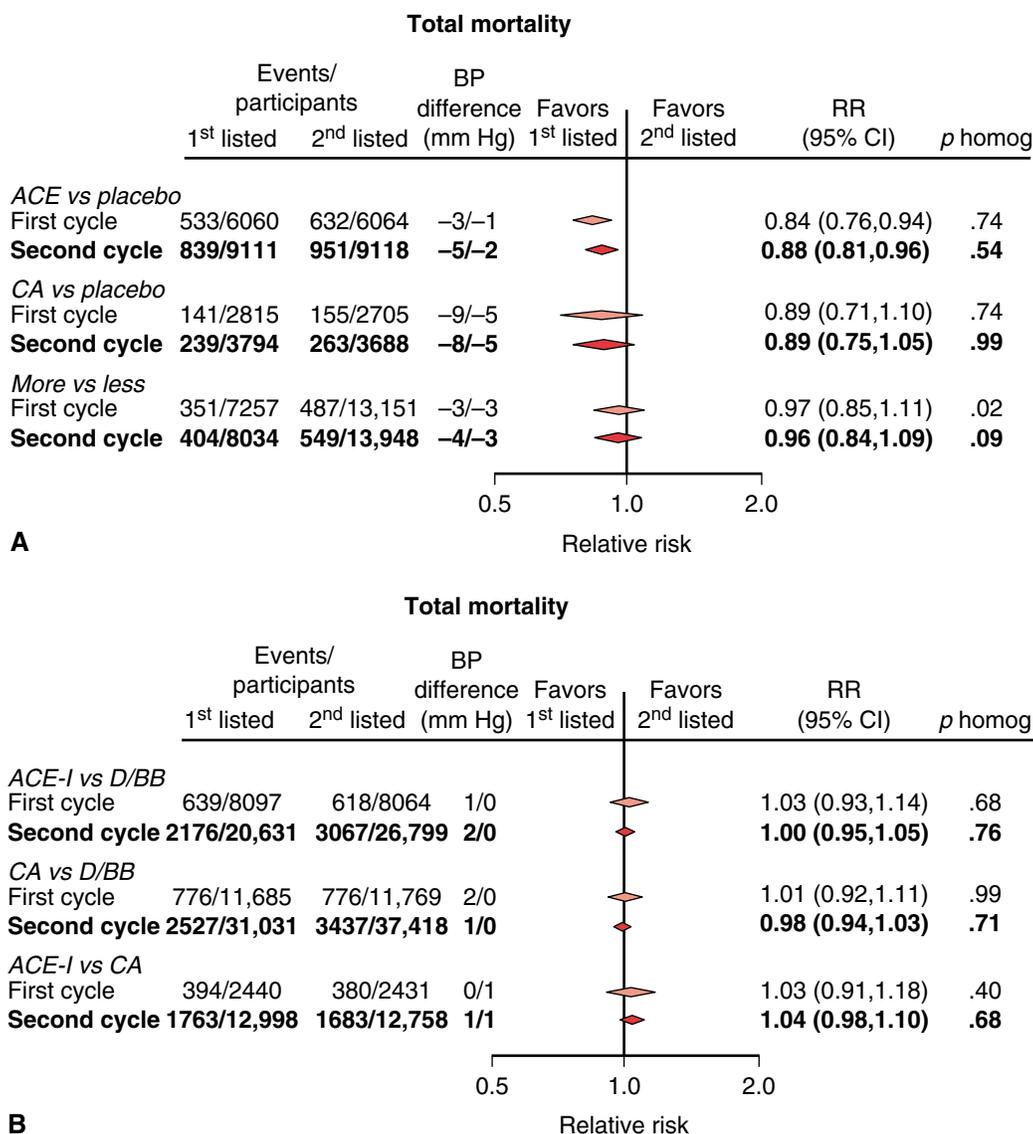

Figure 29-6 Comparisons of active and control regimens (**A**) and comparisons of different active regimens (**B**) for the outcome of total mortality. BP, blood pressure; RR, relative risk; CI, confidence interval; ACE, angiotensin-converting enzyme; CA, calcium antagonist; ACE-I, ACE inhibitor; D/BB, diuretic/ β -blocker.

is particularly enriched with patients having other vascular conditions. The decision not to be restricted to trials in hypertensive patients was based on the continuous, monotonic increase of cardiovascular risk with higher blood pressure levels starting below 115/75 mm Hg³³ and has not been challenged. However, it would be strengthened by analyses according to entry blood pressure levels. One non-prespecified subgrouping factor is race/ethnicity; completed trials have provided some basis for pursuing such analyses, albeit post hoc.³⁴

Another issue of scope and methodology involves the treatment comparisons. The design decision to group diuretics and β -blockers as “traditional regimens” was based on results from a few completed large trials that compared diuretic-based with β -blocker-based treatments and found no differences in cardiovascular events or total mortality, along with the fact that several of the later large direct comparator trials adopted a “control” arm giving participating clinicians free choice between a diuretic, a β -blocker, or combined treat-

ment. A meta-analysis³⁵ published subsequent to the BPLTTC protocol suggested that these classes were not wholly equivalent in their effects and that larger reductions in CHD might be seen with diuretics. Although secondary analyses separating trials with these classes as traditional arms have been included in the second cycle papers, there are few trials contributing to these analyses.

With regard to endpoints, the protocol included definitions of the prespecified events according to ICD codes but did not specify clinical criteria, because such definitions would have been very difficult to apply to trials that had been independently designed and were largely ongoing already. Nevertheless, regional variations in diagnostic practices and medical management constitute a legitimate area for exploration regarding interpretations of overviews of this kind, although randomization largely protects against biased effect estimates. One post hoc decision needed to be made with regard to heart failure events in pursuit of greater uniformity—namely, to

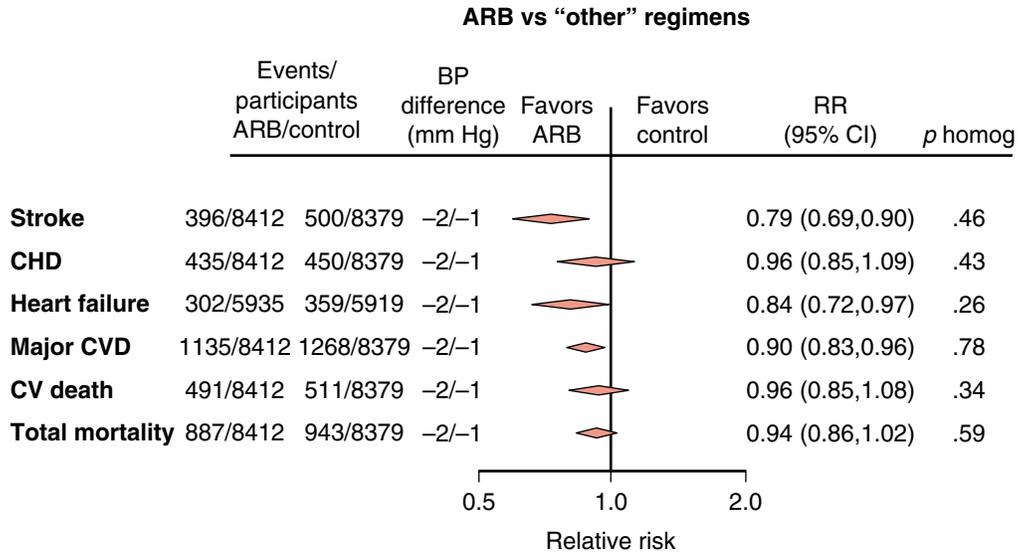

Figure 29-7 Comparisons of ARB-based and control regimens for all cardiovascular outcomes. ARB, angiotensin receptor blocker; BP, blood pressure; RR, relative risk; CI, confidence interval; CHD, coronary heart disease; CVD, cardiovascular disease; CV, cardiovascular.

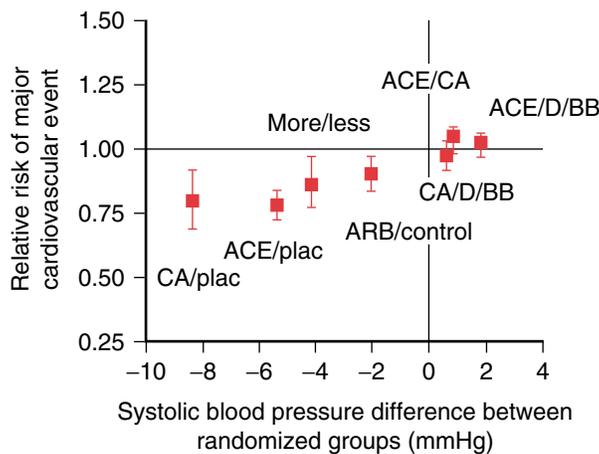

Figure 29-8 Association of blood pressure differences between groups with risks of major cardiovascular events.

exclude cases diagnosed outside the hospital. Such a decision would influence absolute rates and therefore could affect the net effects on a composite such as major cardiovascular events if treatment regimens affect types of events in different ways (as appears to be the case). The same result could arise from medical care systems that lead to differential hospitalization rates for a variety of nonfatal events.

Finally, to be successful, the BPLTTC requires continuity of staff support and long-term funding. Clearly, an enterprise such as the Collaboration that seeks to inform practice policies broadly but is not likely to provide novel research findings nor serve any particular commercial interest inevitably faces continuing struggles for financial support. Nevertheless, it would appear to represent a valuable resource for informing national and international practice guidelines.³⁶⁻³⁹

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)

Jackson T. Wright, Jr., Suzanne Oparil

INTRODUCTION

The Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Trial (ALLHAT) is arguably the most important hypertension study since the demonstration that lowering blood pressure (BP) was associated with reduced adverse clinical outcomes. Its findings have also made it one of the most controversial trials.

Once the benefit of lowering BP in hypertensive patients was established, the next major issue was to determine the optimal treatment regimen to do so. Although thiazide diuretics and β -blockers (alone and in combination) and other sympatholytics and vasodilating drugs were the drugs originally used to demonstrate the benefit of BP lowering, they are also associated with adverse effects on markers associated with increased cardiovascular disease (CVD) risk (e.g., glucose, lipids, potassium, uric acid). Furthermore, evidence suggested that coronary heart disease (CHD) events in trials using these agents were reduced less effectively than predicted from epidemiologic studies.

Although previous trials were designed to examine the effect of treatment on either stroke or composite CVD, they did not have the statistical power to evaluate CHD. Thus the primary objective of ALLHAT was to determine whether antihypertensive drug therapy initiated with newer agents with more favorable metabolic profiles (i.e., angiotensin-converting enzyme inhibitors [ACEIs], α -blockers, or calcium channel blockers [CCBs]) was more effective in preventing CVD, especially CHD, than the older (and less costly) drugs represented by a thiazide-type diuretic. Another objective was to examine the effect of antihypertensive drug selection in populations known to suffer excessively from the hypertension and related target organ damage but who were underrepresented in previous studies. ALLHAT was the largest hypertension trial ever conducted, the first clinical outcome trial to evaluate newer agents in Blacks, and the largest clinical outcome trial in diabetics, and it had large numbers of women and participants older than age 65 years.

METHODS

Patient Selection

The rationale and design of ALLHAT have been presented elsewhere.¹ The goal was to recruit high-risk participants with relatively mild BP elevation and thus a high likelihood of successful control on monotherapy. Participants were men and women with either untreated systolic (≥ 140 mm Hg) and/or diastolic (≥ 90 mm Hg) hypertension (but $\leq 180/110$ mm Hg at

two visits) or treated hypertension ($\leq 160/100$ mm Hg on one to two antihypertensive drugs at visit 1 and $\leq 180/110$ mm Hg at visit 2 when medication may have been withdrawn) and at least one additional risk factor for CHD events.^{1,2} The risk factors included age ≥ 55 years, previous (>6 months) myocardial infarction (MI) or stroke, left ventricular hypertrophy (LVH) by electrocardiography or echocardiography, history of type 2 diabetes, current cigarette smoking, high-density lipoprotein cholesterol (HDL) <35 mg/dl, or documentation of other atherosclerotic CVD. Individuals with a history of hospitalized or treated symptomatic heart failure (HF), serum creatinine >2.0 mg/dl, and/or known left ventricular ejection fraction $<35\%$ were excluded. Race was defined by self-report as Black, white, Asian, Native American, and other.

Interventions

There was no washout period, and unless the drug regimen required tapering for safety reasons, individuals continued any prior antihypertensive medications until they received randomized study drug (after which previous antihypertensive medications were discontinued). Previous antihypertensive drug treatment was similar in participants across the randomized treatment groups. Participants were randomly assigned to chlorthalidone, amlodipine, doxazosin, or lisinopril in a ratio of 1.7:1:1:1, respectively.

Chlorthalidone was selected to represent the older therapy (thiazide-type diuretic) for several reasons. First, the largest experience in clinical outcome trials (especially in preventing CHD in older patients) was with this class of antihypertensive agents.³⁻⁹ Previous data suggested similar endpoint reduction, regardless of the specific thiazide-type diuretic utilized. Although chlorthalidone was not the most common diuretic prescribed by providers, there was substantial experience with this agent in clinical trials.⁷⁻⁹ Last, when ALLHAT was conceived, consistent with the contemporary emphasis on low-dose diuretic therapy, the dosages of 12.5 and 25 mg of chlorthalidone were thought to be more acceptable to potential clinical sites than 25 and 50 mg/day of hydrochlorothiazide.

Participants ($n = 42,418$) were recruited at 623 centers in the United States, Canada, Puerto Rico, and the U.S. Virgin Islands between February 1994 and January 1998. More than half of the clinical centers were private practice sites.¹⁰ Closeout ended on March 31, 2002, for the amlodipine and lisinopril versus chlorthalidone comparison; closeout for the doxazosin arm ended approximately 2 years earlier on February 15, 2000.

BPs during the trial were measured by trained observers using standardized techniques.¹¹ Visit BP was the average of

two seated measurements. Goal BP for all participants was both systolic BP (SBP) <140 mm Hg and diastolic BP (DBP) <90 mm Hg. This was achieved by titrating the assigned study drug (step 1), then adding open-label agents (step 2 or 3) when necessary. Non-pharmacologic approaches to treatment of hypertension were recommended according to contemporary national guidelines.¹²

The identity of the step 1 agents was double-masked at each dosage level. Dosages were 12.5, 12.5 (sham titration), and 25 mg/day for chlorthalidone; 2.5, 5, and 10 mg/day for amlodipine; and 10, 20, and 40 mg/day for lisinopril. In participants not controlled on monotherapy, open-label drugs were provided by the study. They included the following: step 2: atenolol, 25 to 100 mg/day; reserpine, 0.05 to 0.2 mg/day; or clonidine, 0.1 to 0.3 mg twice/day; step 3: hydralazine, 25 to 100 mg twice/day. Slow-release potassium chloride was also provided for serum potassium consistently <3.5 mEq/L. After randomization, if a clear indication arose, half doses of open-label step 1 drug classes were permitted along with blinded drugs.^{1,11} After initial monthly titration visits, participants were seen every 3 months during the first year and every 4 months thereafter.

Outcomes

The primary outcome was a composite of fatal CHD or nonfatal MI.¹ Previous primary prevention comparative outcome trials used a composite CVD outcome as the primary outcome. Designating fatal CHD and nonfatal MI as the primary outcome substantially increased the sample size required for the trial. Four major prespecified secondary outcomes were (1) all-cause mortality, (2) fatal and nonfatal stroke, (3) combined CHD (the primary outcome + coronary revascularization + hospitalized angina), and (4) combined CVD (combined CHD + stroke + nonhospitalized treated angina + HF [fatal, hospitalized, or treated nonhospitalized], and treated peripheral arterial disease). Individual components of the combined outcomes also were examined. Other pre-specified secondary outcomes included incident cancer, incident electrocardiogram (ECG) LVH, and end-stage renal disease (ESRD) (dialysis, renal transplant, or renal death). Change in estimated glomerular filtration rate (eGFR)¹³ was examined posthoc.

Study endpoints were assessed at follow-up visits, reported to the Clinical Trials Center (CTC), and verified by several mechanisms.¹ Because of the large number of total events (>10,000), blinded review of all events was not feasible. A minimal goal was to ensure that no bias was introduced that favored any of the randomized treatment groups. Hospitalized outcomes were primarily based on clinic investigator reports, with copies of death certificates and hospital discharge summaries requested for central review. Among all combined CVD events that resulted in deaths and/or hospitalizations, the proportion with documentation (i.e., a death certificate or a hospital discharge summary) was 99% in the amlodipine and lisinopril versus chlorthalidone comparisons and 97% in the doxazosin versus chlorthalidone comparison. Searches for outcomes were also accomplished through the Centers for Medicare and Medicaid Services (CMS), the Department of Veterans Affairs (VA), the National Death Index, and the Social Security Administration databases. Medical reviewers at the CTC verified the clinician-assigned diagnoses of outcomes by using death certificates and hospital discharge summaries.

More-detailed information was collected on a random (10%) subset of CHD and stroke events to validate the procedure of using clinician diagnoses.¹ When a large excess of HF became evident in the doxazosin arm, a one-time sample of HF hospitalizations was reviewed by the ALLHAT Endpoints Subcommittee. Agreement rates between the subcommittee and clinic investigators were 90% (155/172) for the primary endpoint, 84% (129/153) for stroke, and 85% (33/39) for HF hospitalizations¹⁴ and were similar in all treatment groups. Blinded review of 98% of the HF hospitalizations in 97% of the participants with HF has confirmed the validity of this outcome.^{14,15}

Statistical Analyses

Data were analyzed according to participants' randomized treatment assignments regardless of their subsequent medications (intent-to-treat analysis). ALLHAT had 83% power to detect a 16% reduction in nonfatal MI and fatal CHD at a two-sided $\alpha = 0.0178$.

RESULTS

Patient Characteristics

Table 30–1 presents baseline characteristics for the 42,418 participants in the trial. The mean age was 67 years; 47% were women, 35% were Black, 36% were diabetic. There were nearly identical distributions of baseline risk factors across the four treatment groups.²

Visit and Medication Adherence

The mean duration of follow-up was 4.9 years in the chlorthalidone, amlodipine, and lisinopril arms and 3.2 years in the doxazosin arm.^{16,17} Approximately 99% of expected person-years were observed for the chlorthalidone, amlodipine, and lisinopril arms, and in the doxazosin arm (which was stopped early), the figure was 95%. The maximum duration of follow-up was 8.0, 7.9, 8.1, and 5.9 years in the chlorthalidone, amlodipine, lisinopril, and doxazosin groups, respectively. Thus, ALLHAT had one of the longest periods of on-treatment follow-up of any clinical outcome trial. Despite the trial's size and length of follow-up, visit and medication adherence were excellent. At trial closeout, only 419 of 15,255 (2.7%) of the chlorthalidone group, 258 of 9048 (2.8%) of the amlodipine group, 276 of 9054 (3.0%) of the lisinopril group, and 449 of 9061 (4.9%) of the doxazosin group had unknown vital status. Visit adherence was 92% at 1 year and 84% to 87% at 5 years in the chlorthalidone, amlodipine, and lisinopril arms.¹⁶ At 4 years, visit adherence was 80% for the doxazosin/chlorthalidone comparison.¹⁷

It is noteworthy that with the double-blind design, fewer participants randomized to ACEI or α -blocker remained on their assigned drug than those randomized to the diuretic or CCB. Among participants in the chlorthalidone group who were contacted in the clinic or by telephone within 12 months of annual scheduled visits, 87.1% were taking chlorthalidone or another diuretic at 1 year, decreasing to 80.5% at 5 years. Among participants in the amlodipine group, 87.6% were taking amlodipine or another CCB at 1 year, decreasing to 80.4%

at 5 years. Among participants in the lisinopril group, 82.4% were taking lisinopril or another ACEI at 1 year, decreasing to 72.6% at 5 years. In the doxazosin group, 71% of participants were taking doxazosin or another α -blocker at 4 years. The most common reasons for not taking step 1 medication were unspecified refusals and symptomatic adverse effects in more than 50% of cases.

Intermediate Outcomes

Mean seated BP at randomization was 146/84 mm Hg in all four groups, with 90% of participants reporting current antihypertensive drug treatment (Table 30–1). Among participants returning for follow-up visits, diastolic BP was reduced to a similar degree in all four treatment arms. However, mean systolic BP was ~1 mm Hg greater in the amlodipine arm than in the chlorthalidone arm and ~3 mm Hg greater in the lisinopril and doxazosin arms than in the chlorthalidone arm (Table 30–2). At the initial visit, the proportion of participants at or below the BP goal (<140/90 mm Hg) was ~27%; at 5 years, it was 68%, 66%, and 61% for the chlorthalidone, amlodipine, and lisinopril groups, respectively; and 58% for the doxazosin group at 4 years (Table 30–2).

The metabolic changes in the treatment groups were similar to what had been reported in multiple studies prior to ALLHAT. Mean total serum cholesterol levels at baseline were about 216 mg/dl in all four groups. At 4 years, the respective mean levels were 197.2 (chlorthalidone), 195.6 (amlodipine), 195.0 (lisinopril), and 187 mg/dl (Table 30–3). By 4 years, about 35% to 36% of participants in all three groups reported taking lipid-lowering drugs, largely hydroxymethylglutaryl coenzyme A reductase inhibitors, some as a result of participation in the ALLHAT lipid trial. Mean serum potassium levels at baseline were 4.3 to 4.4 mmol/L; at 4 years, the respective mean levels were 0.3 to 0.4 mmol/L lower for those in the chlorthalidone group than in the other groups.

Mean fasting serum glucose levels at baseline were similar (122–124 mg/dl) in the four groups; at 4 years, the respective mean levels were 126.3, 123.7, 121.5, and 117 mg/dl. Among individuals classified as nondiabetic at baseline, with baseline fasting serum glucose <126 mg/dl (7.0 mmol/L), the incidence of diabetes (fasting serum glucose \geq 126 mg/dl) at 4 years was 11.6%, 9.8%, 8.1%, and 8.8%, respectively.

Mean eGFR at baseline was about 78 ml/min/1.73 m² in all groups. At 4 years, it was 70.0, 75.1, 70.7, and 72.8 ml/min/1.73 m² in the chlorthalidone, amlodipine, lisinopril, and doxazosin groups, respectively. The slopes of the reciprocal of serum creatinine over time were virtually identical in the chlorthalidone and lisinopril groups, whereas the decline in the amlodipine slope was less than that of the chlorthalidone slope.¹⁶

Primary and Secondary Outcomes

The effects of the treatment regimens as compared with chlorthalidone are displayed in Table 30–4.

Amlodipine Versus Chlorthalidone

No significant difference was observed between amlodipine and chlorthalidone for the primary outcome (relative risk [RR], 0.98; 95% confidence interval [CI] 0.90–1.07) or for the

secondary outcomes of all-cause mortality, combined CHD, stroke, combined CVD, angina, coronary revascularization, peripheral arterial disease, cancer, or ESRD (Figure 30–1). The amlodipine group had a 38% higher risk of HF ($p < .001$) and a 35% higher risk of hospitalized/fatal HF ($p < .001$). The treatment effects for all outcomes were consistent across the predefined subgroups and by absence or presence of CHD at baseline.

Lisinopril Versus Chlorthalidone

No significant difference was observed between lisinopril and chlorthalidone for the primary outcome (RR, 0.99; 95% CI 0.91–1.08) or for the secondary outcomes of all-cause mortality, combined CHD, peripheral arterial disease, cancer, or ESRD (Figure 30–2). The lisinopril group had a 15% higher risk for stroke ($p = .02$) and a 10% higher risk of combined CVD ($p < .001$). Included in this were a 19% higher risk of HF ($p < .001$), a 10% higher risk of hospitalized/fatal HF ($p = .11$), an 11% higher risk of hospitalized/treated angina ($p = .01$), and a 10% higher risk of coronary revascularization ($p = .05$). The treatment effects for all outcomes were consistent across subgroups by gender, diabetic status, and baseline CHD status. For stroke and combined CVD, there were significant differential effects by race ($p = .01$ and $.04$ for interaction, respectively). The relative risks (lisinopril versus chlorthalidone) for stroke were 1.40 ($p < .001$) in Blacks and 1.00 ($p = .96$) in non-Blacks; they were 1.19 ($p < .001$) and 1.06 ($p = .05$) for combined CVD in Blacks and non-Blacks, respectively.

The mean follow-up systolic BP for all participants was 2 mm Hg higher in the lisinopril group than in the chlorthalidone group, 4 mm Hg higher in Blacks, and 3 mm Hg higher in those age 65 years or older. Adjustment for follow-up BP as time-dependent covariates in a proportional hazards model slightly reduced the relative risks for stroke (RR 1.15 to 1.11) and HF (RR 1.20 to 1.17) overall and in the Black subgroup (stroke RR 1.40 to 1.36, and HF RR 1.32 to 1.28), but the results remained statistically significant.

Doxazosin Versus Chlorthalidone

No significant difference was observed between doxazosin and chlorthalidone for the primary outcome (RR, 1.03; 95% CI 0.92–1.15) or for the secondary outcomes of all-cause mortality, combined CHD, peripheral arterial disease, cancer, or ESRD (Figure 30–3). The doxazosin group had a 26% higher risk for stroke ($p = .001$) and a 20% higher risk of combined CVD ($p < .001$). Included in this were an 80% higher risk of HF ($p < .001$), a 66% higher risk of hospitalized/fatal HF ($p < .001$), a 13% higher risk of hospitalized/treated angina ($p = .01$), and a 12% higher risk of coronary revascularization ($p = .05$). The treatment effects for all outcomes were consistent across subgroups by gender, diabetic status, baseline CHD status, and race.

Primary Safety Outcomes

Six-year rates of hospitalization for gastrointestinal bleeding, available only for Medicare and VA participants, were similar in the chlorthalidone, amlodipine, and lisinopril treatment groups, with no significant differences. Angioedema occurred in 0.4% of persons in the lisinopril treatment group, a rate

Table 30-1 Baseline Characteristics of the ALLHAT Antihypertensive Component Participants

	Chlorthalidone	Amlodipine	Lisinopril	Doxazosin

*For trial eligibility, participants had to have at least one other risk factor in addition to hypertension. Thus the indicated risk factors are not mutually exclusive or exhaustive and may not represent prevalence.

[†]History of myocardial infarction (MI) or stroke; history of coronary revascularization; major ST segment depression or T wave inversion on any electrocardiogram (ECG) in the past two years; other ASCVD (history of angina pectoris; history of intermittent claudication, gangrene, or ischemic ulcers; history of transient ischemic attack; coronary, peripheral vascular, or carotid stenosis 50% or more documented by angiography or Doppler studies; ischemic heart disease documented by reversible or fixed ischemia on stress thallium or dipyridamole thallium, ST depression ≥ 1 mm for ≥ 1 minute on exercise testing or Holter monitoring; reversible wall motion abnormality on stress echocardiogram; ankle-arm index less than 0.9; abdominal aortic aneurysm detected by ultrasonography, CT scan, or X-ray; carotid or femoral bruits).

[‡] $p = 0.03$ for comparison of groups.

four times higher than in the other treatment groups. Significant differences were seen for the lisinopril versus chlorthalidone comparison overall ($p < .001$); in Blacks (2/5369 [$<0.1\%$] for chlorthalidone, 23/3210 [0.7%] for lisinopril, $p < .001$) and in non-Blacks (6/9886 [0.1%] for chlorthalidone, 15/5844 for lisinopril [0.3%], $p = .002$). The only death from angioedema was in the lisinopril group.

DISCUSSION

ALLHAT demonstrated that antihypertensive drug therapy initiated with ACEIs, α -blockers, and dihydropyridine-CCBs was not superior to that initiated with a thiazide-type diuretic in preventing CHD or any other CVD outcome.^{16,17} Furthermore, the diuretic was superior to the CCB in pre-

venting HF, superior to the ACEI in preventing HF and stroke (especially in Blacks), and superior to the α -blocker in preventing HF, stroke (in all subgroups), combined CHD, and combined CVD. Blood pressure adjustment by multiple procedures accounts for some of the differences in outcomes between the diuretic and the ACEI and α -blocker treatment groups. Finally, the diuretic was shown to be no less effective than the ACEI in preventing progression of kidney disease or

development of ESRD. These findings were noted in all pre specified subgroups defined by age older than and younger than 65, gender, race, diabetic status, and the presence or absence of CHD or whether the participant was on previous antihypertensive therapy. Importantly, ALLHAT demonstrated these differences in outcomes despite the anticipated more-favorable metabolic effects that were seen with the newer agents.

ALLHAT also confirmed the increases in glucose and cholesterol and decrease in potassium seen in previous studies with diuretics as compared with other agents.^{7,18} The increase in glucose in the diuretic arm resulted in a larger number of participants in this treatment arm reaching the threshold defining diabetes. These unfavorable metabolic characteristics of diuretic therapy were one of the major reasons for the hypothesized advantage of the newer agents in preventing CHD and a major motivation for the conduct of ALLHAT. However, despite having one of the longest periods of follow-up of any antihypertensive trial (4-8 years), ALLHAT produced no evidence of this translating into more clinical (specifically CHD) events, as hypothesized by some authors.¹⁸⁻²³ Those who suggest that the risk of diabetes may overwhelm the early short-term benefit of diuretics must consider the increase in outcomes such as HF, stroke, and composite CVD that may occur while awaiting these hypothesized events.

It is worth noting that the selection of chlorthalidone to represent the thiazide-type diuretics represents an extreme test of diuretic therapy. Chlorthalidone is 1.5 to 2 times more potent than hydrochlorothiazide, has 2 to 3 times longer half-life, and is consequently more kaliuretic.²⁴ Thus the chlorthalidone dose (12.5-25 mg/day) administered in ALLHAT is higher than low-dose diuretic therapy. The hypokalemia seen with diuretics has been reported to result in worsened glucose tolerance, and potassium replacement ameliorates this effect.²⁵ Thus, more-aggressive potassium replacement may have lessened the effect of the diuretic on glycemic control in ALLHAT.

Although some of the findings of the trial surprised many, there is substantial support in the literature that could have foretold these results. ALLHAT confirmed the findings of trials such as (1) STOP-2 and CAPPP showing no difference in coronary events between ACEI, CCB, and diuretic therapy^{26,27}; (2) SHEP as compared with Syst-Eur, CONVINCE, and INVEST showing a lower rate of HF with diuretic versus calcium channel blocker therapy^{7,28-30}; (3) Syst-Eur and the Hypertension Optimal Treatment (HOT) trial showing excellent CVD protection in diabetic hypertensives with calcium channel blockers^{28,31}; and (4) multiple studies documenting lesser BP lowering with ACEI monotherapy in Black hypertensive patients.³²

The ALLHAT trial has clearly caused substantial controversy, and there have been misconceptions regarding the objectives of the trial. Despite having a randomized, double-blind design; clearly prespecified endpoints; and the largest and most-diverse study population of any antihypertensive trial, the design of ALLHAT has been criticized by some as flawed.³³⁻³⁶ The primary objective of ALLHAT was to determine whether the newer agents are superior to diuretic-based therapy in preventing CHD when prescribed as initial therapy; the trial clearly demonstrated that they are not. Some have suggested that because there was no difference in the primary outcome, the trial was negative and no further conclusions can be drawn from it. In fact, the objectives of the trial were achieved, including the finding of no difference in the primary outcome. If they are few in number and prespecified, it is valid to consider secondary outcomes. Thus, the ALLHAT results demonstrate that the diuretic was either unsurpassed or superior in preventing mortality, stroke, combined CHD (consisting of the primary outcomes + coronary revascularization and hospitalized angina), and combined CVD (combined CHD +

stroke + nonhospitalized treated angina + HF [fatal, hospitalized, or treated nonhospitalized], and treated peripheral arterial disease).

The difference in achieved BP between the diuretic and the ACEI and α -blocker arms has been the center of multiple commentaries. If the difference in achieved BP explained much of the favorable effect on outcomes of the diuretic, this would not suggest an advantage for initial therapy with agents that are less effective in lowering BP. If ACEIs and α -blockers require a diuretic to achieve adequate BP control but offer less benefit over diuretics in diuretic-free regimens, there is little reason to select them first. However, even in subgroups in which similar BP lowering was achieved (e.g., non-Blacks representing two thirds of the study population), the ACEI was not superior to the diuretic for any outcome.

Thus, ALLHAT definitively confirmed that thiazide-type diuretics are unsurpassed in preventing the major complications of hypertension compared to three of the most promising newer classes of antihypertensive drugs. This finding, along with their unsurpassed BP lowering, tolerability, and cost, confirms the validity of the recommendations by most guideline panels that diuretics should remain the preferred first-step drug for treatment of hypertension.

Nieminen, Per Omvik, Suzanne Oparil, Hans Wedel, Jonathan M. Edelman, Steve Snapinn, Katherine E. Harris, Gilbert W. Gleim

The Losartan Intervention For Endpoint Reduction (LIFE) in Hypertension Study represents a seminal clinical trial in patients with hypertension and evidence of target organ damage, manifest as electrocardiographic evidence of left ventricular hypertrophy (ECG LVH). LIFE had a double-blind, randomized design with an active control. LIFE achieved nearly identical goal blood pressure (BP) reductions in each treatment arm, permitting the assessment of features of losartan that are independent of its antihypertensive action.

LIFE was conceived in late 1993, and the first investigators' meeting was held in 1994. The first patient, from one of 945 clinical centers worldwide, entered the study in June of 1995 and the last patient was randomized in April, 1997. A total of 9222 patients, 29 of whom were excluded soon after randomization for irregularities, were randomized, leaving an analysis group of 9193. The study was terminated in September, 2001, when sufficient endpoints were predicted to have occurred, resulting in an average follow-up of 4.8 years. The primary composite endpoint was cardiovascular death, nonfatal myocardial infarction (MI), and stroke. The group assigned to treatment based on losartan, the first marketed angiotensin II receptor blocker (ARB), had fewer primary events (508, or 23.8/1000 patients × years) compared with the group assigned to the β-blocker, atenolol (588, or 27.9/1000 patients × years) ($p = .021$).¹ BP was kept nearly identical between the two treatment groups throughout the study, providing evidence that the benefit of losartan extends beyond its BP-lowering effects.

This chapter reviews many of the findings of the LIFE study, including the effects of treatment on the study population as a whole, in prespecified subgroups, and in post hoc analyses. Studies exploring the relationship of echocardiographic and electrocardiographic measurements of LVH to outcomes and differential responses to treatments have also been a major focus of the analyses of LIFE and are included here. Other issues relating to the pathology associated with hypertension among LIFE participants have been explored and are discussed in this chapter.

LIFE STUDY BACKGROUND, DESIGN CONSIDERATIONS, AND METHODS

Hypertension Treatment in the Early 1990s

Direct blockade of angiotensin II (Ang II) by ARBs was first accomplished with the octapeptide saralasin [Sar¹, Val⁵, Ala⁸] angiotensin-(1-8) by Pals et al. in 1971.² Saralasin had intrinsic

pressor activity, and it was not until the development of losartan potassium (C₂₂H₂₂ClKN₆O), the first of a new class of orally active antihypertensive agents that block the Ang II type 1 (AT₁) receptor,³ that an ARB became a viable agent for treating hypertension in humans. As a direct blocker of the AT₁ receptor, losartan did not delay catabolism of bradykinin, as had been seen with the angiotensin-converting enzyme (ACE) inhibitors. Perhaps as a consequence, losartan was associated with a lower incidence of cough and angioedema than the ACE inhibitors.

The Fifth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC V), published in 1993, recommended diuretics or β-blockers for initial pharmacologic treatment of hypertension because these agents had been shown to reduce morbidity and mortality in randomized trials (Box 31-1).³ Furthermore, as discussed by Frohlich⁴ after JNC V was published, concurrent meta-analyses had demonstrated that there was a highly significant reduction in stroke⁵ and MI^{5,6} with β-blockers.

Other major points of interest to the designers of the LIFE study were the additional risk associated with LVH in patients with hypertension and the potential for an ARB to block the mitogenic and growth effects of Ang II.⁷ Ample epidemiologic evidence from the Framingham Heart Study had documented the increased morbidity and mortality associated with LVH.⁸⁻¹¹ The Survival and Ventricular Enlargement (SAVE) trial had shown that blockade of the renin-angiotensin system (RAS) with an ACE inhibitor was associated with reduced mortality and less ventricular hypertrophy following MI.¹² These findings were also supported by the Studies of Left Ventricular Dysfunction (SOLVD) registry. Because it was known that Ang II could be formed locally in tissues as well as in the circulation,^{13,14} blockade of the AT₁ receptor in the heart was an attractive target for preventing or regressing the LVH that accompanies chronic hypertension. Losartan had already been shown to prevent or ameliorate LVH in animal models of hypertension, perhaps because of blockade of the AT₁ receptor in the heart.^{15,16}

A meta-analysis by Dahlöf et al.¹⁷ had shown that ACE inhibitors, β-blockers, calcium antagonists, and diuretics were all associated with reductions in left ventricular (LV) mass during treatment for hypertension. As discussed in the LIFE design paper, a β-blocker was chosen over a diuretic (both preferred agents in JNC V) as the active comparator because this class had a more favorable record in prevention (particularly secondary prevention) of coronary artery disease in control of arrhythmias.⁷ The diuretic hydrochlorothiazide

Box 31-1 Medical and Scientific Rationale at the Time of LIFE Design (1993-1994)

- JNC V published 1993: β -Blockers and diuretics preferred first-line agents in treatment of hypertension.
- Epidemiologic evidence for β -blockers and diuretics, not other classes.
- LVH associated with increased morbidity and mortality.
- Known trophic effects of renin-angiotensin system (RAS) on LV mass.
- Tissue sources of angiotensin II production, not only renal \rightarrow pulmonary.
- Cardioprotective effects of β -blockers.
- Losartan, first marketed ARB, blocks AT_1 receptor.

(HCTZ) could be added to treatment with either a β -blocker or losartan. Atenolol was chosen as the β -blocker for the trial because it was the most widely used agent in its class and its efficacy and tolerability had been previously documented.¹

Design of the LIFE Study

LIFE was a prospective, multicenter, multinational, double-blind, double-dummy, randomized, active controlled study with two parallel groups. The primary objective was to study the effects of long-term treatment (≥ 4 years) with losartan compared with atenolol in patients with hypertension and ECG LVH. The primary composite outcome was cardiovascular morbidity and mortality defined as nonfatal, clinically evident MI or stroke and fatal MI, stroke, sudden death, progressive heart failure, or death due to other cardiovascular cause.⁷ Several prespecified data analyses and protocols were approved prior to unblinding, including analysis of patients with diabetes mellitus (DM) at baseline, isolated systolic hypertension (ISH), cost-benefit analysis, new-onset DM, ECG substudy, echocardiographic substudy, microalbuminuria substudy, QT-dispersion substudy, insulin sensitivity and carotid ultrasound substudy (Insulin Carotids United States Scandinavia [ICARUS]), uric acid analysis, physical activity analysis, smoking analysis, and alcohol analysis.

Eligibility and exclusion criteria are shown in Box 31-2. Importantly, hypertension had to be documented following a 2-week single-blind placebo run-in period in order for a patient to qualify for the study. Patients were eligible with sitting trough diastolic blood pressure (DBP) of 95 to 115 mm Hg and/or systolic blood pressure (SBP) of 160 to 200 mm Hg, allowing for those with ISH. Entry criteria for ECG LVH changed during the study for women. Patients qualified initially by having a Cornell voltage ($RaVL + SV_3$) \times QRS duration product >2440 mm \times msec in men with an added gender adjustment of 8 mm for women. The adjustment was reduced to 6 mm for women on the basis of data published after the LIFE study had started.¹⁸ Additionally, the Sokolow-Lyon voltage combination ($SV_1 + RV_5$ or V_6) >38 mm qualified men or women as having ECG LVH. Although these patients were at higher risk for cardiovascular events than those with hypertension without LVH, a noteworthy exclusion criterion was that enrollees could not have had a stroke or MI within 6 months of study entry.

Box 31-2 Inclusion and Exclusion Criteria for the LIFE Study**Inclusion**

Age 55 to 80 years.
Previously treated or untreated hypertension.
ECG LVH by Cornell product or Sokolow-Lyon criteria.
Sitting trough DBP 95-115 mm Hg or SBP of 160-200 mm Hg following 1 and 2 weeks of single blind placebo.

Exclusion

Known secondary hypertension.
DBP >115 mm Hg or SBP >200 mm Hg during 2-week placebo trial.
History of stroke or MI within 6 months.
Angina pectoris requiring treatment with β -blockers or calcium antagonists.
Severe renal impairment with serum creatinine ≥ 1.5 mg/dl or solitary kidney.
Severe liver impairment.
Significant known aortic stenosis (antegrade Doppler gradient ≥ 20 mm Hg).
Known hypersensitivity to losartan, atenolol, or hydrochlorothiazide (HCTZ).
Known condition requiring treatment with losartan, any β -blocker, ACE inhibitor, or HCTZ.
Serious concurrent disease expected to deteriorate patient's health in 4-6 years.
Current or recent history of alcohol or drug abuse.
Mental or legal incapacitation.
Participation in last 10 days in other investigational drug trial using nonapproved drug. (Participation in other drug trial providing it would not interfere was allowed.)
Low compliance at end of placebo—judged by the investigator.
Unwillingness to participate.

From Kannel WB, Gordon T, Castelli WP, et al. Electrocardiographic left ventricular hypertrophy and risk of coronary heart disease. The Framingham Study. *Ann Intern Med* 72:813-822, 1970.

Trough BPs (24 hours following the once-daily dosage of study medication, range 22-26 hours) were used to titrate study medication. Figure 31-1 schematizes the drug titration regimen. Following randomization and the 2-week placebo run-in period, patients received either 50 mg losartan or 50 mg atenolol daily. If goal BP (140/90 mm Hg) was not attained after 2 months, 12.5 mg HCTZ was added. After an additional 2 months, if goal BP was still not achieved, losartan or atenolol was doubled to 100 mg. Those still above target following an additional 2 months were to receive either an additional 12.5 mg HCTZ or other open-label antihypertensive agents, excluding ACE inhibitors, other ARBs, or β -blockers. Other open-label agents could be added after this time was necessary only if BP was $\geq 165/95$ mm Hg.⁷

Analysis was done by intention-to-treat (ITT). LIFE was powered to detect a relative difference in the primary composite endpoint of 15% with 80% power and a two-sided significance level of 5%. Sample size was calculated so that with an absolute event rate of 15% over 5 years in the atenolol

Values in parentheses represent standard deviation or percent. Abbreviations: LOS, losartan; ATNL, atenolol; CVD, cardiovascular disease; Cornell V, Cornell voltage-duration product; ISH, isolated systolic hypertension; DM, diabetes mellitus. The **bolded cells** indicate the numbers for the primary study, as well as those factors that distinguished the subgroups of interest.

contributing to a mean voltage with the latter (30.0 ± 10.5 mm) that was lower than the entry criterion of 38 mm. Satisfaction of either criterion was necessary for inclusion and increased the sensitivity for detection of LVH. Characteristics of patients satisfying either criterion served as a topic for an interim publication²⁰ and is discussed later in the chapter. Patients were eligible based on their electrocardiogram at the screening visit, whereas the means in the interim publication were calculated based on the randomization visit.

Other important characteristics of the sample are the mean body mass index (BMI) of 28.0 kg/m^2 , and that 92% of patients classified themselves ethnically as white, resulting in a sample with only 533 Blacks. Characteristics of the various subgroups presented in Table 31–1 are discussed later with the subgroup analyses. Inspection of the three subgroups in Table 31–1 indicates that they are not mutually exclusive. For example, some 20% of patients with DM also had ISH and would thus be counted in both studies.

DIFFERENCES IN THERAPEUTIC OUTCOMES, LOSARTAN VERSUS ATENOLOL

Blood Pressure Control and Medications Used

In keeping with the study design, BP was controlled similarly in the losartan and atenolol arms as shown in Figure 31–3. SBP at the end of follow-up or at the last visit before a primary event had fallen by 30.2 ± 18.5 mm Hg in the losartan group and by 29.1 ± 19.2 mm Hg in the atenolol group ($p = .017$). DBP had declined by 16.1 ± 10.1 mm Hg and 16.8 ± 10.1 mm Hg in the losartan and atenolol groups, respectively ($p = .37$). Mean arterial pressures (MAPs) at this point were nearly identical, 102.2 and 102.4 mm Hg, for the losartan and atenolol groups, respectively. In the three subgroup analyses (ISH, DM, and No-CVD), BP was controlled similarly in the two treatment groups (Table 31–2).

The average dosage of losartan during the study was 82 mg daily, and the average dosage for atenolol was 79 mg daily. As might be expected in treating patients with an initial mean SBP exceeding 170 mm Hg, the majority required the study medication plus HCTZ or another open-label medication (Table 31–3). In this regard, the LIFE study mimics the reality of treating patients with hypertension and can be viewed as a test of beginning therapy with losartan or atenolol in a stepped-care approach. The subgroup studies indicate a similar drug dosing profile to the entire LIFE cohort, but it must be remembered that current recommendations for BP control in patients with DM are SBP ≤ 130 mm Hg and DBP ≤ 80 mm Hg, likely necessitating a more consistent multidrug regimen than was used in this trial.

Outcomes in the Main LIFE Study

LIFE is the first study in the treatment of hypertension, with equivalent BP control, to demonstrate therapeutic superiority of one treatment modality (losartan) over another established active treatment modality (atenolol) for preventing the combined primary outcome of cardiovascular death, nonfatal MI, and stroke. This finding to date has not been replicated by other studies, including Nordic Diltiazem (NORDIL),²¹ Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),²² Study on Cognition and Prognosis in the Elderly (SCOPE),²³ Controlled Onset Verapamil Investigation of Cardiovascular End Points (CONVINCE),²⁴ and International Verapamil/Trandolapril Study (INVEST),²⁵ using other antihypertensive agents. The main finding from LIFE was that 11% of participants treated with losartan compared with 13% treated with atenolol experienced a primary endpoint, with an adjusted (for LVH and Framingham Score) risk reduction of 13% ($p = .021$). The most significant contributor to the composite endpoint was fatal and nonfatal stroke, with the losartan group experiencing a rate of 10.8 of 1000 patients \times years compared with a rate of 14.5 of 1000 patients \times years for the atenolol group ($p = .001$ for adjusted hazard ratio). Figure 31–4 displays the Kaplan-Meier

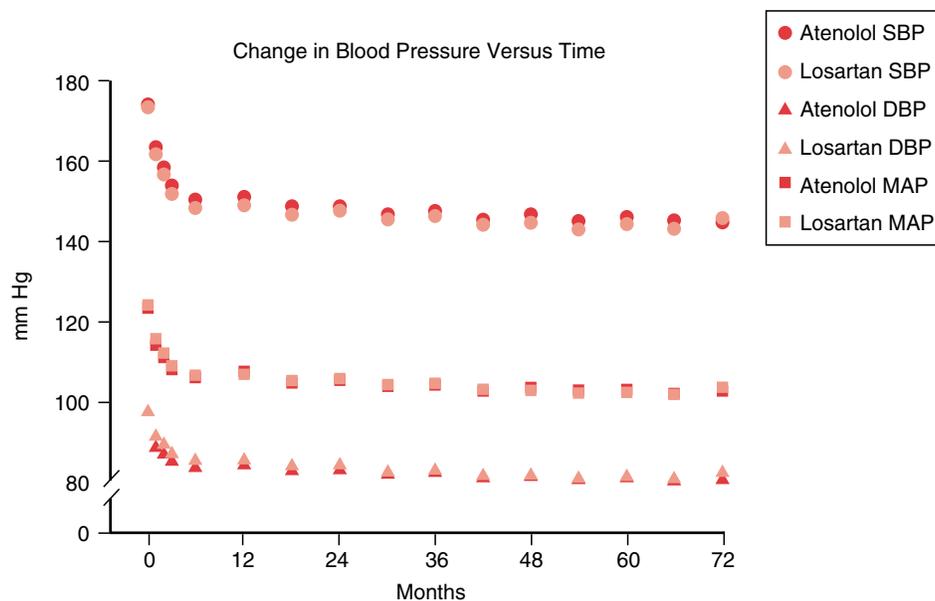

Figure 31–3 The decline in systolic blood pressure (SBP), mean arterial pressure (MAP), and diastolic blood pressure (DBP) during the course of the LIFE study. Points on the graph that overlap are shown as only one point.

Table 31–2 Change in Blood Pressure (mm Hg, Mean ± SD) Between Last Follow-up and Baseline, for the Entire LIFE Cohort and Subgroup Analyses

Study		Losartan	Atenolol	p-Value for Difference in Change from Baseline
LIFE	SBP	−30.2 ± 18.6	−29.1 ± 19.2	.015
	DBP	−16.6 ± 10.2	−16.8 ± 10.1	.035
	MAP	−21.1 ± 11.4	−20.9 ± 11.4	.435

No-CVD	SBP	−30.2 ± 18.1	−29.3 ± 18.7	.071
	DBP	−16.7 ± 9.9	−16.8 ± 9.8	.549
	MAP	−21.2 ± 11.0	−21.0 ± 11.0	.521

ISH, isolated systolic hypertension; DM, diabetes mellitus; No-CVD, no clinical history of cardiovascular disease.

plots for the primary composite endpoint and the three major individual endpoints: cardiovascular mortality, stroke, and MI. This figure depicts that when losartan was used to lower BP in patients with hypertension and LVH, it provided more protection from the composite endpoint, primarily because of its effect on stroke reduction (25%). The group randomized to atenolol, a drug associated with cardioprotective effects, did not differ from the losartan group in the endpoints of MI and cardiovascular mortality.

Table 31–4 depicts the other prespecified endpoints of interest in the main LIFE study, as well as in the substudies. New-onset DM was less common in the losartan-treated group ($p = .001$). To further examine this finding in a separate analysis, a risk model was developed to predict new-onset DM based on baseline serum glucose (nonfasting), BMI, serum high-density lipoprotein (HDL) cholesterol, SBP, and history of previous antihypertensive drugs. Independent of these factors, losartan was found to reduce the incidence of new-onset DM over the course of the LIFE trial.²⁶

Other prespecified endpoints were in favor of the losartan group (cardiovascular mortality, total mortality, heart failure hospitalization, and revascularization), but did not attain statistical significance. Alternatively, those endpoints likely to be

more influenced by the known cardioprotective actions of atenolol (MI, hospitalization for angina pectoris, and resuscitated cardiac arrest) were in favor of atenolol without attaining statistical significance in any case.

ISH, DM, and No-CVD Substudies

Two higher-risk subgroups of the main LIFE cohort were topics of specific investigation from the LIFE study, namely those patients with ISH²⁷ and those patients with DM.²⁸ By contrast, a large posthoc subgroup analysis of patients without a history of clinically evident CVD (i.e., “No-CVD,” defined as no previous diagnosis of coronary, cerebral, or peripheral vascular disease by either self-report or report of treating physicians) was also performed.²⁹ Importantly, the three subgroups are not mutually exclusive, as discussed previously. Figure 31–5 illustrates the event rates and hazard ratios for the primary composite endpoint and individual endpoints for the subgroups and for the main LIFE cohort.

By referring back to Table 31–1 and remembering that some overlap exists between the groups, certain baseline differences are apparent. Patients with ISH represented an older portion of the LIFE cohort, whereas those in the No-CVD group were

ISH, isolated systolic hypertension; DM, diabetes mellitus; No-CVD, no clinical history of cardiovascular disease; HR, hazard ratio; CI, confidence interval; NA, not applicable.

*Rates are given per 1000 patients × years. Hazard ratios are adjusted for Framingham Risk Score and ECG LVH.

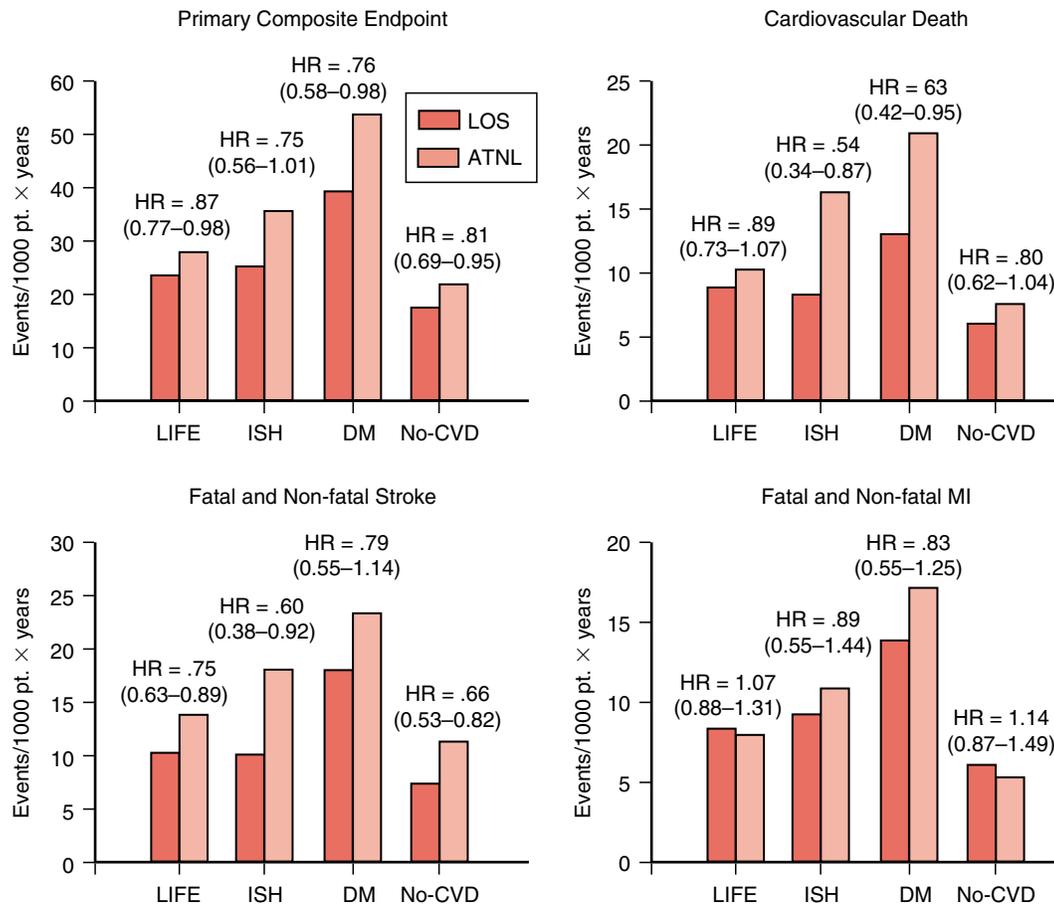

Figure 31-5 Event rates and hazard ratios for the primary composite endpoint and individual endpoints for the main LIFE cohort and subgroups. Bar graphs depicting the rate of events in the main LIFE study and the isolated systolic hypertension (ISH), diabetic mellitus (DM), and no clinical history of cardiovascular disease (No-CVD) subgroup analyses. Hazard ratios (HR) are depicted followed by the 95% confidence interval and are adjusted for ECG LVH and Framingham Risk Score.

younger. Patients with DM had higher BMIs and higher Framingham Risk Scores. Although a very small portion of the LIFE cohort, Black patients comprised a greater percentage of those with DM. Sample sizes in the ISH and DM groups were smaller, decreasing the power to detect statistically significant results, than in the No-CVD group. Larger treatment effects are typically necessary for statistical significance as sample size decreases.

Figure 31-5 illustrates the event rates in the various subgroups and how they relate to the entire LIFE sample. Both the ISH and DM groups experienced a greater rate of outcomes than the entire LIFE sample and the No-CVD group, underscoring the more serious nature of systolic hypertension and the presence of DM as a concomitant risk factor. In addition, the LIFE study and its subgroup analyses corroborate the finding that stroke is a more common outcome than MI in patients with hypertension.³⁰

For the primary composite endpoint, all subgroups responded more favorably to losartan than atenolol treatment, although statistical significance was not attained for the 25% reduction (95% confidence interval [CI]; -1% to 44%) in the ISH group. The subgroup analyses also demonstrated that losartan had the most consistent and dramatic impact on fatal and nonfatal stroke, most prominently the 40% reduc-

tion in the ISH group and least prominently (21%) in the DM group (heart rate = 0.79, 95% CI 0.55-1.14). As in the entire LIFE sample, there was no significant benefit of losartan over atenolol for fatal and nonfatal MI.

Not illustrated is the important exception that there was no evidence for a beneficial effect of losartan over atenolol in Black participants in the LIFE study.³¹ Prespecified in the data analysis plan was a test for interaction by ethnic background. A statistical trend for interaction was noted and, when dichotomized to non-Blacks and Blacks, statistical significance was found. These findings revealed that Blacks in the LIFE study had more favorable outcomes with atenolol than losartan treatment.

In both the No-CVD and ISH patients, new-onset DM was significantly less in the losartan group (Table 31-4), paralleling the findings for the entire LIFE cohort. Whether this indicates a protective effect of losartan or a promoting effect of atenolol is not known from the results of the LIFE trial. However, evidence from the ICARUS substudy (n = 99) indicates that insulin sensitivity increased nonsignificantly in the group randomized to losartan, despite the aging that occurred during the study, but decreased significantly in the atenolol group.³² Hospitalizations for angina were consistently nonsignificantly higher in all subgroups

randomized to losartan, whereas in the DM group, fewer patients assigned to losartan were hospitalized for heart failure ($p = .019$).

The occurrence of sudden death was not significantly different between treatment groups in the overall LIFE cohort. In a posthoc analysis of patients with DM, there were 44 occurrences of sudden death that comprised 44% of all cardiovascular deaths. Fourteen of these deaths occurred in the losartan group compared with 30 in the atenolol group ($p = .027$). Less sudden death in patients with DM and atrial fibrillation was observed in the losartan group than in the atenolol group (6% vs. 13%).³³

Prespecified adverse events (not necessarily drug related) and any other adverse events that attained statistical significance between treatments are shown in Table 31–5. Overall, losartan was associated with fewer adverse events in the main LIFE cohort and the subgroup analyses. Bradycardia is a known consequence of β -blockade, and the increased reporting of this as an adverse event is expected in the atenolol group. A consistent finding across all subgroups and the entire LIFE cohort was the observation of more reporting of albuminuria as an adverse event in the atenolol group compared with the losartan group. Dyspnea and lower extremity edema were consistently more common in the atenolol group, whereas the reporting of lower back pain was more common in the losartan group.

Treatment-Related Differences in Markers of Hypertensive Disease

BP in the two treatment groups differed little throughout LIFE, making BP effect an unlikely cause of the difference in outcomes. Possible mechanisms for the outcome difference that were explored include differential effects on regression of LVH, on serum uric acid (SUA) levels, on protein excretion, and on vascular structure. Many of these findings have been published in either abstract or manuscript form and provide some insight into the mechanism of superiority of losartan over atenolol in the LIFE trial.

ECG LVH Regression

A qualifying inclusion characteristic for the LIFE study was the presence of ECG LVH in addition to hypertension. It had previously been shown that regression of LVH in hypertension related to improved prognosis,³⁴ and attenuation of the actions of the RAS as a therapeutic intervention for preventing or regressing LVH had considerable historic precedent.¹⁷ The LIFE study allowed for a direct test of the question, does it matter how BP is lowered when a goal of therapy is regression of LVH?

By 6 months of treatment, both the Cornell product and Sokolow-Lyon voltage had declined significantly, with statistically greater reductions in losartan group ($p < .001$).³⁵ The difference in the ECG LVH regression (after adjustment for baseline measures of either the Cornell product or Sokolow-Lyon voltage and in treatment SBP and DBP and for diuretics) was consistent and statistically significant at $p < .001$ over the 5 years of treatment. Because of different units for the Cornell product and Sokolow-Lyon voltage, Figure 31–6 demonstrates the difference between treatments as the percent change over the course of the study.

Although there was no difference in the prevalence of LVH at the outset of the study, beginning at 6 months of treatment and continuing throughout the study, significantly fewer patients in the losartan group had LVH by either criterion ($p < .001$, at all measurement intervals). Furthermore, regression lines plotting the change in SBP versus the change in either the Cornell product or Sokolow-Lyon voltage demonstrated that for any change in SBP, the decline of ECG LVH was consistently greater for the losartan group.³⁵

The Framingham study demonstrated that the odds of having CVD were increased in those patients who had an increase in serial voltage change on the electrocardiogram as opposed to those who decreased.³⁶ Consequently, the greater decrease in ECG LVH evident in the losartan group may have contributed to the reduction of events in the composite outcome of the LIFE study. Furthermore, previous work has demonstrated that cerebrovascular events are more common in patients with ECG LVH.³⁷ The fact that losartan produced a greater regression of LVH, with similar BP control, provides a possible mechanism explaining the reduced occurrence of fatal and nonfatal stroke that was noted in the primary LIFE cohort and the subsequent subgroup analyses, as well. LVH can increase atrial size, possibly increasing the occurrence of atrial fibrillation, a major risk factor for cardioembolic stroke.

Serum Uric Acid

Losartan is the only ARB with uricosuric properties, and SUA has been independently associated with cardiovascular morbidity and mortality. In the LIFE study, baseline SUA was significantly associated with increased cardiovascular risk (heart rate = 1.024, 95% CI; 1.017–1.032 per 10- μ mol/L increase).³⁸ Losartan attenuated the age-related increase in SUA in comparison with atenolol (17.0 ± 69.8 vs. 44.4 ± 72.5 μ mol/L, $p < .0001$) over the duration of the study. Furthermore, 29% of the treatment effect of losartan on the primary composite endpoint could be explained by the SUA ($p = .004$).³⁸ A trend toward an interaction of gender with SUA was not significant; however, the association with time-varying SUA and risk was higher in women ($p < .0001$) than in men ($p = .0695$). In men, there was a strong relationship of the Framingham Risk Score (along with degree of LVH, a prespecified adjustment in the risk models) that complicates the interpretation of these results.

Lacking controlled intervention studies, only statistical adjustment has established SUA as an independent risk factor for CVD. The association between cardiovascular risk and SUA is well accepted, but the causality is not. In the LIFE trial, the effect of losartan on the relationship of cardiovascular risk to SUA was more profound in women than in men. The enigma presented by these findings adds further to the controversy surrounding cardiovascular risk and SUA. Nevertheless, the LIFE trial suggests that the unique uricosuric quality of losartan may be an added benefit of this particular ARB.

Urinary Albumin Excretion

The association of microalbuminuria with “benign” essential hypertension was first documented in 1974³⁹ and only later was microalbuminuria associated with CVD and mortality.^{40–42} Microalbuminuria was also found to be associated with LVH in the LIFE study.⁴³

ISH, isolated systolic hypertension; LOS, losartan; ATNL, atenolol; DM, diabetes mellitus; No-CVD, no clinical history of cardiovascular disease. *Bolded figures are significant at $p < .05$.

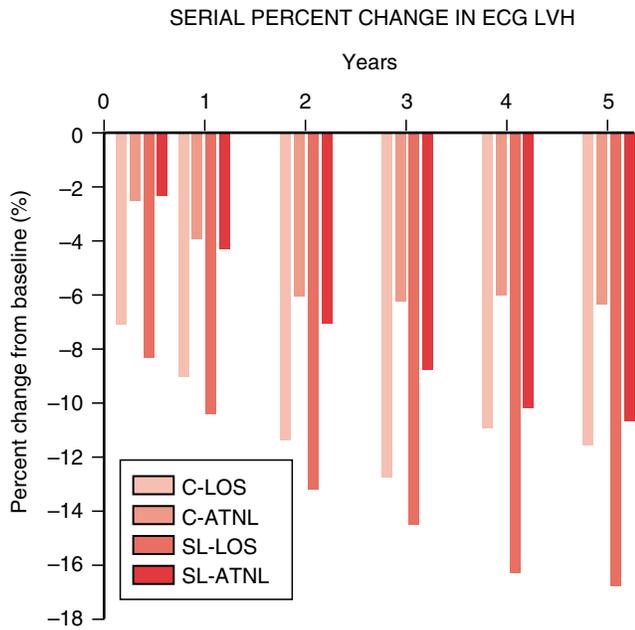

Figure 31-6 Bar graphs depicting the percent change (decrease) in the ECG indicators of LVH over the course of the LIFE study. At all times, the differences between losartan (LOS) and atenolol (ATNL), for the mean adjusted values was significant at $p < .001$. The adjustments made were for baseline measurements of electrocardiographic evidence of left ventricular hypertrophy (ECG LVH) (Cornell product [C] or Sokolow-Lyon [SL] voltage); baseline in and in-treatment systolic blood pressure (SBP) and diastolic blood pressure (DBP); and diuretic use.

Losartan was associated with greater reductions in albuminuria than atenolol (33% greater after the first year, and 25% greater after the second year of study, both $p < .001$) in the 8206 LIFE patients who were studied. Baseline albuminuria did not clearly identify patients who benefited most from losartan, but ~20% of the differential benefits of losartan on the primary composite endpoint could be statistically accounted for by the greater effect of losartan on reducing albuminuria.⁴⁴ Thus the antiproteinuric effects of losartan exerted an apparent protection against cardiovascular outcomes in the LIFE cohort, adding to its known renal protective effect in patients with type 2 DM and nephropathy from the results of the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) study.⁴⁵

Carotid Hypertrophy

As a part of the ICARUS substudy, measurements of carotid artery intima-media cross-sectional area were made at baseline and after 1, 2, and 3 years of treatment ($n = 57$).⁴⁶ Losartan decreased intima-media cross-sectional area indexed by height at every measurement interval compared with baseline (baseline = 11.2, year 1 = 10.6, year 2 = 10.2, and year 3 = 10.1 mm²/m, all $p < .01$). Atenolol did not have a consistent effect (baseline = 11.9; year 1 = 11.6, not significant [NS], year 2 = 11.2; $p < .05$; and year 3 = 11.4, NS). Regression of carotid artery hypertrophy may have contributed to the observed reduced incidence of stroke in the losartan group.

POOLED TREATMENT GROUP ANALYSES

The initial study design and baseline characteristics of the study population have been published previously.^{7,47} The interrelationships of variables under study, most prominently echocardiographic characteristics, were examined by analyses of unblinded data. Following are important findings from LIFE that have contributed to our knowledge of patients with hypertension and LVH.

Characteristics of LVH Determination by Electrocardiogram

Obesity can affect the magnitude of the voltage measured by surface electrocardiogram, and can lead to LVH, and many participants in the LIFE study were obese. Therefore, the LIFE investigators asked whether LVH determination by electrocardiogram was influenced by obesity. By analyzing the prevalence of LVH by both Cornell product and Sokolow-Lyon voltage against tertiles of BMI, the LIFE investigators demonstrated that obesity had a greater effect on LVH determination by the Sokolow-Lyon method than the Cornell product method.²⁰ A progressive increase in the Cornell product was noted, but a progressive decrease in the Sokolow-Lyon voltage was observed as BMI tertile increased.

Further examination of the characteristics of LVH determination by the Cornell product and Sokolow-Lyon voltage showed that the Cornell product criterion was satisfied by 65.9% of participants, whereas the Sokolow-Lyon voltage criterion was met by only 23.1% of the sample.⁴⁸ Multivariate analysis revealed that the best predictors of LVH by Cornell product criteria were higher BMI, increased age, and female gender. The Sokolow-Lyon criteria for LVH were predicted by lower BMI, male gender, and Black race.

The presence of albuminuria was also investigated in relation to the ECG LVH. In this examination, baseline albuminuria was associated independently with DM, higher BP, older age, serum creatinine, smoking, and ECG LVH.⁴³ Following 1 year of treatment, the decline in albuminuria was independently associated with ECG-measured regression of LVH,⁴⁹ leading the investigators to conclude that albuminuria represented generalized vascular damage.

Echocardiography Substudies

A representative sample of 964 LIFE participants also enrolled in the echocardiographic substudy. Among 906 participants with measurable echocardiographic mass and baseline ECG measures, 75% had ECG LVH at screening and at baseline. Because of regression to the mean, 25% did not satisfy ECG criteria for LVH at baseline but did at screening. Those found to satisfy criteria at both time points had an increased prevalence of echocardiographic LVH (86% vs. 55%, $p < .001$).^{50,51} The ECG criteria used to identify participants with LVH indicated a prevalence of >70% LVH by echocardiography.⁴⁹

In 750 participants who had complete measures of LV dimensions and Doppler filling patterns, many correlates were observed.⁵² Multiple regression analysis demonstrated that LV mass correlated with isovolumetric relaxation time, but LV mass and geometry were not related to peak early LV filling velocity (E), peak atrial filling velocity (A), or mitral valve

E peak deceleration time. The E/A ratio was independently correlated with isovolumetric relaxation time.

These LIFE patients were also compared with groups of 282 employed hypertensive and 366 apparently normal adults to study wall stress and myocardial oxygen demand (measured as a triple product of heart rate, mass, and wall stress).⁵³ The LIFE participants were heavier and older than the comparison groups and had substantially supranormal wall stresses and increased triple product compared with the other groups when compared by gender. These changes indicate an increased myocardial oxygen demand and predisposition for myocardial ischemia in the LIFE cohort. The main LIFE outcome study and substudies indicated no difference between the losartan and atenolol groups with respect to fatal and nonfatal MI, even though the β -blocking action of atenolol decreased heart rate, a component of the triple product and correlate of myocardial oxygen demand.
